Age at Puberty

Age at puberty is a measure of the age when a heifer first cycles or presents her first corpus luteum that can be palpated. Age at puberty is closely related to HP, as some of the variation in HP can be attributable to breeding failure when heifers are still maturing. Selection for age at puberty allows producers to breed replacement females at an earlier age. Heritability estimates vary extensively and estimates for taurine breeds are lower than indicine or taurine and indicine crosses (Table 76.2).

Pregnancy Traits

Pregnancy and Conception

Heifer pregnancy is a trait currently used in Angus, Gelbvieh, and Red Angus evaluations (Table 76.3) to indicate fertility in replacement females. HP and other pregnancy success traits are binary records (encoded as success or failure) and represent the probability progeny will be pregnant at the end of the breeding season. HP is a direct measure of the likelihood of heifer progeny becoming pregnant as first-calf heifers [79, 151]. Like age at puberty, HP heritabilities tend to vary significantly between taurine and indicine cattle (Table 76.2). Like HP, DPR, cow conception rate, and heifer conception rate are binary traits. DPR is evaluated for all breeds evaluated by the Council for Dairy Cattle Breeding (CDCB) [78] and indicates the likelihood a sire's daughters will become pregnant during a given estrus. Heifer and cow conception rate are analogous to HP in dairy cattle, with the exception of cow conception rate being measured on females that have already achieved first parity. Heifer and cow conception rate are evaluated for all breeds reported by the CDCB [78].

Gestation Length

Gestation length is expressed in days and is measured as the interval from conception to parturition. Gestation length is evaluated in all breeds evaluated by the CDCB as well as in Limousin [78, 154] (Table 76.3). Heritability estimates ranged from 0.27 to 0.64, but tended to be highly heritable and range from 0.40 to 0.50 [164–171] (Table 76.2).

Thirty-Month Pregnancy

Thirty-month pregnancy is a Gelbvieh-specific evaluation [155] (Table 76.3). It is similar to HP but is the probability a cow will calve as a three-year-old if she calved as a two-year-old. It aims to capture variation associated with achieving and maintaining pregnancy as a cow rather than a heifer.

Pregnancy Rate

Pregnancy rate (PR) is a reflection of a female's lifetime productivity and is calculated as the ratio between the number of pregnancies and number of breeding seasons in which she had an opportunity to conceive. PR can be influenced by the length of the breeding season as well as sampling error when a female is exposed to a shorter number of breeding seasons (which may be alleviated by requiring multiple breeding seasons of data) [151]. Furthermore, PR fails to capture variation associated with successfully producing a live calf and only emphasizes a female becoming pregnant at any time, rather than becoming pregnant early on in a breeding season [123] (unlike first-service conception rate, for example). PR tends to be low to moderately heritable (Table 76.2).

Probability of Pregnancy

Probability of pregnancy is the likelihood a female will conceive and remain pregnant. It is binary and the interpretation when comparing two animals is similar to heifer PR and PR. Like PR, probability of pregnancy fails to take into account when an animal becomes pregnant in the breeding season (females conceiving late in the season are treated identically to those that conceive early). Unlike PR, probability of pregnancy does allow for selection on pregnancy maintenance [151]. Interestingly, probability of pregnancy heritability estimates tend to be moderate, but there are few estimates available (Table 76.2).

Calving Traits

Age at First Calving

Age at first calving is an easily measurable trait because it can be calculated using a calf's birth date and the dam's birth date. Selection for age at first calving would reduce the gestational period and select for earlier maturing females [90]. Age at first calving is also favorably correlated with calving interval, calving date, lifetime productivity, and calving age in subsequent calving seasons [91, 151], creating favorable correlated responses to selection. This is intuitive, as heifers calving later tend to have a longer calving interval, a later calving date, and potentially less offspring over their lifetime. However, the date of birth for a given animal greatly influences measurements of age at first calving as animals born later in a calving season tend to be younger when the breeding season occurs. Therefore, selection for age at first calving can lead to indirect selection for heifers born later in a calving season, given breeding seasons tend to be fixed in the beef industry rather than being based on the age of the

animal [90]. Age at first calving heritability estimates range from low to moderately heritable and have been the focus of a large number of studies (Table 76.2).

Stillbirth

Stillbirth is evaluated in Holsteins by the CDCB [78]. Stillbirth indicates the percentage of offspring born dead or that die during the first 48 hours post-parturition. The CDCB estimated the heritability of stillbirth to be 0.03 and 0.065 for sire and daughter stillbirth, respectively [172].

Calving Date and Days to Calving

Calving date is the day of a calving season in which a female calved. For example, when the first female calves, the day she calved becomes day one of the calving season, and an animal calving a week later would have a calving date value of eight. Like age at first calving, it is easily calculated from calf birth date and captures variation associated with early conception in the breeding season and gestation length. Calving date could easily be incorporated into genetic evaluations and avoids some of the unwanted side effects present in selecting for age at first calving, such as selecting for later-calving females [90]. Days to calving is similar to calving date and is measured as the time period from the first AI or bull exposure to parturition. Like calving date, selection for days to calving would select for greater conception rates and shorter gestation lengths. Days to calving is lowly heritable (Table 76.2).

Calving Success

Calving success is a binary trait similar to HP. Unlike HP, calving success can capture variation associated with multiple pregnancies and maintaining a pregnancy through parturition. Calving success has not been widely used and appears to have a very low heritability (Table 76.2).

Calving to First Insemination

Calving to first insemination is a trait used in all dairy breeds evaluated by the CDCB [78]. In the dairy industry, calving to first insemination is measured in days as an interval from calving to the first breeding day [119]. In evaluations conducted by the CDCB, calving to first insemination is estimated as a linear function of DPR and cow conception rate; values are expressed in days, where a larger number indicates a longer interval before a cow begins to cycle again after parturition. Heritability estimates in beef populations are low (Table 76.2).

Lifetime Productivity and Longevity

Productive Life

Productive life is a trait used in all CDCB genetic evaluations [78]. Productive life measures the amount of time in months a female remains in lactation, thus capturing variation associated with producing calves and longevity. It is currently analyzed in a multitrait model with stillbirth, DPR, yield traits, mastitis resistance, type traits, and calving ease traits, which serve as correlated indicator traits to give information about productive life, given they tend to be measured earlier [78]. Heritability for productive life was estimated at 0.08 [173].

Sustained Cow Fertility and Stayability

Sustained cow fertility is a Hereford-specific evaluation similar to stayability [152] (Table 76.3). It is expressed as a probability, where the difference between two animals indicates the probability female progeny will have one more calf by age 12 relative to the second animal. A difference of 10 indicates a female has a 10% greater probability of having one more calf. Sustained cow fertility has gradually been rising in Herefords (Figure 76.12).

Stayability is a more general form of sustained cow fertility utilized in Chianina, Gelbvieh, Limousin, Red Angus, Shorthorn, and Simmental evaluations [154–159] (Table 76.3). Stayability represents the probability progeny of a given animal will remain in the herd till at least six years of age. Stayability captures variation associated with fertility, as animals failing to achieve pregnancy will likely be culled from the herd, but can be biased by other forms of culling (such as culling for faster genetic progress) if culling codes are not used appropriately. Stayability heritabilities tended to be similar across taurine breeds, but increase slightly on average when the age of evaluation increases from three to six years (0.16–0.18) [174].

Calving Rate

Calving rate is the proportion of calves produced by a cow relative to the total number she could have potentially produced. Calving rate is a measure of reproductive efficiency and attempts to capture the entire lifecycle of fertility in a female [118] rather than just achieving pregnancy. However, record collection for calving rate is slow and records are incomplete until late in the productive life of a female. Heritability for calving rate is low but has not been widely studied (Table 76.2).

Number of Calves

Number of calves aims to measure a female's lifetime productivity by measuring the total number of calves over a female's lifetime. Due to the nature of total lifetime productivity traits, data collection occurs later in life, leading to low accuracies until many progeny and grand-progeny have been recorded. This is a general disadvantage, but it underscores the potential for genomic technologies to increase accuracy of evaluation earlier in an animal's lifetime. Number of calves captures information associated with nearly every aspect of fertility (including stayability). Heritability estimates are moderately high in some studies but generally tend to be low (Table 76.2).

Cumulative Productivity

Similar to stayability and number of calves, cumulative productivity, a relatively new trait in the literature, tracks the production over a female's lifetime. Unlike number of calves and stayability, cumulative productivity can be used to ascertain fertility variation associated with stayability and number of calves as well as production (i.e. total weaning weight of all calves rather than just the number of weaned calves). Like stayability, estimates of heritability for different measures of cumulative productivity increase with age. From two years to eight years of age, heritability increased from 0.10 to 0.24 for calves born and 0.04 to 0.23 for calves weaned. Likewise, weight weaned increased from less than 0.10 to 0.36 at eight years [175].

Unlike many male fertility traits, most female fertility traits are considered lowly heritable and data collection is often more difficult. Under these constraints, genetic progress tends to be slow, though it can be made and should not be ignored. Greater immediate gain can often be realized by managing non-additive effects (like heterosis) using crossbreeding systems. Given the importance associated with accurately selecting replacement females due to the substantial economic investment made by producers, genomics can provide much-needed information to bolster genetic prediction for fertility traits.

Emerging Genomic Technologies

The incorporation of genotype data into genetic evaluations is crucial for genetic improvement in the livestock industry. However, there are also many emerging genomic technologies that have the potential for commercialization and utilization within the beef and dairy industries. We will review a number of these technologies in this section – embryonic lethal haplotypes, embryo biopsying, and gene editing.

Embryonic Lethal Haplotypes

A haplotype is a series of SNPs located in close proximity that are inherited together. They can be thought of as blocks of the genome, represented by concatenated SNPs that are inherited together (Figure 76.13). Researchers can use haplotypes to better model the potential causal mutation(s) associated with a trait when the causal mutation is not known.

One type of mutation that is of particular interest to producers is embryonic lethal mutations. These mutations are typically recessive "broken genes" that manifest themselves during embryonic development at the time point when that gene product is needed for development. At this time, spontaneous abortion occurs due to the lack of a necessary gene product and the cow will come back into heat. This will result in greater numbers of open cows (especially with shorter breeding seasons) and cows conceiving much later in the breeding season. The manifestation of these mutations as open cows and the lack of stillborn or abnormal progeny makes these types of mutations particularly hard to identify and manage, absent genomic testing, because their effects cannot be easily separated from other environmental effects on PR. However, these mutations have a unique feature that facilitates their identification: the fact that we never see these alleles/haplotypes in homozygous form in populations of live animals because homozygous animals are never born [176].

There are currently 14 known haplotypes connected to female infertility or progeny loss in dairy cattle, and

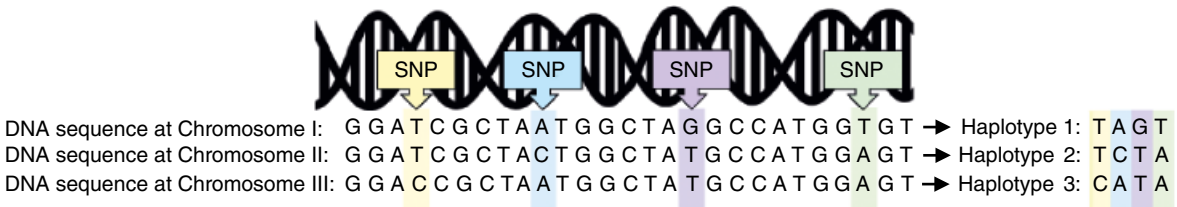

Figure 76.13 Haplotypes are made up of concatenating SNPs.

another 10 fertility haplotypes have been discovered in beef cattle. All 24 haplotypes are summarized in Table 76.4.

Fertility haplotypes that occur at higher frequencies are associated with greater pregnancy loss. For example, in Table 76.4, AA14H3 is present in Angus populations at a frequency of 15.2%, which is higher than any other haplotype listed. This indicates that AA14H3 is more likely to be homozygous in an embryo by chance, thus causing pregnancy loss. In contrast, homozygous haplotype deficiency (HHD) is very rare in Holsteins and is only reported to occur at a frequency of 0.01%, so it is unlikely that two animals chosen at random will both be carriers of this mutation and little pregnancy loss is expected due to this mutation. Fortunately, with genomic testing, these mutations can be managed within the population similarly to the recessive genetic abnormalities already discussed at the beginning of this chapter. As long as two carriers of the same mutation/haplotype are not mated together, there should be no pregnancy loss expected as a result of that mutation. Because of this, producers should not immediately cull heterozygote carriers of a lethal allele, but rather manage the herd and matings accordingly.

Embryo Biopsying and Genotyping

Genotyping of embryo biopsies enables breeders to make selection decisions on animals that have not been born yet. For example, calves with poor genetic merit that would be traditionally culled after birth or those of an undesirable sex can be culled before the embryos are implanted. Embryo biopsying and genotyping are tools that are not yet commonly utilized in cattle but would enable screening of embryos for heritable diseases, genetic defects, and sex in addition to evaluation of genetic merit for production traits before the animal is even born.

Table 76.4 Fertility haplotypes in dairy and beef cattle.

Breed	Haplotype	Chromosome	Region (bp)	Frequency (%)
Brown Swiss	BH1 [176]	7	42 811 272–47 002 161	6.67
	BH2 [177]	19	11 063 520	7.78

Charolais	CH19H2 [192]	19	48 874 999–48 902 319	14.4

The capability to biopsy and genotype animal embryos facilitates quicker generational intervals when making selection decisions for even faster genetic gains. Moreover, biopsying embryos early in development takes advantage of the embryo's natural plasticity in its resilience to environmental stressors [193].

There are many assisted reproductive technologies available to cattle producers, but embryo biopsying is one of the only methods able to guarantee the sex of progeny before birth. Scrutinizing the sex of embryos might sound trivial but can be very important to the overall profit and productivity of an operation. For instance, the goal of many dairy farms is to raise replacement heifers, which can be impaired by a surplus of male births. Although sexed semen technology exists, it can only dramatically increase the chance of producing a calf of the desired sex. Fetuses can be sexed by ultrasound beginning 60 days after conception [194], but biopsied embryos allow filtering of embryos based on sex before implantation occurs.

Furthermore, genotyping embryos can reveal the alleles present for deleterious genetic conditions or important SNPs of interest [1]. With the increased use of genomic testing, it has become more common to find livestock producers not only genotyping animals at birth, but also now genotyping embryos [1]. Another advantage to genotyping embryos is the ability to reduce the costs associated with multiple embryo transfers by selecting only the most desirable embryos for implantation [195].

There are two approaches to cultivating embryos for biopsying and genotyping: *in vivo* (VV) and *in vitro*-produced (IVP). VV embryos are cultivated in the living animal and flushed for genomic evaluation, whereas IVP embryos are grown in laboratory settings, with oocytes collected from the dam [196].

Once the fertilized egg reaches the blastocyst or morula stage, it can be biopsied for genomic analysis and subsequently implanted into the recipient dam. Biopsying an embryo requires aspirating part of the trophectoderm, or inner cell mass, and extracting its DNA for further evaluation [193]. However, this requires breaching the protective outer layer of the embryo, the zona pellucida. Thus, a biopsied embryo is compromised and at a greater risk of degradation than an embryo with an intact zona pellucida [193]. If embryos cannot be implanted immediately after biopsy, they must be cryogenically preserved, which can also increase risk of damage to the embryo and influence embryo viability [193]. There are three commonly used approaches to collect embryonic cells for genotype analysis: needle, aspiration, and microblade techniques.

Studies have concluded that there is no significant difference in embryo viability between the three common biopsy techniques when embryos are implanted soon after the procedure [193, 197], but embryos that have been cryogenically preserved have a greater chance of survival when the zona pellucida remains as intact as possible [193].

A study from 2012 compared the effectiveness of each technique and found that frozen embryos biopsied via the needle technique yielded a PR of 57%, but those biopsied with the aspiration and microblade techniques were associated with lower PRs at 43 and 31%, respectively [193]. The greater pregnancy successes of needle and aspiration techniques are attributed to less zona pellucida damage, but these techniques are more laborious and yield less DNA than the microblade method.

In 2016, the cost of embryo biopsy and genotyping was estimated at $150 USD, which is more expensive than many other assisted reproductive technologies [198]. Although embryo biopsies involve similar levels of risk to the oocyte donor and recipient dam as embryo transfers, embryo biopsying is an invasive procedure that presents an additional level of risk for the embryo. The success of implanting a biopsied embryo will ultimately depend on technician skill, the embryo's developmental stage at the time of biopsy, biopsy technique, time between biopsy and implantation, and animal health. Embryo biopsying is a relatively recent genomic tool that has the potential to expedite genetic improvement in the livestock industry, but its practical application and cost-benefit ratio may vary among species and individual producers.

Gene Editing

Genomic selection can increase the productivity and profitability of cattle enterprises, but gene editing, or precision breeding, could be used as an effective complement to genomic prediction in cattle. Gene editing is currently most practical for simple Mendelian traits controlled by one mutation. Quantitative traits involve the interaction of many alleles, and for most traits the causal mutations are unknown, thereby increasing the potential complexity involved in precision breeding. Gene editing is the process of permanently altering the genomic sequence at specific sites in the DNA sequence [199]. There are three major gene editing tools used today: zinc finger nucleases (ZFNs), transcription activator-like effector nucleases (TALENs), and clustered regularly interspaced short palindromic repeats (CRISPR). Although these methods all result in permanent genome modification, the molecular mechanisms behind them differ. Even if the mechanisms differ, all of them involve making targeted cuts to the DNA sequence and allowing the cell's repair mechanism to either directly repair the break (often silencing the gene where the cut was made) or repair the break by inserting

donor DNA (which can be used to add a sequence of interest to the genome or "correct" mutations within the DNA).

Once the site-directed nuclease system, either ZFNs, TALENs, or CRISPR, cuts the targeted DNA sequence, scientists use the cell's natural DNA repair machinery to permanently alter the genome. Once both DNA strands are cleaved, the cell will perform one of two repair processes. Both are illustrated in Figure 76.14. The first is non-homologous end joining (NHEJ), whereby the DNA strands are annealed back together. However, this repair process typically causes a mutation (addition or deletion of a DNA base or bases) in the sequence. The mutation(s) introduced by NHEJ often disrupt the gene enough to render it inactive, resulting in what is known as a knockout. Knockouts can be useful in determining the function of a gene and its importance for normal growth and development. They could also be used to prevent a particularly detrimental gene from being expressed. Alternatively, the cell will undergo homology-directed repair (HDR) if a separate strand of intact DNA is used as a template to reconstruct the broken strands. The specificity by which HDR functions is important for introducing a predesigned sequence to replace the nucleotides originally at the locus of interest. This process can be used to correct deleterious alleles associated with heritable diseases or disorders, as an example. Single nucleotides can be pinpointed and altered, or entire strings of nucleotides can be added to the sequence of interest by taking advantage of the cell's natural HDR mechanism [200].

In the cattle industry, applications of gene editing technology have mostly centered on traits with large phenotypic effect as a proof of concept. For example, some mutations in the myostatin gene (*MSTN*) result in the double-muscled phenotype often seen in Belgian Blue and Piedmontese cattle. In 2015, researchers out of Texas A&M University altered the *MSTN* gene in a Nelore bull so that it would be identical to the mutation found in Belgian Blue cattle responsible for at least part of the double-muscled phenotype. This simple edit resulted in a Nelore bull with increased muscle mass and increased retail product [201].

Gene editing technology has also shown potential in animal management. For example, polled cattle present a lower risk of injury to themselves, their handlers, and their herdmates than their horned counterparts [202]. Dairy cattle tend to be more intensively managed than beef cattle, making polled animals even more valuable in dairy operations. However, the POLLED allele is currently much more common in beef animals than dairy. Traditional selection for the polled trait in dairy cattle would be slow and the necessary backcrossing to either polled beef cattle or polled dairy cattle (which have substantially lower average milk production than horned dairy cattle) would result in a dramatic decrease in performance. Gene editing offers a way to fast-track this process by inserting the polled allele into the genome of an animal with exceptional milk production performance [203]. It is far easier to incorporate polled alleles into dairy cattle embryos through precise gene editing rather than traditional breeding methods [204].

Additionally, gene editing could be used to correct deleterious alleles, like lethal recessives. Recent research in mice has demonstrated that prenatal gene editing can alter nucleotides responsible for producing lethal phenotypes to increase survivability after birth and mitigate developmental abnormalities [205, 206]. This has the potential to easily and effectively eradicate recessive lethal alleles from the population without any negative effect on cattle performance, such as we might observe if carriers are culled indiscriminately from the population.

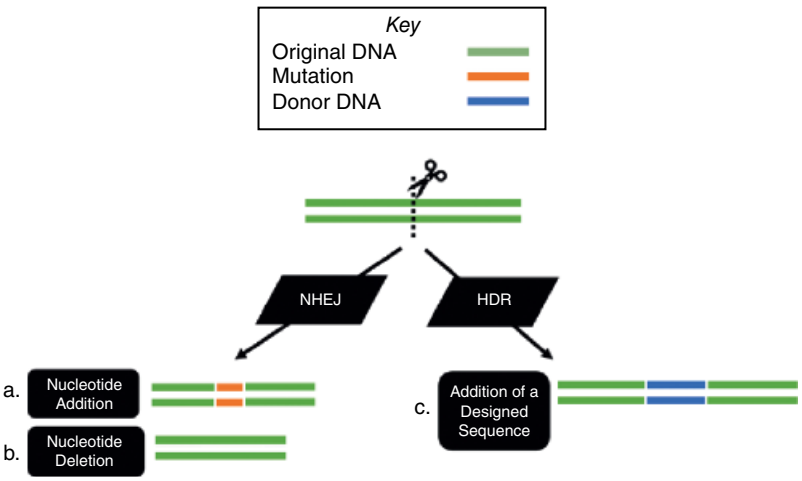

Figure 76.14 DNA repair processes.

Summary

Genomic technologies have enabled producers to more effectively select the most desirable animals, manage genetic abnormalities, improve management, and make rapid genetic progress. New genomic tools, such as embryo biopsying and precision breeding, hold promise that breeders will soon be able to directly and precisely influence the genetic merit and characteristics of their herds to better fit various breeding objectives [207]. As genomic technology continues to advance, there is no doubt that the livestock industry will benefit greatly from the genomic developments ahead.

Technological Advances that Enhance the Quantity and Quality of Spermatogenic Production

Muhammad Salman Waqas

Department of Theriogenology, University of Agriculture, Faisalabad, Pakistan

Feeding the 10 Billion Human Population

The human population will grow to about 10 billion by 2050 [1, 2]. Feeding the 10 billion will require enhanced livestock production which necessitates improved livestock reproductive efficiency. While we can control some other inputs for more efficient food production, the genetic potential of animals is an intrinsic limiting factor which cannot be controlled after birth. Thus, there is a need to further enhance the genetic potential to boost more efficient food production. The extensive use of elite gametes is the best tool to enhance this [3] by increasing genetic potential. Human beings have been breeding animal females selectively with elite males since the domestication of animals. Artificial insemination (AI) has been used to spread elite male germplasm especially in dairy production since the 1960s [3]. As the male germplasm is the major tool to spread elite genetics, spermatozoa are and will remain the main target to fill the need [3]. Both the quantity and quality in terms of genetic potential of spermatozoa from the bull must be improved to ensure profitable and efficient spread of elite genetics for more efficient food production. The increased quantity of spermatozoa per animal will decrease the price of the semen, while the increased genetic quality will enhance the production potential of the progeny.

Increasing the Quantity of Spermatogenesis per Bull

Historically and traditionally, males of livestock species have been selected for breeding based upon scrotal size. Increased sperm production from the elite male will enhance the speed of genetic improvement in livestock through widespread use of desired genetics. Increased sperm production per bull will decrease the cost of semen production per bull at a fixed cost of maintenance. The bulls will produce more spermatozoa per ejaculate, enhancing their utilization in semen sexing programs. Sexed semen enables rapid herd expansion by supplying replacement heifers for dairy and increases profit through male calves for beef production [4]. One of the criterion for a bull to be enrolled in a sex sorting program is that it must give ejaculate(s) with six billion spermatozoa for each run of the semen sexing process [4]. Lower daily sperm production (DSP) in some adult bulls makes them unsuitable for supplying these many spermatozoa for the semen sexing process, hence such bulls are not enrolled to sex sorting programs even if they possess elite production potential. Moreover, younger bulls cannot produce the required six billion sperm cells for each run of the semen sexing process because they have lesser DSP. So, such bulls are enrolled in sex sorting programs at or after two years of age. As the bull attains puberty at about one year of age, this late enrollment at or after two years of age delays genetic improvement [4]. An increase in DSP will reduce the problem of no enrollment to the semen sexing program of a bull with lower DSP or late enrollment due to lower DSP in younger bulls at or after two years of age. Thus, an increased DSP in the bull will enhance the speed of genetic improvement through sex sorting [5]. Moreover, the cost of bull maintenance and DSP are major factors affecting the cost of sexed semen and of AI [6, 7]. The cost of semen production can be reduced by obtaining more spermatozoa per bull at the fixed cost of maintenance per bull, i.e. by increasing DSP per bull. Increased DSP in the bull is advantageous for rapid genetic improvement in cattle production, for decreasing cost of semen production in (AI) and semen sexing programs, and for obtaining more spermatogonial

stem cells (SSCs) for SSC transplantation [8], and therefore is of interest to livestock industries.

Methods to Increase Sperm Production per Bull

Several methods including unilateral castration, immunization against inhibin, and immunization against estradiol have been used to increase the testicular size and DSP of the bull; however, none of these has gained commercial success [8, 9]. DSP in the bull is positively correlated (R = +0.83) to the number of total Sertoli cells (SCs) per testes and becomes fixed once proliferation of SCs stops [10]. SC number in the testes of an individual, excluding some seasonal breeders, is fixed at a species-specific age when SCs have differentiated and stop dividing indefinitely. A potential method to increase DSP in the bull is by increasing SC number per testis through the induction of temporary hypothyroidism [5].

Thyroid Hormone and Testicular Function

Effect of thyroid hormone (TH) on body organs including liver, kidney, and skeletal muscles is by indirect actions on the tissue metabolism [11]. However, TH alterations do not affect testicular metabolism [11] or testicular function [12] in the adult animal. Unlike other body organs, adult testes do not respond metabolically to TH by increasing oxygen consumption and mitochondrial alpha-glycerophosphate dehydrogenase and possess meager TH receptors [13]. Thus, adult testes are not affected by hypothyroidism or hyperthyroidism. Conversely, adverse effect of TH manipulation, precisely of hypothyroidism, on prepubertal ovarian [14] or testicular [15] function has been known for a long time. Maqsood (1952) [15] reported that hypothyroidism inhibited testicular development and delayed the onset of spermatogenesis. Though these effects of hypothyroidism on testicular function could have been attributed to effects of the deficiency on testicular metabolism or gonadotropins, effects of TH on the testicular function were verified as direct actions of TH on testicular parenchyma during the late 1980s [8].

Though adult testes lack significant TH receptors, demonstration of TH receptors in neonatal testes suggested a possible role of TH in testicular function during prepubertal development [8]. Nuclear receptors of thyroid hormone (TNRs) [16] and associated mRNA [17] are highly expressed in neonatal testes predominantly in SCs and the expression is the highest until a few days after birth in the rat.

Postnatal hypothyroidism inhibits SC maturation [18], delays seminiferous tubular lumen formation by inhibiting proluminal fluid secretion from SCs and increases germ cell degeneration [19]. TH also affects secretion of androgen binding proteins [20] and insulin-like growth factor (IGF)-1 [21], glucose transport [22], protein synthesis and other metabolic processes of developing SCs [18].

Thus, TH is required for proliferation, capacity building to support complete spermatogenesis, development of secretory function, and differentiation and maturation of SCs [8].

Induced Transient Hypothyroidism (ITH)

Hypothyroidism adversely affects SC development and hence testicular function, and thyroxine treatment reverses these adverse effects [23]. *However, if hypothyroidism is induced transiently, the animal reverts to euthyroidism and the induction helps to boost sperm production through increasing SC number* [5].

ITH Enhances Sperm Production in the Bull

To increase sperm production transient hypothyroidism must be induced before the time-point when SC division stops and must be stopped sometime after the time-point. The bull must return to euthyroidism after the induction is removed, otherwise permanent hypothyroidism will adversely affect testicular function. SC proliferation in the bull stops sometime between 4.5 and 5 months of age [5]. ITH was successfully achieved in hybrid beef bulls (Angus cross Wagyu) with the antithyroid compound methimazole (2 mg/kg body weight) twice daily from four to six months of age [5]. Based on serum levels of triiodothyronine (T_3) and thyroxine (T_4), induction of a hypothyroidic state occurred by three weeks of treatment, before the bulls had reached five months of age. Following the treatment period, serum levels of T_3 and T_4 returned to normal by about 6.25–6.75 months of age of the bulls.

During the age period when puberty is normally established in the bull (10–16 months), mean body weight and scrotal circumference were significantly reduced for the treated bulls compared to the control group. However, by 16 months of age both parameters were not significantly different between the two groups. These findings indicate that transient induction of hypothyroidism during the period of SC development delays the normal timeline for the onset of puberty in bulls. Although the growth rate is reduced during the peripubertal period, ITH does not affect mature body weight. ITH resulted in ~2.3-fold increase in SC number and increased sperm production from the treated bulls. The treated bulls produced ~30–180% (i.e. 1.3- to 2.8-fold) more spermatozoa compared to the control bulls at 24–28 months of age. The fresh sperm motility or

morphology and the post-thaw survivability and motility were not affected by the temporary hypothyroidism. Cleavage and blastocyst rate for the freshly collected or post-thaw spermatozoa after *in vitro* fertilization (IVF) were not different between the groups. The treated bulls had a 22% increase in paired testes weight and 50% increase in paired epididymal weight, reflecting increased testicular and epididymal germ reservoir. Thus, transient induction of hypothyroidism during prepubertal development in bulls leads to permanent increase in normal spermatogenesis in adulthood [5].

ITH extends the period of SC proliferation by slowing down the inhibition of their proliferation. During the treatment phase, ITH results in germ cell degeneration, delay in seminiferous tubular lumen formation, and smaller diameter of the seminiferous tubules. However, once the treatment is stopped, these maturational defects are quickly reversed and normal testicular development and maturation starts [24]. ITH increases number reduces volume of LH receptors and decreases steroidogenic capacity of Leydig cells. However, their increased number compensates for the reductions to maintain normal blood testosterone levels [25]. The absence of TNRs from Leydig cells suggests that their number increases in response to paracrine factors from an increased number of germ cells, peritubular myoid cells, and particularly SCs [8].

Possible Mechanism of ITH

Two hypotheses have been proposed regarding the mechanism of action of TH on SCs.

1) TH acts on SCs through cell cycle proteins: cyclin-dependent kinase inhibitors (CDKIs) $p27^{Kip1}$ and $p21^{Cip1}$. TH upregulates $p27^{Kip1}$ (CDKN1B) and $p21^{Cip1}$ (CDKN1A) which then inhibit subsequent phosphorylation activity of cyclins D and E. In proliferating SCs, cyclins D and E bind to cyclin-dependent kinases (Cdk) 4 or 6 and Cdk 2. Once the cyclin–Cdk complex is activated, it phosphorylates the pocket proteins, p^{Rb}, p^{130}, and p^{107}. This phosphorylation releases transcription factors of the E2F family which activate downstream genes for progression of the cell through G1 restriction point [26]. This mechanism has been suggested by the findings that TH induces the expression of $p27^{Kip1}$ and $p21^{Cip1}$ in neonatal murine SCs, whereas ITH decreases $p27^{Kip}$ [27, 28]. Moreover, $p27^{Kip1}$ knockout (p27KO), $p21^{Cip1}$ KO (p21KO), and p27/p21 double-KO (DBKO) mice showed 42, 27, and 86% increase in testes weight, respectively. SC numbers were increased by 126, 48, and 126%, respectively. DSP was also increased in all the knockouts. However, p27KO had 5% and DBKO had 1.5% seminiferous tubules with abnormal spermatogenesis as compared to only 0.5% for the wild-type control. Furthermore, in KO mice, developing germ cells, pyknotic spermatogenic cells, and fewer spermatozoa were found within the epididymides [26].
2) The finding that hypothyroidic treatment of p27KO and DBKO mice results in increased testes weight and DSP [29] suggested that ITH actions on SCs involve some other mechanism also. Another possible mechanism involves Connexin43 (Cx43). Just before puberty, SCs form specific intercellular junctions with neighboring SCs and with adjacent germ cells [30]. Connexin-based gap junctions are cell membrane channels that allow intercellular communication and thus control cell proliferation and differentiation [31]. Cx43 is the most abundant testicular gap junction protein [32]. Inhibitory effect of TH on SC proliferation is associated with a time- and dose-dependent increase in Cx43 which increases gap junction communication and stops SC proliferation. Oleamide and glycyrrhetinic acid, specific blockers of gap junction coupling, reverse the inhibitory effect of TH on SC proliferation [33]. SC-specific Cx43 knockout (SC-Cx43 KO) mice are infertile and have continued SC proliferation, actively proliferating early spermatogonia without advancement to subsequent spermatogenesis and delayed age at maturity [34–36].

Transgenesis to Increase Sertoli Cell Number

Application of CRISPR/Cas technology to livestock may be used to increase SC number and DSP. Knocking out $p27^{Kip1}$, $p21^{Cip1}$, or Cx43 may lead to an increase in SC number and DSP as seen in the mice. However, the knockout mice had abnormal spermatogenesis and were infertile. At present, induction of transient hypothyroidism to increase SC number is the most applicable method to increase DSP in the bull. Moreover, ITH to increase SC number in germ cell ablated *NANOS2*-knockout surrogate bulls may increase the success rate of SSCs transplantation in the bull.

Improving the Genetic Quality of Spermatogenesis

The majority of genetic improvement in cattle production has resulted from expansion of elite male germplasm through AI. In the USA, adaptation of AI led to a 4.5-fold increase in milk production per average dairy cow from 1940 to 2009 [37]. While AI has been a successful tool for genetic gain in dairy cattle, it has not been adopted by beef

cattlemen due to different management systems. Only about 5–10% of beef cattle production systems use AI, in contrast to 80% of dairy production systems. Thus, the male germplasm from elite bulls cannot be spread through AI in beef production systems. Through natural mating, an elite bull can impregnate only a limited number of cows per breeding season based upon its DSP. Hence, there is a need to find a suitable technique to spread the spermatozoa from elite beef bulls to large-scale beef production. One such possibility is through donor-derived spermatogenesis in surrogate sires [3].

Surrogate Sires

A surrogate sire refers to a bull that lacks his own germ cells but produces spermatozoa of another bull after SSC transplantation [38] (Figure 77.1). Having many recipient surrogate bulls producing donor-derived spermatogenesis of desired elite genetics will preserve the elite genetics for indefinite time, hasten the spread of desired male genetics [37, 39], provide more bulls producing genetically elite spermatozoa for natural mating in beef production, and decrease cost of semen production in AI programs. Additionally, spermatozoa of an elite prepubertal bull calf can be produced in a recipient by transplantation well before the donor would have reached puberty [3]. Importantly, this will solve the problem of poor semen quality of AI bulls of temperate breeds, imported to tropical conditions [40–42], as recipient bulls local to the tropical regions can produce spermatozoa of the elite temperate breeds not well adapted to the tropics. Such donor-derived spermatogenesis in the recipient bull from the donor bull requires: (i) ablation of the germline of the recipient so that it does not produce its own spermatozoa but has normal libido, physiology, and testicular architecture; and (ii) transplantation of germ cells/SSCs from the testes of an elite bull to the testes of the donor bull. The objective is the production of elite spermatozoa of the donor haplotype by the germ cell ablated recipient bull [3]. The ultimate success in such transplantation is fertile donor-derived spermatogenesis without any indigenous spermatogenesis so that all (100%) next generation will be from the spermatozoa of the elite donor genetics [3].

Recipient Preparation: Ablation of Germ Cells

SSC transplantation leading to commercially adaptable continuous donor-derived spermatogenesis has not been successful in any livestock species. One major limiting factor for success of this technique in cattle has been unavailability of fully germ cell ablated recipients having intact seminiferous epithelium and testicular somatic cells [43]. One fundamental requirement for donor-derived spermatogenesis without any indigenous spermatogenesis is complete ablation of the germ cells in the recipient testes. While the germ cells are ablated, the somatic cells and histological architecture of the testes must not be disturbed. Possible ways to ablate indigenous germ cells are as follows: (i) chemical ablation with

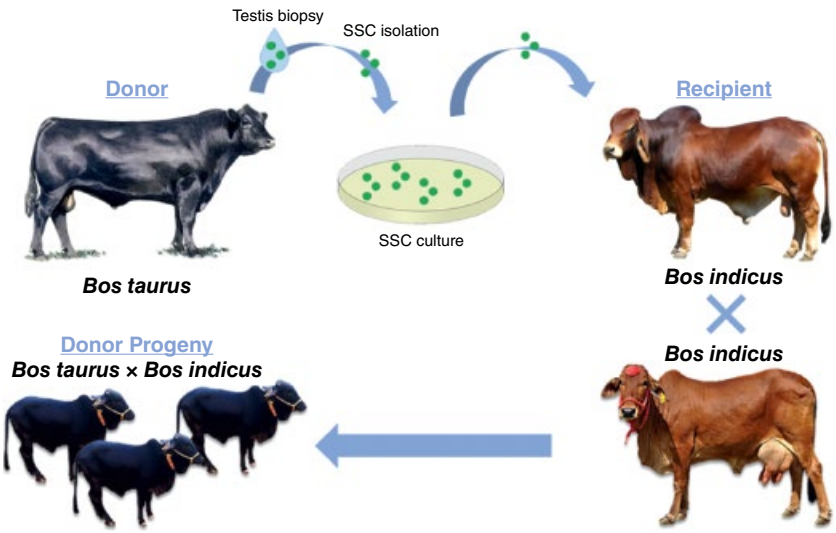

Figure 77.1 Schematic representation of surrogate sire technology. Spermatogonial stem cells (SSCs) can be obtained from an elite sire (*Bos taurus* here) through testicular biopsy. SSCs can be expanded *in vitro* to increase their number before transplantation to a germ cell ablated recipient (*Bos indicus* here). Breeding the recipient *Bos indicus* bull to a *Bos indicus* female will result in *Bos taurus* × *Bos indicus* progeny.

chemotherapeutic agents such as busulfan is practiced in rodents for germ line ablation in research settings. However, the technique is practically difficult for the bull due to the large dose required; (ii) degeneration of germ cells with high-dose testicular X-ray irradiation has been studied in cattle [44]. The ablation and subsequent donor's germ cell transplantation resulted in donor-derived spermatogenesis. However, the indigenous germ cells were not completely degenerated. Moreover, both donor- and recipient-derived spermatozoa were present in the ejaculate. Thus, this technique did not gain commercial success; (iii) a recently studied technique is the ablation of indigenous male germ line through gene editing. Inactivation of the *NANOS2* gene in mice and pigs completely ablates germ cells from testes by apoptosis of prospermatogonia; moreover, histological organization of seminiferous tubules and levels of serum testosterone are not affected [43, 45, 46]. Such genetically modified recipient cattle could serve as suitable recipients for exogenous SSCs transplantation. Embryologically, SSCs are derived from prospermatogonia at species-specific time in the testicular development process [47]. Apoptosis of prospermatogonia is expected to be the method of choice to prepare recipient males for exogenous SSC transplantation in livestock [48]. *NANOS2* is expressed in male primordial germ cells and *NANOS2* knockout mice lack germ cells in intact seminiferous tubules [45, 46]. Recently, the strategy to eliminate prospermatogonia by biallelically inactivating *NANOS2* to completely ablate germ cells has been successful in male pigs. The pig had histologically normal seminiferous tubules and normal serum testosterone levels [43]. Both in pigs and mice, homozygous *NANOS2* knockout (biallelically gene edited) males lack germ cells, while homozygous and heterozygous knockout (monoallelically gene edited) females and heterozygous knockout males are fertile [43, 45, 46]. Practically, biallelically *NANOS2* gene edited males lacking any germ cells will serve as suitable recipients for exogenous SSC transplantation. Furthermore, breeding of biallelically *NANOS2* gene edited females and monoallelically *NANOS2* gene edited males, both fertile, can be used to generate more biallelically knockout males (Park et al., 2016).

Presently, *NANOS2* gene edited males are the best candidates for surrogate sire technology to trasplant elite SSCs and subsequent donor-derived spermatogenesis [3]. However, the production of *NANOS2* gene edited bulls, testing their ability to support donor-derived spermatogenesis without any indigenous spermatogenesis, and the birth of offspring of the elite donor-derived genetics are under study [3].

Germ Cell Transplantation

The germ cells are transplanted through ultrasound-guided needle injection into the rete testis through gravity flow [49]. In the author's experience, the gravity flow of the germ cell suspension solution into the rete testis is more efficient for filling the seminiferous tubules than pushing the cells into the rete testis by using a peristaltic pump. The following cells can be transplanted [50] (Figure 77.2):

- SSCs
- Total testicular digest as it has SSCs
- Non-teratoma-forming subpopulations of primordial germ cell-like cells derived from:
- embryonic stem cells from an embryo of elite genetics
- mesenchymal stromal cells from any tissue
- induced pluripotent cells obtained after inducing pluripotency in somatic cells.

SSCs are considered the most suitable candidate for transplantation into the recipient testes. Spermatogenesis in the seminiferous tubules of testes produces millions of spermatozoa per day. SSCs residing on basement membrane of seminiferous tubules provide more germ cells, along with maintaining their own number, by their divisions for this enormous sperm production per day [47, 51]. SSCs reestablish spermatogenesis after their transplantation to germ cell depleted recipient testes [52]. The donor-derived spermatogenesis can produce offspring of the donor haplotype [53]. Donor-derived spermatogenesis after exogenous SSC transplantation is well established in mice and currently is the main criteria to study functional characteristics of rodent SSCs [54]. Also, donor-derived spermatogenesis after germ cell transplantation has been reported for non-human primates [55], goat [56], pig [57], and cattle [44]. However, offspring from donor-derived spermatogenesis or continuous robust donor-derived spermatogenesis has not been achieved in cattle [37].

SSCs can be obtained from testicular biopsy, expanded *in vitro* through SSCs culture and then transplanted to recipient testes. However, at present, an efficient culture system for bovine SSCs is not available [38].

The surrogate sire technology could materialize into a commercially viable tool for rapidly expanding desirable genetics, thereby having a positive impact on cattle production systems worldwide.

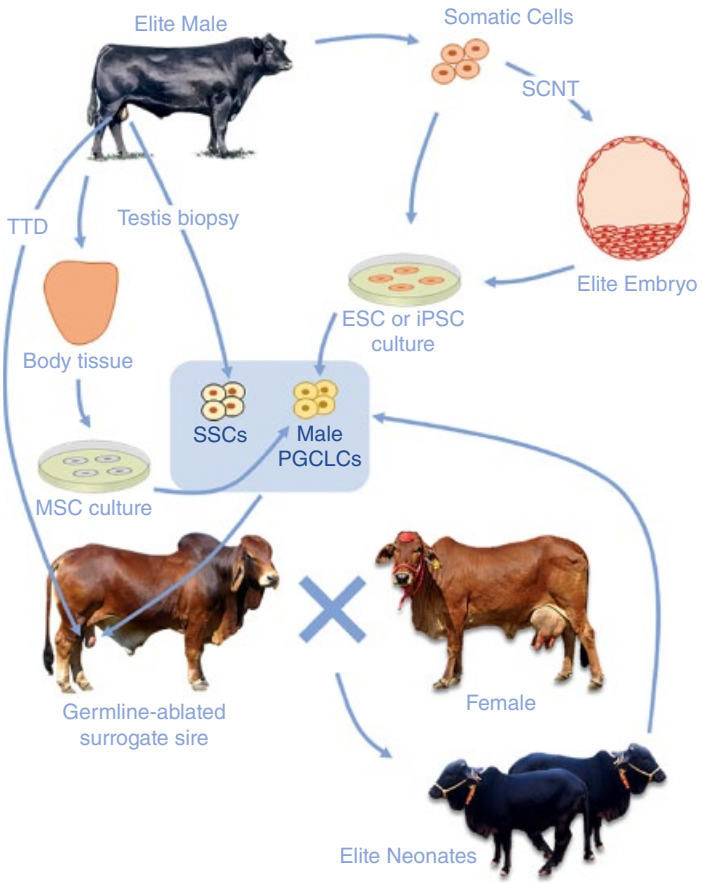

Figure 77.2 Options for donor germ cell types for germ cell transplantation to a germline-ablated recipient bull. Testes can be digested to single cell suspension and total testicular digest (TTD) transplanted to the recipient testes. SSCs obtained from testicular biopsy can be expanded *in vitro* before transplantation to a recipient bull – the most applicable and logical option. Primordial germ cell-like cells (PGCLCs) can be derived from an embryonic stem cell (ESC) of an elite embryo obtained after somatic cell nuclear transfer (SCNT) using elite male genetics, from mesenchymal stem cells (MSCs) from some body tissue of the elite male, or from induced pluripotent stem cells (iPSC) derived from an elite bull. *Source:* Modified from [50].

Cryopreservation of Semen

Swanand Sathe

Cambridge Equine Hospital, Cambridge, New Zealand

Introduction

Artificial insemination (AI) and cryopreservation of spermatozoa are probably the two great advances that have revolutionized the breeding industry. The dairy industry in particular has benefited from the extensive use of AI, which has permitted an accelerated rate of genetic selection and improvement. It is estimated that more than 60% of dairy cattle in the USA are bred with AI programs as compared with just 10% of beef cattle. The history of semen cryopreservation dates back half a century to the discoveries of the protective agents in egg yolk for cooling and glycerol for freezing fowl and bull sperm [1] and the birth of the first calf by AI using frozen/thawed spermatozoa [2]. Bratton et al. [3] in their field trials demonstrated that bovine sperm frozen to −79 °C and packed on dry ice could still yield high fertility. Since then several media formulations termed "extenders" have been investigated based on their ability to improve the survivability and post-thaw motility of cryopreserved sperm. Similarly, several cryoprotective compounds have been investigated for their protective role during cryopreservation of semen. There is little doubt of the profound effect this technology has had on the cattle industry. This has largely been possible due to the remarkable success that has been achieved with bull semen as compared with semen of other species. This has mainly been due to the higher tolerance of bovine sperm to cryoprotectants such as glycerol as compared with other species and the relatively few number of spermatozoa required for conception [4].

Principles of Cryopreservation

Mechanisms of Cell Injury During Cryopreservation

Semen cryopreservation techniques have been in practice for the past several decades and allow long-term storage of semen and hence its virtually unlimited availability. This facilitates the large-scale provision and dissemination of highly valuable genetic material at will. Cryopreservation of semen involves the freezing of spermatozoa to −196 °C, the boiling point of liquid nitrogen, a commonly used medium for freezing and storage purposes. This increases the viability of the individual cells by slowing down their metabolic rate, thereby reducing the rate at which substrates are used and toxins are produced. Semen may also be stored after cooling to 5–8 °C and will survive for 24–48 hours without a significant decline in motility, and even up to 96 hours without a significant drop in fertilization rates. Although this may provide an efficient and successful means of short-term storage, it has some adverse effects on the spermatozoa manifested as a decline in viability rate, structural integrity, motility, and conception rates [5, 6]. Cryopreservation, on the other hand, offers the option of indefinite storage of semen in liquid nitrogen with acceptable post-thaw fertility rates. Cryopreservation can be detrimental to sperm function and fertility even with the latest advances in techniques. However, it is not the long-term storage of cells at these temperatures that is damaging, but rather the progression to these temperatures

and back to normothermia which results in cryoinjury [7]. Thus the changes that occur during freezing are mainly ultrastructural, biochemical, and functional. These can impair sperm transport and survival in the female reproductive tract and reduce fertility in domestic species [8].

The effects of cryopreservation on function and viability have been extensively studied for bovine sperm. Spermatozoa have a very limited biosynthetic activity of their own and depend mostly on catabolic processes to function [9]. Thus to halt these metabolic processes the cells need to be cooled below −130 °C. Sperm, like other cells in the body, are composed of various organelles containing water, which can form intracellular and extracellular ice crystals during the freezing process. At temperatures around −5 °C the intracellular and extracellular water remains unfrozen in a supercooled metastable state. However, between −5 and −10 °C, ice forms in the extracellular medium, while intracellular water remains supercooled. At this point, the rate of cooling must be slow enough to permit cellular dehydration to occur, avoiding the freezing of the intracellular water yet fast enough to avoid exposing the cell to a hyperosmotic condition subsequent to dehydration. Severe dehydration leads to solution-effect injury caused by denaturation of macromolecules and extreme shrinkage of the cell up to irreversible membrane collapse [10]. Another damaging effect is the mechanical stress of ice formation all around the cell, which will be constrained to a very limited space of unfrozen solutes [10]. Cell viability plotted as a function of rate of freezing presents an inverted U-shaped curve. Primary causes for cellular damage are largely dependent on the cooling rate employed during the freezing process. The most appropriate freezing rate is the fastest one that allows freezing of extracellular water without intracellular ice formation. Fast cooling between 30 and 0 °C results in cell injury in some sperm cells, called "cold shock," with deleterious effects on the cytoskeleton and genome-related structures and causing cytoplasmic fracture [11]. Cold shock also alters the permeability of various membrane structures on the plasma membrane, mitochondria, and acrosome. During cryopreservation, ice crystals form in the extracellular medium, increasing the osmolality of the unfrozen water. Because of this difference in the osmotic gradient, the intracellular water diffuses out of the sperm, thus dehydrating the cell and the plasma membrane. At thawing, this phenomenon is repeated in reverse order as extracellular ice crystals melt and water starts diffusing in and rehydrating the cell. Because of such drastic changes in the volume and osmotic stress, there can be irreversible damage and ultrastructural deformation of the plasma membrane.

Sperm membranes are composed of many phospholipids (depending on species), with each phospholipid having a precise phase transition temperature. The degree of structural damage to these membranes depends on the temperature and the lipid composition of the membrane [12]. The characteristics of membranes that affect their sensitivity include cholesterol/phospholipid ratio, content of non-bilayer-preferring lipids, degree of hydrocarbon chain saturation, and protein/phospholipid ratio [1]. Some lipids aggregate in domains of gel-like (frozen) lipid, thus excluding other lipid types that remain in the liquid crystalline (melted) state [1, 13]. This ultimately leads to phase separation in which membrane proteins can become irreversibly clustered, leading to loss of function [14]. The specific phase transition temperatures for the different phospholipids in the membrane result in lateral migration with rearrangement of membrane components and lipid phase separations within the plane of the membrane. The lateral migration may create microdomains of non-bilayer-forming lipids and may modify protein surrounding environments. On thawing, these alterations predispose apposing membranes to fuse and affect protein activity, leading to overall altered membrane permeability to water and solutes [1]. This loss of membrane permeability also interferes with ion pumps and results in influx of Ca^{2+} into the sperm cell as well as loss of membrane ATPase activity. Damage to the Ca^{2+} regulatory systems by freezing and thawing may predispose spermatozoa to inaccurate timing of capacitation and the acrosome reaction, contributing to reduced fertilizing capacity of cryopreserved bull semen [15].

Another side effect observed as a consequence of cryopreservation is the generation of reactive oxygen species (ROS) leading to a reduction of the functional and structural integrity of the spermatozoa [16]. The main ROS that are known to affect sperm functionality are superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and most hydroxyl radicals (-OH). During the cryopreservation process, large amounts of cytoplasmic components with antioxidant activity could also irreversibly leak into the intracellular space, making the cell vulnerable to the action of these free radicals [17].

DNA integrity and chromatin structure have been identified as the crucial factors related to ability of the sperm cell to endure the cryopreservation process and support embryonic development [18]. Freeze-thawing adversely affects the DNA integrity of cells, making the DNA vulnerable to molecular and epigenetic modifications which can affect embryo development [19]. DNA damage can occur due to several mechanisms during cryopreservation such as: double strand breaks due to high levels of ROS production [20], impairment of DNA repair enzymes [21], and mechanical stress of genomic regions of the DNA molecule in which chromatin compaction is increased because of cell shrinkage [22]. Apoptosis has been correlated with cryoinjury of

sperm DNA and that excessive generation of ROS can cause DNA damage. These parameters can differ greatly between fertile and subfertile bulls [23].

Role of Extenders Used for Cryopreservation

Extenders or diluents are routinely added to protect sperm during liquid storage or cryopreservation. Regardless of species, the role of semen extenders is to (i) provide nutrients as an energy source; (ii) buffer against harmful changes in pH; (iii) ensure appropriate physiologic osmotic pressure and concentration of electrolytes; (iv) prevent growth of bacteria; (v) protect from cold shock during cooling; and (vi) have cryoprotectant(s) to reduce the amount of freezing damage [24]. Over the past several decades, the cryoprotective media for sperm storage have been continuously revised but the basic ingredients remain unchanged, with egg yolk and/or milk and glycerol representing the indispensable compounds of practically all media used for bull sperm preservation in the liquid or frozen states. Extenders used for diluting bull semen typically are egg yolk and/or skimmed milk-citrate/Tris-based buffers with added simple sugars and antibiotics, with or without cryoprotectants depending on whether they are one-step or two-step extenders. These components provide an acceptable buffering capacity and osmolality and energy in the form of metabolizable substrates, minimize bacterial growth, and protect sperm from decreases in temperature.

As mentioned earlier (in the section "Mechanisms of Cell Injury During Cryopreservation"), sperm can suffer cold shock as a result of a sudden reduction in temperature, which causes structural and biochemical damage. This can be prevented by cooling semen slowly in the presence of protective agents. Phillips [25] first reported the value of adding egg yolk to bovine semen to afford such protection. Subsequent studies have shown that egg yolk not only increases the fertilizing ability of spermatozoa at ambient temperatures but also appears to prevent sperm cell damage during cooling and freezing [26–29]. Over the years the concentration of egg yolk added to extenders has been reduced from 1 : 1 (volume/volume) to 20–25% of volume as this has been shown to improve sperm survival [30, 31]. The low-density lipoproteins (LDLs) in yolk have been shown to play an important role in protecting sperm, with some studies reporting that LDL by itself is better than whole egg yolk in preserving sperm motility after freezing [32, 33]. Besides egg yolk, skimmed milk has also been found to be very efficient in protecting sperm during semen storage at 4 °C or in cryopreservation [34–36], and has the same composition as whole milk but contains less than 0.1% lipids (mostly triglycerides). The protective constituent of skimmed milk is not the lipid fraction but rather the protein constituents known as casein micelles. There are various hypotheses on how LDLs provide protection. It has been suggested that the phospholipid fraction of LDL protects sperm by forming a protective film on the sperm surface [37] or by replacing sperm membrane phospholipids that are lost or damaged during the cryopreservation process [38, 39]. Vishwanath et al. [40] suggested that egg yolk lipoproteins compete with detrimental seminal plasma cationic peptides (<5 kDa) in binding to the sperm membrane and thus protect the sperm. However, recent studies and research favors the idea that LDL interacts with the major proteins of bull seminal plasma and this interaction appears to be crucial for sperm protection [41]. A family of major proteins, known as *b*inder of *sp*erm (BSP), found in seminal plasma binds to sperm at ejaculation and modifies the sperm membrane by removing cholesterol and phospholipids. This may adversely affect the ability of sperm to be preserved. LDL from egg yolk and casein micelles and whey proteins in skimmed milk sequester these BSPs, thereby maintaining sperm motility and viability during storage [42].

Apart from egg yolk and skimmed milk, extenders used for diluting bovine semen contain various buffers, with phosphate being one of the earliest to be used. However, sodium citrate has largely replaced phosphate due to its superior ability to promote sperm survival at 5 °C. Citrate also improves the solubility of protein fractions in the egg yolk due to its chelating properties. Many zwitterionic buffers such as Tris [tris(hydroxymethyl)aminomethane], TES [*N*-tris(hydroxymethyl)-methyl-2-aminoethane sulfonic acid], and Tris titrated with TES (TEST) have been developed and tested over a wide pH range and have proved comparable or superior to citrate buffers. Of these, Tris-based diluents combined with egg yolk have been tested extensively and are used universally for extending bovine semen. In addition, protein components of skimmed milk extenders have been thought to provide buffering capacity to semen diluents. Because of the potential risk of xenobiotic contamination, research has started focusing on animal product-free extenders such as coconut and soymilk with satisfactory results. A recent study comparing soymilk tris (SMT) extender with an egg yolk tris (EYT) extender showed no significant differences between sperm in EYT extender and SMT extender with regard to post-thaw motility, viability, membrane integrity, acrosome integrity, and cryocapacitation [43].

Spermatozoa require energy for motility and are capable of both aerobic and anaerobic metabolism [44]. Most diluents provide an energy source in the form of simple sugars such as lactose, mannose, fructose, and arabinose. Sugars

also add osmotic pressure to the medium and act as cryoprotectants. The main effect of sugars and polyols such as glycerol is their ability to replace the water molecule in the normally hydrated polar groups, which helps to stabilize the sperm plasma membrane during transition through the critical temperature zones [13]. Sugars, like glycerol, also increase the viscosity of the diluent and prevent the eutectic crystallization of solutes, increasing the glass-forming tendency of the medium, a property used increasingly in vitrification media [45].

Most commercial bovine semen extenders contain antibiotics to reduce the rate of bacterial overgrowth and its subsequent deleterious effect on semen quality. Bacteria are present in the genitalia and reproductive tract of bulls regardless of fertility status and can be difficult to screen, even with the most hygienic and sanitary collection procedures and processing. Moreover, the presence of egg yolk and other extending media provides a good nutrient environment for the growth of these organisms. Historically, penicillin and streptomycin have been the preferred antibiotics used in combination with bovine semen extenders as they are relatively harmless to sperm and, when combined, inhibit a broad spectrum of microorganisms. However, these antibiotics fail to control growth of organisms such as *Campylobacter fetus* subsp. *venerealis* and have questionable efficacy against *Mycoplasma* and *Ureaplasma* spp. which can survive the freezing process. Continued use of these antibiotics has led to development of bacterial resistance. Because of these drawbacks the current international standards for semen extenders favor protocols that include treatment of semen and extender with the antibiotics gentamicin, tylosin, lincomycin, and spectinomycin (GTLS), as they are more effective in controlling *Mycoplasma*, *Ureaplasma*, *Campylobacter fetus*, *Haemophilus somnus*, and *Pseudomonas* in bovine semen [46, 47]. Recent studies have shown that bacterial presence in semen can adversely affect the DNA integrity of sperm, and the rate at which this damage takes place correlates positively with the initial bacterial load and bacterial growth rate [48]. Longevity of DNA is also adversely affected in the presence of GTLS combination. Use of the quinolone class of antibiotics has been shown to increase sperm DNA longevity in semen samples containing bacteria and thus could be of interest in terms of promoting alternative cryopreservation strategies to increase reproductive outcome [49].

The use of antimicrobials is not without problems, as many may have a detrimental effect on sperm survival, and the choice of agents that can be added to semen extenders is limited in food-producing animals. More importantly, continued use of antibiotics can result in development of resistance within an animal species, thus leading to an urgent need to find alternatives to antibiotic usage within the AI industry. Several strategies such as strict hygiene during collection and processing of semen samples under laminar flow have been suggested. Cationic antimicrobial peptides that act through destabilization of bacterial cell membranes have been investigated as alternatives to antimicrobials in semen extenders with promising results [50]. Physical methods for removal of bacterial load such as colloid centrifugation of semen have been investigated for human boar and stallion semen [51–53]. This technique in combination with strict hygienic and aseptic handling has resulted in abolishing almost all bacterial load in semen samples and improving the post-thaw quality of frozen samples. Considering the sheer volume of bovine semen frozen, preserved, and transported worldwide, these methods properly implemented and employed could help by reducing the use of a staggering volume of antibiotics used in semen extenders, thus minimizing their entry into the food chain and preventing bacterial resistance.

Role of Cryoprotectants in Bovine Semen Freezing

In 1949, Polge et al. [54] made a pivotal discovery showing that the use of glycerol (a permeating solute) could provide protection to cells at low temperatures. This is often cited as the defining moment in the establishment of modern sperm cryobiology. The development of cryopreservation protocols for the bull to be used for AI in the dairy industry began in the 1950s. Bratton et al. [3] demonstrated in field trials that bovine sperm frozen to −79 °C and packed on dry ice could still yield high fertility. The discovery of the protective properties of egg yolk lipids and glycerol further aided the development of freezing extenders for cryopreservation of bull sperm. The sum of these discoveries led to the development of the Tris–egg yolk–glycerol method for freezing bull sperm, which has now become a standard [36, 55]. Cryoprotectants are included in cryopreservation medium to reduce the physical and chemical stresses derived from cooling, freezing, and thawing of sperm cells [10, 56], and are classified as either penetrating or non-penetrating based on their ability to cross membranes. Penetrating cryoprotectants (glycerol, dimethyl sulfoxide, ethylene glycol, propylene glycol) cause membrane lipid and protein rearrangement, resulting in increased membrane fluidity, greater dehydration at lower temperatures, reduced intracellular ice formation, and increased survival to cryopreservation [4]. They act like solvents and dissolve sugars and salts in the medium [56]. Non-penetrating cryoprotectants (egg yolk, non-fat skimmed milk, trehalose, amino acids, dextrans, sucrose) do not cross the plasma membrane and act extracellularly.

They may alter the plasma membrane or act as a solute, lowering the freezing temperature of the medium and decreasing extracellular ice formation [57, 58].

Glycerol, a penetrating cryoprotective agent, is the most favored of cryoprotectants, largely because of the ability of bovine semen to withstand much higher levels of glycerol compared with other species. Numerous studies have shown that glycerol yields better post-thaw motility, lesser membrane damage, and better survival rates compared with other cryoprotective agents [59, 60]. Glycerol readily enters the cell after its addition and acts to lower the freezing point of the medium to a temperature lower than that of water. This reduces the proportion of the medium that is frozen at any one time, reducing the effect of low temperature on solute concentrations and hence on osmotic pressure differences [1, 61, 62]. It also provides channels of unfrozen medium between ice crystals in which spermatozoa may exist while at low temperatures and acts as a salt buffering agent. Cryoprotective agents in general are believed to act by increasing the osmotic pressure of the extracellular fluid and hence draw water out of the spermatozoa, thereby decreasing the risk of formation of ice crystals and hence physical damage. However, they do not alleviate, and may even exacerbate, the problem of dehydration and increases in solute concentration. Glycerol and dimethyl sulfoxide can induce osmotic stress and toxic effects on spermatozoa, the extent of which vary according to the species and their concentration in the extender solution [56]. The concentration of glycerol in the diluent for optimal cryosurvival for bull semen ranges between 6 and 9%, with upper levels causing damage to sperm and lowering their post-thaw survival rate. While formulating semen extenders, glycerol may be added initially or later in a separate fraction after semen refrigeration. In the first situation, also known as the one-step method, the entire semen extender along with glycerol is joined after semen collection. In the second situation, or two-step method, a fraction of extender without glycerol is joined first. This is followed by refrigeration, after which the glycerolated fraction is joined just before semen freezing [63]. The protocols used for adding cryoprotectants and freezing are ultimately a compromise between the advantages and detrimental effects of their incorporation and may vary between individual breeding bulls in order to obtain optimal results.

Steps for Cryopreservation of Bovine Semen

Semen cryopreservation procedures have been evolving over the past few decades. However, despite continued advances in the development of newer extenders and cryoprotectants, the post-thaw motility of bovine sperm remains at around 50%. This is because semen cryopreservation involves several general steps, of which dilution, cryoprotection, cooling and freezing, storage, and thawing can affect sperm structure and function [64]. Bovine sperm are thought to be relatively more resistant to higher concentrations of cryoprotective agents and the freezing process. However, to optimize post-thaw motility and membrane stability rates, the semen collected should be of high quality and more detailed attention should be paid to evaluation techniques than with those performed during a routine breeding soundness examination. Similarly, individual differences can be observed based on sensitivity of semen to extenders and freezing techniques among bulls. Thus, allowances have to be made by packaging straws with more spermatozoa or by adjusting freezing protocols for individual bulls [65]. Certified Semen Services Inc. (CSS), a wholly owned subsidiary of the National Association of Animal Breeders (NAAB), was established to assure standards and authenticity of semen products. It is also responsible for disseminating information concerning the handling and processing of semen. There are currently two standard protocols approved commercially by the CSS for freezing bovine semen. The standard CSS protocol or the two-step method is the most common method utilized in the USA, whereas the one-step method (also known as the alternative CSS protocol) is more popular in Europe. We routinely employ the two-step method for bovine semen freezing, which is described in greater detail in the section 'Two-Step Protocol for Cryopreservation of Bovine Semen."

Dilution, Initial Cooling, and Packaging

After collection and evaluation, the semen should be extended to an appropriate dilution/concentration using various diluents/extenders. The dilution stage is performed to minimize any potential toxic effects of seminal plasma, to suspend the spermatozoa in the freezing diluent, and to extend the semen to allow maximum usage [66]. A wide range of diluents of varying composition have been used in successful freezing protocols but the basic requirements are the same in all cases. The diluent must maintain osmolality, pH, and ionic strength, provide an energy substrate, contain a cryoprotective agent, and usually contain antimicrobial agents. A number of commercially available diluents for bovine semen seem to adequately fulfill these requirements (Table 78.1). The most commonly used diluents contain Tris–egg yolk/milk–glycerol as buffers and cryoprotective agents, although there are some extenders

Table 78.1 Some common commercially available extenders for bovine semen cryopreservation and their components.

Extender name and manufacturer	Diluents used	Cryoprotective agents	Freezing protocol	Antibiotics
Bovine Semen Extender by Agtech®	Tris buffer + citric acid + fructose	Glycerol and egg yolk[a]	Two step	GTLS[b]
Biladyl® by Minitube	Tris buffer + citric acid + sugars	Glycerol and egg yolk	Two step	GTLS
Triladyl® by Minitube	Tris buffer + citric acid + fructose	Glycerol and egg yolk	One step	GTLS
Triladyl CSS by Minitube	Tris buffer + citric acid + sugars	Glycerol and egg yolk	One step	None[c]
AndroMed® by Minitube	Tris buffer + citric acid + fructose + antioxidants	Glycerol and soybean lecithin	Two step	GTLS
AndroMed CSS by Minitube	Tris buffer + citric acid + fructose + antioxidants	Glycerol and phospholipids (animal origin free)	Available as one step and two step	None
BioXcell® Bovine semen preservation medium by IMV Technologies	N/A	Glycerol and soybean lecithin	Available as one step and two step	GTLS
Biociphos-Plus® by IMV, L'Aigle, France	N/A	Glycerol and soybean lecithin	One step	GTLS

[a] Egg yolk and water to be added prior to the addition of semen.
[b] Gentamicin sulfate, tylosin tartrate, lincomycin, and spectinomycin combination.
[c] None: one-step extenders require additional quantities of GTLS antibiotics usually supplied by the manufacturer.

available now in the market that are free of products of animal origin and contain phospholipids instead. These have been manufactured given current needs for disease control and therefore the avoidance of biologically derived substances in cryoprotective media. The diluents are usually available as a mixture of buffers and antibiotics to which the egg yolk is added at the time of semen extension. Similarly, depending on the process (one-step or two-step method), the glycerol fraction of the extender is added initially or later after refrigeration and cooling of the extended semen. The more commonly used two-step protocol will yield a final concentration of 20% egg yolk, 7% glycerol, 50 µg tylosin, 250 µg gentamicin, 150 µg lincomycin, and 300 µg spectinomycin in each milliliter of extended frozen semen. The one-step protocol yields an antibiotic concentration double that of the two-step procedure.

Dilution rates for bovine semen may vary depending on the concentration of spermatozoa in the ejaculate. In general, high dilution rates (typically 1 : 5 semen/diluent) are usually sufficient as the insemination doses used to achieve fertilization in the bovine are surprisingly low (typically 10–15 million) compared with those required for other species such as the horse and pig. However, care has to be taken to expose semen to an appropriate volume and concentration of extender, as overdilution may in fact result in loss of motility and increase in vital staining [67]. This phenomenon is known as the "dilution effect" and represents loss of cell viability, probably through leaching of structural components of the cell membrane [68]. The quantitative difference in the ratio of semen to extender between species is an important determinant of the fertility of cryopreserved semen [4]. In species where a large number of spermatozoa are required for conception, the dilution rates are correspondingly low, which means spermatozoa are more tightly packed, resulting in lesser tolerance to the cryopreservation process and poor survival rates.

Semen thus diluted is then cooled slowly to 4 °C over a period of two hours. This helps in reducing the metabolic rate of sperm greatly and minimizes the damage due to cold shock, apparent when semen is cooled below 15 °C [66]. Metabolic rate is believed to double for every 10 °C rise in temperature; hence cooling semen from body temperature of about 39 °C to refrigerator temperature of 4 °C reduces the metabolic rate to about one-tenth that at body temperature. Though bull spermatozoa are sensitive to cooling to refrigerated temperatures, the phospholipid components present in the egg yolk and whey proteins in skimmed milk play an important role in reducing the damage and also permit faster cooling. Once the partially diluted semen attains a holding temperature of 4 °C, it is extended to its final desired concentration by addition of the glycerol fraction if the two-step protocol for cryopreservation is followed. (Note that in the one-step protocol, semen is extended to its desired concentration and includes addition of glycerol prior to the cooling process.) The step involving addition of glycerol is sometimes erroneously

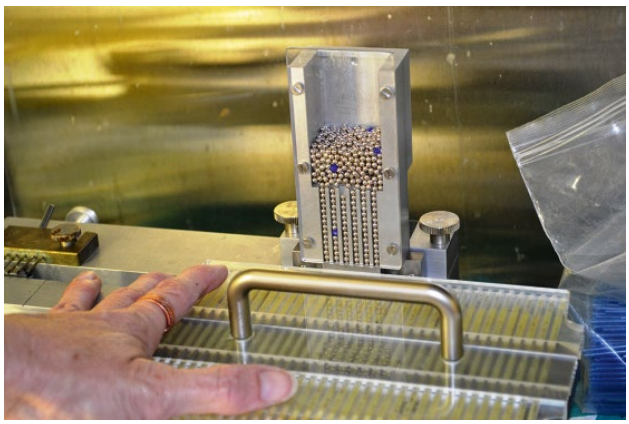

Figure 78.1 Sealing of straws using metal beads.

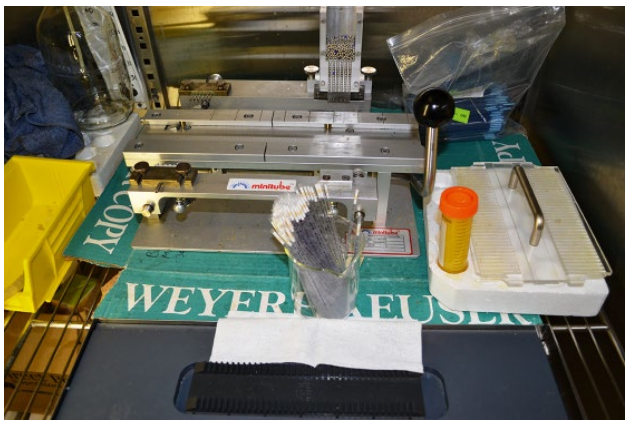

Figure 78.2 Cold cabinet used for semen cooling and packaging.

referred to as the glycerol equilibration period. Since glycerol has the ability to equilibrate quite rapidly across the cell membrane at 5 °C, it can realistically be added at any time during the cooling period [29, 69]. The equilibration period is thought to involve a process of membrane stabilization. Semen thus extended to its appropriate concentration contains around 7% glycerol and is further held at 4 °C for a few hours. During this holding period semen may be filled, packed, and sealed in 0.25- or 0.5-ml (standard size used in the USA) polyvinyl straws for further processing (Figure 78.1). All procedures involving the handling of cooled semen are performed in a cold-handling cabinet in order to maintain the semen equilibration temperature (Figure 78.2).

Cooling Rates and Freezing

During the process of freezing and thawing semen, spermatozoa are prone to damage caused by the rapid and dramatic changes in the physiochemical conditions occurring during cooling and ice formation. The extent of damage brought about by these abrupt changes is strongly affected by the cooling rate and composition of the cryoprotective medium. Cooling rates for cryopreservation of semen have been determined for various domestic species of animals and humans, sometimes in combination with the cryoprotectant concentration. Optimal rates ideally should fall in ranges that are neither too fast nor too slow. During the process of cooling and freezing, the first change that spermatozoa have to cope with is reduction from body temperatures to near freezing point of water [1, 6]. During semen refrigeration with slow cooling rates (0.5–1 °C/min), temperature reduction induces stresses on membranes, probably ascribed to the phase changes in lipid bilayers and altered functional state of membranes [6]. This is believed to impair the function of membrane proteins that are necessary for structural integrity (cytoskeleton) or ion metabolism (ion pumps) [6]. Major changes in bull spermatozoa during this phase occur in the vicinity of 15–5 °C but do not occur below 0 °C [6]. A second major change in the environment is coincident with the formation of ice crystals after the solution is cooled to a temperature between −5 and −15 °C. The release of the "latent heat of fusion" then causes the sample to warm up abruptly, until the freezing/melting temperature of the solution (of the remaining unfrozen fraction) is reached [6]. This results in spontaneous ice nucleation as the solution is supercooled and ice crystals then grow rapidly in all directions. Ice formation will depend on the rate at which the medium is further cooled and what remains is the so-called unfrozen fraction in which all solutes are confined. The osmolality of this fraction increases due to the increased concentration of glycerol, sugars, and salts and causes a rapid efflux of water from the cells or cellular dehydration. Fast cooling at such a stage can in fact lead to very sudden changes in size, shape, and ultrastructure of cells and lead to structural deformation. Spermatozoa may find themselves confined to very narrow channels of unfrozen solution, squeezed between growing masses of ice, which could lead to mechanical stress in cells. As cooling continues, these processes continue until the viscosity of the unfrozen fraction becomes too high for any further crystallization.

A two-factor theory accounts for the effects of cooling rates on spermatozoa [70, 71]. Slow cooling rates expose spermatozoa to "solution effects" such as increasing salt concentration, increasing osmolality, and changing pH, whereas fast rates may not allow intracellular water to pass out, leading to intracellular ice nucleation. Optimal cooling rates for semen before freezing in domestic species are generally considered to be in the range 10–100 °C/min [66], resulting in good survival rates after thawing. In bulls, cooling rates can range between 50 and 60 °C/min, although

Woelders et al. [13] have suggested cooling rates as high as 100 °C/min with optimal results. One advantage of such high cooling rates could be a decrease in glycerol concentration in the medium, since glycerol is thought to protect from effects of slow cooling damage. This would also help avoid the osmotic damage caused due to the high glycerol concentrations used presently for freezing bovine sperm. However, there are technical difficulties in achieving such uniform cooling rates for straws independent of their position in the freezing apparatuses [13].

Currently there are two options available for freezing bovine sperm: controlled freezing by use of automated programmable freezers, and conventional vapor freezing (non-programmable) by holding semen straws over liquid nitrogen vapors at a specific time and distance. Commercial semen freezing machines (Figure 78.3) offer the option of accurately controlling the temperature inside the cooling chamber as well as programming the time course of the temperature. However, because semen straws are placed in more than one layer, this contributes to considerable variation in cooling rates in individual layers within a freezing cycle and the time course of temperature inside the straws may be different due to the generation of latent heat of fusion. Also, programmable freezers are more expensive, and they do not necessarily yield more satisfactory results, especially for experienced technicians and cryobiologists. Conventional vapor freezing or non-programmable freezing can be performed by partially filling a non-ventilated Styrofoam box with liquid nitrogen and freezing straws by arranging them on a rack placed inside the box (Figure 78.4). The height of the straws above the liquid nitrogen determines the rate of heat exchange, with the rate of decrease in temperature being between 150 and 300 °C/min. In addition, the advantage of conventional freezers is that all the straws in any given freezing cycle are subjected to the same cooling rates, because the straws are placed in one layer above the liquid nitrogen level. In non-programmable freezers the cooling curve (the time course of cooling and freezing) is by default the form theoretically predicted to be optimal for slow freezing [72]. This results in relatively low cooling rates directly after ice formation begins and higher cooling rates later. The overall steepness of the freezing curve can be adjusted in non-programmable systems by choosing the height of the straws above the liquid nitrogen, which is proportional to the temperature of the vapor around the straws.

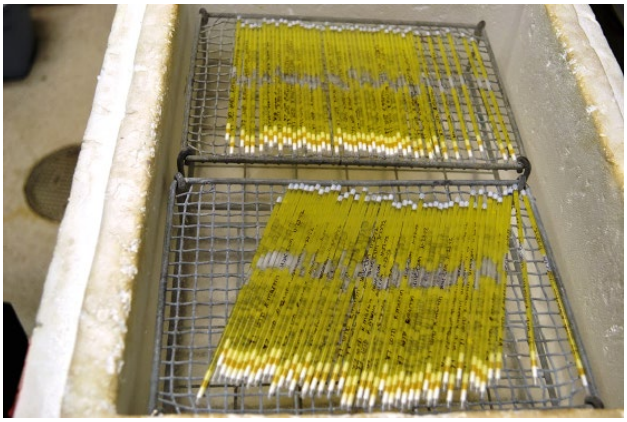

Figure 78.4 Vapor freezing by placing straws on a rack 5 cm above liquid nitrogen level in a Styrofoam box.

Figure 78.3 Programmable freezers for semen straws as well as embryos.

Semen Thawing and Storage

Frozen spermatozoa can experience damage during the thawing process as there is a complete reversal of the cellular events that occur during freezing. During slow thawing, the recrystallization of ultramicroscopic ice crystals to form comparatively large ice crystals [6, 13] can occur when spermatozoa pass through the critical temperature zone of −5 to −15 °C [73] and can be harmful to spermatozoa. Faster thawing rates (optimum: 37 °C for at least 45 seconds) limit the time for recrystallization and thus increase the survivability of sperm. However, when the duration of thawing is insufficient for the outflow of excess cryoprotectant from the cell, it suffers osmotic stress and the spermatozoa swell and lyse as the medium becomes abruptly diluted by the melting of extracellular ice [74]. The thawing rate can be influenced by factors such as the temperature and nature of the environment (air or water bath) and the thermal conductivity of the packaging as related to the diameter of the lumen of the packing. Faster thawing rates may be achieved by using higher temperatures for shorter periods of time (e.g. 65 °C for 5 seconds); however, care needs to be taken to avoid overheating the semen.

Optimal storage and handling of semen straws is a crucial factor that can contribute significantly toward the success of any AI program. Semen is usually packaged in 0.5-ml straws, although some organizations (especially in Europe) prefer packaging in 0.25-ml straws. Regardless of size, the handling procedure is common and straws are usually placed in goblets which in turn are clipped onto a metal cane. The canes are thus identified properly with the bull's name or identification number and are stored in canisters of specifically designed liquid nitrogen tanks. Though a detailed description of the construction of a liquid nitrogen tank is beyond the scope of this chapter, the need for proper care in storage and handling of these tanks cannot be overemphasized. Though semen tanks are designed to be sturdy, they are more fragile than they appear and require regular care and attention to prolong their productive life. Failure to do so can lead to a lost inventory or reduced pregnancy rates because semen quality is compromised. Tanks should be stored in a dry, well-lit, and well-ventilated area away from direct sunlight. They should be kept elevated above the concrete floor or other wet and poorly ventilated surfaces as corrosion of the outer shell shortens the functional life of the tank and can possibly cause tank failure. One of the key external signs of tank failure is frost build-up (especially around the neck), indicating loss of vacuum. The level of liquid nitrogen in the tanks needs to be regularly monitored and topped up when necessary. While retrieving straws from the tank, the canisters should be kept suspended as low as possible in the tank in order to maintain the temperature of the straws at a constant −196 °C. When straws cannot be retrieved from or located in canisters in less than 10 seconds, the canister should be lowered back into the tank and held for a period of at least 20 seconds to recool before trying again.

Stepwise Procedure for the Two-Step Protocol for Cryopreservation of Bovine Semen

Note that if directions for the extender supplied by the manufacturer differ, then it is advisable to follow those.

1) Prepare Fraction A (containing buffers and added 200 g of egg yolk) of the extender and place in the incubator before semen collection. Place Fraction B (containing glycerol) of the extender in the refrigerator.
2) After examining and assessing semen quality and concentration, dilute the semen slowly with a small volume of the warmed Fraction A extender in a 50-ml dilution tube. Depending on the calculated number of straws to be processed, the ejaculate can be extended with Fraction A to 50% of the calculated final volume.
3) The extended semen can be cooled to 4 °C by first keeping at ambient room temperature and later placing in a refrigerator or a cold room. The sample should be held at 4 °C for a minimum of two hours. The extended semen can also be placed in a water bath having the same temperature, and then placed to be cooled to 4 °C. This helps with the cooling rate.
4) Fraction B, which has been previously cooled to 4 °C, can now be added to the extended cooled semen in a 1 : 1 ratio gradually over a period of 20 minutes.
5) The semen now extended to its final concentration should be placed again in the cold room or cabinet to equilibrate for a period of four hours. During this time straws may be labeled with the appropriate information (e.g. breed, registration, number, name, date). They are filled, sealed, and placed on racks for freezing and counting. Straws should be shaken so that the air bubble is in the center after filling and before freezing. All procedures should be performed at 4 °C in a cold room or cooling cabinet.
6) Straws are frozen by placing them on a rack at a distance of 5 cm above the liquid nitrogen level in a Styrofoam airtight container. They are thus held over the liquid nitrogen vapor for about 15 minutes and then plunged in liquid nitrogen (Figure 78.5).
7) Straws are loaded into canes (labeled with the bull information) and transferred to liquid nitrogen canisters. One straw should be thawed for assessing post-thaw motility as well as concentration. Ideally the concentration per straw should be equal to one insemination dose (10–15 million sperm). This may be adjusted to bull fertility data if available.

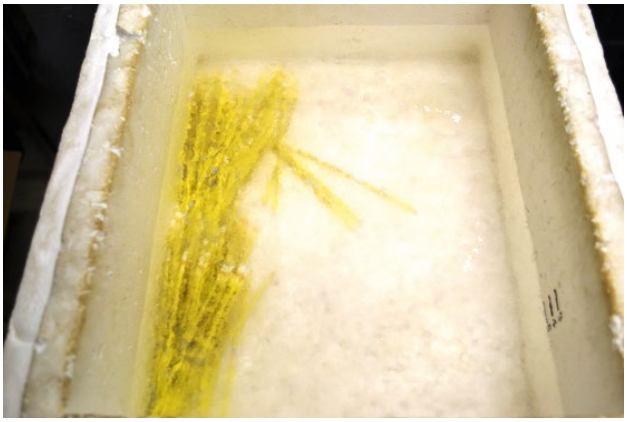

Figure 78.5 Straws plunged into liquid nitrogen.

Newer Advances in Bovine Semen Cryopreservation

Over the years several advances in the field of cryobiology have benefited the bovine AI industry greatly. These have resulted in the development of superior semen diluents,

standardized optimal freezing protocols, predictable fertilizing ability of sperm through different semen viability tests, and a better understanding of the pathophysiology of cryopreservation-related sperm damage.

Recent studies have shown that addition of 8% coconut oil as a source of lauric acid to egg yolk based-extender [75], 5 ng/ml α-linoleic acid to the BioXcell extender [76], and 20 ng/ml arachidonic acid to tris-citric acid extender [77] enhanced the post-thaw parameters of spermatozoa following cryopreservation. Iodixanol, a medium used for density gradient centrifugation, when added to semen extender has shown to enhance sperm motility post-thaw via reducing the formation of ice crystals during the freezing process [78].

The current need for disease control and the avoidance of biologically derived substances of animal origin in cryoprotective media have led to development of coconut milk and soy lecithin-based semen extenders, which have been shown to have comparable protective properties as egg yolk and skimmed milk. However, the quality of soybeans can vary from batch to batch and can affect the quality of the extended and subsequent fertility rates [79]. Substances such as synthetic liposomes [80] and cholesterol-loaded cyclodextrins [81] have been shown to afford better protection to sperm during cryopreservation and have yielded increased post-thaw survival rates. A recent research [82] evaluated the ability of Tris-glycerol extender pretreated with cholesterol-loaded cyclodextrins to preserve sperm motility post-thaw as well as the *in-vitro* fertilization potentials in absence of any source of animal proteins (milk or egg yolk). The cholesterol-loaded cyclodextrins not only were able to preserve sperm motility comparable to rates achieved using conventional egg-yolk based extender, but also had similar cleavage and blastocyst rates.

Antioxidants are molecules that inhibit the formation of ROS and lipid peroxidation. Superoxide dismutase, glutathione peroxidase, and catalase are the well-known antioxidants that are significant for sperm function because they protect sperm cells from oxidative stress [83]. However, endogenous antioxidants present in seminal plasma are not enough to protect spermatozoa against the stresses endured during cryopreservation. Hence, addition of substances demonstrating antioxidant properties to semen extenders to protect the sperm from ROS and ultimately lipid peroxidation-associated damage has been investigated. Glutathione (GSH) has been shown to increase motility, integrity of the plasma membrane, and cell viability of buffalo semen via its action against free oxygen radicals [84]. Similarly, resveratrol and vitamin E supplementation have shown to improve post-thaw motility and viability of spermatozoa through their roles in protecting sperm chromatin and membranes and maintaining membrane potentials in ram and boar semen [85, 86]. Curcumin and erythritol and *n*-3 fatty acids combined with α-tocopherol [87] have shown promising results pertaining to better cryosurvival of spermatozoa by altering membrane lipid composition. Supplementation with antioxidants such as methionine, carnitine, and inositol prior to the cryopreservation process has been shown to protect DNA integrity against cryodamage [88].

Several advances have been made or are under investigation currently with the aim of solving or mitigating old issues associated with conventional semen cryopreservation techniques. Vitrification is a rapid freezing method requiring only a brief manipulation procedure, thus decreasing the probability of chilling injury (cold shock) [89]. Semen vitrification has been carried out successfully in various species including human, equine, caprine, and canine. Human studies have found that semen functionality was better preserved via vitrification as compared to the standard slow freezing techniques, allowing a higher percentage of motile sperm to retain intact mitochondrial function and DNA integrity [90]. Its use in the bovine industry is non-existent and still in the experimental phase. This technique, however, has the potential of being a viable alternative in the near future and seems to have biological, operational, and economic advantages over the conventional freezing methods. Lyophilization or freeze-drying techniques for equine spermatozoa and subsequent birth of live foals [91] have opened a whole new perspective for cryopreservation of sperm. Though no live calves have been reported yet, lyophilization of bovine sperm may offer an attractive alternative to liquid nitrogen storage of sperm. Since lyophilized sperm can fertilize an oocyte only via procedures such as intracytoplasmic sperm injection, and requires fewer numbers per dose, the number of doses obtained per ejaculate could literally be in the hundreds of thousands. Lyophilization of semen may help overcome several drawbacks associated with conventional cryopreservation such as high maintenance costs and problems associated with transportation of the frozen semen, as well as accidental loss due to improper temperature control. Microencapsulation is yet another alternative technology that has recently been perfected for bovine semen, which maintains sperm viability by prolonging sperm survival at low temperatures [92, 93]. This technology consists of immobilization and cryopreservation of semen within a solid gel made of calcium alginate, thus increasing the availability of fertile spermatozoa in the reproductive tract by release of gametes over time. Availability of discrete populations of viable sperm over a prolonged period of time for fertilization would help in making the choice of time to perform AI less critical [92].

Utilization of Sex-Selected Semen

Ram Kasimanickam

Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, WA, USA

Introduction

Gender selection of offspring has considerable benefit for livestock management systems. Planning the sex of the offspring prior to conception is the most cost-effective means of achieving the desired outcome. Utilization of gender-selected semen allows production of male and female offspring to take advantage of sex-limited and sex-influenced traits [1]. To be widely used, gender preselection should be effective and efficient, result in acceptable fertility, and be reasonably inexpensive and convenient [1]. In mammals, sex is determined by gonosomes: an XX chromosome combination determines a female, whereas an XY results in a male. Since X and Y chromosomes differ significantly in length, discrimination of X and Y chromosome-bearing sperm populations is possible due to the difference in their DNA content. Several methods to separate X and Y chromosome-bearing sperm populations of ejaculates have been investigated. The only accurate and potentially cost-effective approach for achieving gender selection currently involves separating X from Y chromosome-bearing sperm by flow cytometry, followed by its use for artificial insemination (AI) for breeding or multiple embryo production systems, or for *in vitro* fertilization (IVF) with subsequent embryo transfer programs [2, 3]. This method can produce populations of X or Y sperm with up to 90% accuracy and subsequent offspring whose phenotypic sex is consistent with the initial accuracy of the sex-sorted sperm population. Limitations of the technology are associated with the number of sperm required for fertilization, timing of insemination, individual bull variation in sexed-sperm sorting, and subsequent production of offspring. This technology examines each sperm separately for its DNA content, thus limiting the number of sorted X or Y sperm to approximately 5–6 million sperm per hour [2].

Sorting Sperm by DNA Content for Gender Selection

Flow cytometric examination of the DNA content of X and Y chromosome-bearing sperm of cattle (*Bos taurus* and *Bos indicus*) indicated a difference in their DNA content. The difference in total DNA content between those from bulls and those from cows is approximately 4.2% [4]. This average DNA content difference is sufficient to detect by flow cytometric systems [5–7] (Table 79.1) and subsequent sorting of X and Y chromosome-bearing sperm.

The sperm sex-sorting procedure involves several steps. Briefly, sperm DNA is quantitatively stained with Hoechst 33342 and the sperm are then forced in a stream in front of a laser beam at specific wavelengths [3, 8, 9]. The illuminated stained sperm emit a very bright-blue fluorescence. This fluorescence is rapidly measured using a photomultiplier tube as the sperm flow in single file in front of the tube. A computer is used to rapidly analyze the relative fluorescence of the X and Y sperm populations as they flow through the instrument in a fluidic stream. A crystal vibrator is used to break the stream into individual droplets, many of which contain a sperm. The fluorescently stained sperm are sorted by DNA content by placing opposite charges on droplets containing X sperm from those containing Y sperm (Figures 79.1 and 79.2). The droplets fall past positive and negative electrical fields, and since opposite charges attract, the droplets separate into two streams for collection. A third stream of uncharged droplets is discarded, as these droplets have sperm that could not accurately be sexed (over half), no sperm, rarely two sperm, and dead sperm (gating out dead sperm is a valuable additional benefit). This sperm sorting technique is known as Beltsville Sperm Sexing Technology [3, 8, 9].

Commercialization of Bovine Gender-Selected Semen

Advances in sex-sorting sperm have enabled its incorporation into commercial reproductive management. Currently, gender-selected semen is more applicable on a large-scale basis to the dairy industry than to the beef industry. Sexed semen will contribute to increase profitability of dairy and beef cattle production in several ways. It could be used to produce offspring of the desired sex from a particular mating to take advantage of differences in value of males and females for specific marketing purposes. Dairy herds are more interested in producing replacement heifers, as dairy bull calves are inherently less valuable. Advantages are production of more replacement heifers, thereby enabling greater selection pressure, contributing to more rapid

Figure 79.2 Genesis III sperm sorter for gender selection. *Source:* Image courtesy of XY Inc.

genetic gains [10]. There are opportunities for herd size increase, sale of more females, and simultaneous increase in milk production and decrease in milk price (the latter is an advantage for consumers). Furthermore, once replacement heifer needs are met, dairy producers could use sexed semen to produce beef crossbred bulls from the remainder of their cow population. Seed-stock dairy producers gain their income from selling genetically superior animals in addition to selling milk. Their goal is to maximize genetic merit of breeding stock for economically important commercial production traits in a cost-effective manner. Sexed semen will be useful to seed-stock breeders if it allows them to increase rate of response to selection or if it reduces the cost of achieving genetic change.

In order to produce genetically superior replacement heifers using sexed semen, commercial dairy farmers should first rank their cows according to estimated genetic and economic merit for dairy production traits and then use X chromosome enriched semen from genetically superior bulls to inseminate a sufficient number of the highest-ranking cows to produce the needed number of replacements. By selecting only the best cows to produce replacement heifers, farmers would increase selection pressure for dairy production traits. Methods to assess the

economic impact, generated through increased response to selection among dams of commercial cows, of a unit of semen with an increased proportion of X chromosome-bearing sperm have been discussed [11]. It was reported that the predicted impact on annual genetic progress for sexed semen technology is a 9% [12] or 15% [13] increase compared with a mating system using artificial insemination (AI) with conventional semen.

The commercial beef cattle farmer produces calves for eventual sale as slaughter animals and for female herd replacements. Depending on the planned role for a calf, males and females are of quite different value, so sexed semen potentially is a powerful technology to affect genetic and economic efficiency. With beef cattle herds, the value of shifting the calf crop gender ratio to favor bulls or heifers depends on herd genetics and marketing plans. For beef cattle seed-stock producers, bull sales to commercial cattle producers are often the most significant source of revenue. Replacement heifers are also important for genetic improvement. For beef cattle producers who depend on bull sales and require fewer replacement heifers, utilization of male (Y-bearing) gender-selected semen could be practical. Steers are usually heavier at weaning and more valuable than heifers. Thus, for commercial cattle producers who market feeder calves, utilization of Y-bearing semen in a commercial setting would lead to more steer calves that could offset increased semen cost. Furthermore, if heifers are retained as replacements, individual hand-selected matings could be done to produce heifers from more maternal dams and bull calves from terminal crosses. It should also be noted that in some beef cattle breeding programs, heifers are more valuable than their male counterparts.

Artificial Insemination

Sexed semen technology became practical with the live birth of offspring of the predicted sex [14]. Continued research recognized the ability of flow sorting to consistently produce approximately 90% gender-selected offspring and facilitated eventual commercial adaptation [15, 16]. The technology was introduced into commercial application in the UK in 2000. Currently, several US AI centers have this technology and market sexed semen from their bulls worldwide.

Conception rates to AI in cattle are related to sire, semen processing, sperm dosage, timing of insemination, and service number. Despite successes, the invasive nature of the sex-sorting procedure has detrimental effects on sperm viability and quality [17, 18]. In addition, for economic reasons, the number of sperm in sex-sorted samples is reduced to approximately 2 million sperm per dose [18]. In breeding programs that use conventional semen, some factors that cause differences in fertility are amenable to increased sperm numbers in an insemination dose (compensable), whereas others are not (uncompensable) [19]. An extensive insemination dosage trial concluded that the compensable component is mostly satisfied at total sperm dosages of approximately 4.0 million; however, considering differences among sires, the range is 1–11 million sperm per dose. Seidel [18] and Schenk et al. [16] predicted that commercial application of doses of 2.1 million sex-sorted sperm in Holstein heifers would yield conception rates approximately 75–80% of those obtained with conventional semen, consistent with field results in the USA [20]. Increasing sperm number in the insemination dose seems to be a plausible solution to increase fertility. A study compared conception rates for 2.1 or 10 million sperm dosages of sex-sorted or conventional sperm, respectively [21]. Across herds and sires, the conception rates of sperm dosage by semen type combinations were 38 and 44% for 2.1 and 10 million sex-sorted semen, and 55 and 60% for 2.1 and 10 million conventional semen dosages, respectively. A marginal improvement in conception rates was observed with an insemination dose of 10 million for some sires, suggesting that a portion of the decrease in conception rates with sex-sorted sperm may be compensable. However, the conception rates achieved with 10 million gender-selected sperm are not comparable to either dosages of conventional semen in this study. Therefore it implies that a portion of the decrease in the conception rate using sex-sorted semen is induced by the staining and/or sorting procedure. Further, although the sorting method is standardized, bull-related dilution effects may contribute to the decreased fertility independent of sorting stress [22], but this remains unproven as insemination of high numbers of sex-sorted sperm (10 million) led to reduced pregnancy rates compared with unsorted sperm inseminated at the reduced dose (2.1 million) [21]. Further, reducing the available insemination sex-sorted semen dose to 20% to achieve a 6% increase in pregnancy rate is a poor use of genetic potential [21].

Current recommendations for use of sex-sorted semen in a commercial operation are as follows:

1. Use only in herds with AI pregnancy rates of 60% or more with conventional semen.
2. Select healthy cycling females with good body condition, preferably heifers.
3. Inseminate only animals observed in standing estrus. If using fixed-time AI, make sure a high percentage of the animals were in estrus beforehand.
4. Inseminate heifers with sex-sorted semen once and subsequently with conventional semen if they do not conceive.

5. Be extremely careful with semen thawing and handling.
6. The inseminator should have experience and be known to achieve good pregnancy rates.

At present, the recommendation for use of sex-sorted semen is restricted to females exhibiting estrus [23]. However, the use of sex-sorted semen in conjunction with estrus synchronization for a timed AI has huge commercial appeal. Besides, estrus synchronization schemes are of particular value for insemination with sex-sorted sperm, as highly accurate insemination time is extremely important. The current focus is to develop an optimal protocol for fixed-timed AI of sex-sorted sperm. Insemination with sex-sorted sperm closer to ovulation [16, 24, 25] and insemination of females with large follicles at the time of AI [23] increased the likelihood of pregnancy. Additionally, uterine horn insemination could improve the conception rate when using sex-sorted sperm [15, 26, 27]. However, placement of sex-sorted sperm deeper into the uterus did not increase pregnancy rates to timed AI [23].

Multiple Ovulation and Embryo Transfer

Several studies have reported *in vivo* embryo production from superovulated cows and heifers following insemination with sex-sorted sperm. In many of those studies, there was a reduced fertilization rate and increased percentage of degenerate embryos from sexed sperm, which resulted in fewer recovered transferable embryos [28–30]. Suboptimal sperm quality and improper timing of AI were regarded as major factors contributing to fewer embryos per flush from sorted sperm [28, 29]. In contrast to single-ovulating cattle, multiple inseminations are believed necessary to cover the interval required for multiple ovulations [31]. Because the number of sperm per insemination dose is limited by the high cost of sexed semen, multiple inseminations with low dose (2 million) sorted sperm have been adopted [29, 30]. When donors were inseminated with sexed semen 12 and 24 hours after detected estrus, the number of transferable embryos was increased compared with donors receiving only one dose of sexed semen [29], indicating that two inseminations of sexed semen were more effective than one insemination at attaining embryo production characteristics similar to those for conventional semen. However, another study claimed that superstimulated donor cows inseminated four times had fewer Grade 1 embryos and more unfertilized ova with sexed versus conventional semen [32]. Additionally, when sexed semen was inseminated at various times after a detected estrus [30], the number of transferable embryos was decreased compared with donors receiving conventional semen.

Higher numbers of sperm are normally required for superovulated cows. The successful use of sexed sperm in bovine multiple ovulation and embryo transfer (MOET) schemes critically depends on the AI dose. The dose of sex-sorted semen that is used for regular AI, 2 million sperm, is insufficient [29]. The success with higher doses (10–20 million sperm) seems to depend on the sire or MOET conditions. Further, increasing the dosage to 20 million sex-sorted sperm lowered fertilization rates compared with controls [29]. Superstimulated heifers inseminated with 5 million sexed (X-sorted; $n = 5$) or unsexed ($n = 5$) frozen–thawed sperm from one bull at 12 and 24 hours after detection of estrus showed no difference in rates of transferable embryos (53.4 vs 68.1%) [33]. Furthermore, rates of degenerate embryos and unfertilized ova between sexed and unsexed sperm were 24.8 versus 26.6% and 21.8 versus 5.3%, respectively [33]. Producing higher numbers of good-quality transferable embryos and better pregnancy rates after transfer has great potential for a significant impact on the efficiency of utilization of sex-sorted sperm.

Contract matings between elite sires and dams that use MOET greatly increase the probability of producing a desirable offspring, even without sexed semen. Suppose that a MOET procedure resulted in three embryos that produced viable offspring. With conventional semen, the probability that at least one of the calves is of the desired gender would be 0.879 (1 minus the probability that all the offspring are the other gender). With 90% purity, the probability of producing at least one calf of the desired sex would be 0.999. For four viable offspring, the probabilities would be 0.934 and 0.999, respectively. Thus, it should be noted that whereas sexed semen increases the likelihood of producing at least one offspring with desired gender from a planned mating, the improvement is not huge.

The goal of most embryo transfer programs is to promote genetic gain from both the dam and sire. Utilization of sexed semen should yield such genetic gain equal to or better than conventional semen. A study estimated that the genetic trend in the entire population was improved by 3.0% when X chromosome-bearing semen was used on all production heifers without use of MOET in the nucleus herd and by 2.2% when MOET was performed on all bulls and dams [34]. When sexed semen was combined with MOET in the nucleus, the effect of using sexed semen was minimal, except when marker-assisted selection was applied [35]. Despite small genetic gain, a recent study reported a beneficial effect on the rate of inbreeding by using sexed semen in the breeding scheme [36].

In Vitro Fertilization

In vitro fertlization (IVF) requires low numbers of sperm for embryo production. Thus, use of sex-sorted sperm in IVF seems advantageous. Cleavage rates were similar to unsorted sperm, but blastocyst development with sorted sperm was approximately 70% of controls produced with unsorted sperm [37]. Further, there was a 0.5- to 1-day delay of embryonic development when oocytes were inseminated with sex-sorted sperm compared with unsorted sperm [37]. Similarly, in other studies, cleavage rates after IVF with sex-sorted sperm were 30% below those using unsorted sperm from the same ejaculate; blastocyst formation on day 8 was 30–40% lower than for the controls and the number of cell cycles was reduced [38, 39]. It was postulated that the impact of sorting on molecular aspects of sperm function, including capacitation, acrosome reaction, zona binding, and embryonic development, is a reason for decreased blastocyst production. Regardless, subsequent reports indicated negative effects of sorting on sperm integrity, but neither cleavage nor blastocyst rates were affected when sperm were centrifuged with a Percoll gradient [40]. IVF results are also affected by sperm concentration, which needs to be higher than for IVF with unsorted sperm, and by the hydrodynamic pressure used for sorting [41]. Additionally, there was a positive correlation between the percentage of progressively moving sorted sperm and blastocyst development [42].

Regarding differences in the expression of developmentally important genes, bovine IVF embryos derived from sex-sorted sperm had a reduction in the relative abundances of glucose transporter 3 (Glut3) and glucose 6-phosphate dehydrogenase (G6PD) compared with embryos derived from unsorted sperm, which may be deleterious to the developmental competence of embryos [43]. Further, it is interesting to note that there are significant sex-related (X- vs Y-bearing sperm) differences in day-7 blastocysts for several genes, namely glutathione *S*-transferase M3 (*GSTM3*), DNA (cytosine-5)-methyltransferase 3A (*DNMT3A*), and progesterone receptor membrane component 1 (*PGRMC1*), plausibly contributing to delayed onset of the first cleavage [38, 44]. Additionally, blastocysts produced from sex-sorted sperm are observed with immature mitochondria and rough endoplasmic reticulum, as well as a lower percentage of intact nuclear envelope membranes than the non-sorted controls [42]. Although the sorting process has significant effects on sperm viability, and bull effects are obvious, compromised DNA does not affect reduced fertility, as most non-viable sperm, and those with fragmented DNA, are outgated during sorting. Regardless, further research is needed to investigate this phenomenon, as there is time-related DNA damage to sex-sorted sperm compared with non-sorted counterparts.

Reverse Sorting

Reverse sorting is sex-sorting of sperm from previously frozen samples and refreezing those samples after sorting. This technique allows previously frozen sperm to be separated for sex. This technique is useful for males that are located at a greater distance from a sex-sorting site or which are deceased and thus unable to provide fresh ejaculates for sex-sorting. The “reverse sorting” technique surmounts staining problems [45] by washing frozen sperm through a density gradient, thereby eliminating dead sperm, glycerol, and egg yolk, which may interfere with staining or negatively impact the remaining viable sperm [46, 47].

The first presexed offspring produced from reverse-sorted sperm were achieved in sheep following IVF and embryo transfer [48], and a few years later using AI [49]. Reverse-sorted bull sperm have poorer motility and viability *in vitro* compared with frozen–thawed controls [50]. Although presexed calves have been born following AI of reverse-sorted bull sperm, fertility is very low, with increased pregnancy loss [51, 52]. Greater success has been achieved with the use of reverse-sorted bull sperm in IVF, where cleavage and blastocyst production has been comparable to those obtained with sex-sorted frozen sperm and non-sorted frozen controls [53].

It was apparent that there was a difference among individual sheep with regard to success following reverse sorting. Although the reason for this difference between the species is the source of some disagreement [54], a better understanding would likely improve fertility of sorted and reverse-sorted bull sperm.

Effect of Sex-Sorting Procedure on Structural and Functional Parameters of Sperm

During the sorting procedure, sperm are subjected to several steps, including (i) high working pressures during hydrodynamic focusing and passage through the injection nozzle; (ii) DNA staining with the fluorescent dye bis-benzimide (Hoechst 33342); (iii) sperm exposure to wavelengths of the ultraviolet light spectrum; (iv) repeated exposure of sperm DNA to electrical currents and fields; and (v) subsequent passage through the electrostatic deflection field that may cause stress to sex-sorted sperm [55, 56]. Further impact on sperm quality may be related to preservation of stained sperm at low temperature until insemination. In addition, impact on the motility, viability, and functional integrity of sorted sperm may be attributable to a dilution effect following removal of seminal plasma. Perhaps a

major reason for a decrease in sorted sperm survival is production of reactive oxygen species (ROS) during several steps of the sorting process. Addition of sodium pyruvate and catalase to the dilution medium and freezing extenders exerted a positive effect on the motility, morphology, acrosomal status, and viability of the sex-sorted frozen–thawed sperm, confirming production of ROS in several steps during the sorting process [57].

Hoechst 33342 (bis-benzimide) is suitable for sperm DNA labeling as it preferentially binds to the minor groove of the DNA helix (for review see [58]). However, this dye is known to be mutagenic to cells and may induce disturbances in embryo development. Moreover, the fate of this dye transported by the spermatozoon into the oocyte and thereby into the embryo and offspring is an area that requires further investigation [59].

Assessment of sperm DNA fragmentation using non-sorted and sex-sorted sperm samples during a 72-hour incubation at 37 °C detected reduced DNA longevity in sex-sorted frozen–thawed sperm, with sperm DNA damage appearing between 24 and 48 hours [60]. Although the baseline DNA fragmentation level was higher in conventional frozen–thawed than in sex-sorted frozen–thawed sperm samples initially [60, 61], after approximately 30 hours of incubation there was cross-over in the tendency of DNA fragmentation for both conventional and sex-sorted sperm samples, with higher DNA fragmentation for sex-sorted than conventional semen [60]. Furthermore, it was concluded that sperm chromatin was more resistant to external stressors affecting sperm after sorting [60].

Cost and Revenues

Comparisons of heifers that were inseminated at their first AI breeding with either sexed or conventional semen (in both groups, all services after first AI used conventional semen) were made to evaluate subsequent reproductive performance and health, production, and reproductive performance during their first lactations (refer to [62] for detailed economic outcomes). Briefly, age of heifers at first insemination was 13.1 ± 0.1 and 13.8 ± 0.1 months for sex-sorted and conventional semen, respectively. Rearing cost from first AI to calving was greater for sex-sorted heifers than for conventional heifers (USD $775.3 ± 6.7 vs $750.0 ± 5.9). However, calf revenue tended to be greater for sex-sorted heifers ($142.0 ± 7.2 vs $126.7 ± 6.4) and cost per female calf produced was less for sex-sorted heifers than for conventional heifers ($–809.4 ± 10.8 vs $–1249.7 ± 10.9). Treatment did not affect calving difficulty, proportion of heifers needing assistance, and incidence of retained fetal membranes or metritis. Among heifers that conceived to first AI, those inseminated with sex-sorted semen were more likely to be culled within 30 days in milk (3.3 vs 1.6%) and tended to be more likely to be culled within 60 days in milk (5.5 vs 3.4%) compared with heifers inseminated with conventional semen, but overall replacement cost was not different ($136.8 ± 13.4). Total milk yield (9245.5 ± 84.7 kg) and income over feed cost ($554.7 ± 5.1) were not different. Overall economic return was greater for heifers inseminated with sex-sorted semen than conventional semen ($−83.7 ± 36.7 vs $−175.3 ± 33.4). Use of sex-sorted semen for first insemination of virgin heifers reduced the cost per female calf produced and increased the economic return during the first lactation. Female to male sex ratios were 0.86 : 0.14 and 0.48 : 0.52 for sex-sorted and conventional semen, respectively. Heifers inseminated with sex-sorted semen were more likely to deliver a dead calf (8.8 vs 3.4%), and thus the difference in proportion of heifers delivering a live female calf was lower than reported (sex-sorted 79.1%; conventional 47.2%).

Using sex-sorted semen, dairy herds could eliminate 70% of cows in third and greater parity as dams of replacements while maintaining heifer birth rates equal to those of conventional semen [63]. Elimination of older cows as dams of replacements reduces age of dam of replacements and increases genetic merit of dams by about $23. This change doubles the genetic change per year in the dam–daughter path compared with conventional semen, primarily due to shorter generation intervals [63]. Calculated economic values of sexed semen programs for dairy and beef heifers are available [64, 65].

Incidence of Stillbirth

Incidence of stillbirth was similar between heifers inseminated with conventional or sex-sorted semen [20, 66]. Furthermore, there were no breed differences for incidence of stillbirth among Holstein, Jersey, and Danish Red heifers inseminated with sex-sorted or conventional semen from the same bulls [67]. In contrast, a higher incidence of stillbirth following insemination with sex-sorted semen has also been reported [62]. In three years of using sex-sorted semen, total incidence of stillbirths was not influenced by the use of sex-sorted semen compared with conventional semen (10.4 vs 11.8%) [20]. Stillbirth for female calves resulting from sex-sorted semen (9.2%) is similar or slightly lower than conventional semen stillbirths. However, the incidence of stillborn births for male calves from sex-sorted semen (19.9%) is much higher than for conventional semen (12.9%). Even though heifers

delivering bull calves seemed to have a higher stillbirth rate, only 10% of calves born were male. However, this might be a concern where a higher sex ratio toward males is preferred. It was suggested that increased incidence of stillbirths may occur when pregnancies result from Y chromosome-bearing sperm that are mistakenly identified as X chromosome-bearing sperm during the sorting process due to the presence of aneuploidy, which would result in greater DNA content and increased risk for malformation [20]. In this case, it should be noted that the Y-bearing sperm sorted for male selection based on sperm having lesser DNA and the Y-bearing sperm that have aneuploidism with greater DNA will not be mixed with this Y-bearing sperm population as they will be selected out. Hence the stillbirth incidence will be similar to conventional semen when selection for male sperm is occurring.

SexedULTRA Technology

The fertility of sex-sorted semen in cattle has always been lower than that of conventional semen. Sperm compensable elements, higher sperm numbers, or a higher proportion of sperm with better morphological features, which normally would increase the fertility of a subfertile sire with conventional semen, did not yield better results with sexed sperm [17]. The reasons for the lower fertility of sex-sorted semen have been ascribed to the diverse biochemical changes that sperm undergo during the sex-sorting process. There are more than 20 different subprocesses involved in the sex-sorting procedure, including an extended holding time before staining, exposure to a laser beam to induce fluorescence, separation into X and Y sperm, and finally exposure to an electrical field for drafting as a relatively pure population into an appropriate vessel, all of which may contribute to the reduction in fertility [68].

SexedULTRA™, a new era in sexed semen technology, delivers conception rates up to 95% of those achieved through use of conventional semen [69]. The SexedULTRA™ process was devised as a system to simplify and optimize the media used for the sex-sorting protocol. The main changes included a modified protocol to pretreat sperm before the staining stage. In addition, the modified protocol includes a new staining medium with a balanced pH which keeps it stable across an extended period. To account for the low-dose freezing required for sex-sorted semen, the sheath fluid and the freezing medium were also modified. All these changes showed that SexedULTRA media had improved sperm motility as well as acrosome integrity compared with the XY technology at the same sperm concentrations [70]. In addition, SexedULTRA semen used in IVF trials resulted in a greater number of freezable embryos compared with the XY method (13.2 and 9.2%, respectively) [70]. Improvements made to the technologies and processes used to produce sex-sorted semen now allow units of SexedULTRA sex-sorted semen to be generated economically at 4.0×10^6 sperm per unit, as compared with the 2.0×10^6 cells per unit that had previously become the industry standard dose for sex-sorted semen [15, 17, 70, 71]. Extensive evaluations of SexedULTRA semen have indicated both improved fertility associated with the SexedULTRA process in comparison to sex-sorted semen produced using previous-generation technology [69] and improved fertility when using the higher dose rate of 4.0×10^6 cells per unit of SexedULTRA 4M™ [70]. Research efforts also suggest improved comparability between pregnancy rates obtained using SexedULTRA 4M sex-sorted semen and those obtained using conventional semen [70]. A large field trial was carried out in which semen from eight Holstein bulls was sorted by either the SexedULTRA or XY processing methods and used to inseminate 6930 Holstein heifers across 41 commercial herds in the USA. The SexedULTRA method resulted in a 4.5 percentage points (10.8% relative) improvement ($P<0.001$) in conception rate compared with the XY method (46.1 vs 41.6%, respectively) [70, 72].

Pregnancy rates to timed AI among mature beef cows following the 7-day CO-Synch + CIDR (controlled internal drug release) were reduced when using SexedULTRA 4M sex-sorted semen compared with conventional semen [73]. Further, pregnancy rates to AI were affected ($P = 0.04$) by the interaction of bull and semen type. Greater pregnancy rates were obtained with conventional semen versus SexedULTRA 4M sex-sorted semen when using semen from Bull A (64% [176/277] vs 36% [100/278]; $P<0.0001$) and Bull B (72% [200/277] vs 57% [156/276]; $P<0.01$), whereas pregnancy rates to AI did not differ between conventional and SexedULTRA 4M sex-sorted semen when using semen from Bull C (58% [149/258] vs 52% [131/254]). Pregnancy rates did not differ significantly between cows inseminated using a split-time artificial insemination (STAI) versus fixed-time artificial insemination (FTAI) approach, regardless of whether insemination was performed with conventional semen (65% [265/409] vs 65% [260/403]) or SexedULTRA 4M sex-sorted semen (50% [200/403] vs 48% [187/405]). Given the differences observed among bulls in this experiment, basic research efforts are warranted to better characterize sire fertility and develop predictive assessments of sperm fertility following sex sorting. However, as in a previous evaluation of SexedULTRA 4M sex-sorted semen, pregnancy rates to AI across

locations tended to be higher ($P < 0.1$) for heifers inseminated with conventional semen (60%; 257/429) compared with sex-sorted semen (52%; 218/422) [74]. Thus, pregnancy rates to timed AI with SexedULTRA 4M sex-sorted semen are near 50% and, as such, may be commercially acceptable in some beef production settings.

Conclusion

It is now clear that sexed semen is a commercial reality for cattle, deer, and sheep, and is nearing commercial application in several other species, particularly pigs, horses, and dogs. Reports on sexed semen being applied for conservation purposes have also become common in zoo animals and other wildlife, some of which are of threatened or endangered status [75].

The one aspect that has remained constant until recently and perhaps most concerning is fertility. In cattle and possibly other species it is believed that fertility of sexed semen is compromised by about 10 percentage points by an unknown mechanism that appears uncompensable by increasing the number of sperm per inseminate [17]. Sexing Technologies (Navasota, USA) has invested significantly in research and development in modifying processing media as well as biochemically altering the overall sorting process. Several recently completed trials indicate a significant increase in fertility; however, observed bull-to-bull variation is a major factor that needs to be ironed out. Some reports do show that in sheep, sexed semen outperforms conventional semen as far as fertility is concerned [54]. Reasons for this are varied, but the sorting process does clear out many dead and compromised sperm, and if conditions are right and timing of insemination is accurately matched with ovulation, there is a real opportunity to improve the fertilization outcome.

Summary

Despite key technological developments in recent decades, most commercial operations that utilize sorted sperm are dairy herds. Research to improve sperm sexing has been largely focused on improving sample throughput by increasing the rate at which sperm are introduced to the sorter, and on improving measurement resolution, which has increased the proportion of sperm that can be reliably measured and sorted. Although the speed of sorting has greatly increased, sperm still need to be individually assessed and sorted. As a consequence, the use of lower sperm dosage for AI has reduced fertility (compared with conventional sperm) and has contributed greatly to the limited commercial use. Furthermore, more than half of the sperm are discarded. Several improvements have recently made sperm sorting more efficient and less harmful to sperm. Modification of the technology with a harmless sorting method has great promise to improve the longevity and fertilizing capacity of sorted sperm. With further improvements in speed of sorting and precision, the cost of the process will be reduced, particularly for high-value samples. In the future, the focus may shift to other aspects of the overall process such as improvement in post-sort sperm quality to reduce bull-to-bull variations and increase the semen supply from high-demand bulls. Further, it is essential that, as commercialization increases, more data regarding fertility, embryonic losses, stillbirth, and heifer health be collected. Such information will help to evaluate the technology correctly for its practical use.

Control of Semen-Borne Pathogens

M. Daniel Givens

Virginia-Maryland College of Veterinary Medicine, Virginia Tech, Blacksburg, VA, USA

Introduction

Preventing the dissemination of pathogens is an essential responsibility for the bovine artificial insemination (AI) industry. Each year, millions of units of cryopreserved bovine semen are produced and distributed within the USA and around the globe. To reduce the risk of spreading disease, clear and detailed standards for production of semen from donor bulls have been established. To comply with these standards, donor bulls must complete a rigorous, prescribed testing protocol before entry is permitted into a biosecure AI center (AIC) and donor bulls must be continually monitored using prescribed testing protocols while they are producing semen. As new diagnostic tests are developed and research reveals new information regarding the epidemiology of disease transmission, these testing protocols are continually assessed and improved to ensure the absence of transmissible pathogens in semen.

In the USA, Certified Semen Services, Inc. (CSS) establishes minimum testing requirements for donor bulls entering and residing in AICs for domestic distribution of semen that is validated to be free of pathogens. Additional testing requirements may have to be met if frozen semen is intended for international export. These requirements are negotiated by the United States Department of Agriculture (USDA) and the specific importing country. Countries may establish their own requirements for testing, though these requirements are often based on guidelines published by the World Organisation for Animal Health (OIE) for the collection and processing of bovine semen. An intended purpose of the OIE guidelines is to maintain the health of animals in an AIC to allow the international distribution of semen with negligible risk of infecting people or animals with pathogens [1].

In general, donor bulls and animals intended for use as mount animals undergo testing in three phases. Selected animals are first tested prior to entering isolation (i.e. quarantine) facilities of the AIC. The second phase involves testing throughout and at the end of a quarantine period. The isolation facilities and equipment must be effectively separate from those used for the AIC resident herd. In optimal situations for quarantine, no additional animals should be added to or contacted by the distinct group of animals after completing assembly in the isolation facility. Finally, once animals have entered the resident population of the biosecure AIC, testing is maintained on an annual or semi-annual basis to monitor the population's disease-free status. Additional testing may be necessary depending on the requirements of various export markets.

This chapter covers the major diseases which – in the absence of appropriate control procedures – could be transmitted via frozen bovine semen. The pathogens involved and appropriate testing strategies to minimize the risk of disease transmission are reviewed.

Bovine Viral Diarrhea

Bovine viral diarrhea virus (BVDV) is a single-stranded RNA *Pestivirus* belonging to the Flaviviridae family. This virus has been detected throughout the world and can cause disease that significantly impacts the production and profitability of infected herds. Clinical consequences vary and include respiratory, gastrointestinal, and reproductive effects, with the major source of infection being persistently infected (PI) animals. These PI animals will efficiently transmit BVDV to susceptible animals in the herd, causing acute, transient infections that may lead to reduced

Companion website: www.wiley.com/go/hopper/bovine

pregnancy rates in heifers and cows. Several studies have demonstrated that BVDV can be present in semen from bulls that are persistently or acutely infected [2–5]. These bulls can transmit BVDV through semen to susceptible recipient cattle [2–5]. In addition, bulls may exhibit testicular infections in the absence of viremia [6–8]. These localized testicular infections, which are notably rare, can result in transmission of BVDV in semen [6–8].

PI animals are a result of exposure to non-cytopathic virus through transplacental infection of the developing fetus prior to 125 days of gestation. Bulls that are PI can appear normal but are immunotolerant to the infecting strain of BVDV [9]. The PI bull is capable of shedding BVDV for long periods of time and in very high concentrations despite producing semen with normal concentration, motility, and morphology [2]. The effect of using semen from PI bulls to inseminate susceptible females is significant. One study showed that 12 of 12 seronegative and virus-negative heifers artificially inseminated with semen from a PI bull seroconverted within two weeks after exposure [3]. Another study showed that 161 of 162 cows that were inseminated with semen from a PI bull were seropositive compared with 95 of 143 cows that were inseminated with semen from other bulls, indicating that semen from PI bulls has the potential to consistently transmit BVD infection in susceptible herds [2]. This potential highlights the importance of properly screening bulls for PI status prior to entry into an AIC.

Before entry into an AIC, testing requirements to preclude BVD PI status of bulls include two negative tests (at least 10 days apart) for BVDV antigen in serum or whole blood. Because of interference of maternal antibodies with detection of circulating BVDV in serum, bulls that are less than six months of age must be tested using whole blood [10]. CSS standards require that serum or whole blood is tested using virus isolation (VI), polymerase chain reaction (PCR), or antigen capture enzyme-linked immunosorbent assay (ELISA), with the first sample collected within 30 days prior to entry into the AIC isolation facility. The bull is then sampled for a second BVDV antigen test on serum or whole blood at least 10 days after entry into the AIC isolation facility.

Susceptible bulls exposed to BVDV can become acutely infected and exhibit viremias for a period of 6–21 days after exposure. This period of viremia coincides with increasing production of antibodies specific to the infecting strain of virus [11]. Thus, increasing specific antibody concentrations indicate immune response to a recent viral exposure, while high antibody concentrations indicate prior exposure. BVDV may be detected in semen from acutely infected bulls throughout and slightly beyond the duration of viremia. Yet, concentrations of virus in semen from acutely infected bulls are significantly less than those produced by bulls that are PI [2, 7, 12]. As a result, the immediate seroconversion rates of animals inseminated with contaminated semen from acutely infected bulls (1.8–15.4%) are notably lower than those of animals inseminated with semen from PI bulls (often 100%) [3–5]. Despite the lower seroconversion rates, testing for acutely infected bulls in an AIC is important to prevent the transmission of BVDV to susceptible herds because transmission to a single naïve animal can lead to rapid amplification of virus within susceptible herds [4].

Testing requirements to prevent semen being collected and distributed from bulls that are exhibiting an acute infection with BVDV include all the testing previously described to prevent entry into AICs of PI bulls, with some additional specifications. If the result of the described test during isolation is positive, the test-positive bull is effectively isolated from other animals in the quarantine facility and tested again at least 21 days later. Other animals in the isolation facility at the time of sample resulting in the positive test must undergo additional testing. If the second result is again positive, this indicates the bull is a PI animal and is not allowed entry into the AIC resident herd. If the second test result is negative, the previous test-positive bull must be tested a third time, with the sample collected at least 10 days after the second sample. The third test must produce a negative result before the bull can enter the production herd [10]. In the event that BVDV is isolated from a bull as a result of an acute infection, all semen batches collected 30 days prior and 30 days after the blood sample that produced the positive result must be tested with VI or PCR and determined to be test-negative before they can be distributed.

Optional testing for BVDV acute infections recommended by the OIE includes a test for the detection of BVDV antibodies. Serum samples are collected prior to or at the beginning of the isolation period and at least 21 days after entry into the isolation facility. Seroconversion indicates exposure during the isolation period and the bull must be retested prior to entering the resident herd. The OIE also recommends that bulls are sampled on an annual basis and tested for BVDV antibodies to monitor for seroconversion while they are residents of the production herd of the AIC [1].

Multiple reports describe bulls with persistent testicular infections that shed infectious virus in semen despite absence of a viremic state and presence of circulating antibodies for BVDV [6–8]. This is thought to be caused by an initial infection which generates an antibody response that is unable to rapidly clear virus from within seminiferous tubules due to the blood–testes barrier [6, 7]. Reports demonstrate that bulls may consistently produce semen containing virus over an extended period of time, although the viral load in the insemination dose was less than that of

semen produced by PI bulls but more than that present in semen from acutely affected bulls [6, 8, 13]. One study reported that use of cryopreserved semen from one of these bulls resulted in seroconversion in one of three heifers that were inseminated [14].

Prolonged testicular infections (PTIs) are also reported in bulls that had detectable RNA of BVDV in the semen for up to 2.75 years following experimental acute infections [7]. However, infectious BVDV could be detected in semen using VI testing only during the viremic period of infection, despite presence of infectious virus in testicular biopsies up to 12.5 months after exposure [7, 15]. So, while VI was unable to detect infectious BVDV in semen from these bulls beyond 17 days after experimental infection, PCR detected viral RNA of neutralized virus for prolonged periods. Uniquely, one experiment demonstrated that raw semen collected from a PTI bull at five months after infection resulted in the seroconversion of a six-month-old calf when the semen was injected intravenously [15]. In another trial, repeated attempts resulted in neither seroconversions of calves inoculated intravenously with raw semen, nor seroconversions of heifers inseminated with frozen semen. It was concluded that the risk of viral transmission from PTIs with BVDV may be negligible, but additional information is required to substantiate this conclusion [7].

CSS requires that bulls housed in an AIC must be tested in one of two ways for testicular infections prior to semen release for distribution. The first method is to test all bulls in isolation with a BVDV serum neutralization test. Bulls that test antibody positive are required to have one batch code of frozen processed semen tested using VI or PCR. The second method is to require all bulls in isolation, regardless of their antibody status, to have one batch code of frozen processed semen tested using VI or PCR. Any bull found to have persistent testicular infection for BVDV is not eligible for semen distribution and is not permitted to remain in the resident production herd [10].

Leptospirosis

Leptospirosis is caused by a Gram-negative spirochete bacterium that occurs worldwide in cattle, sheep, goats, pigs, and horses. It is also a zoonotic disease and humans may acquire the infection by contact with the urine of affected animals. *Leptospira interrogans* is the pathogenic form of the bacteria and has many serovars based on cell surface antigens. Clinical signs in cattle include hemolytic anemia, drop in milk production, and changes in milk quality, stillbirths, and abortions [16, 17]. In the USA, common serovars include *L. interrogans* serovar *hardjo* (*Leptospira hardjo*), *Leptospira pomona*, *Leptospira grippotyphosa*, *Leptospira canicola*, and *Leptospira icterohaemorrhagiae*. Cattle are the reservoir host for *L. hardjo*.

Although the main route of transmission of leptospirosis is urine, studies have demonstrated that transmission of the organism may be possible through fresh and frozen semen [18, 19]. To reduce the risk of transmission through AI, the addition of antibiotics to extended semen is effective in reducing infectious leptospiral organisms that may be present in the semen without affecting semen quality [18].

In the USA, CSS requires bulls entering an AIC to be negative to a microscopic agglutination test (MAT) at 1 : 100 or demonstrate a low stable titer (negative at less than 1 : 400) when tested at least two to four weeks apart within 30 days of entering the isolation facility of the AIC for each of the following serovars: *L. hardjo*, *L. pomona*, *L. grippotyphosa*, *L. canicola*, and *L. icterohaemorrhagiae*. The same test and test results must be obtained while the bull is in the isolation facility before entering the resident production facility and the test repeated at six-month intervals while the bull is in the resident production facility of the AIC [10]. Because of the test requirements for bulls to enter an AIC, vaccination for leptospirosis is not done as the MAT is not able to distinguish between titers that are the result of natural infections and those due to vaccines.

Brucellosis

Brucella abortus is the main causative agent of brucellosis in cattle that causes abortion, retained placenta, orchitis, epididymitis, and impaired fertility. Transmission occurs primarily through contact with the uterine discharges associated with an aborted or full-term fetus, but spread through bovine milk and semen is also possible. Bulls will shed *B. abortus* organisms in semen during the acute phase of infection, after which shedding will cease or become intermittent [20]. Brucellosis as an important zoonotic disease in humans and many countries have implemented programs to eradicate *B. abortus* through vaccination and test and slaughter strategies. In the USA, the USDA has designated all 50 states brucellosis free since 2009, although infections continue to be detected in the Greater Yellowstone Area of Idaho, Montana, and Wyoming.

Several serological tests are available to detect antibodies to *B. abortus*. For bulls entering an AIC, CSS requires a negative result on a buffered *Brucella* antigen test (card or buffered acidified plate antigen [BAPA]) or a complement fixation (CF) test within 30 days prior to entry into the isolation facility of the AIC. During the isolation period, the bull is required to have a negative result on both the buffered *Brucella* antigen test (card or BAPA) and the CF test

before the bull can enter the resident production facility, and the same tests are repeated at six-month intervals while the bull is in the resident production facility. If the test results are non-negative, another approved serological test can be completed with a negative result; however, final classification of the bull is determined by the regulatory officials of the state from which the testing is completed [10].

Tuberculosis

Mycobacterium bovis is the main causative agent of tuberculosis in cattle and is a chronic progressive disease that frequently causes progressive emaciation of the affected animal. It is spread to other animals through inhalation or ingestion of *M. bovis* organisms via exhaled air, sputum, milk, urine, and feces. Transmission of tuberculosis has been reported via natural breeding from bulls with genital lesions caused by *M. bovis* and the organism has been demonstrated in fresh and frozen semen samples using PCR [21, 22]. Like brucellosis, bovine tuberculosis is a zoonotic disease and many countries have attempted to eradicate the disease through test and slaughter programs. In the USA, the USDA has designated the majority of the states as Accredited-free states, with the remainder classified as Modified Accredited Advanced states with designated prevalence rates of less than 0.01% [23].

In the USA, surveillance testing for *M. bovis* is performed on cattle by intradermal injection of bovine tuberculin in the caudal fold area at the base of the tail and observation for a reaction by the injecting, accredited veterinarian is performed 72 hours later. Animals that show a palpable response are followed up with a comparative cervical test using bovine and avian tuberculin, with measurement of the response 72 hours later. A serological test is available that measures gamma interferon response to bovine tuberculin but is limited for use only by regulatory officials.

For bulls entering an AIC, CSS requires a negative intradermal tuberculin test within 60 days prior to entry into the isolation facility. Another intradermal test is completed while the bull is in the isolation facility and a negative test is required to enter the resident production facility; the same test is repeated every six months with a negative result while the bull is a resident of the production facility of the AIC [10].

Campylobacteriosis and Trichomoniasis

Campylobacteriosis and trichomoniasis are venereal diseases in cattle that cause infertility, early embryonic death, and abortion, and, in the case of trichomoniasis, pyometra in infected females. Campylobacteriosis is caused by *Campylobacter fetus* subsp. *venerealis* which is a microaerophilic Gram-negative bacterium. Trichomoniasis is caused by *Tritrichomonas foetus*, a flagellated protozoan. Both organisms reside on the penile and preputial mucosa of infected bulls, causing no clinical signs in the male. Bulls become infected after breeding infected females. A carrier state exists for both diseases, predominantly in older bulls. Infected bulls readily transmit *C. fetus* subsp. *venerealis* and *T. foetus* by natural breeding of females. Transmission through AI is possible for both diseases [24, 25].

Diagnostic testing for *C. fetus* subsp. *venerealis* and *T. foetus* depends on the demonstration of both organisms from preputial smegma collected by aspirating or washing of the internal prepuce and penile mucosa. The preputial smegma is inoculated immediately into transport media and shipped to the diagnostic laboratory for testing. CSS requires a culture test for both organisms for each sample with a negative result. CSS does allow initial screening for *C. fetus* subsp. *venerealis* using a fluorescent antibody test, but all positive results using this test must be confirmed using bacterial culture [10]. Other diagnostic tests on preputial smegma are available including PCR and ELISA for *C. fetus* subsp. *venerealis* [26, 27] and PCR for *T. foetus*.

The prescribed frequency of testing is the same for both *C. fetus* subsp. *venerealis* and *T. foetus*. CSS requires serial testing at weekly intervals of bulls present in the isolation facility of the AIC prior to entering the resident production herd. The number of tests required in isolation depends on the age of the bull, with bulls older than one year of age requiring six tests done at weekly intervals on preputial smegma with negative results. Bulls less than one year of age require three tests on preputial smegma with negative results. While resident in the production herd, bulls are to be tested every six months for each disease with negative results [10]. The OIE recommends that bulls older than six months of age be tested three times at weekly intervals and bulls less than six months of age be tested once with a negative result while in the isolation facility and once on an annual basis when in the resident production herd [1].

The addition of antibiotics has been shown to control *C. fetus* subsp. *venerealis* organisms present in bovine semen [28, 29]. In addition to the testing requirements for *C. fetus* subsp. *venerealis*, for bulls to enter and remain in an AIC, CSS requires the addition of an antibiotic combination of gentamicin, tylosin, and lincomycin–spectinomycin to be added to raw semen and again included in the extender that is added for final dilution prior to freezing semen [10]. Acceptable antibiotic combinations recommended by the OIE for addition to extended semen include gentamicin, tylosin, lincomycin–spectinomycin; penicillin, streptomycin,

lincomycin–spectinomycin; or amikacin and dibekacin [1]. The addition of antibiotics does not control for the presence of *T. foetus* in fresh or frozen semen.

Infectious Bovine Rhinotracheitis

Infectious bovine rhinotracheitis (IBR) is a viral disease of cattle that causes upper respiratory disease, abortions, infertility, encephalitis, conjunctivitis, vulvovaginitis, and balanoposthitis. The disease is caused by bovine herpesvirus type 1 (BHV-1) and type 5 (BHV-5). BHV-1 can be further classified into two subtypes. BHV-1.1 is commonly associated with the respiratory form of the disease (IBR) and BHV-1.2 is commonly associated with the genital form of the disease causing infectious pustular vulvovaginitis (IPV) in females and infectious pustular balanoposthitis (IPB) in males. Both subtypes can cause abortions. BHV-1 is spread via aerosol transmission for the respiratory form and venereally for the genital form. Virus has been found in fresh and frozen semen and transmission through AI has been demonstrated [30]. BHV-5 is an encephalitic form of the disease that is primarily spread through aerosol transmission and has recently been reported to cause genital tract lesions and abortions. BHV-5 has been detected in semen from infected bulls and transmission through AI is possible [31].

Primary infection with BHV-1 in bulls can result in shedding of the virus from the prepuce, beginning 7–10 days after infection, and can last for several days to several weeks. After the initial phase, BHV-1 becomes latent in the infected bull and intermittent shedding can result throughout the animal's lifetime. The virus can remain latent indefinitely, although administration of corticosteroids or a period of stress such as transport can result in the recrudescence of BHV-1 and subsequent shedding of the virus from the prepuce. Contamination of semen with BHV-1 is likely the result of virus present on the mucosa of the prepuce and not from the testicles, epididymis, or accessory sex glands [30]. Although exposure leads to antibody production, the presence of antibodies may not prevent the recrudescence and shedding of latent virus in the prepuce and levels of antibodies may be very low or absent in bulls that have remained latent for a long period [19].

There are several recommendations for the testing and maintenance of bulls in an AIC. CSS does not require testing of bulls for IBR [10]. This is based on several studies showing that semen from seropositive bulls appropriately managed in AICs did not shed BHV-1 in semen [32]. This lack of shedding was attributed to the stress-free environment in which bulls reside in AICs [32]. Serologic tests are available to detect antibodies to BHV-1 and include serum neutralization and ELISA. A seronegative antibody test prior to and at least 21 days after semen production will indicate that the bull was not actively infected during the collection interval. For seropositive bulls, VI and PCR tests are available to test semen batches for presence of virus. The OIE recommends maintenance of an IBR-free herd in an AIC [1]. Bulls entering an isolation facility are to come from an IBR-free herd or undergo a serologic test for antibodies within 28 days prior to entry with a negative result. The bull is to be tested in isolation with a serologic test with a negative result and all the bulls in the isolation facility must be negative on a serologic test prior to entry into the production herd. The production herd is tested with a serologic test on an annual basis and all resident bulls are required to produce a negative result [1].

Arboviruses

Cattle are susceptible to arthropod-borne viruses that have the potential to be transmitted through semen. Cattle may become infected via insects that harbor the virus after feeding on viremic animals and subsequently feeding on susceptible animals, thus transmitting the virus. Distribution of disease is limited to the endemic areas where the insect vectors reside, and viruses are often maintained in these areas through wildlife reservoirs. New epidemic areas occur through the movements of virus-infected vectors or movements of viremic host animals into new areas with competent vectors.

Bluetongue virus (BTV) and epizootic hemorrhagic disease (EHD) virus are orbiviruses that have worldwide distribution. There are at least 27 distinct serotypes of BTV and the virus is mainly transmitted by midges (*Culicoides* species). Cattle are a major reservoir host for the virus. Infected cattle rarely show clinical symptoms, but the disease may infrequently cause fever, facial edema, hemorrhages, and ulceration of the mucous membranes in some cattle. BTV has been found in semen but only consistently during the viremic period of infection in bulls, possibly associated with blood that has leaked from the genital tract [9].

EHD is similar to BTV and there are at least seven serotypes, with significant immunological cross-reactivity between the two viruses. EHD is also similar to BTV in that it rarely causes clinical signs in cattle and is mainly transmitted by midges (*Culicoides* species). The presence of EHD in semen has not been demonstrated, but, due to its similarity to BTV, international recommendations include testing for the virus in bulls used for AI [1].

Serologic and virus identification tests are available for monitoring bulls and semen used for AI. Serologic tests that are available include agar gel immunodiffu-

sion and ELISA. The OIE recommends that seronegative bulls are tested prior to semen collection and again 21–60 days after collection with negative results. Virus identification tests include VI and PCR done on whole blood. The OIE recommends either VI or PCR prior to collection and again at least every 7 days during the collection period for VI or at least every 28 days during the collection period for PCR and a final test at the end of the collection period [33]. VI and PCR tests are also available for frozen semen.

Recently, a novel arboviral disease emerged in Europe caused by Schmallenberg virus (SBV). Disease was first detected in November 2011 in dairy cattle that had reduced milk production and diarrhea. The virus was later found to cause congenital malformations in aborted and newborn calves. SBV is an *Orthobunyavirus* and is a member of the Simbu serogroup and is transmitted by *Culicoides* midges. The virus has been detected in bovine semen by PCR and is able to be shed in consecutive semen batches or intermittently for 43 days in one report [34] and as long as three months in another report [35]. A single insemination dose of semen can contain SBV sufficient to infect naïve cattle through experimental subcutaneous injection, though transmission of SBV by natural breeding or AI remains to be demonstrated [36]. Serological tests are available including serum neutralization and ELISA, while PCR and VI are available to detect virus antigen in blood. To validate semen free of SBV, testing of semen samples for SBV RNA using PCR is recommended unless the bull tests negative for SBV-specific antibody at least 28 days after semen collection [37].

Enzootic Bovine Leukosis

Enzootic bovine leukosis is a retroviral disease of cattle that causes persistent lymphocytosis and lymphosarcoma in affected cattle and is caused by bovine leukemia virus (BLV). BLV is found in lymphocytes and can be transmitted horizontally via contact with secretions from infected animals, iatrogenically via contaminated instruments such as tattoo pliers and dehorning gouges, and vertically via transplacental exposure.

There has been one study that reported the presence of BLV in bull semen by demonstrating seroconversion of sheep that were injected intraperitoneally with semen collected from a BLV-positive bull [38]. The semen from this bull was collected by rectal massage, which may have resulted in excess trauma and presence of lymphocytes in the semen. A follow- up study repeated the experiment using 32 seropositive bulls that were collected normally and no seroconversions were reported in inoculated sheep [39]. A study following the use of semen from BLV-seropositive bulls collected and processed in an AIC showed no evidence of seroconversion of females in a BLV-free herd over a five-year period when bred with AI [40]. Another study tested frozen semen batches from BLV-seropositive bulls using PCR and did not find any evidence of BLV [41]. Semen collected in these studies were from bulls residing in AICs where semen was collected using an artificial vagina and routine laboratory procedures used to evaluate the semen for quality to exclude the presence of white blood cells.

Serologic tests for BLV, including agar gel immunodiffusion and ELISA, are available to accommodate international requirements for trade in bovine semen. The OIE recommends either that donor bulls reside in a BLV-free herd or serologic testing of the bull at least 30 days before and at least 90 days after the collection of semen. In the USA, CSS does not require testing of donor bulls for leukosis for residence in a production herd [10]. VI and PCR tests are available to detect virus antigen in the blood and a PCR test is available to test semen.

Control

Control of pathogens in bovine semen, especially from bulls residing in AICs, is primarily dependent on frequent testing to demonstrate lack of detection of pathogens of concern as well as antibody responses to the specific pathogens. Several diseases such as BVDV and leptospirosis require the resident production herd to maintain freedom from infection. A positive test result generally requires the removal of the positive animal and retesting of the resident herd population. Other diseases such as BTV and EHD allow seropositive animals to be present in the resident herd and tested differently to minimize the risk of the pathogen being present in semen. Seronegative animals are tested for antibodies before collection of semen and again after the collection to demonstrate lack of exposure to the pathogen. Testing is done on seropositive animals using tests to detect the pathogen during the time of collection in semen or blood. The testing strategy for each AIC will depend on specific regulations and standards of the country where the AIC is located, and standards required for export of cryopreserved semen to foreign markets.

Minimizing the introduction of diseases is an important consideration for maintaining a disease-free herd. Biosecurity protocols are necessary to reduce the probability of introduction of disease. Bulls should be housed indoors or in paddocks with perimeter fencing to prevent contact with other livestock and wildlife. Barn personnel should change into clothing dedicated to the facility and, at a minimum, should wash their boots prior to entry into the facilities and when moving between quarantine and

isolation facilities. Outside vehicles should be clean and have tires disinfected prior to entering the AIC. Bulls should be maintained in a clean environment and not soiled during collection. Bulls should be maintained in good health and physical status. Sick animals should be isolated and not used to collect semen. Many countries require that minimum standards for biosecurity are maintained for semen to be released for distribution both domestically and internationally. Biosecurity and standard operating practice manuals should be present and frequently updated and followed to reduce the potential for introduction of disease into an AIC.

Introduction

Fertility is a multiparametric phenomenon that relies on the use of semen of sufficient quality and quantity, accurate timing and method of insemination, and appropriate herd management. When using artificial insemination (AI), the dairy producer must manage a range of these factors, including heat detection, timing of insemination in relation to estrus, and correct handling of the frozen straws. However, it is the onus of the semen production centers (SPCs) to supply straws containing spermatozoa of good viability that produce acceptable conception rates if all other variables are managed correctly.

To ensure acceptable fertility after AI, frozen–thawed spermatozoa must be present in sufficient number in each straw (concentration) and possess a number of characteristics important for fertilization. Accordingly, spermatozoa must survive the thawing procedure with normal morphology, an intact acrosome, DNA integrity, and active mitochondria, and maintain forward progressive motility to traverse the female reproductive tract. Some or many of these characteristics are measured during post-thaw quality control (QC) procedures undertaken by SPCs prior to distribution. QC is the assurance that each batch of straws has undergone semen analysis to verify that the sample is likely to be fertile.

Although semen analysis may seem easy to perform, meticulous attention to detail and technique is essential in order to obtain an accurate and reproducible analysis. Manual semen analysis using a light microscope has been the standard method for analysis in most SPCs. However, manual analyses can be very subjective and prone to within- and between-technician errors. Similarly, the use of fluorescence microscopy to assess spermatozoa for acrosome, membrane, and DNA integrity is markedly slow and limited due to the low number of spermatozoa analyzed from each sample and the incapacity for an extensive multiparametric analysis.

To maximize accuracy in QC, SPCs are realizing the benefit of a multiparametric approach and have increased the rigor of their semen testing, moving from time-consuming basic subjective assessment of a few hundred spermatozoa for concentration, motility, and morphology using microscopy, to the use of computer-assisted tracking to assess motility and flow cytometry to analyze thousands of cells within seconds for characteristics such as viability, mitochondrial activity, acrosome, DNA and capacitation status. The topics for discussion in this review are the various tools and assays in use in cattle SPCs to determine QC values, factors to consider when using these tools, and how the efficacy of QC procedures may be maximized in order to predict field fertility.

Objective Assessment of Sperm Motility

Computer-assisted sperm analysis (CASA) is a powerful tool for the objective assessment of sperm motility and is hence now frequently used for evaluating semen quality. The basic components of this technology consist of a microscope to visualize the sample, a digital camera to capture images, and a computer with specialized software to analyze the movement of the spermatozoa. The essential principle behind most microscopy-based CASA systems is that a series of successive images of motile spermatozoa

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

within a static field of view are acquired by computer software algorithms, which then scan these image sequences to identify individual spermatozoa and trace their progression across the field of view. This involves recognizing the same cell in each image by its position and inferring its next position by estimating the likelihood that it will only have moved a certain maximum distance between frames. CASA can also provide information about sperm concentration, morphology, viability, and index of DNA fragmentation of frozen–thawed sperm. However, these more specialized techniques are not routinely applied for regular analysis of frozen–thawed semen in SPCs.

With the use of CASA, several motility parameters describing the specific movements of spermatozoa can be obtained in greater detail than possible in subjective assessment. These computerized measurements can be useful for assessing various sperm characteristics simultaneously and objectively, and are valuable for the detection of subtle changes in sperm motion that cannot be identified by conventional subjective semen analysis, as reviewed elsewhere [1–3]. The parameters typically collected using CASA systems are motility, velocity, linearity, and lateral displacement of spermatozoa as they progress along their trajectories in a sample. The percentages of total and progressive motility are the most important motility parameters in the evaluation of spermatozoa. Total motility refers to the fraction of spermatozoa that display any type of movement, whereas progressively motile spermatozoa swim forward in an essentially straight line. Spermatozoa that swim but in an abnormal way, such as in tight circles, are not included in the proportion of progressively motile sperm. In addition to evaluation of sperm motility, the software calculates the kinetic values of each spermatozoon, which covers the velocity of movement, the width of the sperm head's trajectory, and frequency of the change in direction of the sperm head. The velocity values that are determined by CASA are the curvilinear velocity (VCL), straight-line velocity, and average path velocity (VAP) [2]. The amplitude of lateral head displacement and beat cross frequency (BCF) are two other characteristics measured with CASA instruments [2].

Limitations of CASA Instruments

Despite the power of an objective evaluation by CASA, there are some constraints associated with this technology. Many factors are known to affect CASA results. The type of specimen chamber used for analysis can affect the movement of sperm, the accuracy of the cell count number, and therefore the percentage of motile spermatozoa [4]. The temperature at which semen is analyzed is also an important factor that may affect CASA results. Independent studies showed that analyzing semen below 37 °C significantly affected results [5, 6]. These groups performed CASA on spermatozoa maintained at 37 °C with a stage warmer and compared the results with spermatozoa analyzed at room temperature or at 30 °C. The data demonstrated a decrease in the motility parameters (percentage of motile spermatozoa and track speed) when spermatozoa were not analyzed at 37 °C. These experiments suggest that a simple variation introduced in the analysis of sperm motility can have a considerable effect on the results. The concentration at which semen is analyzed is an essential aspect that influences CASA results. It has been established that at low semen concentrations (<20 million/ml), an overestimation of the concentration and thus an underestimation of the percentage of motile cells can occur due to the acquisition of non-spermatic particles (debris). On the other hand, at higher concentrations (>50 million/ml), a large proportion of the fast-moving cells will be excluded from analysis because of cell collisions or spermatozoa exiting the analysis area, or excluded on the basis of nearest-neighbor effects, leading to an underestimation of the motility [5, 7].

Sampling condition is a source of error when acquiring data with CASA. Computer and video camera equipment are continuously evolving and different CASA systems use various models of video camera. Most of the CASA systems allow 30 or 60 Hz as a frame rate to analyze sperm tracks and speed. Studies have shown the importance of the frame rate for reliability of the analysis [8–10]. It is generally accepted that a higher frame rate is required to render an evaluation closer to the real path for a fast non-linear sperm cell. To study a hyperactivated sperm cell, Mortimer and Swan [11] suggested using the highest frame rate available on the system in order to have the most accurate evaluation.

The type of extender in which semen is diluted is another aspect that should be taken into consideration when evaluating spermatozoa with CASA. Some extenders contain debris of a size similar to a sperm head, causing CASA software to include them in the analysis. Egg yolk- and milk-based diluents are examples of extenders containing such particles. In addition, when observing semen diluted with milk extender, the globular lipids mask the spermatozoa, thus rendering CASA analysis impossible. To assess motility analysis in these conditions, samples could be washed to remove extender debris from semen. However, it has been established that washing the semen affects the motility of the spermatozoa [12], making correct evaluation more difficult. To overcome this problem, fluorescence technology allows discrimination of sperm cells from particles in the extender by staining sperm heads with a

DNA-binding fluorochrome. Under fluorescent light, only DNA-containing objects will be detected by the CASA software, thus omitting the need for washes. This technique improves the accuracy of the concentration [13] as well as the motility analysis [14] when working with semen diluted in these extenders. Therefore, standardizing the type of chamber, the temperature, the concentration, and the type of extender is crucial to assure repeatable standard QC at an SPC.

Motility is one of the most important characteristics believed to be associated with the fertilizing ability of spermatozoa. Several groups have reported a significant correlation between total [15–18] and progressive [19] motility of bull semen and its associated field fertility. However, other groups have reported that the subjective analysis of semen motility did not correlate with fertility [20, 21]. CASA instruments collect a wide range of sperm motility parameters, allowing a more detailed and accurate analysis of sperm movements and track speed. Researchers have also tried to correlate the kinetic parameters with the field fertility of semen, with some groups able to show a positive correlation between straight-line velocity of spermatozoa and field fertility [18–22]. Another study used a combination of several motility parameters to reach a very high correlation with bull fertility [20]. Taken together, these studies show the high potential of CASA for estimating the quality of the semen and therefore becoming a powerful tool to measure sperm characteristics and predict bull fertility compared with standard semen evaluation. However, as mentioned above, standardization of conditions and parameters of all CASA analyses is key to obtain repeatable and valid correlations with fertility.

Several models of CASA instruments are now available to evaluate the quality and motility of spermatozoa. Each system operates on similar principles but they differ in their parameter settings and use different algorithms to determine speed and trajectories. Parameter settings, threshold settings, video frame rate, and other variables will affect CASA results, as reviewed by Davis and Katz [23]. As mentioned above, new technologies and CASA software evolve quickly. Our laboratory undertook a small study to measure the aptitude of the CEROS™ (Hamilton-Thorne, USA) and the Sperm Class Analyzer® (SCA; Microptics, Spain) in evaluating the motility and the concentration of frozen–thawed bovine spermatozoa diluted in an egg yolk-based extender (unpublished data). A total of 18 different frozen–thawed ejaculates were analyzed with both systems and the mean total and progressive motility percentages, concentration, VAP, VCL, straight-line velocity, BCF, and amplitude of lateral head displacement were compared (Figure 81.1). Among all parameters analyzed, only the percentage of total motile cells was not significantly different between the systems. The discrepancies can be explained by the better capacity of the SCA to exclude egg yolk particles from the analysis. The SCA discriminated non-spermatic particles based on size in microns, while the CEROS used pixels to estimate the size of the cells. Differences in the algorithms used to calculate slow, medium, and fast spermatozoa may also explain the variation in the motility and kinetic parameters observed between each system. Overall, this mini-study indicates high variability between CEROS and SCA systems in estimating sperm motility parameters.

Analysis of Sperm Function by Flow Cytometry

Flow cytometry analyzes cells suspended in a stream of fluid passing at high velocity in front of one or several lasers. The light emitted by fluorochrome-bound cells is captured by photomultiplier tubes and converted into an electronic signal, subsequently digitalized by cytometry software. Key features of flow cytometry are the acquisition and analysis of thousands of cells within seconds and the multiparametric potential of the technology. The most modern cytometers are routinely equipped with three lasers and at least 10 photomultiplier tubes, allowing cell labeling with several probes at the same time and thus enabling analysis of numerous parameters simultaneously. In the last few years, the multiparametric aspect of flow cytometry has allowed this technology to become a popular tool for evaluating sperm attributes [24–26]. A wide range of fluorochromes has been developed to assess numerous characteristics of sperm cells. Here we review some of the fluorochromes used to study sperm cells with flow cytometry.

Sperm Attributes Analyzed by Flow Cytometry

Viability/Mortality

Propidium iodide is the most popular dye used to identify dead cells. This membrane-permeable fluorochrome enters spermatozoa with damaged cellular membranes and binds to DNA, where it can be excited with a 488-nm laser present on most cytometers [27–29]. Propidium iodide is often used in combination with SYBR-14, another DNA-labeling probe [30, 31]. SYBR-14 is also excited by the 488-nm laser and is a permeant probe staining all cells. Added to the cells simultaneously, propidium iodide displaces or quenches the SYBR-14 fluorescence in damaged cells.

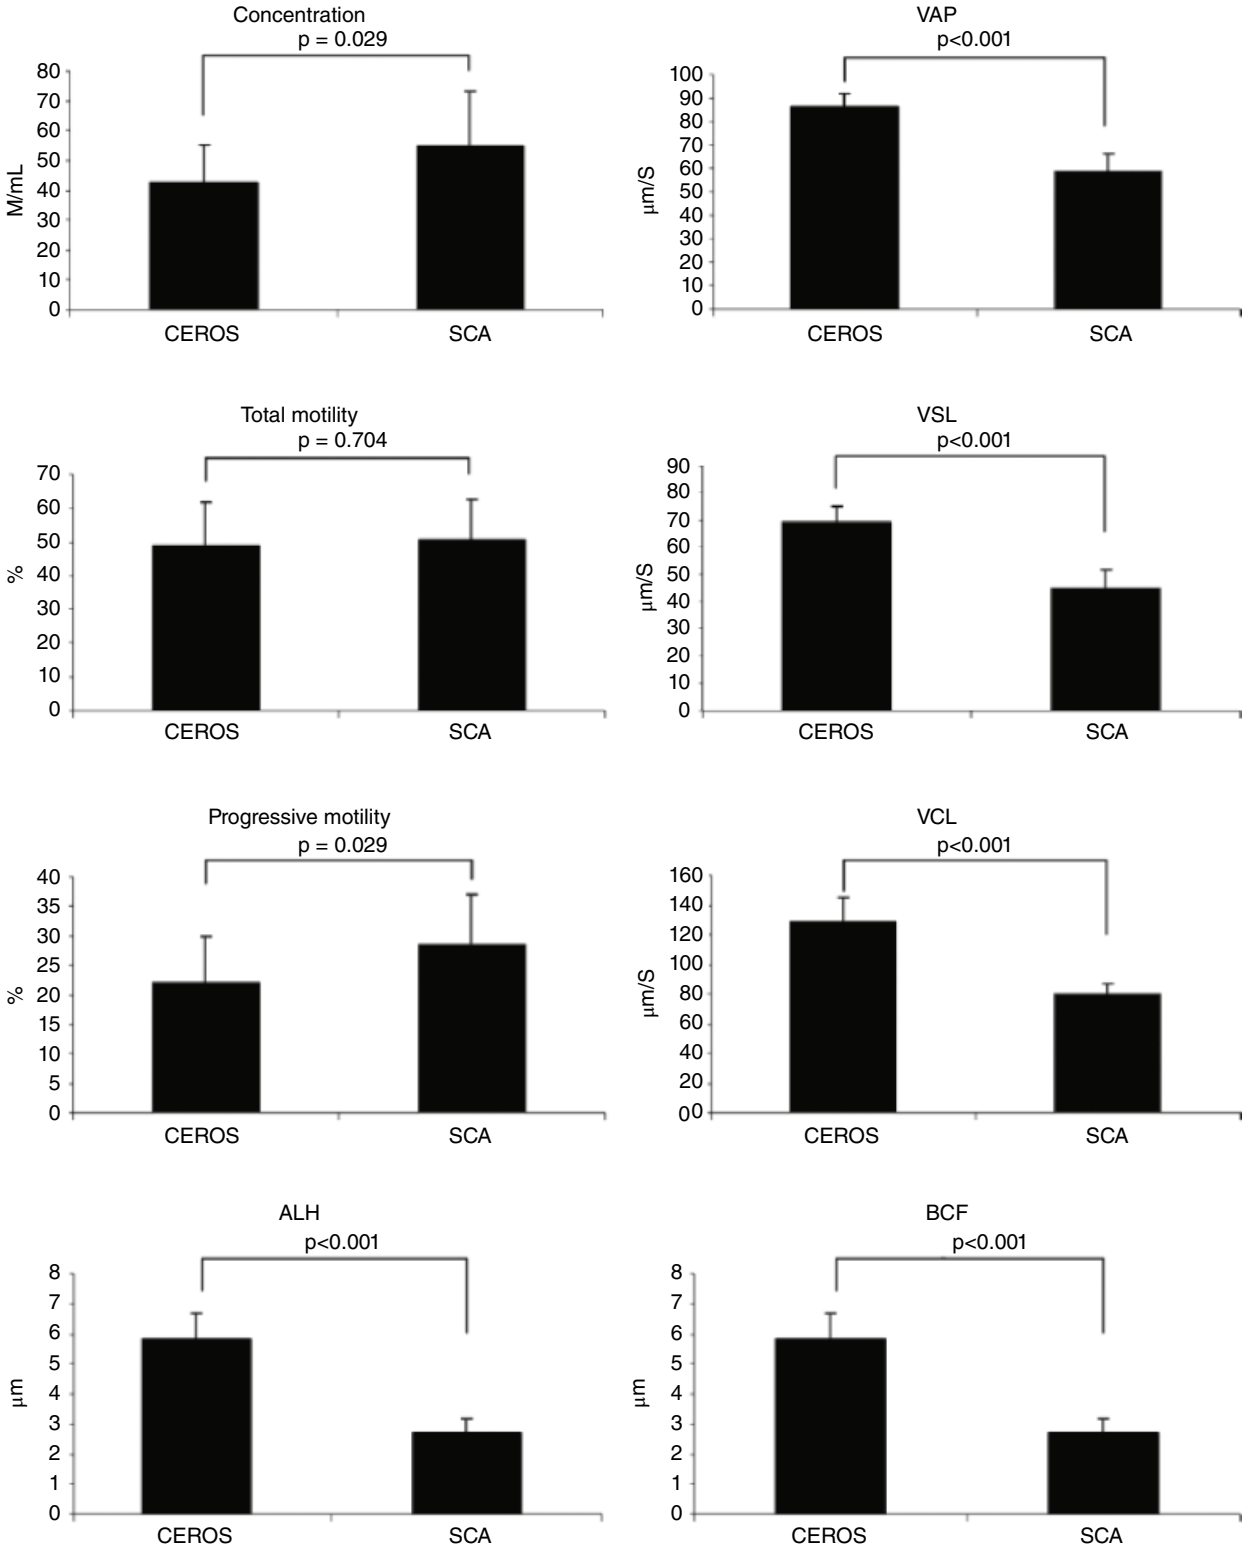

Figure 81.1 Comparison of CEROS (Hamilton-Thorne) and SCA (Sperm Class Analyzer) for determining concentration, percentage of total and progressive motility, lateral head displacement (ALH), average path velocity (VAP), straight line velocity (VSL), VCL, and beat cross frequency (BCF) from 18 different frozen–thawed bovine ejaculates. Columns represent mean values ± SEM. *P*-value <0.05 indicates a statistically significant difference between CEROS and SCA, Student's paired *t*-test.

A new fixable dye commercialized by Invitrogen under the name Live/Dead® fixable dead cell kit is now available to evaluate the viability of cells [32]. This dye reacts with cellular amines on the surface of cells or inside the cytoplasm of cells with damaged membranes. Cell-surface staining of amines of viable cells will result in relatively dim staining compared with the bright staining of dead cells. This fixable dye belongs to a large family available in different wavelengths of excitation/emission, allowing its use on most cytometers.

Acrosome Integrity

Evaluation of acrosomal status is mainly assessed by using plant lectins recognizing acrosomal ligands. *Pisum sativum* agglutinin binds mannose and galactose moieties of the acrosomal matrix. As *P. sativum* agglutinin cannot penetrate the intact acrosomal membrane, only spermatozoa with a reacted or damaged acrosome will be stained [21, 33, 34]. However, it has been shown that *P. sativum* agglutinin has an affinity for egg yolk and non-specific binding sites on the sperm cell surface [35, 36]. This aspect could become a problem when analyzing semen frozen in egg yolk-based extender and result in misinterpretation of the acrosomal status of sperm. *Arachis hypogaea* (peanut) agglutinin binds galactose moieties of the outer acrosome membrane and is the most popular lectin used to study the integrity of the acrosomal membrane with flow cytometry [37–39]. In addition, *A. hypogaea* agglutinin seems the most reliable probe for identifying spermatozoa with a damaged acrosome as it displays less non-specific binding to other areas of spermatozoa [40]. *P. sativum* agglutinin and *A. hypogaea* agglutinin are usually labeled with fluorescein isothiocyanate (FITC) fluorochromes, allowing them to be used by all cytometers.

Mitochondrial Activity

Mitochondria are very important organelles involved primarily in the generation of the energetic substrates for the motility of the sperm cell. Rhodamine 123 was one of the first probes to monitor mitochondrial activity [41, 42]. Rhodamine 123 is sequestered in active mitochondria and washed out from the cell when the membrane potential is lost. This characteristic limits its use when quantification is needed or when fixation of spermatozoa is required. To overcome the fixation problem, Mitotracker® dye could become a solution. This fixable dye accumulates and stains active mitochondria and has the advantage of availability in different ranges of excitation and emission fluorescence [42–44]. The most popular probe for evaluating mitochondrial activity is JC-1 (5,5′,6,6′-tetrachloro-1,1′,3,3′ tetraethylbenzimidazolylcarbocyanine iodide) [45–47]. In spermatozoa containing mitochondria with a high membrane potential, JC-1 enters the mitochondrial matrix where it accumulates and forms J-aggregates and become fluorescent red. In spermatozoa containing mitochondria with low membrane potential, JC-1 cannot accumulate within the mitochondria and remains in the cytoplasm in a green fluorescent monomeric form. JC-1 has the advantage of being able to quantify the mitochondrial burst of the cell compared with Rhodamine 123 and Mitotracker. A disadvantage of the JC-1 probe is its dual fluorescence emission that limits its combination with other probes emitting at the green and red wavelngths.

DNA Integrity

Assessment of chromatin status is important in determination of the fertility potential of spermatozoa. In recent years, the sperm chromatin structure assay developed by Evenson and Jost [48] is the main technique used to evaluate chromatin integrity in spermatozoa by flow cytometry [49, 50]. The sperm chromatin structure assay uses the dual fluorescence emission of acridine orange, depending on whether it binds to single-stranded DNA (red fluorescence) or double-stranded DNA (green fluorescence). Following a denaturation step, the sperm sample is incubated with acridine orange and then analyzed by flow cytometry. Denaturation will induce single-strand DNA formation when DNA breaks are present and generate a heterogeneous population of red and green fluorescence depending on the integrity of the chromatin. The most important result derived from the sperm chromatin structure assay is the ratio of red/green plus red fluorescence called the DNA fragmentation index, where a high DNA fragmentation index correlates with high DNA damage. The DNA fragmentation index has shown correlation with fertility in different species [51–53]. The large luminal spectrum covered by acridine orange and the denaturation step required to induce single-strand DNA are two main inconveniences of the sperm chromatin structure assay for a multiparametric analysis. Acridine orange fluoresces in the green and red spectrum; that leaves few possibilities for adding other fluorochromes in these spectral areas and the denaturation step is performed with an acid/detergent solution not compatible with all probes. Another assay to assess DNA integrity developed for flow cytometry is the terminal transferase dUTP nick end labeling (TUNEL) assay, which can identify DNA strand breaks [54–56]. Transferase enzyme incorporates fluorescently modified nucleotides at the sites of DNA breakage. The resultant labeled cells can then be analyzed by flow cytometry. The TUNEL assay allows quantification of

labeled nucleotides incorporated into fragmented DNA reflected by the increase in fluorescence, which gives an appreciable advantage over the sperm chromatin structure assay.

Calcium Influx

Calcium influx is one of the primary steps involved in the sperm capacitation process. The rise in intracellular calcium ultimately leads to the phosphorylation of tyrosine and serine residues in proteins regulating the signaling cascade. The most popular dye used to determine the intracellular calcium concentration in sperm cells is the Fluo-3/4 family probe excited by the 488-nm laser line [57–59]. Calcium-unbound Fluo-3 is a non-fluorescent molecule, but when calcium ions enter the cell and bind Fluo-3 the latter becomes fluorescent. Fluo-4 is a derivative of Fluo-3, bearing higher fluorescence intensity. Fura red is a probe also excited by the 488-nm laser whose fluorescence emission decreases on calcium binding. Dual labeling of spermatozoa with Fluo-3/Fura red allows calculation of the ratio of unbound to bound calcium. The ratio between the two mean fluorescence intensities (Fluo-3/Fura red) is proportional to the intracellular calcium concentration of the spermatozoa. This experimental approach has been used to assess dog semen by Peña et al. [60]. One critical aspect when using these dyes is cell loading. Because mean fluorescence intensity is the parameter used to indicate the level of intracellular calcium, errors in pipetting of the probe will change the mean intensity and result in misinterpretation of the results. The drawback of Fluo-3/Fura red combination is the need for two different fluorescence detectors, which decreases the scope of a multiparametric approach. Indo-1 pentaacetoxymethyl ester is a membrane-permeable calcium sensor dye used to monitor changes in intracellular calcium. Once Indo-1 enters the cell, esterases cleave the acetoxymethyl group, yielding a membrane-permeable dye. Unbound Indo-1 has peak emission at 485 nm. On binding calcium, the peak emission shifts down to 410 nm. Measurement over time can be represented as a ratio of the two emission wavelengths. As Indo-1 acetoxymethyl is a ratiometric probe, cell-loading concerns (as for Fluo-3/4) are less important. One restriction with this probe is that not all laboratories are equipped with an instrument comprising the ultraviolet laser needed to excite Indo-1 acetoxymethyl. For those with this instrument, Indo-1 acetoxymethyl becomes a very good probe for a multiparametric approach because it is one among few probes using the ultraviolet laser, thus leaving the 488- and 633-nm lasers available to study other parameters.

Limitations of Flow Cytometry

Several factors influence the choice of cytometer for the analysis of sperm cells. The price of the instrument remains a major factor that will influence this choice. Multiparametric analysis is usually obtained with instruments containing more than one laser and many photomultiplier tubes, which increases the price of the equipment substantially. Indeed, the type of analyses to be performed is also a factor that will determine the choice of flow cytometer. Depending on the objectives of the breeding center and the experimental design, the combination of lasers (number and wavelength) and the number of photomultiplier tubes included in the instrument must be taken into account. An instrument with only one laser and three photomultiplier tubes allows detection of a maximum of three parameters on each cell, while a multiparametric analysis including four or more parameters will usually require an instrument having at least two lasers and four photomultiplier tubes. The software operating the flow cytometer is another important aspect in the choice of instrument. Most software products available are fairly easy and straightforward to operate for a novice user in flow cytometry. However, some software requires certain knowledge of flow cytometry concepts, making the instrument more difficult to operate. As an example, samples stained with a cocktail containing several probes are subjected to subpopulation gating analysis. In order to obtain representative results, gates need to be associated to the proper population in the correct hierarchy, a perspective that is difficult to handle with some software for a novice user. Moreover, some programs have gaps in export and data compilation, making it more difficult to analyze the data, and these shortcomings are time-consuming for the user.

As mentioned in the section on "Analysis of Sperm Function by Flow Cytometry," flow cytometry is a relatively new avenue for the SPCs. The unique characteristics of spermatozoa must be considered when selecting an instrument. The paddle shape of the head and presence of the flagellum make spermatozoa very different in size and cellular complexity compared with most cells studied by flow cytometry. Indeed, the majority of cells studied with this technology have a round shape, and passage in front of the laser leads to a neat forward scatter versus side scatter plot. However, when a sperm cell hits the laser, it could be on the thick or the thin side of the head. This unique feature of sperm cells will lead to a scatter plot of different size and complexity. A very important aspect we found when studying frozen–thawed spermatozoa with flow cytometry, and which has been discussed in this chapter, is the extender in which semen is diluted. As stated, different types of extenders are used to dilute semen, and some contain particles of

a similar size to spermatozoa. This aspect of particle contamination of the target population is a concern when considering the purchase of a cytometer for multiparametric analyses. An apparatus powerful enough to discriminate sperm cells from particles based only on the size and complexity of the cells allows gating of the sperm cell population without using any fluorochromes. As a result, more photomultiplier tubes are left available for cell characterization with fluorochromes. Our laboratory has compared several flow cytometers, and only half of them were sensitive enough to accomplish this discrimination between foreign particles and spermatozoa without having to use any fluorochromes. A research laboratory possessing a cytometer that cannot discriminate debris from spermatozoa will have to either wash the cells to remove particles or stain the sperm cells with a fluorochrome, which leaves fewer photomultiplier tubes to study other parameters. Not all fluorochromes are suitable with semen extenders, especially egg yolk-derived extenders known to quench some fluorescent dyes. Hoechst 33342 is routinely used to stain the nucleic acid of spermatozoa when using a cytometer equipped with an ultraviolet or violet laser. This approach allows elimination of the particles by gating them out, resulting in a more accurate analysis (Figure 81.2). Unfortunately, not all systems are equipped with such lasers to use Hoechst 33342 as a cell tracking dye, but a cell permeant dye like SYBR-14 could be added to sperm cells and this fluorescent population gated for further analysis.

A Multiparametric Approach for Standardization and QC among SPCs

Use of CASA and Flow Cytometry as QC Tools

Subjective evaluation of semen by conventional microscopy is still used by numerous SPCs. As discussed in the Introduction, this type of semen evaluation results in variation of the final decision regarding whether the semen lot will be accepted or rejected during QC. Even though CASA is used in some SPCs, fertility is a multiparametric phenomenon; thus motility parameters of spermatozoa are not sufficient for evaluating the global fertility potential of a semen sample. Introduction of flow cytometry in SPCs will allow better characterization of the spermatozoa because, by itself, flow cytometry has the potential for multiparametric analysis of spermatozoa. Combining CASA and cytometry will provide SPCs with a powerful multiparametric approach to evaluate the quality of the semen produced and allow the establishment of standardized procedures to make accurate and repeatable decisions on the outcome of the semen.

We have evaluated the potential of these tools to accurately estimate the quality of semen produced in SPCs across Canada. The percentage of total and progressive motility and the percentage of viability, acrosome integrity, and high mitochondrial activity were evaluated with CASA and flow cytometry. We obtained and reanalyzed 660 lots of semen diluted in egg yolk produced by different SPCs that had previously been processed by standard subjective QC, where 58% ($n = 385$) were accepted and 42% ($n = 275$) were rejected. Semen evaluation was performed at two different time points: immediately after thawing and two hours later after a thermoresistance stress. Cutoff values (Table 81.1) were established for each parameter analyzed with CASA/flow cytometry at each time point. Semen lots that did not reach our cutoff standard would have been rejected and discarded. On the other hand, if the quality of the semen was good and met our cutoff values, the lot was considered as accepted using CASA and flow cytometry and would have been distributed.

Table 81.2 highlights the percentage of lots rejected after analyzing the 660 lots with CASA and flow cytometry. CASA analyses revealed that 14% (94 of 660) unique lots failed to meet the cutoff immediately after thawing compared with 27% (178 of 660) unique lots after two hours' incubation. The same observation could be made from flow cytometry analyses, where 24% (156 of 660) unique lots were rejected after thawing compared with 32% (214 of 660) unique lots after two hours' incubation. This analysis demonstrates the need for a thermoresistance test to be included in QC to increase precision where the majority of lots were discarded based on the two-hour incubation. In addition, CASA evaluation alone resulted in the discard of 28% of the lots while flow cytometry analysis alone discarded 34% (224 of 660) of the lots. When CASA and flow cytometry are used in combination, a total of 41% (268 of 660) unique lots were rejected, resulting in an increase in rejection of 13% compared with CASA alone (28%). Overall, these results demonstrate the ability of the multiparametric approach to provide very high authority to the rejection/acceptance decision.

Detailed analyses of accepted and rejected lots with CASA/flow cytometry compared with standard QC showed 77.4% agreement in the decision made using the two different methods of QC assessment, but 22.6% of the samples were discordant between them (Figure 81.3). This discrepancy would be considered the "precision impact" of the multiparametric technique over the standard subjective evaluation. This 22.6% consists of 10.8% of the accepted lots by standard methods that would have been rejected with our multiparametric tools and 11.8% of the rejected lots by standard methods that would have been accepted with the multiparametric approach. At first sight, 22.6% of

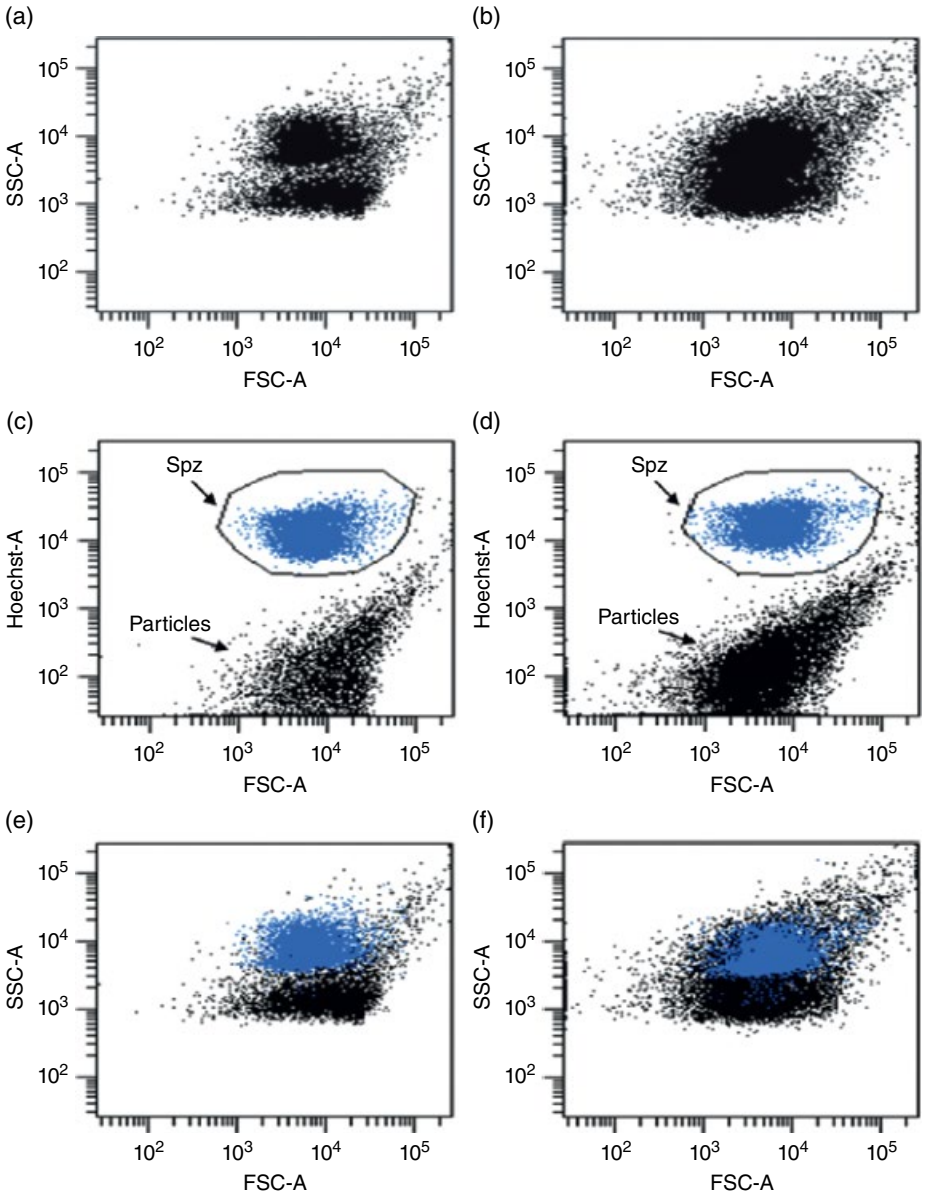

Figure 81.2 Comparison of (a) good and (b) bad resolution of spermatozoa from non-spermatic particles in frozen–thawed ejaculates. Labeling cells with Hoechst 33342 (blue cells in c, d) allows exclusive staining of spermatozoa and discrimination from cellular debris and egg yolk-derived non-spermatic particles. The positive population can be used for further characterizations in a multiparametric approach (e, f). Spz, Spermatozoa; SSC, side scatter plot; FSC, forward scatter plot.

discrepancies between objective and subjective evaluation would appear high. However, CASA/flow cytometry would have discarded 268 lots (Table 81.2) while accepting 392 lots compared with the original 385 accepted lots and 275 rejected by the SPCs. This represents a 1% difference of semen production and would be considered as the "production impact" of CASA/flow cytometry over standard QC. This study demonstrates that the production impact would be negligible but the precision impact would be quite considerable.

To estimate the impact of this multiparametric approach on semen fertility in the field, we applied this analysis on semen lots of known fertility that were released in the field after using standard QC. CASA and flow cytometry were performed on 192 lots with at least 250 first inseminations. The fertility associated to each lot was obtained from the Canadian Dairy Network and was expressed as FERTSOL, which represents the 56-day non-return rate, adjusted for multiple parameters including season of insemination, inseminator, and number of inseminations. Using our

Table 81.1 CASA/flow cytometry cutoff values (%) used to determine pass/fail rates during QC of frozen–thawed semen immediately after thawing and after two hours' thermoresistant stress. Semen lots meeting or exceeding these cutoff values passed the evaluation.

Parameter	Post thaw	After 2 hours' stress
Total motility	40	35
Progressive motility	15	10
Intact acrosome	66	61
Membrane intact cells	40	40
Mitochondrial activity	40	45

Table 81.2 Of 660 total (first number), number (%, second number in parentheses) of samples rejected for at least one QC parameter based on CASA alone, flow cytometry alone, or CASA plus flow cytometry.

Parameter	Post-thaw (0 hours)	After 2 hours' stress	0 hours + 2 hours[a]
CASA alone			
Total motility	76 (12)	157 (24)	163 (25)
Progressive motility	70 (11)	137 (21)	151 (23)
Total CASA	94 (14)	178 (27)	188 (28)
Flow cytometry alone			
Intact acrosome	104 (16)	97 (15)	117 (18)
Membrane intact cells	132 (20)	144 (22)	159 (24)
Mitochondrial activity	133 (20)	208 (32)	212 (32)
Total flow cytometry	156 (24)	214 (32)	224 (34)
Total CASA+ flow cytometry	176 (27)	260 (39)	268 (41)

[a] Unique lots rejected at 0 hours + unique lots rejected at 2 hours.

multiparametric approach, 9.4% (18 of 192) of the semen lots would have been discarded before distribution. These lots corresponded to 5.3% of the low-fertility semen (<−1 FERTSOL), 3.6% of average fertility semen (between −1 and +1 FERTSOL), and 0.5% of high-fertility semen (>+1 FERTSOL). Again, this multiparametric approach would have increased the overall fertility of semen released in the field.

Specific Applications of the Multiparametric Approach in Semen Evaluation

The multifactorial aspect of fertility can result in misevaluation of semen quality when assessing only a few parameters. Even semen that passes rigorous QC steps may have

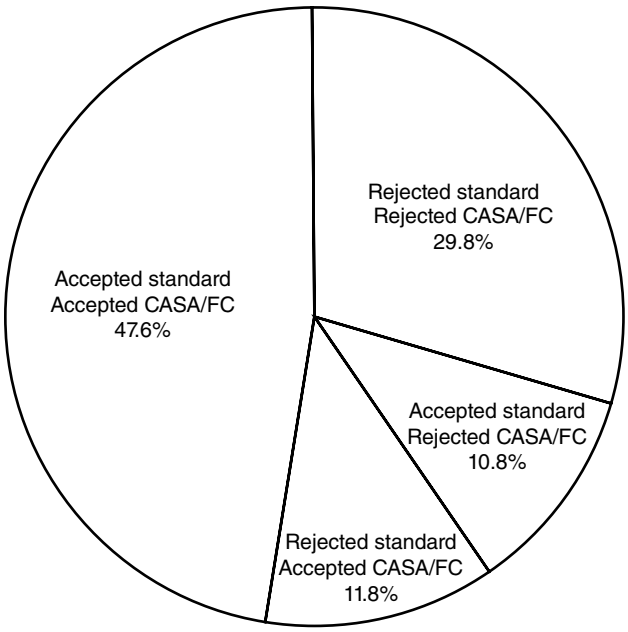

Figure 81.3 Comparative analysis of pass/fail percentage between standard QC and CASA/flow cytometry during QC of 660 frozen–thawed semen lots.

low fertility once distributed in the field. Such lots would have passed all our CASA/flow cytometry cutoff values but still resulted in few calves despite the high number of inseminations. A more detailed analysis of this semen is then required to understand its low fertility. However, deeper analyses of semen samples are time-consuming and expensive, so they are performed only on high-value semen. Here, we report two cases where flow cytometry helped us to target a putative cause of low fertility-associated semen.

The first case involved a young bull (bull A), one of whose semen lots produced very few embryos after *in vitro;* fertilization compared with the average embryo production. This lot of semen was compared (in triplicate) with one from an average bull (bull C) used as an internal control for most of our experiments. Motility and viability parameters estimated with CASA/flow cytometry showed average quality spermatozoa from both bulls (average of 36% total motility and 15% progressive motility). Evaluation of the level of intracellular calcium and the integrity of the acrosome membrane was carried out immediately after thawing and after five hours of post-thaw incubation with heparin at 38.5 °C. At both time points, an aliquot of spermatozoa was incubated with Indo-1 acetoxymethyl and FITC-peanut agglutinin, and then challenged with thapsigargin to induce the intracellular cascade involved in the capacitation process. The percentages of live spermatozoa with high intracellular levels of calcium and reacted

acrosomes were determined by flow cytometry. Analysis immediately after thawing before the heparin incubation and thapsigargin challenge showed a similar percentage of acrosome-reacted cells and cells with high intracellular calcium between bull A and bull C. Following thapsigargin stimulation, a similar percentage of spermatozoa from each bull acrosome reacted, but semen from bull A showed an increase in cells with high calcium compared with bull C (23.3 ± 6.3% vs 13.3 ± 2.5%, respectively; $P = 0.14$) (Table 81.3). After five hours of incubation with heparin at 38.5 °C and without thapsigargin challenge, spermatozoa from bull A had fewer (10.5 ± 2.3% vs 24.1 ± 0.9%; $P < 0.01$) acrosome-reacted cells compared with bull C, but a similar percentage of cells possessing elevated calcium (5.3 ± 0.5% vs 5.7 ± 0.1%, respectively; $P = 0.4$) (Table 81.3). After the thapsigargin challenge, bull A still had fewer acrosome-reacted cells compared with bull C (10.5 ± 2.0% vs 23.1 ± 0.5%; $P < 0.01$), but also had a proportionally smaller increase in the percentage of cells having high calcium. These observations suggest that bull A spermatozoa could not capacitate in heparin-containing medium, demonstrated by fewer acrosome-reacted cells and high intracellular calcium sperm. Altogether, this analysis suggests that this specific lot of semen from bull A was not mature enough to reach its full capacitation process and fertility potential. Saacke et al. [61] described some compensable and uncompensable seminal deficiencies related to subfertility. Compensable factors include functional or molecular traits reflected in this case study by the low percentage of cells having reacted acrosomes or elevated calcium. This case could benefit from increasing the number of spermatozoa per straw of bull A to compensate its subfertility.

The second case studied was an adult bull (bull B) that exhibited extremely low fertility in the field (FERTSOL <−2) based on several different semen lots released from an SPC after standard QC tests. We firstly performed the basic CASA/flow cytometry tests on five different batches and compared the results with an average bull (bull C). All the lots studied would have passed our QC cutoffs. Surprisingly, total and progressive motility percentages were not significantly different in bull B compared with bull C (Table 81.4). On the other hand, acrosomal reaction, cell death, and mitochondrial activity were significantly different in some lots analyzed compared with bull C (Table 81.4). As these results could not explain the very low fertility of bull B, we conducted a sperm chromatin structure assay analysis

Table 81.3 Comparison of acrosome integrity and calcium level of live spermatozoa from bulls A and C before and after a thapsigargin challenge, both post-thaw and after five hours' incubation with heparin.

	Immediately post-thaw				After 5 hours incubation with heparin			
	−Thaps		+Thaps		−Thaps		+Thaps	
Bull	AR	High Ca	AR	High Ca	AR	High Ca	AR	High Ca
A	1.8 ± 0.7	3.1 ± 1.2	16.3 ± 3.8	23.3 ± 6.3	10.5 ± 2.3[a]	5.3 ± 0.5	10.5 ± 2.0[a]	25.3 ± 2.3

Values are mean percentages from three replications ± SEM. Different letters (a, b) on the same column represent significant differences, $P < 0.01$, Student's paired *t*-test.
AR, Acrosome reacted; High Ca, elevated calcium level; Thaps, thapsigargin.

Table 81.4 Comparison of sperm functions based on CASA and flow cytometry analysis of bull B and C immediately after thawing.

Bull	Batch	Total motility (%)	Progressive motility (%)	Acrosome reacted (%)	Dead (%)	Mitochondrial activity (%)	DNA fragmentation index (%)
B	1	57.5 ± 4.5	32.5 ± 2.5	19.1 ± 0.2	43.5 ± 0.1*	55.3 ± 0.2*	7.05 ± 0.09**
B	2	44.5 ± 3.5	24.5 ± 3.5	19.0 ± 0.2	51.7 ± 1.2**	46.7 ± 1.1**	5.76 ± 0.12**
B	3	63.5 ± 1.5	34.5 ± 2.5	17.9 ± 0.1	39.8 ± 0.7	60.0 ± 0.6	4.24 ± 0.01**
B	4	56.0 ± 0.0	32.5 ± 0.5	16.1 ± 0.5	38.7 ± 1.3	60.3 ± 2.1	4.83 ± 0.11**
B	5	61.0 ± 5.0	34.5 ± 1.5	14.0 ± 0.3*	35.0 ± 0.3	64.6 ± 0.4	3.85 ± 0.03**
C	1	60.5 ± 0.5	29.5 ± 0.5	17.6 ± 1.0	38.6 ± 0.9	62.7 ± 0.2	1.61 ± 0.16

Values are mean percentages from two replications ± SEM. Significant differences from control are represented by *, $P < 0.05$ and **, $P < 0.001$, Dunnett's multiple comparison test.

(as discussed in the section "DNA Integrity") on the same batches and compared results with those obtained by bull C. The DNA fragmentation index percentage was approximately two to four times higher in bull B than in bull C ($P < 0.001$; Table 81.4). High DNA fragmentation index percentage has been correlated with subfertility, mostly in humans [53, 62]. Therefore the very low fertility observed for bull B could be explained by his high level of DNA denaturation as measured by the sperm chromatin structure assay. In opposition to the first case study, chromatin aberration is a non-compensable deficiency in subfertility [61]. Increasing the number of spermatozoa per straw in this case cannot compensate for the extremely low fertility of bull B observed in the field.

Summary

Multiparametric analyses of the semen produced by SPCs with CASA and flow cytometry demonstrate very high predictive potential for semen quality and fertility. As fertility has multiparametric aspects, research and development of new markers to identify high-fertility semen needs to be extensive. Incorporation of new markers in a multiparametric approach will lead to a better evaluation of semen quality and fertility. In addition, the implementation of these tools in SPCs will help to standardize the QC procedures by eliminating the subjective aspect of semen evaluation. This will standardize semen produced within a SPC and within multiple SPCs for AI companies that have semen produced in multiple laboratories. Another application of these tools in the AI industry is the characterization of semen with high genetic value. In the AI industry, most of the semen produced arises from a few high genetic value animals. These highly demanded semen samples should be very well characterized to optimize production in the number of straws produced and in the quality of the semen available for the market. Overall, the AI industry will benefit from the implementation of CASA and flow cytometry in SPCs.

The authors gratefully acknowledge Drs. Reuben Mapletoft and Gabriel Bó, authors of this chapter which appeared in the first edition of this book, for their substantial contributions to this manuscript. We also thank Drs. Mapletoft and Bó for their numerous contributions to the bovine embryo transfer industry.

Introduction

The objective of superovulation in cattle is to maximize the number of transferable quality embryos (TQEs) possessing a high probability of producing pregnancies [1]. Wide ranges in superovulatory responses and embryo yield have been reported in reviews of commercial embryo transfer records. In 2048 beef donor embryo collections, a mean of 11.5 ova/embryos with 6.2 TQEs was recorded [2]. Variability in both the superovulatory response and embryo quality was substantial; 24% of collections did not yield viable embryos, 64% produced fewer than average numbers of TQEs, and 30% of donors yielded 70% of the embryos. Embryo recovery from 987 dairy cows yielded slightly fewer ova/embryos, but there was similar variability in response [3]. The high degree of unpredictability in superovulatory response creates problems that affect both the efficiency and profitability of embryo transfer programs [4].

Variability in ovarian response to superovulation has been related to differences in superstimulatory treatments (e.g. gonadotropin preparation), batch and total dose of gonadotropins, duration and timing of superovulatory treatments, and the concomitant use of non-superovulatory reproductive hormones. Additional factors influencing superovulatory response, which may be more important, are inherent to the animal and its environment. These factors may include season of the year as well as donor nutritional status, reproductive history, age, breed, prior superstimulation, and ovarian status at the time of treatment initiation. While considerable progress has been made in the understanding of bovine reproductive physiology in recent years, factors inherent to the donor animal that influence superovulatory response are not yet well understood.

Gonadotropins and Superovulation

Factors affecting superovulatory response include source, batch, and biological activity of the exogenous gonadotrophins [5]. Three different types of gonadotropin preparations have been used to induce superovulation in the cow: gonadotropins from extracts of porcine or other domestic animal pituitaries, equine chorionic gonadotropin (eCG; formerly called pregnant mare serum gonadotropin [PMSG]), and human menopausal gonadotropin [5, 6]. Human menopausal gonadotropin did not offer any advantages in cattle [7] and has not been used commercially; therefore, it will not be discussed further.

Pituitary extracts contain follicle stimulating hormone (FSH). The biological half-life of FSH in the cow is estimated to be five hours or less [8], so it must be injected twice-daily to successfully induce superovulation [9, 10]. The usual treatment regimen is twice-daily intramuscular treatments with FSH for four or five days, with a total dose of 28–50 mg (Armour) of a crude pituitary extract, or 260–400 mg NIH-FSH-PI of a partially purified pituitary extract (Folltropin®-V, Vetoquinol SA, Lure, France). At 48–72 hours after initiation of treatment, prostaglandin $F_2\alpha$ (PGF2α) is administered to induce luteolysis. Estrus occurs in 36–48 hours, with ovulations beginning 24–36 hours later [11, 12].

Equine chorionic gonadotropin is a complex glycoprotein with both FSH and luteinizing hormone (LH) activity [13]. Its half-life in the cow is 40 hours, and it persists for up to 10 days in the bovine circulation; thus, it is normally injected intramuscularly once followed by a $PGF_2\alpha$ injection 48 hours later [14]. The long half-life of eCG causes prolonged ovarian stimulation, an increase in the number of unovulated follicles, abnormal endocrine profiles, and reduced embryo quality [15–18]. These problems have been largely overcome by the intravenous injection of antibodies to eCG at the time of the first insemination, 12–18 hours after the onset of estrus [14, 19]. Recommended doses of eCG range from 1500 to 3000 IU, with 2500 IU by intramuscular injection commonly chosen.

In one study, groups of cows were treated with either 2500 IU eCG or 50 mg (Armour) pituitary FSH [10]. Ovulation rate and the percentage of cows with more than three TQEs was slightly higher in cows treated with FSH than with eCG. Although these results were in agreement with one previous study [20], others have found no differences in superovulatory response between pituitary extracts containing FSH and eCG [21, 22]. Endocrine studies revealed that eCG-treated animals more frequently had abnormal profiles of LH and progesterone [15, 23], which were associated with reductions in both ovulation and fertilization rates [24], as compared with FSH-treated cows.

Although folliculogenesis in mammals requires both FSH and LH, there is considerable variability in FSH and LH content of crude gonadotropin preparations [5]. Radioreceptor assays and *in vitro* bioassays have revealed variability in both the FSH and LH activity of eCG, not only among pregnant mares but also within the same mare at different times during gestation [13]. The effects of the FSH/LH ratio of eCG on superovulatory responses have been examined, and there was a positive correlation between the ratio of FSH/LH activity and superovulatory response. Lower ratios of FSH/LH activity reduced ovulatory response in immature rats, and LH added to eCG reduced superovulatory response in cows [5, 13].

Purified pituitary extracts with low LH contamination seem to improve superovulatory response in cattle. Three groups of dairy cows were superstimulated with an equivalent amount of 450 μg pure porcine (p) FSH and varying amounts of LH and showed that the mean ovulation rate and the number of total and transferable embryos increased as the dose of LH decreased [25]. High levels of LH during superstimulation can cause premature activation of the oocyte [16] which often leads to a decreased fertilization rate. Several experiments with an LH-reduced pituitary extract [26] utilizing doses ranging from 100 to 900 mg of NIH-FSH-P1 revealed no evidence of detrimental effects of dose on embryo quality [6, 27]. On the other hand, doubling the dose of crude pituitary extracts containing both FSH and LH resulted in significantly reduced fertilization rates and percentages of TQEs [6]. Collectively, data support the hypothesis that the detrimental effect of high doses of pituitary gonadotropins on ova/embryo quality is due to an excess of LH.

Although it is generally believed that some LH is required for successful superovulation, endogenous LH levels may be adequate. One study [28] with recombinantly produced bovine bFSH induced high superovulatory responses without the addition of exogenous LH. These data suggest that LH is not needed in superstimulatory preparations and that embryo quality may be superior with pure FSH. The very high fertilization and TQE production rates in the absence of exogenous LH suggest that administration of LH in superstimulation protocols, at any dose, may be detrimental to embryo quality. Further, these results and more recent results with recombinant bFSH [29] indicate that future progress in bovine superovulation can be enhanced by the use of recombinantly derived gonadotropins.

The effect of LH on superovulatory response has also been demonstrated in an experiment involving Brahman (*Bos indicus*) crossbred heifers superstimulated with 400 mg NIH-FSH-P1 containing 100, 16, or 2% LH [30]. Although the more purified preparations in this experiment caused higher superovulatory responses, there were obvious seasonal effects; responses with the most purified and intermediate preparations were superior to the least purified preparation during summer months, but only the most purified preparation was highly efficacious during winter months. These results appear to contradict one report [31] that superovulatory response and embryo quality in Holstein heifers were not affected by LH levels in cool weather, but that during heat stress a more purified preparation yielded more corpora lutea and significantly more fertilized ova and TQEs. It becomes apparent that stress is the common factor; *Bos taurus* breeds likely find summer heat stressful, whereas *B. indicus* breeds likely find winter temperatures stressful. In either case, the more purified extracts resulted in greater superovulatory responses during conditions of environmental stress.

Follicular Wave Dynamics and Superstimulation

Superstimulatory response typically is greater if exogenous gonadotrophin treatment is initiated before selection of a dominant follicle. Recombinant bFSH given to heifers on day 1 of the cycle (ovulation = day 0), before the time of

selection of the dominant follicular of wave 1, resulted in more ovulations than when given on day 5 (after the time of dominant follicle selection) [32]. A subsequent study was conducted to determine if exogenous FSH given at the expected time of the endogenous wave-eliciting FSH surge had a positive effect on the superstimulatory response [33]. As the endogenous surge of FSH was expected to peak one day before wave emergence [34], superstimulatory treatments were initiated on the day before, the day of, or one or two days after follicular wave emergence. More follicles were recruited when treatments were initiated on the day of or on the day before follicular wave emergence, and more ovulations were detected when treatment was initiated on the day of wave emergence rather than the day before or one or two days after wave emergence. A subsequent study indicated that superovulation was induced with equal efficacy when treatments were initiated during the first or second follicular waves and that the superstimulatory response was optimized when treatment was initiated at the time of follicle wave emergence [35].

Superstimulation: The Traditional Approach

In the very early days of bovine embryo transfer, treatment with eCG was made to coincide with natural regression of the corpus luteum (i.e. approximately day 16 of the cycle) [12]. With the introduction of an exogenous $PGF_{2\alpha}$ commercial product in the 1970s, it became possible to initiate gonadotropin treatments at other times during the estrous cycle; most practitioners began treating donors with FSH during mid-cycle (i.e. 8–12 days after estrus) [36, 37]. Although this approach was initially based on anecdotal evidence, and then some experimental data [38], it is now known that this encompasses the time of emergence of the second follicular wave in cattle exhibiting two or three ovarian follicular waves per estrous cycle [39, 40].

Many practitioners prefer to use a descending FSH dose superovulation protocol (which mimics the naturally occurring decline in circulating FSH levels caused by inhibin near the time of ovulation) and treat donors with $PGF_{2\alpha}$ on the third day of the FSH treatment protocol. Others prefer to treat with $PGF_{2\alpha}$ on the fourth day of FSH, and many do not treat with FSH on the day after the administration of $PGF_{2\alpha}$. Although no differences have been found between four- and five-day FSH treatment protocols, recent experiments have shown that ovulation rate can be improved in some donors if FSH treatments are prolonged to six or seven days [41, 42]. Regardless, most superstimulation protocols have been successful in inducing superovulation under most circumstances [12]. Still others incorporate progestin into the protocol which ensures that donors do not come into estrus early, especially if it is not possible to confirm the presence of a corpus luteum before initiating FSH treatments. In all cases, inseminations are normally performed 12 and 24 hours after the onset of estrus [11, 37].

Although the initiation of superstimulatory treatments during mid-cycle has served the embryo transfer industry quite well over the years, conventional treatment protocols have two drawbacks: (i) the need for trained personnel dedicated to the detection of estrus, both before and after initiating treatments; and (ii) the necessity to have all donors in estrus at the same time in order to begin the superstimulatory treatments at the most appropriate time in groups of cows (i.e. mid-cycle). To obviate these problems, protocols that facilitate superstimulation subsequent to elective induction of follicular wave emergence have been developed.

Synchronization of Follicular Wave Emergence for Superovulation

Estradiol and Progesterone

The ability to electively induce follicular wave emergence permits initiation of superstimulation without regard to the stage of the estrous cycle and eliminates the need for estrus detection or waiting 8–12 days after observation of estrus in a prospective donor to initiate gonadotropin treatments [37]. In the 1990s the use of progestins and estradiol to induce synchronous emergence of a new follicular wave was reported [36], and its use in superstimulation protocols has been reviewed extensively [37, 43]. The estradiol treatment causes suppression of FSH release and follicle atresia. Once the estradiol has been metabolized, FSH surges and a new follicular wave emerges an average of four days after treatment [36, 44].

The most common protocol involves administration of 5 mg estradiol-17β or 2.5 mg estradiol benzoate, plus 100 or 50 mg progesterone by intramuscular injections at the time of insertion of an intravaginal progestin device (day 0) [37, 43]. Twice-daily intramuscular FSH treatments are then initiated on day 4. On day 6, $PGF_{2\alpha}$ is injected in the morning and evening, and the progestin device is removed in the evening. Estrus normally occurs on day 8 (approximately 48 hours after the first $PGF_{2\alpha}$ injection) and inseminations are performed 12 and 24 hours later.

Unfortunately, estradiol cannot be used in many countries around the world because of concerns about the effects of estrogenic substances in the human food supply [45]. This restriction leaves many embryo transfer

practitioners with a serious dilemma and created the need to develop treatments for initiation of a new follicular wave that do not involve the use of estradiol.

Follicle Ablation

An alternative to the use of estradiol in superstimulation protocols is to eliminate the suppressive effect of the dominant follicle by ultrasound-guided follicle aspiration of all follicles of 5 mm or greater diameter [46]. Follicle wave emergence occurs very consistently 24–36 hours later, and superstimulatory treatments are initiated at that time. This approach to the synchronization of follicle wave emergence for superstimulation is very efficacious and results in superovulatory responses that do not differ from the use of estradiol [46]. In addition, it is necessary to ablate only the two largest follicles to effectively synchronize follicle wave emergence [47]. The protocol involves the ablation of the two largest follicles at random stages of the estrous cycle and the insertion of a progestin device; FSH treatments are initiated 24–48 hours later and the remainder of the protocol is as described above. The disadvantage of ultrasound-guided follicle aspiration is that it requires ultrasound equipment and trained personnel, making it most practical when donors are held in an embryo production facility; it is difficult to routinely implement follicle ablation in the field.

Gonadotropin-Releasing Hormone

Another alternative to the use of estradiol for the synchronization of follicle wave emergence is to induce ovulation of the dominant follicle by treatment with gonadotropin-releasing hormone (GnRH) [48, 49], which is followed by wave emergence one to two days later [50]. However, emergence of the new follicular wave is synchronized only when treatment causes ovulation. When administered at random stages of the estrous cycle, GnRH results in fewer than 60% of animals ovulating [50, 51]. Not surprisingly, treatment with GnRH prior to initiating superstimulatory treatments at random stages of the estrous cycle resulted in lower superovulatory responses than treatments initiated after follicular ablation or estradiol treatment [52].

More recently, retrospective analysis of commercial embryo transfer data revealed no differences in the numbers of TQEs between donors superstimulated four days after treatment with estradiol and those superstimulated two days after treatment with GnRH (Randall Hinshaw, personal communication) [53, 54]. It is noteworthy that in each of these reports GnRH was administered two days after insertion of a progestin device. The improved responses may have been a consequence of progestin-induced development of a persistent dominant follicle that was more responsive to treatment with GnRH [55]. Obviously, controlled studies with the use of GnRH must be conducted to validate these promising results.

Improving the Ovulatory Response to GnRH

Most fixed-time artificial insemination (AI) protocols utilizing GnRH to synchronize follicle wave emergence employ a form of presynchronization to improve the ovulatory response to the first injection of GnRH [55, 56]. An alternative to that approach is to synchronize ovulation and then initiate FSH treatments at the time of emergence of the first follicular wave [33]. To avoid the need to detect estrus and ovulation in Nelore (*B. indicus*) donors, synchronous ovulation was induced with an estradiol-based protocol designed for fixed-time AI [57]. Gonadotropin treatments were then initiated at the expected time of ovulation (and emergence of the first follicular wave). Superovulatory response did not differ from a contemporary group superstimulated four days after treatment with estradiol. However, the number of TQEs was reduced in cows superstimulated during the first follicular wave unless accompanied by the use of a progestin device. A study with Holstein cows superstimulated during the first follicular wave also produced a greater number of viable embryos following the addition of a progestin device [58].

A series of experiments with the overall objective of developing a protocol for superstimulation following ovulation induced synchronously by the administration of GnRH was reported [59]. This approach was based on a previous study in which ovulatory response was increased by causing a persistent ovarian follicle to develop with the insertion of a progestin device 7–10 days before the administration of GnRH [55]. Ovulation and follicle wave emergence occurred one to two days after the administration of GnRH, indicating that this approach could be used in groups of randomly cycling donors.

The recommended superstimulation protocol is schematically presented in Figure 82.1. It consists of the administration of $PGF_{2\alpha}$ at the time of insertion of a progestin device. Seven days later (with the progestin device still in place) GnRH is administered to induce ovulation of the persistent ovarian follicle and subsequent follicle wave emergence; FSH treatments are initiated 36 hours after the administration of GnRH. Although this protocol was designed for four days of FSH treatments, a five-day superstimulation protocol can be accomplished by simply delaying the removal of the progestin device by one day. In this series of experiments, more than 95% of animals ovulated to the first GnRH administration,

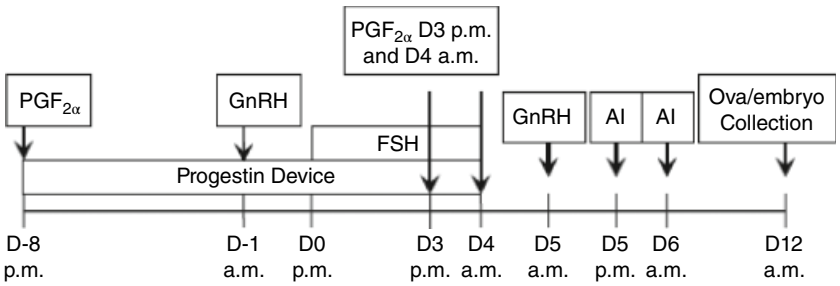

Figure 82.1 Treatment schedule for superovulation of donor cows during the first follicular wave after GnRH-induced ovulation. Donors receive a progestin device along with $PGF_{2\alpha}$ followed by GnRH seven days later. On day (D) 0 (36 hours after GnRH), superstimulation with FSH is initiated (twice-daily decreasing doses over four days). $PGF_{2\alpha}$ is administered with the last two FSH injections and the progestin device is removed with the last FSH injection. Ovulation is induced with GnRH 24 hours after progestin removal, donors are fixed-time inseminated (AI) 12 and 24 hours later, and ova/embryos are collected 7 days later. *Source:* From [59].

and superovulatory response and ova/ embryo numbers and quality were similar to that obtained when estradiol was used to synchronize follicular wave emergence [59].

Fixed-Time AI of Donors

A superstimulatory protocol specifically for *B. indicus* cattle (known as the P-36 protocol) has been developed [60]. In this protocol a progestin device inserted prior to the initiation of superstimulatory treatments is left in place for 36 hours after $PGF_{2\alpha}$ administration, and ovulation is induced by the administration of porcine LH (pLH) 12 hours after withdrawal of the progestin device (i.e. 48 hours after $PGF_{2\alpha}$ administration). Because ovulation occurs between 24 and 36 hours after pLH administration [61], fixed-time AI is scheduled 12 and 24 hours later, eliminating the need for detection of estrus.

In a series of experiments in which the timings of ovulations were monitored ultrasonically, a protocol for fixed-time AI in *B. taurus* donors without the need for estrus detection and without compromising results was developed [11]. Basically, the time of progestin device removal was delayed to prevent early ovulations and allow late-developing follicles to "catch up," followed by induction of ovulation with GnRH or pLH. In this protocol follicular wave emergence was synchronized with estradiol and a progestin device on day 0 and FSH treatments were initiated on day 4. On day 6, $PGF_{2\alpha}$ was administered in the morning and evening and the progestin device was removed on the morning of day 7 (24 hours after the first administration of $PGF_{2\alpha}$). On the morning of day 8 (24 hours after the removal of the progestin device), GnRH or pLH was administered and fixed-time AI was performed 12 and 24 hours later. Delaying the removal of the progestin device until the morning of day 7 resulted in a higher number of ova/embryos and fertilized ova than removal on the morning of day 6 [62]. From a practical perspective, fixed-time AI of donors eliminates the need for detection of estrus [63].

Studies in high-producing Holstein cows (*B. taurus*) in Brazil indicated that it is preferable to allow an additional 12 hours before removing the progestin device (i.e. evening day 7; P36), followed by GnRH or pLH 24 hours later (i.e. evening day 8) [64]. In *B. indicus* breeds, it was preferable to remove the progestin device on the evening of day 7 (P36), followed by GnRH 12 hours later (i.e. morning day 8) [65]. Although donors are typically inseminated twice, 12 and 24 hours after administration of pLH or GnRH [11], it is possible to use a single insemination with high-quality semen 16 hours after pLH [65].

Reducing the Need for Multiple Treatments with FSH

Because the half-life of pituitary FSH is short in the cow [8], traditional superstimulatory treatment protocols consist of twice-daily intramuscular injections over four or five days [9]. This approach requires frequent attention by farm personnel and increases the possibility of failures due to non-compliance with treatment protocol. In addition, twice-daily treatments may cause undue stress in donors, resulting in a decreased superovulatory response and/or altered preovulatory LH surge [66, 67]. Simplified protocols may reduce donor handling and improve response, particularly in less tractable animals.

A single subcutaneous dose of exogenous FSH can induce a superovulatory response equivalent to the traditional twice-daily treatment protocols in beef cows in high

Table 82.1 Mean (±SEM) ova/embryo production in beef donors treated with Folltropin-V given by twice-daily intramuscular injections over four days (control) or diluted in 2% hyaluronan and given by a single intramuscular injection.

Treatment	*N*	Total ova/embryos	Fertilized ova	Transferable embryos	Cows with "0" transferable embryos (%)
Control (twice daily)	146	12.1 ± 0.6	8.8 ± 0.5	6.7 ± 0.4	12(8.2%)
Single injection	146	11.2 ± 0.8	8.3 ± 0.6	6.4 ± 0.5	19(13.0%)

Source: From [59].
Means and percentages did not differ ($P > 0.10$) [59].

body condition (i.e. body condition score >3 on a scale of 5) [68], but not in Holstein cows which had less adipose tissue (lower body condition score). However, superovulatory responses were improved in Holstein cows when the total dose of exogenous FSH was split into two; 75% of the FSH dose was administered subcutaneously on the first day of treatment and the remaining 25% was administered 48 hours later (when $PGF_{2\alpha}$ is normally administered during superovulation) [69].

An alternative for inducing a consistent superovulatory response with a single injection of FSH is to combine the pituitary extract with agents that cause the hormone to be released slowly over several days. These agents can be polymers that are biodegradable and non-reactive in the tissues, facilitating use in animals [70]. In a series of experiments in which FSH diluted in a 2% hyaluronan solution was administered as a single intramuscular injection (to avoid the effects of body condition), a similar number of ova/embryos was produced as compared with the traditional twice-daily FSH protocol [71] (Table 82.1). However, 2% hyaluronan is viscous and difficult to mix with FSH, especially in the field. Although more dilute preparations of hyaluronan were less efficacious as a single administration than the 2% concentration, their use was improved by splitting them into two injections 48 hours apart, as was described previously with subcutaneous injections of FSH.

The split intramuscular treatment protocol consists of diluting the FSH lyophilized powder with 10 ml of a 1 or 0.5% hyaluronan solution and the administration of two-thirds of the total dosage of FSH on the first day, followed by administration of the remaining one-third 48 hours later, when $PGF_{2\alpha}$ is normally administered [72]. When compared with the twice-daily treatment protocol (controls) in 29 beef cows superstimulated three times in a cross-over design, the number of TQEs with the split-injection protocol (1.0% hyaluronan: 5.0 ± 0.9; 0.5% hyaluronan: 6.1 ± 1.3) did not differ from controls (4.0 ± 0.8). Data were interpreted to suggest that splitting the FSH dose (in either concentration of hyaluronan) into two intramuscular injections 48 hours apart results in a superovulatory response comparable to the traditional twice-daily intramuscular injection protocol in beef cattle. Furthermore, the less concentrated solutions of hyaluronan were not difficult to mix with FSH, even under field conditions. Data from a commercial embryo transfer company have confirmed these results in beef cattle in the USA [73].

Summary

Although the development of protocols that control follicular wave emergence and ovulation has not eliminated the variability in superovulatory response, these treatments have had a positive impact on the application of commercial on-farm embryo transfer by permitting the initiation of superovulatory treatments at a self-appointed time. These protocols offer the convenience of initiating superstimulatory treatments quickly without the necessity of estrus detection. In addition these protocols have facilitated fixed-time AI of donors, thereby avoiding the necessity of estrus detection during the superstimulatory protocol. However, estradiol, which has proven to be most useful in the field, has been withdrawn from many veterinary markets around the world, leaving only follicle ablation (which is difficult to utilize routinely in the field) as a reliable method to synchronize follicular wave emergence for superstimulation. Although the synchrony of follicular wave emergence following the administration of GnRH or pLH at random stages of the estrous cycle has been too variable for superstimulation, several recent reports suggest that this approach should be revisited. An alternative may be to initiate FSH treatments at the time of emergence of the first follicular wave following GnRH-induced ovulation of a progestin-induced persistent follicle. Finally, a single or split-single intramuscular injection of FSH in hyaluronan can be used to induce a satisfactory superovulatory response in beef donors, simplifying the entire protocol and reducing animal handling and the stress associated with the administration of superstimulatory treatments.

Embryo Transfer and Embryo Collection

Nicole Noga and Charles Looney

Animal Science Department, Division of Agriculture, University of Arkansas, Fayetteville, AR, USA

A Brief History of Embryo Transfer

Embryo transfer began with rudimentary experimentation dating back centuries. In 1672, a young Dutch physician and anatomist named Regnier de Graaf observed the blastocyst of a rabbit without the aid of a microscope. Though he died only a few years later at the age of thirty-two, his contributions built the foundation for the future of embryo transfer [1]. Embryos from other domestic animals were observed nearly a century later, but it was the experiments performed by Walter Heape at the end of the nineteenth century that significantly influenced the field of reproductive biology and made development of embryo transfer technologies possible [2].

In April of 1890, the first live embryo transfer rabbits were born in his private lab at his home in Prestwich, Manchester. This novel achievement prompted other animal scientists to continue embryo transfer experiments in rabbits through the late 1920s and early 1930s, which, in turn, inspired the study of cultured embryos and their respective outcomes. It was during this time that using embryo transfer for advancements in agriculture gained the attention of the scientific community.

The first documented use of embryo transfer in farm species occurred at the Agricultural and Mechanical College of Texas in 1934, by Drs Warwick, Berry, and Horlacher using sheep, goats, and hybrids from the two species [2, 3]. Artificial insemination (AI), developed in the 1930s, was proving useful in improving genetic selection and would later become vital to embryo transfer. The success of AI led to interest in applying embryo transfer procedures to cattle embryos for the benefit of the animal agriculture industry. Support for more research grew throughout the 1940s, but World War II significantly slowed scientific progress.

Later in December 1950, the research efforts of Elwyn Willett, the Bureau of Dairy Industry of the United States Department of Agriculture, and the Department of Genetics at the University of Wisconsin produced the first embryo transfer calf [3]. The success came at a cost, however; Willett noted that it was not possible at the time to apply the practice of embryo transfer on a wide scale.

It was not until the 1970s that non-surgical embryo transfer became sufficiently developed to be used in practice and became possible to perform on the farm. In 1971, Dr. James Dula and Dr. Duane Kraemer produced the first commercial calf for Livestock Breeders International (LBI), a company they had established. The first calf to be born from a frozen embryo followed in 1973 [3–5]. Later, maturation of oocytes and *in vitro:* fertilization (IVF) were areas of progress, but much of the work done with livestock was outshined by the novel developments in human IVF and the birth of the first "test-tube" baby.

The growth in the decade to follow was due largely to advancements in embryo micromanipulation, embryo splitting, IVF, and molecular biology, all of which revolutionized the techniques performed in the industry. Commercial use of IVF grew in popularity and literature on the subject increased exponentially throughout the 1980s [6].

From the 1990s to the present, embryo transfer technology and research has continued to grow. Embryo transfer is an effective management tool, and those that delve into the field find a thrilling new frontier of research and innovation.

Applications for Embryo Transfer

Disease control and lower costs for animal imports and exports are significant advantages of utilizing this technology [7]. The principal advantage of embryo transfer,

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

however, is increased reproductive capacity of a genetically superior heifer or cow. The most conventional function of embryo transfer is to produce large numbers of offspring from valuable donors. Donor cows may be valued because they have excellent production records, an outstanding show ring record, are related to superior cows or bulls, have a popular trait such as the polled trait, or are in limited numbers. With shorter generation intervals, embryo transfer also provides the opportunity to test individual cows for possible genetic defects. This could prove tremendously useful in evaluating dams of AI bulls for undesirable recessive genes.

In addition, these techniques have a variety of applications in research. The fertilizing capacity of sperm cells is currently being studied using IVF techniques associated with embryo transfer [6]. With the growth of the genetic engineering field, there is expected to be an increase in its usage.

Overview of the Embryo Collection Procedure

Timing

Since embryos are most versatile at day 6–7, most practitioners plan collections 6.5–7 days after first observation of the donor's standing heat. When several donors are to be collected on the same day, there will usually be at least 12–24 hours variation in the onset of standing heat among them. Since embryos may hatch by day 7.5–8.0 and become less useable, it is usually wise to collect the donors first that exhibit standing heat the earliest. Also realize that collection on or before day 6 may result in embryos being too immature to endure the freezing process very well.

Collection Media

Many commercially prepared collection media are available today. Some use a ready-to-go medium from Vetoquinol called Vigro Complete Flush™, which contains a surfactant (polyvinyl alcohol) and antibiotics (gentamicin and kanamycin). Other practitioners use lactated Ringers which they have available in their veterinary clinics and simply add 0.1% bovine serum albumin as a surfactant. For short-term holding, this appears to work well and is much more economic.

If embryos are collected for export, some countries will not allow animal byproducts such as bovine serum albumin to be added due to the scare over bovine spongiform encephalopathy [BSE]. In these collections, use of a complete medium that uses polyvinyl alcohol as the surfactant is acceptable.

Donor Preparation

Elevation shifts the viscera posteriorly and tends to lift the uterus upward for ease of accessing it for manipulation. Although it sounds like a good idea to reduce feed intake prior to the technician's arrival in order to lessen feces, one of an embryo transfer practitioner's best friends is a full rumen. The full rumen not only elevates the uterus upward and caudally, but also prevents negative abdominal pressure caused by an empty rumen. Negative abdominal pressure causes air to be sucked around your arm and into the rectum and colon during the flush, making manipulation of the uterus very difficult. Ramps and feed are two great friends.

Once the donor is in the chute or stanchion, a lidocaine (3–5 ml) epidural is administered using an 18-gauge × 3.75-cm needle. Generally, no preparation is needed for the epidural. Little is accomplished by clipping or washing the hair unless one is willing to surgically prepare the tailhead. Immediately after the epidural, palpate each ovary and record an estimate as to the number of corpora lutea that are on each. Unovulated follicles are identified as well as the size of ovaries if they are unusual. This information is helpful once the results are in, whether good or bad.

Tranquilization is another friend, in some opinions, an enemy in others. According to experienced practitioners, giving 10 mg xylazine subcutaneously (SC) or intramuscularly (IM) just before the epidural works quite well. Although it causes a slight increase in uterine tone, it is usually not considered to be a problem. It is possible to collect cows without xylazine, but experienced practitioners like it because it takes the edge off excitable cows; they will stand still throughout the collection process.

Avoid using disinfectants around the collection materials. Simply wipe the perineal region after the tail is tied off to the side. In the absence of water, wipe the perineal area clean with a disposable towel. Once prepared, the cow is ready for collection.

Embryo Flushing Equipment (and Supplier)

Note that the items on this list are suggested, and due to the unpredictable nature of company acquisitions, some or all suppliers may differ.

- Catheter: 52 cm silicone, 16 French with 5-ml cuff (Vetoquinol)
- Stylet: 60 cm stainless steel (Vetoquinol)
- Y tubing: 150 cm plastic tubing, one end with syringe tip and the other attaches to EZ Way filter (PETS Inc.)
- Disposable three-way plastic valve (PETS Inc.)
- 50- or 60-ml airtight syringe (PETS Inc.)
- EZ Way Embryo Filter (PETS Inc.)

- Obstetric (OB) Lube (local farm supply store)
- Sterile lube (PETS Inc.)
- Cervical dilator (IMV Technologies)
- Medium: Vigro Complete (Vetoquinol)
- 10-ml syringe to inflate cuff (local farm supply store)

Sterilization

Most equipment is sterilized by the manufacturer using gamma radiation. Ethylene oxide was found to be embryotoxic years ago and is no longer used. If catheters and tubing are not autoclavable, simple washing with Alconox™ laboratory detergent and several rinses with distilled water is sufficient. Many practitioners discard all equipment after single use. Some practitioners reuse as much as feasible, depending on price.

Embryo Collection

The choice of catheter is affected by the type of flush (horn or body), age of the cow, and size of the cow. Today we have many choices available to add to the practitioner's ease and comfort during the collection. A 52-cm silicone 16 or 18 French catheter with a 5-ml balloon is a common choice for most flushes. The 5-ml balloon can inflate up to 20 ml if needed and it gives a rounder, more defined shape than the more elongated effect the 30-ml balloon may produce (Figure 83.1). However, a larger (20 or greater) catheter can be passed through the cervix, giving an opportunity for increased flow and decreasing the chance of a blockage due to mucus.

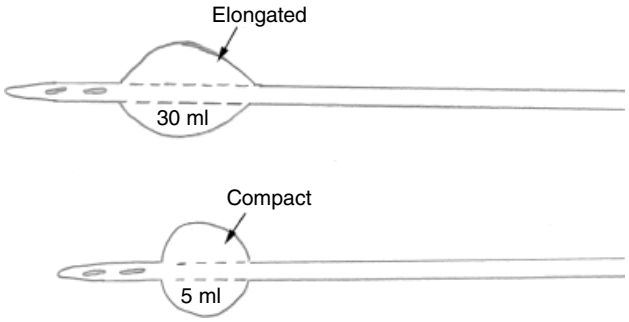

Figure 83.1 Shapes of Foley catheter balloon when inflated.

Catheter placement is the first critical step in non-surgical embryo collection. The placement of the catheter and collection procedures for both single horn and uterine body collection techniques will be discussed in further detail (Figure 83.2).

The following are important considerations. Is the donor a virgin heifer or cow? If virgin, how mature is her tract? Does the donor have a healthy reproductive tract or are there abnormalities? If abnormalities (e.g. adhesions, deformities, presence of infection, breed, age), what are they and how will they potentially affect the collection? What is the temperament of the donor? What are the facilities available for the flush? Thorough investigation prior to the procedure will benefit the practitioner and help determine whether to make adjustments.

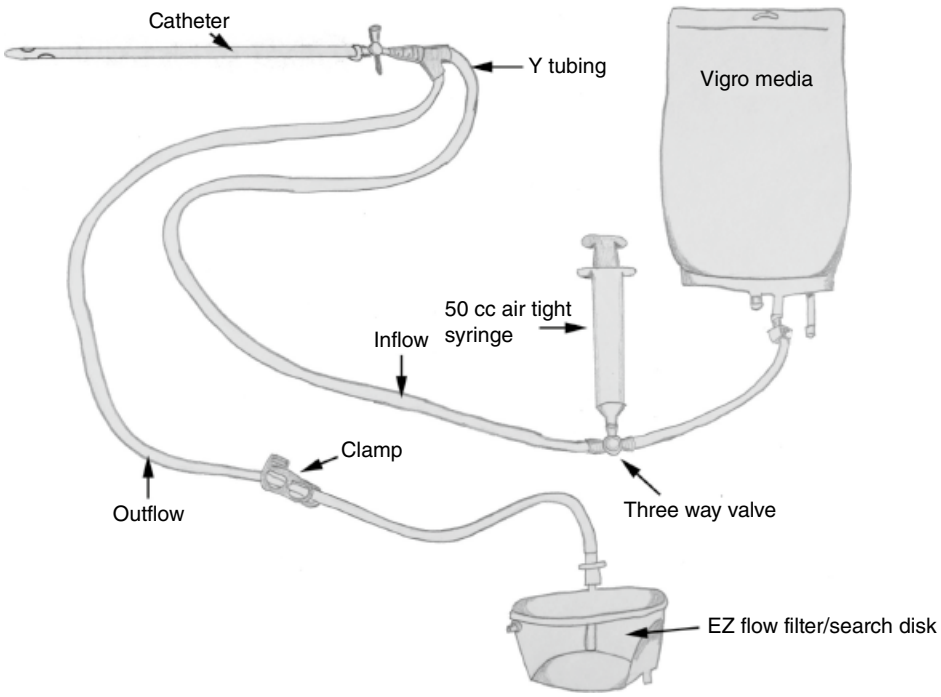

Figure 83.2 Schematic of flush equipment set-up.

Figure 83.3 Stylet protruding through catheter.

A metal stylet must be inserted into the catheter to make it rigid enough to be passed through the cervix. A small amount of KY jelly is applied to the tip of the stylet before entry into the catheter to aid in its withdrawal after passage. The stylet should be slightly longer than the catheter (60-cm stylet, 52-cm catheter) to allow the catheter to be stretched so the stylet will fit tightly inside it (Figure 83.3). This prevents the tip of the stylet from accidentally popping out of one of the fluid ports (holes) near the catheter tip during its passage through the cervix. Cervical damage and uterine hemorrhage are enemies. Passage of the catheter is similar to that in AI except the catheter is considerably larger. In addition, stretch must be kept on the catheter or finger pressure on the cervix may manipulate the stylet tip out of the lumen through the fluid port on the side of the catheter tip.

Eventually, every practitioner runs into a crooked cervix that cannot be passed with a catheter and stylet. An invaluable tool is a cervical dilator. The dilator can be passed through the most difficult cervix. Then, as the dilator is withdrawn by an assistant, one can quickly pass the catheter through before the cervix has time to return to its abnormal shape. Dilators are especially useful in Brahman and Brahman crossbreeds, which tend to get "S" curves and/or 90° bends in the cervix as they age (Figure 83.4).

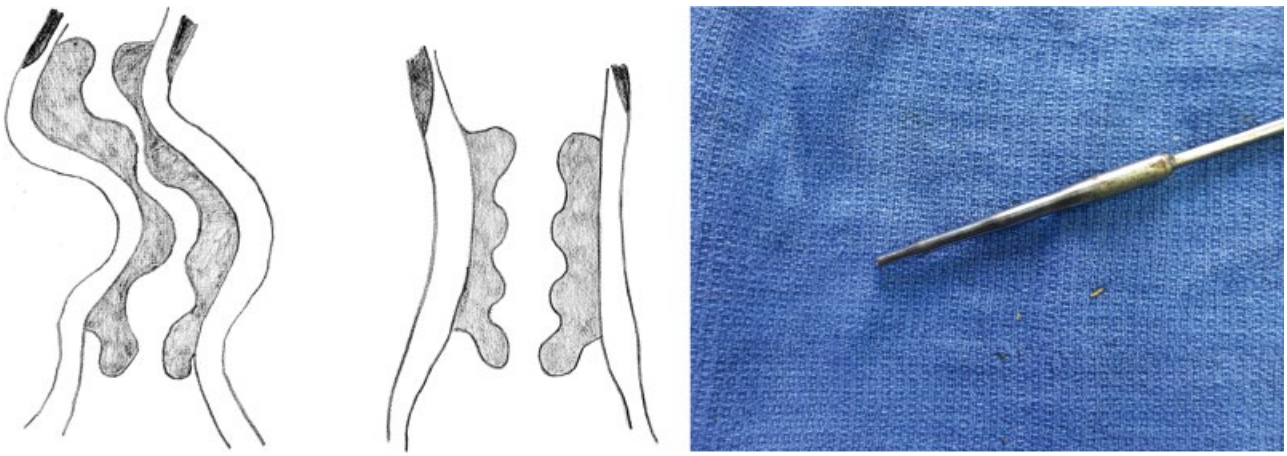
Passing catheters through difficult or crooked cervices requires tenacity. Steady forward pressure must be kept on the stylet. Squeezing each cervical ring in front of the catheter often helps by "flattening" the ring, thereby making a "wide slit" out of the ring whose opening may be offset to one side or the other. The four cervical rings are usually aligned, with the opening of each ring being straight in front of the preceding one, but it is not uncommon to have one ring's opening in the center, the next at 9 o'clock, the next at 3 o'clock, and the last at 12 o'clock. Pressing holes into slits often aids passage. Dilators are diagnostic friends in discovering where each "hole" is located.

Body Flush

For the body flush, understanding the anatomy of the uterine body is necessary to prevent frustration (Figure 83.5). Depending on the age, breed, and size of the cow, the external bifurcation can be 5–15 cm from the cervical opening, causing practitioners to believe there is a lot of open space in the uterine body immediately anterior to the cervical os; however, this is not so. In reality, there is only 1.25–5 cm of open space (heifers usually 1.25–1.9 cm, while larger aged cows have 2.5–5 cm of space). Because the catheter has 2.5–3.75 cm of tip anterior to the cuff balloon, when the cuff is inflated the tip of the catheter protrudes into one of the horns. The balloon will occupy 1.25 cm with 2–3 ml of inflation but will occupy 2.5–3.75 cm if 6–10 ml inflation is required to make the balloon large enough so that it will not retract into the cervix. Catheter placement is easiest if you direct the catheter tip into the uterine horn opposite whichever arm you have in the rectum. For example, the practioner may use their left arm in the rectum, so it is easiest for them to place the tip of the catheter into the right horn.

Inflation of the cuff and seating the catheter's balloon is the *most important* part of a successful flush. Some veteran

(a) (b)



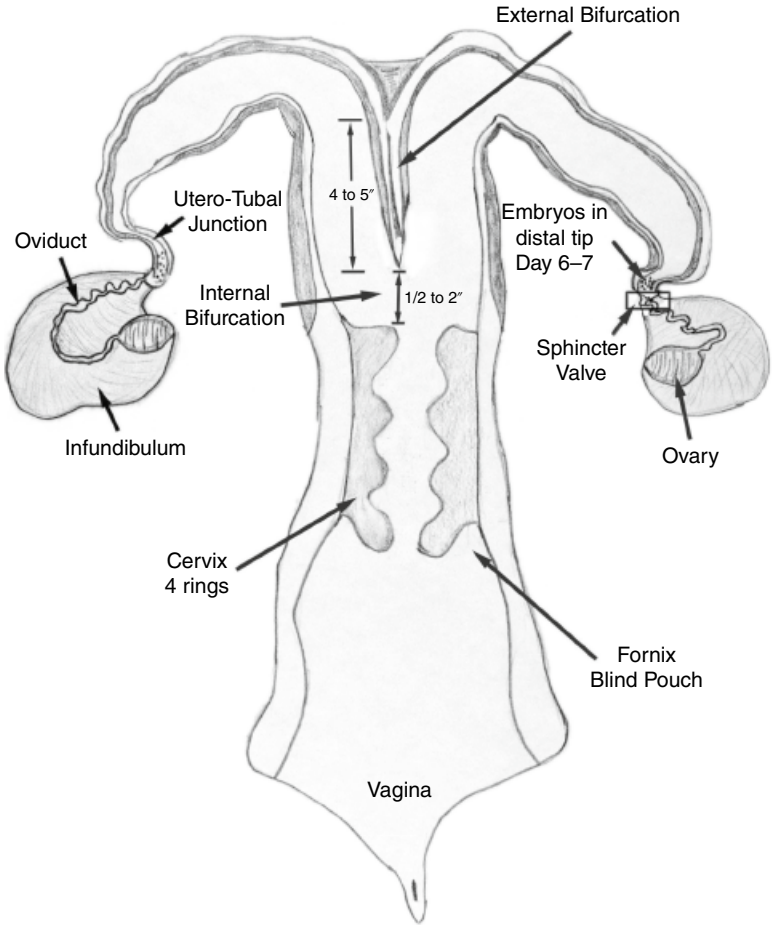


Figure 83.4 (a) Normal vs crooked cervix. (b) Cervical dilator tip.

Figure 83.5 Normal anatomy.

practitioners use flush media rather than air to inflate the cuff so they can see it dripping out of the valve if it leaks. The catheter should be gently introduced into the uterine horn 5 cm or so. Then, 1–2 ml of collection fluid should be injected through the valve into the cuff until you can manually feel the cuff expand. After the slightly expanded cuff is located with your fingertips, retract the stylet about 5 cm into the catheter and then gently retract the catheter until the cuff is in the uterine body just anterior to the cervical os. Once there, continue inflating the cuff. Gently tug the catheter caudally to see if sufficient inflation has been achieved to keep the cuff from retracting into the cervix – typically 2–3 ml is required in heifers and 4–10 ml in mature cows. Once satisfied that the inflation is correct, gently remove the stylet. (Note: Always put small amounts of KY jelly on the stylet tip when it is introduced into the catheter to prevent difficulty in withdrawing the stylet at this point.)

Overinflating and underinflating the cuff are both enemies. If underinflated, the cuff will pull back into the last cervical ring of the cervix as it relaxes. Even though the catheter tip will still protrude into the uterine body, the cervical pressure on the cuff will cause the catheter lumen to collapse and no fluid can be retrieved. If that happens, you must "pinch" behind the cuff in the cervix and squirt it back out into the uterine body where you can add more inflation. The only other option is to deflate the cuff, remove the catheter, reinsert the stylet, and start over. Usually it can be pinched forward without having to remove the catheter, which could result in loss of some embryos (Figure 83.6).

Overinflation results in only one horn being flushed unless some inflation is removed (Figure 83.7). Note that if a heifer or cow has only 1.9–2.5 cm or so in her uterine body, overinflation causes the cuff to engage both the cervical os and the leaf of the internal bifurcation, preventing fluid from entering both horns. Whenever this occurs, you will only be flushing one horn and unless you figure out what is not normal (i.e. "counterfeit") embryos will be left in the other horn.

Once the catheter is seated correctly, flush medium may be infused by gravity, syringe, or pump (Figure 83.8). It is recommended to use a 50-ml airtight syringe connected to a disposable three-way valve so it is possible to measure exactly how much fluid is being used. (Note: Prime the tubing to cut down

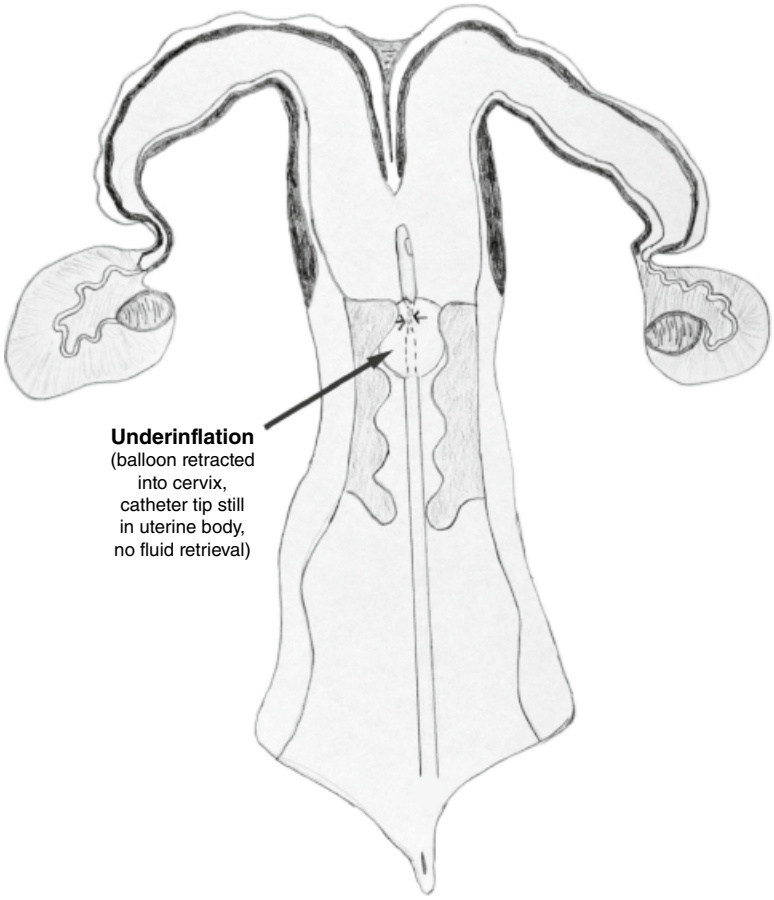

Figure 83.6 Underinflation.

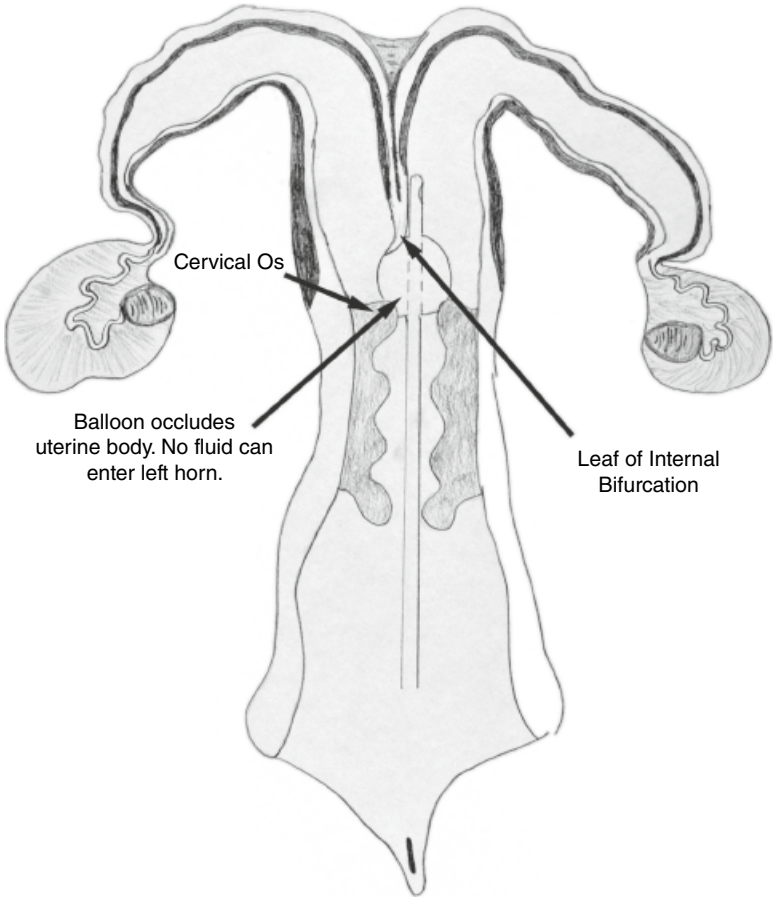

Figure 83.7 Overinflation and the occlusion of one horn.

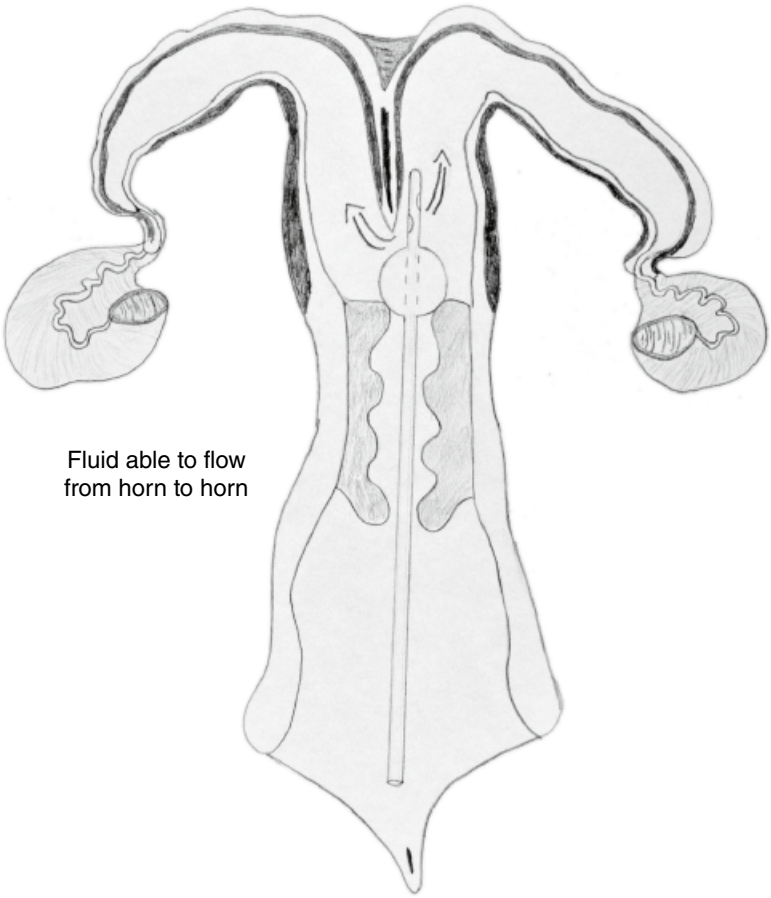

Figure 83.8 Correct catheter-balloon placement allows flush media to flow freely throughout both horns.

on air in the uterus. Figure 83.2 displays the contemporary set-up used for collections.) It is best to use a total of 400 ml of flush medium to collect both horns at the same time. Five infusions and retrievals are performed with the following amounts. Make sure to remove each infusion as completely as possible. Prior to the first infusion, the inflow side of the Y tubing should be filled (primed) with flush fluid to prevent air from being injected into the uterus, causing bubbles in the fluid.

- First infusion: 50 ml (25 ml into each horn), remove fluid.
- Second infusion: 50 ml (25 ml into each horn), remove fluid.
- Third infusion: 100 ml (50 ml into each horn), remove fluid.
- Fourth infusion: 150 ml (75 ml into each horn), remove fluid.
- Fifth infusion: 50 ml (25 ml into each horn), remove fluid.

Follow the flush with infusion of 25 mg Lutalyse through the catheter and into the uterus, deflate the cuff with a 10-ml syringe and gently remove. To assure that there are equal amounts in each horn, hold off the first horn just in front of the catheter tip. This forces the first half of each infusion to "dam up" and then run over into the other horn. Then allow the next half of that infusion to go straight ahead into that horn. You actually learn to "feel" the fluid running under your hand and into the opposite horn as it is injected via the syringe. If the fluid continues to "dam up" between your fingers and the cuff and does not run over into the opposite horn, the cuff inflation is too large and must be reduced sufficiently to allow fluid to flow between the cuff and the leaf of the internal bifurcation and into the opposite horn. Be sure the outflow side of the tubing is clamped closed before each infusion and then opened after you have massaged the fluid throughout the tract (Figure 83.9). After each infusion, the fluid is squeezed forward into the tip of each uterine horn and vigorously massaged to suspend the embryos. This massage forces media all the way to the uterotubal junction (UTJ) where the embryos are located.

Once the massage is completed, the clamp is removed from the outflow tubing and the fluid is retrieved. About half of the fluid usually runs out by gravity, while the other half must be reverse milked out. To reverse milk the fluid, generally it is recommended to clamp the horn near the

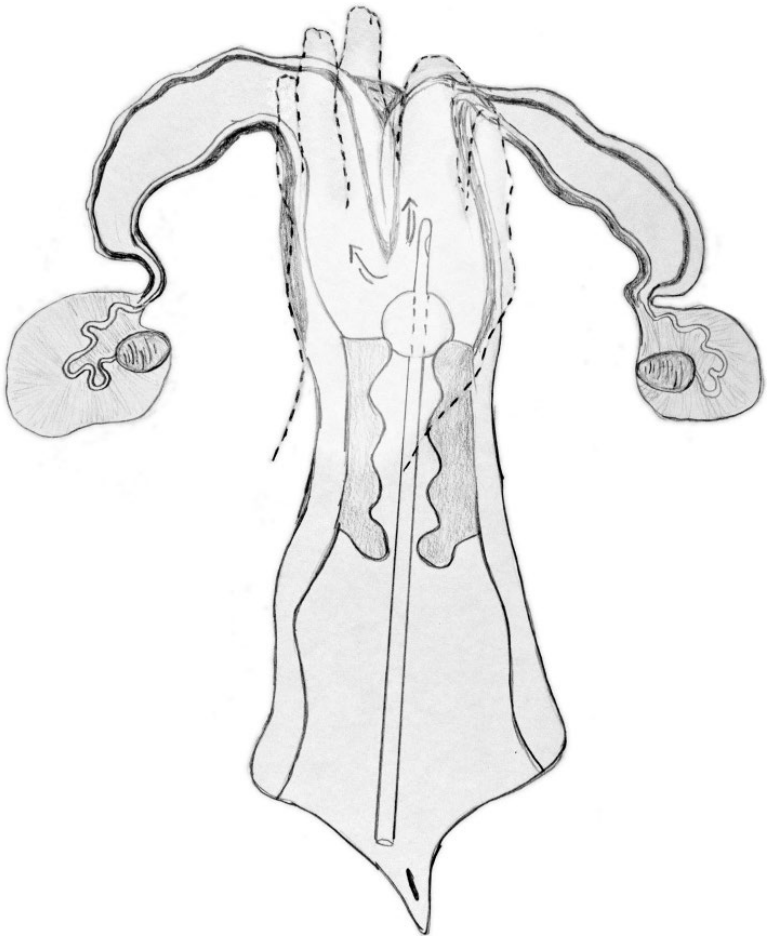

Figure 83.9 One horn can be held off to better fill the opposite horn.

uterine tip between the second and third fingers and use your thumb to pull fingers caudally with a motion similar to that of an inchworm. Alternate doing this between both horns and the fluid is easily moved back into the uterine body where it drains out the catheter. Sometimes you may gently tug on the catheter, which produces a pumping action in the body area that aids in fluid retrieval. Each person develops his or her own technique for fluid retrieval. Repeat this removal procedure after each infusion, trying to ensure the uterus is evacuated after each infusion.

Before embryo filters were available, technicians collected all the fluid and searched it all. It was very time-consuming to search 12 bowls or Petri plates for each flush. However, that method taught many practitioners a lot about their technique and efficiency (or lack of) in getting the embryos removed early in the flush. Beginners are encouraged to do the same today to build confidence in their technique.

To run this quality assurance assessment on yourself, use 12 plastic embryo transfer search bowls, each capped with a plastic lid that fits tightly (these lids can be acquired from a fast-food restaurant) (Figure 83.10). Drain infusion no. 1 into dishes 1 and 2, infusion no. 2 into dishes 3 and 4, infusion no. 3 into dishes 5 and 6, infusion no. 4 into dishes 7–10, and infusion no. 5 (the last) into dishes 11 and 12. By searching those dishes quickly, you can determine at what point in the flush you are retrieving the most embryos; 90% of the embryos will be found in the first six dishes if you are doing a good job. If you find embryos in dishes 11 or 12, you may have left embryos in the donor. By repeating the flush, you can determine if you have left any behind or not.

Note that using this technique the fluid will be too deep in each dish for you to easily see the embryos on the bottom. Since the embryos sink to the bottom quickly, you can use a 20-ml syringe to "skim" the top of the fluid until you have got the depth down to 0.6–1.25 cm so you can see the debris on the bottom of the dish easily. After you have searched every dish and recorded the number of embryos found per dish, pour all the flush fluid through a filter and find any embryos missed while searching the bowls.

To further illustrate the significance of this technique, take into account the following studies. In one study, 210 embryo recovery procedures were conducted using a double uterine flushing method, and the results were compared

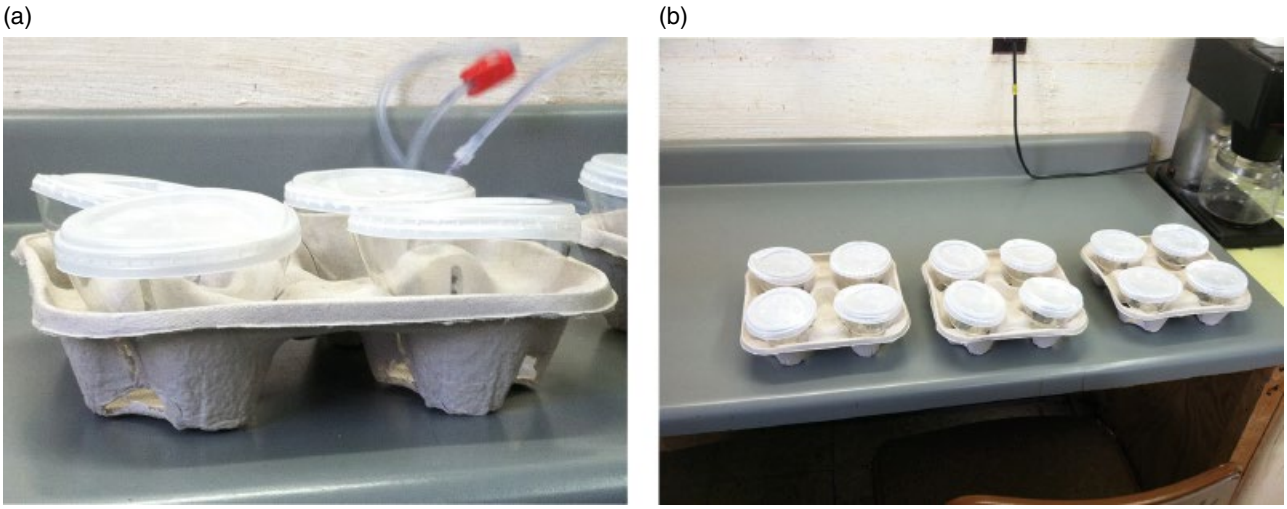

Figure 83.10 (a) and (b) Search bowls safely held in fast-food containers and covered with Solo™ cup lids.

with 432 conventional single-flushing treatments [8]. Double-flushing increased the average number of embryos recovered per procedure compared to single flushing procedures (6.7 ± 0.4 versus 4.6 ± 0.2, respectively). The results of this study highlight the underestimated value in reflushing donors.

In another study using 10 superovulated Holstein heifers, two different flushing techniques were used in a crossover design. At embryo recovery, one uterine horn was flushed with the deep method (about 7 cm caudal to the tip of the horn) and the other with the shallow (about 5 cm cranial to the beginning of the uterine bifurcation) [9]. The shallow flushing technique was superior to the deep technique for percentage of embryos or ova recovered per corpus luteum (63.9 ± 8.6 versus $37.4 \pm 6.5\%$).

One major lesson gleaned from this study was that the virgin uterus, having never been expanded by a pregnancy, often requires more dilation with fluid and massage to get fluid into that distal horn near the UTJ, which is where the embryos are on day 7. Although care must be taken not to overexpand the virgin uterus, causing hemorrhage or rupture, it must be expanded until full and tight and the uterine tips must be massaged to agitate fluid into that area.

The suggestion is for all novice practitioners to devise some way to evaluate their collection technique in order to develop confidence that all embryos are being efficiently collected. Collecting fluid into bottles and pouring the fluid through several filters is more costly but would be quicker than any method used in the era before filters.

Horn Flush

Note that the horn flush is considered an interrupted technique; you must remove the catheter and replace it, exposing it to the external environment. A body flush in contrast is considered a continuous closed system in which there is no contamination from the facility surroundings. This is an important distinction to consider when deciding whether to perform a horn flush.

Horn flushes require less flush medium, but their main value is in the single-egg flush or when oviductal blockage is suspected. For instance, if a cow had six corpora lutea on each ovary and only six embryos were recovered with a body flush, it is impossible to know where they came from. With a horn flush, if the fluid is searched separately from each horn, it is possible to diagnose oviductal blockage.

The horn flush is quick and safe in the hands of the experienced but has more potential pitfalls for the beginner. The key to a successful horn flush is to have a perfectly seated cuff in the horn each time. If the balloon is overinflated, the endometrium will tear, allowing flush medium and embryos to leak into the broad ligament, causing crepitation in the uterine wall and broad ligament that resembles the feel of blackleg-infected tissue. In addition, there will be a lot of hemorrhage to deal with. To salvage the flush, deflate the cuff, reinsert the stylet and go past the site of the tear, reinflate the cuff, and continue the flush.

If you underinflate the cuff, the catheter will slip caudally, eventually ending up at the cervix. In that event, you may choose to reinsert the stylet and reposition the catheter in the horn or just reduce cuff inflation enough to allow fluid to freely pass from horn to horn and switch to a body flush. When properly inflated one-half to two-thirds down the horn, the cuff will require 8–15 ml of inflation. Fingers should sense the cuff's expansion and inflation should stop when the cuff causes the horn to bulge slightly when adequately engaged; the cuff should feel slightly flattened and elongated rather than still round (Figure 83.11).

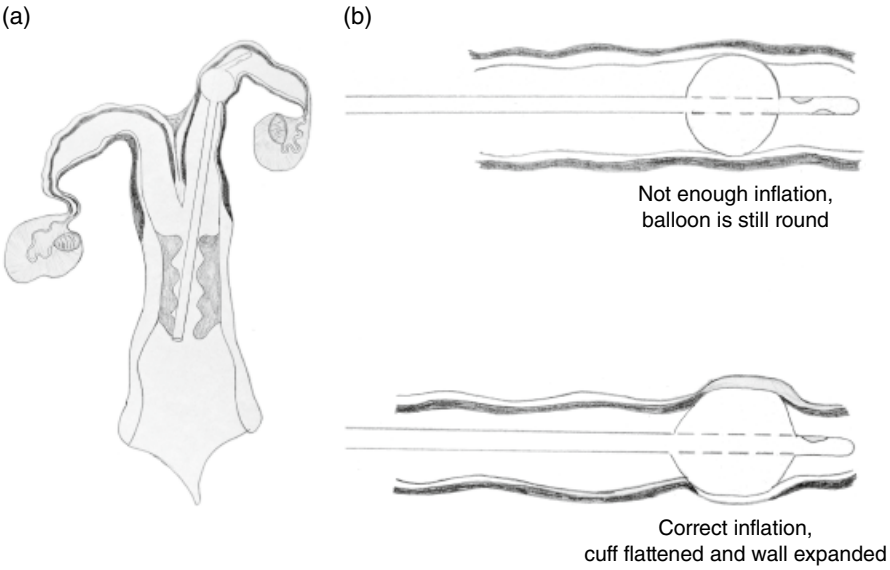

Figure 83.11 (a) and (b) Proper position and inflation for "horn" flush.

When properly positioned, the cuff should be as far as possible down the horn. Minimal amounts of fluid will be required for each flush. It is usually best to infuse medium five to six times into each horn tip with amounts that vary according to that necessary to achieve slight expansion of the horn. During each infusion, the uterine tip near the UTJ should be massaged before the fluid is retrieved. Most of the fluid will drain out by gravity flow, only slight manipulation being required to finish evacuation of all medium. Veteran practitioners usually begin with 15-ml infusions, increasing to 30–50 ml if the horn is large enough. When one horn is completed, the catheter is removed, the stylet reinserted, and the catheter then seated in the opposite horn. Experienced practitioners can rethread the stylet while the catheter is still in utero, but it is best not to try that at first.

The gravity flow technique of infusing medium is used by many practitioners, but some prefer to use syringes so they will have a known quantity infused each time to standardize the procedure. If gravity flow infusion is used, it is still necessary to massage the uterine tip after each infusion or embryos will be left behind. If collecting virgin heifers, vigorous massage of fluid into the UTJ area is a must. Some practitioners use injection pumps to infuse the fluid, but "simple" works well for others.

Filter and Search

Once the fluid is in the EZ Way filter, the filter is tilted so all the remaining flush fluid drains out through the filter mesh. Embryos are approximately 120 µm in diameter; therefore all the embryos should be on the 75-µm filter mesh on the side of the EZ Way. A 20-ml syringe filled with fresh flush medium with a 22-gauge × 2.5-cm needle attached can be used to spray the filter mesh off, allowing the wash to collect in the bottom of the EZ Way dish, which will then be used as the search dish. It is best to rinse the filter mesh off twice using 20 ml each time.

"Counterfeit Money"

In rare cases, abnormalities will be encountered and can be discouraging or even confusing for new practitioners. To think about these obstacles, consider the following metaphor. Experts train bank tellers to detect counterfeit money by first learning to identify what real money looks like, then they can spot any abnormality. The same holds true for embryo collection and transfer. Once you learn to collect normal cows efficiently and with confidence, then when trouble arises you will, hopefully, not panic but will smartly navigate through the trouble and salvage a successful but difficult collection. Some physical issues may be due to genetic abnormalities, AI technician damage, or self-inflicted trauma.

Genetic Abnormalities Encountered

Breed associations should be notified when these genetic abnormalities are found so that family lines that are carriers can be identified.

Unicorn Uterus

Strangely enough, some donors make it to the flush barn with only one uterine horn. This condition is called *uterus*

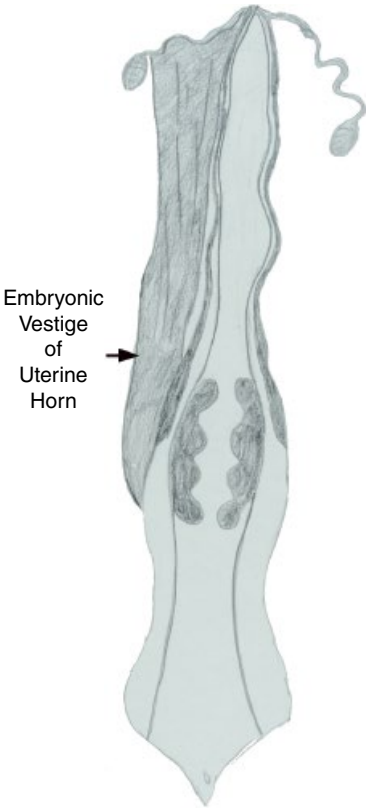

Figure 83.12 Uterus unicornis (segmental aplasia of the uterine horn).

unicornis. They are easy to flush because there is just one straight horn. Although many still have two ovaries, only half the number of embryos can be expected by corpus luteum count of the ovaries. The conclusion is that one ovary is connected to only a vestige of the missing horn while the other is connected to the existing horn (Figure 83.12). This condition is very likely an inherited defect.

Cervical Deformities

In time, all three of the cervical anomalies discussed below will be encountered. Cervical deformities can be a serious cause for frustration as it is vital to navigate this anatomical structure for a successful collection or transfer.

Y Cervix

The "Y" cervix has one opening in the vagina, and then somewhere midway through the cervix, the cervix bifurcates. Occasionally there is a common uterine body, but frequently each cervical opening goes to only one horn that does not communicate via a common uterine body. This means that, for both AI and embryo collection, each horn must be managed separately. Usually one of the cervical pathways is larger and unless the abnormality is diagnosed, all breedings will go to the same horn. Astute practitioners will notice the counterfeit cervix due to the lack of an internal uterine body. These are especially noticeable with recipients that have Y cervices. Non-professionals frequently artificially inseminate and even collect these abnormal uteri without knowing what was wrong (Figure 83.13).

Inverted Y Cervix

The inverted Y cervix has two openings in the vaginal vault, but both converge mid-cervix and only one opening is into the internal uterine body. These may be artificially inseminated and flushed, and if the practitioner is not astute they may not even be diagnosed as counterfeit but just classified as a difficult cervix to pass. These are not as critical for diagnosis since they share a common uterine body; therefore all embryos should be fertilized and collected regardless of which vaginal opening is used (Figure 83.14).

Double-Barrel Cervix

The double-barrel cervix has two openings in the vagina and two completely separate cervices, each going to its own horn. These are easier to diagnose by palpation. The cervix is noticeably wider than normal. With deep palpation, a groove can be felt which resembles the groove between the barrels of a double-barrel shotgun. Each "barrel" must be artificially inseminated separately and each horn collected separately since there is no common uterine body (Figure 83.15).

AI Technician Damage

Thickened Rectal Wall

When the donor for collection is palpated seven days after AI and a thickened edematous rectal wall is felt, it is a good sign the technician had difficulty with the AI. Occasionally, the rectum is so badly traumatized that it is impossible to safely collect ova from the cow. If collected, it is not unusual to collect non-fertile ova, indicating that the semen was never deposited in the uterus.

Brown Blood Clots

Finding brown blood clots in the first fluid retrieved usually indicates that the AI rod traumatized the uterine body resulting in mild to severe hemorrhage. The brown color indicates it is several days old, most likely from AI. This is another serious sign that embryos may not be fertile.

Infused Fluid Disappears, Not Retrieved

There are several reasons why fluid may not be retrieved during the embryo flushing procedure. First, there may be

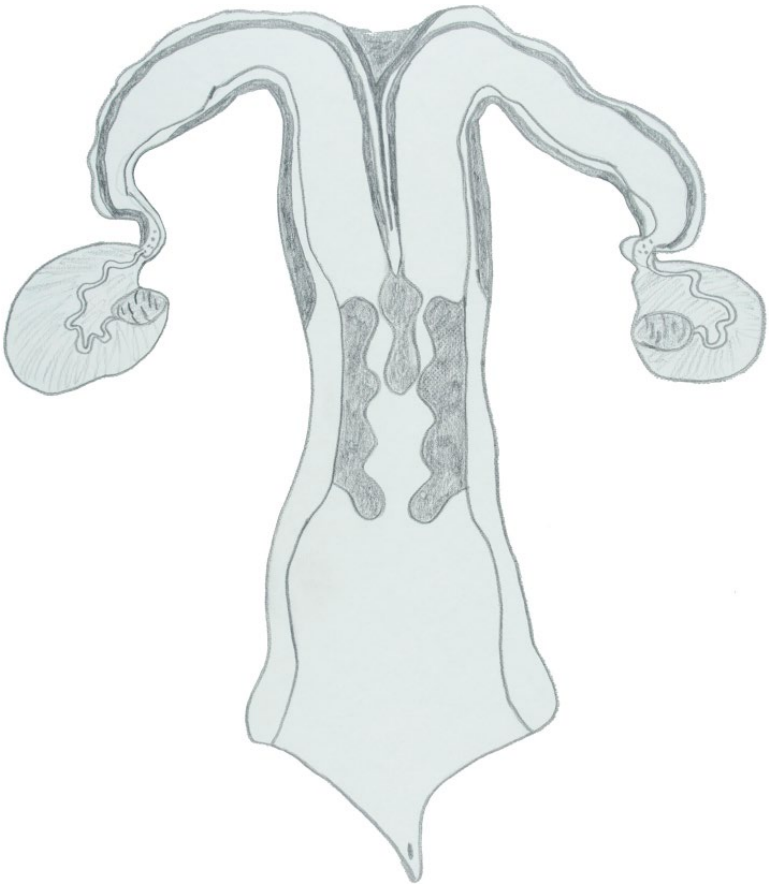

Figure 83.13 Y-shaped cervix (one external os, but a separate opening to each uterine horn).

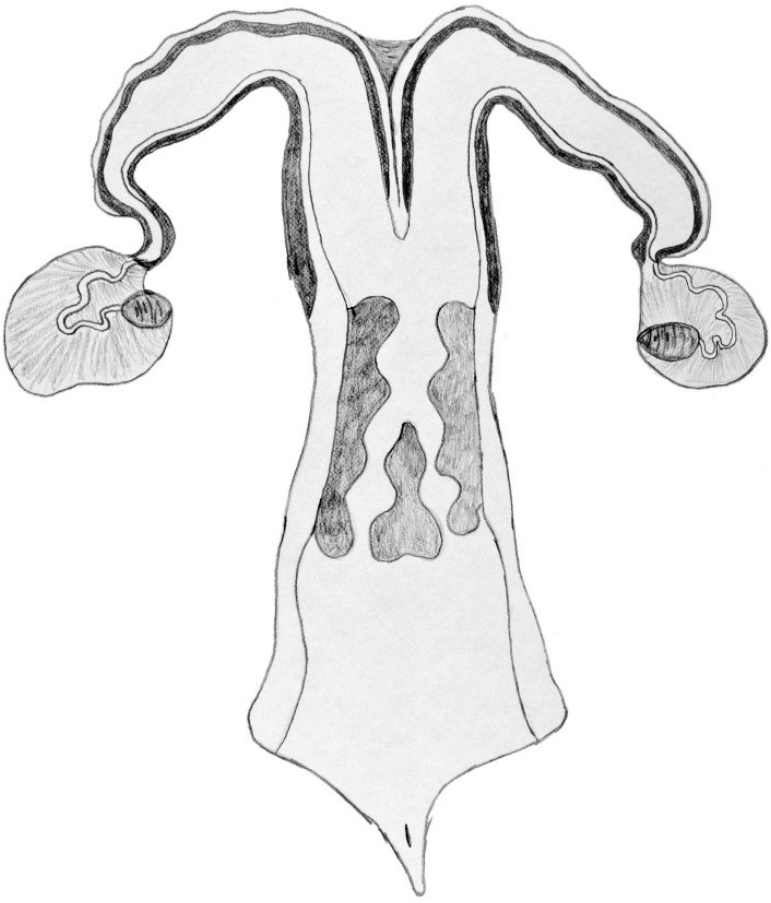

Figure 83.14 Inverted Y cervix (there are two external os, but only one internal os).

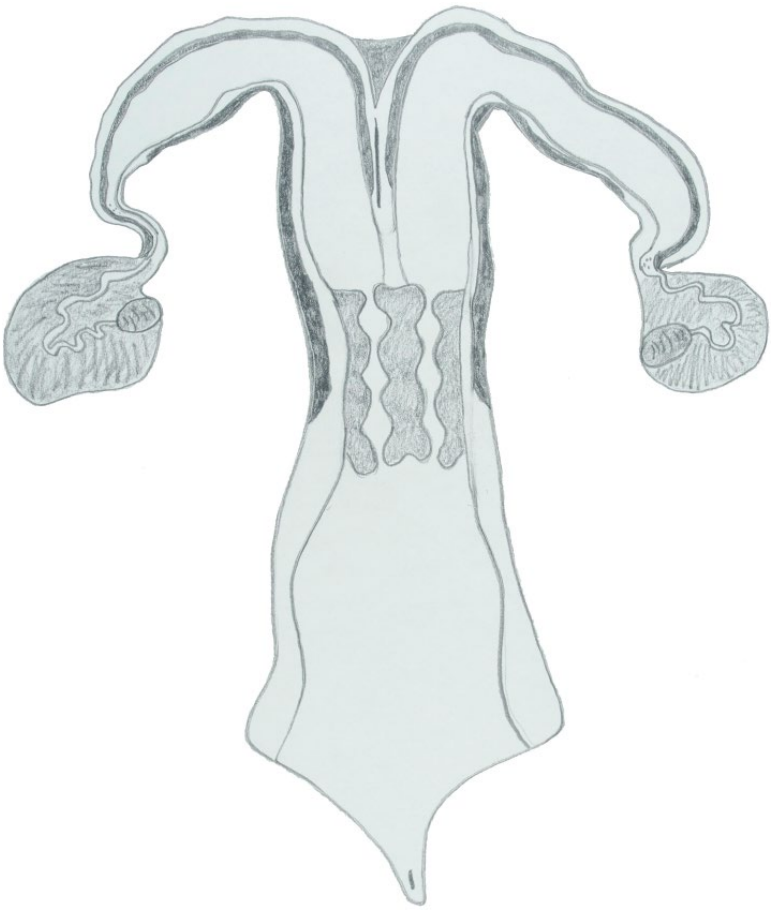

Figure 83.15 Double-barrel cervix.

a perforation from the AI rod that has not yet healed. Second, the wall may have been perforated. Previous trauma usually has brown blood clots whereas fresh trauma is always red. The flush can be salvaged in either case if the perforation can be located; just go past the hole, inflate the balloon, and flush horns separately.

The third cause is serious and almost always results in all embryos being lost. When many unovulated follicles exist that are full of active estrogen, the sphincter valve at the UTJ does not close properly on day 5 or so. When fluid is infused into the uterus on day 7, it simply flows through the UTJ, into the oviduct, and out into the abdomen, carrying all the embryos with it. This leaky valve is not common, but some veteran practitioners, including the author, have frequently encountered such cases. Some may not leak on early flushes of 25 ml per horn but will give way when the volume is increased to 50 or 75 ml per horn. This is reason to make the first two infusions of fluid a lesser amount and then increase volume on subsequent infusions. Consoling news is that these embryos are usually not fertilized anyway due to the increased estrogen level.

External Uterine Masses

A marble- to golfball-size mass found near the uterine body indicates probable trauma from the AI gun or harsh palpation resulting in hematoma. These will resolve in time, but if very large, they cause difficulty that day during the flush.

Pelvic Hematomas

Pelvic hematomas due to trauma from improper controlled internal drug release (CIDR) intravaginal placement may prevent you from accessing the uterus. These are generally unilateral, from either 3 o'clock or 9 o'clock, and protrude into the pelvic canal. Treat with systemic antibiotics for one week to prevent abscessation. If an abscess occurs, drain via vaginal puncture.

Embryo Transfer Practitioner Damage

Crepitation in the broad ligament indicates the endometrium has been torn, allowing flush medium to leak into it. The crepitation mimics the gaseous crepitation caused by blackleg in affected muscles. If encountered, stop the flush,

infuse the uterus with penicillin, and give systemic penicillin for five days. Embryos will be lost into the ligament. A frequent cause is slippage of the cuff backwards during horn flushes or overinflation of the cuff on either horn or body flush. It is an unforgettable feel. The palpable presence of crepitation is always a poor prognostic indicator for embryo recovery.

Hematomas can suddenly arise during the flush near the uterine body, especially in the bifurcation, or along the serosa of the horn if the practitioner handles the uterus too roughly. Always use "flat finger pressure" for palpation and avoid "fingertip pressure" as much as possible.

Other Problem Areas

Traumatic Adhesions

Traumatic adhesions have many etiologies. Cesarean section or dystocia that resulted in perforation can cause severe impingements, making uterine manipulation difficult to impossible. The presence of ovarian spider web-like adhesions is likely due to a previous ascending uterine infection or salpingitis. These are enemies and have a poor outlook. These spider-web adhesions often involve the ovarian bursa and interfere with ova pick-up during ovulation. The best long-term therapy is to try to get the cow pregnant by transplanting an embryo and hope the uterine expansion resolves enough adhesions to allow for sperm and ova transport through the oviduct. Alternatively, IVF could be attempted [6].

Sometimes a granular or sandpaper feeling to uterine serosa can be felt during catheter passage. This has an unknown origin but a distinctive feel when it is encountered. Trauma from CIDR "wings" may cause pelvic inflammation resulting in fibrin deposition on serosa. Most respond to repeated infusion of penicillin and systemic penicillin (100 ml daily for seven days).

Ovulation Tags

Ovulation tags, also called ovarian adhesions, are strands or "tags" of fibrin that can be secondary to ovulation. Ovulation tags generally do not impact reproduction and regress with time but can negatively impact reproductive performance if post-inflammatory adhesions are extensive [10]. In the case of severe ovulation tags, the resulting fibrosis may lead to inhibition of ovulation or oocyte transport.

Paraovarian Cysts

Small nodules around the ovarian bursa usually do not cause pathology unless they become very large. Most are less than 10 cm.

Preventing Unwanted or Multiple Pregnancies

Prostaglandin should be given to all donors post flush. Infuse 5 ml Lutalyse into the uterus at the end of the flush and then ask the owner to administer 5 ml (25 mg) IM twice a day on the third day following the flush. This quickly reduces ovarian size as well as aborting unwanted pregnancies. If cows are collected on 21- to 28-day intervals, it is very important to reduce ovary size quickly. However, infusing PGF2α into the uterus before the dishes are searched for embryos negates the ability to reflush the donor if needed. The IM injections twice on day 10 (3 days post flush) will be sufficient to prevent pregnancy if the owner can be trusted to remember to give the injections.

Helpful Hints

Ballottement Test

Even in normal passes of the catheter, occasionally a blockage occurs in the catheter. After the first fluid is infused and before any massage is done on the uterine tips, you can be sure the catheter lumen is patent with a simple test. With the fluid in the uterus before opening the exit clamp or palpating the tips, simply squeeze the bifurcation area gently two or three times. Movement of air bubbles from the catheter back into your clear tubing should be visible each time you squeeze, indicating patency. If no fluid or bubbles move caudally, there is a flow problem. If it cannot be corrected by massaging the catheter tip, adding or reducing cuff inflation, or moving the cuff around in the body, it is best to immediately remove the catheter and reintroduce a new one.

Washout Technique

When cervical passage of the catheter is difficult, quite often the catheter gets impacted with cervical mucus that enters through the side ports near the catheter tip. The mucus can easily be removed by a washout technique before any fluid infusion is allowed to go down the horns. With the catheter cuff inflated in the uterine body, wrap thumb and forefinger completely around both horns just anterior to the uterine body (Figure 83.16). Infuse 15–20 ml of medium through the catheter quickly and open the exit side of the tubing immediately, allowing that fluid to drain onto the floor. Repeat this two or three times until the fluid draining out the exit tubing is mucus-free. Remember, keep both horns pinched off so fluid only enters and exits from

Figure 83.16 Dr. Edwin Robertson's "washout" technique.

the uterine body. Disconnect the tubing from the catheter and completely wash out the tubing before reattaching to both catheter and EZ Way dish.

Cold Weather Outdoor Collections

To prevent chilling of medium, use two plastic stackable storage drawers from a department store. Each one should have a small electric heating pad added on the bottom of the drawer. The top drawer has the medium bag lying on the pad. In the bottom drawer we have the filter dish sitting on the edge of the pad at the front of the drawer where a hole has been made to allow the fluid to drain from the filter cup onto the floor.

To protect the tubing from the cow to the dish, use a 120-cm section of foam rubber water pipe insulation that has its side split open the entire length. Press the tubing inside the foam insulation section so the fluid can be kept relatively warm during the flush. In severely cold situations, an electric heat tape can be run through the piece of insulation as well.

Transferring the Embryo

Non-surgical embryo transfer is a great example of the old saying "A chain is only as strong as its weakest link." Many factors, some of which are beyond your control as the practitioner, will determine your success.

Selection for the Recipient Pool

It is frequently said that "the outside of a cow looks like the way her insides feel." Cows in poor general body condition with dull hair coats and kept in mud lots generally are not the best choice. So, what the embryo transfer practitioner looks for includes the following. (*Editor's note*: The selection and management of the recipient herd is covered in depth in Chapter 84. The following is an overview of areas that the authors feel are critical to the overall success of an embryo transfer program.)

Size

Dystocia can be a serious issue if proper precautions are not taken. Allow for the expected birthweight based on the breed of the embryo when adding cows to the pool.

Milk

Sound udders are ideal. While getting a live calf is important, it is also vital that the recipient be able to milk well and grow an exceptional calf. If transferring dairy embryos, this is not important since they will be bottle raised.

Prior History

Whenever possible, it is great to know that a recipient has calved regularly and has been an early breeder each year. Information is not available oftentimes though.

Lactation

Lactating cows in good body condition are usually great recipients. Usually, cows are usable by 45–50 days after calving *if* they are in good condition. Dry cows are excellent recipients if they have been held open, but if they are problem breeders or have already weaned a calf or been dried off, stay away from them.

Body Condition Score

The optimal body condition score (BCS) for fertility is 4–6 on a 1–9 scale. When ribs and spine are prominent on BCS 3 beef cattle, these are cows that are generally on the verge of going anestrus. They usually have smaller, firmer corpora lutea if they are cycling at all. These usually give disappointing results. Overly fat cows and heifers have gotten a bad reputation from the belief that "fat cows are infertile." This is not always the case. If the cow is fat because

she has been held open or been overfed, she may still have decent fertility. However, if a recipient has received two embryos or been exposed to several AI attempts without conceiving (three at most), she should be turned in with the bull or culled.

Mineral Deficiencies

Every area of the USA has certain mineral supplementation needs. You should know those in your region.

Disposition

Recipients must be handled often, so a good disposition is critical. This becomes especially important during the technical portions of the embryo transfer process.

Low Stress

Stressors need to be eliminated. Adequate shelter from cold in winter and heat in other months is necessary.

Biosecurity

Several diseases will wreck an embryo transfer program and are discussed in detail in previous chapters. Test all recipients and eliminate them from the herd if they are positive for one of the following diseases: bovine viral diarrhea virus (BVDV), *Neospora canis*, Johne's disease, or bovine leukosis.

Vaccination

All recipients should be vaccinated for BVDV, infectious bovine rhinotracheitis (IBR) virus, parainfluenza 3 virus, bovine respiratory syncytial virus, and leptospirosis. In my opinion, killed virus products are safer but not as effective. Modified live virus (MLV) vaccines with fetal protection for BVDV are best on open cattle. If MLV IBR vaccine is used, recipients will have lower fertility for 30 days due to the IBR virus colonizing the corpus luteum, resulting in decreased progesterone levels [11]. Be safe. A leptospirosis vaccine that includes *Leptospira borgpetersonii* (serovar Hardjo) must be added to the staple five-way leptospiral vaccine. This variant causes not only abortion, but also infertility and early embryonic death. It has become a major problem in most of the USA. Administer other vaccines as needed in your locale.

Recipient Synchronization

Estrus synchronization is discussed in Chapter 37. Use whatever means best fits the operation. Experience and data have shown that natural heats are no more fertile than induced heats. Many practitioners today use timed embryo transfer protocols, making heat detection unnecessary. This is a preferable method on farms with average management and poor heat detection. If a farm is well managed and has excellent personnel trained in heat detection, you may choose to use observed heats. In cases of very valuable embryos, observed heats are safer. Using Estrotect™ or another brand of heat-detection patches is highly recommended in this case.

Timed embryo transfer results in a slightly lower pregnancy percentage but produces more total pregnancies from a group of recipients. For example, if 100 recipients are in a group synchronized and heats are observed and recorded, approximately 85 will be seen in heat in the acceptable "window" or time frame for use. On average, 75 of those 85 will have good corpora lutea and will receive an embryo. If timed embryo transfer is used on 100 recipients, approximately 92 will have corpora lutea, so 92 embryos will be transferred. If the pregnancy rate is 60% for observed heats and 55% for timed embryo transfer, the total pregnancies produced will be 45 from the observed heat group and 50.6 from the timed heat group (plus the added advantage of no labor being spent on heat detection).

Acceptable Synchrony on Recipients

Generally, practitioners use heats on recipients that are 24–36 hours before the donor (8-day heats) to 24 hours after the donor (6-day heats). Of course, 7-day recipients are always best. Several considerations must be taken into account.

- Fresh embryos can tolerate greater asynchrony than frozen embryos. It is preferred to use day 7 (exact synchrony) to day 5.5 (36 hours after the donor) recipients for frozen embryos, while 5- to 8-day recipients are acceptable for fresh embryos.
- When more embryos are collected than recipients are available on a given day, the Grade 2 and Grade 3 embryos are usually transferred fresh while the Grade 1 embryos are frozen (see embryo evaluation in Chapter 85).
- Frozen embryos have undergone stress and therefore need closer synchrony. An 8-day recipient is rarely used, but there is no hesitation using a 5.5-day recipient for frozen embryos.
- IVF embryos are readily available today, both fresh and frozen. We use the same guidelines for synchrony on IVF as we do frozen embryos. However, IVF embryos usually are more advanced stages (expanded blastocysts stage 7 and hatched blastocysts stage 8). These embryos should be placed in recipients that are day 8.

Transfer Equipment (and Supplier)

Note that the items on this list are suggested products, and due to the unpredictable nature of company acquisitions, some or all suppliers may differ.

Frozen–thaw transfer:

- CITO™ Thaw unit (Nasco)
- Small Igloo (local store)

Frozen–thaw and direct transfer (DT):

- Scissors (local store)
- Sterile blue (metal tip) transfer sheaths ZT 133 (PETS Inc.)
- 2% Lidocaine HCl (Animal Health International Inc.)
- 18-gauge × 3.75-cm (1½-inch) needles (Animal Health International Inc.)
- Latex gloves (Animal Health International Inc.)
- Fingerless Maxi Sleeve (Animal Health International Inc.)
- ¼-cc Cassou guns – clean and straight (IMV Technologies or AgTech Inc.)
- Paper towels (local store)
- Chemise sanitary shield (IMV Technologies or PETS Inc.)
- 6-cc Monoject syringes (PETS Inc.)
- Sharpie and pens (office supply)
- Scotch Tape (local store)
- Obstetric (OB) lube (local farm supply store)
- Sterile lube (PETS Inc.)

For tracking recipients and record keeping:

- Z-tag blank (Animal Health International Inc.)
- Z-tag marking pen (Animal Health International Inc.)
- Ear tagger (Animal Health International Inc.)

Recipient Preparation

At this point, the first recipient finally goes into the chute. The same feeding principle applies to recipients as well as to donors: full rumens are your friends; empty rumens are enemies. Never withhold feed: a full abdomen makes transferring much easier.

When the recipient enters the chute, inject 3–5 ml of lidocaine as an epidural and quickly palpate for a good corpus luteum. Care must be taken once the epidural is given not to remove the arm from the rectum or a balloon-effect with air will occur. If the corpus luteum is good and the uterus is acceptable on palpation, load the embryo straw into a 52-cm IMV embryo transfer gun with blue sheath and immediately transfer the embryo. Always place an identification ear tag into each recipient, showing the mating and expected calving date.

New learners may wonder whether it is acceptable to move or transport recipients to and from the transfer site. If the weather conditions are very hot or very cold, short-distance hauls should have no bearing on pregnancy rate.

Site of Transfer

Embryos should be deposited into the uterine horn (ipsilateral to the corpus luteum) as deeply as possible without causing trauma (Figure 83.17). Prostaglandin is an enemy and is present in the endometrial cells. If the practitioner causes trauma as they pass the embryo transfer gun down

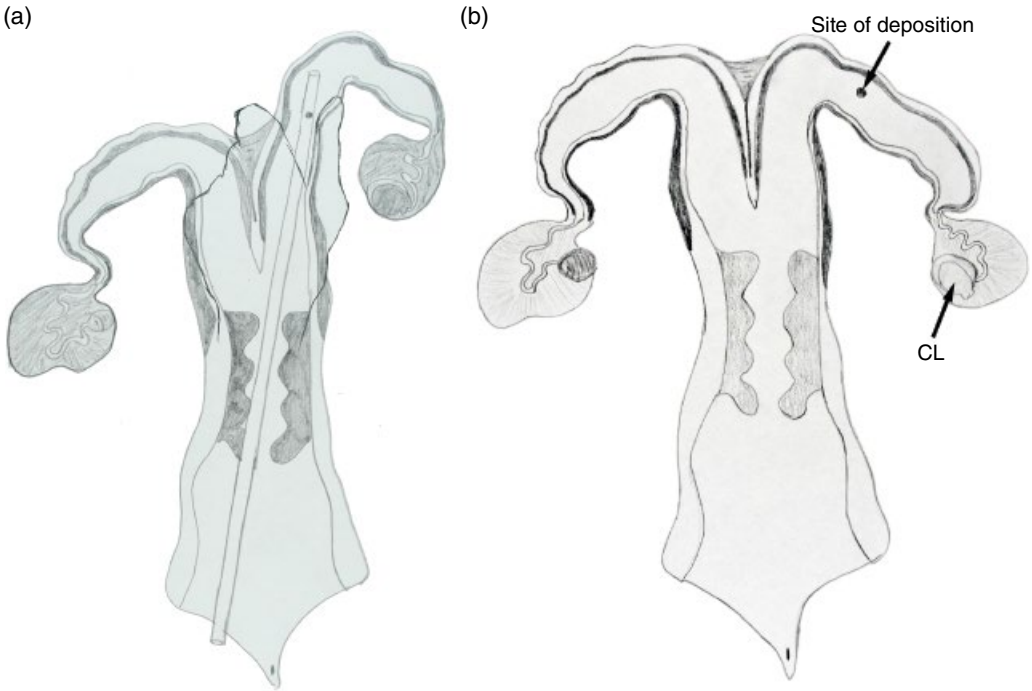

Figure 83.17 (a) and (b) Site of embryo deposition. CL, Corpus luteum.

the uterine horn, $PGF_{2\alpha}$ "leaks" from each damaged cell. Gentle flat-fingered pressure is necessary to smoothly guide the transfer gun without engaging or "bumping" the uterine wall. To do so requires the following conditions.

Restraint of Recipient

Some animals stand more quietly with their head not caught in a head gate, while others must be caught and squeezed. It is very frustrating to have the embryo near the drop zone and the recipient suddenly go berserk or be spooked by someone walking up near her head or yelling.

Footing

Solid footing is a major factor in an animal's willingness to stand still. Metal or slick concrete floors cause animals to panic and struggle. A good layer of bedding in the chute is helpful.

Climate

Overheated animals yield poor results. Every effort must be made to avoid the hot part of the day; alternatively, have fans and air moving. Plenty of water should be available. Minimal cattle movement should be done in the heat. Cold temperatures are generally not a problem unless extreme or if the conditions are also wet and muddy with no dry place to lie down. Recipient comfort is a friend.

Embryo Deposition: Gentle and Fast

Your technique inside the cow will evolve as you gain experience. Gentle and fast are the rules. Data have shown that time spent in passing through the cervix has little effect on pregnancy rates, but increased time spent going down the uterine horn usually affects success negatively. To achieve gentle and fast, the uterine manipulations experienced technicians have used will be described. The details are for being left-handed in the cow, so reverse the following procedure if you use your right hand inside. Here are the steps to follow after the recipient has received an epidural and been checked for a corpus luteum.

After the epidural and before placing your hand in the rectum, place the embryo transfer gun into the vagina and extend it to near the cervix. Once there, push the gun through the thin plastic wrapper that is over the blue sheath. Then place your hand into the rectum, locate the cervix, and stretch it forward, thereby removing any vaginal folds that may be obstructing the gun. Then pass the embryo transfer gun to the fourth cervical ring and hold it there. If the corpus luteum is on the right, before you pass the gun into the uterine body retract the cervix caudally and then reach forward and pull the right uterine tip upward and caudally; envision it as though a cobra snake is raised up to strike you in the face. Now, this horn will not stay there very long, so quickly pass the embryo transfer gun into the right horn and begin sliding the gun down the horn, having your four fingers on the medial side and ventral to the horn, your fingers being used to straighten the horn's wall as you continue forward. When you reach the curvature of the horn, use your thumb and forefinger to pull the horn forward and downward from its upright or sideways position, allowing you to get at least some distance around the curvature.

Each cow will be a different challenge. Some will allow passage almost to the uterine tip, while others must be deposited near the beginning of the curvature due to their size, fatness, etc. The key is to be atraumatic. Use flat finger pressure under the horn. Do not use fingertips to squeeze the horn and do not attempt to "thread" it onto the gun. Both of these movements will usually result in trauma.

For the left horn, start with your four fingers lateral and ventral to the horn with your thumb on top of the horn. Push the uterus slightly to the right in the pelvic cavity to enable you to enter the left horn atraumatically. Then continue down the horn while your fingers push the horn from left to right to allow for a straight path forward. When you reach the curvature, move the gun with your outside hand as far to the right as you can (which moves the gun tip to a left-sided direction internally). With the gun in the lumen at the curvature, wrap your fingers underneath the curvature to the medial side and cradle the curvature, bending it around straight as far as you can and slide the gun as far as possible without bumping or scraping the wall, and then deposit the embryo.

Always visualize yourself as sliding or laying the gun down into the horn rather than threading the horn onto the gun. When depressing the stylet to expel the embryo, envision yourself as laying a bead of toothpaste on your toothbrush. As you depress the stylet, retract the gun a slight distance in order to distance the tip from the embryo as it comes out and some like to rotate the gun 360° to "wipe" the embryo off the gun tip if, by chance, it was still adhered.

Frozen–Thawed Embryo Transfer

The transfer of frozen embryos is identical to that for fresh transfers except that frozen–thawed embryos should be transferred immediately on thawing whereas fresh embryos can be held several hours (six to eight) before transfer.

The preferred thawing process has been debated. The various options are a water thaw, air thaw, or a combination. In a water thaw, embryos from the liquid nitrogen tank (−193 °C) are plunged directly into a water bath at 35 °C. In an air thaw, embryos are held in the air until totally thawed. In combination thawing, embryos are removed from the liquid nitrogen tank, held in the air for five to six seconds, and then plunged into water at 35 °C. Putting embryos directly into water increases the possibility that the zona may crack, which may be undesirable for international work. Embryos may not be frozen for export if the zona is cracked, which could allow viruses or bacteria to gain access to the embryo. Allowing the straw to be held in the air for five to six seconds (or even a total air thaw) has been shown to prevent zona cracking. On a positive side, cracked zonas have been shown to be beneficial in the hatching process, since some embryos have been shown via microphotography to be unable to crack the zona (which enables or allows their growth), resulting in embryonic death. A combination of both methods may be the most efficient choice for some practitioners.

Most embryo transfer practitioners today use the IMV 52-cm embryo transfer gun with blue sheath. The sheath has a highly polished stainless-steel tip that causes much less endometrial trauma than the clear or green-plugged Cassou gun AI sheaths of the 1970s through 1990s. The side port on the IMV sheath (compared with the AI sheath's open end) helps prevent cervical debris from being injected right at the spot where the embryo is deposited.

Success rates for frozen–thawed embryos are very close to those for fresh embryos, usually within 5%, according to annual data published by the American Embryo Transfer Association (AETA).

Summary

Embryo transfer has an intriguing history, which exists in much more depth than most realize. It has led to many more developments in genetic selection and improvement, with additional advancements on the horizon. With the growing world population, novel developments in embryo transfer may play a more significant role and possibly necessitate a new, larger wave of experienced embryo transfer practitioners.

While extremely challenging, learning embryo collection and transfer, in addition to the many nuances of bovine reproductive physiology, can be equally rewarding. Individuals interested in becoming practitioners should strongly consider joining the AETA, the Canadian Embryo Transfer Association (CETA), or the Embryo Transfer Association in their respective country. Consider this quote from Dr. John Hammond:

> The economic success of the animal industry depends on the successful production and proper development of the next generation of our farm animals . . . experience gained on domestic animals will in the future enable man the more easily to control his development also. During the last 100 years great advances have been made in the physical sciences, as witness the steam-engine, motor-car, telephone and wireless. The experiments now proceeding in biological laboratories are beginning to show promise that during the next 100 years an equal advance will be made in the control of the animal.

Dedication

This chapter is dedicated to the lasting memory of the late Dr. Edwin G. Robertson who worked tirelessly to pave the way for future practitioners and students.

After graduation from veterinary school from Auburn University in 1974, he opened Harrogate Hospital for Animals. In 1977 he began practicing embryo transfer in the southeastern USA, eventually expanding to many distant foreign countries. He founded Harrogate Genetics International in 1989. From 1977 to 2014, he collected over 28 000 donors, transferred over 119 000 embryos, and froze over 86 000 embryos. He provided veterinary preceptorships for many veterinary students, becoming the first recipient of the "El Toro" Award (for excellence in food animal medicine) from Auburn University for his mentorship. He coordinated numerous teaching seminars for the American Association of Bovine Practitioners (AABP) from 1980 to 2013 and was named the AABP "Bovine Practitioner of the Year." Additionally, he received the Tennessee Veterinary Medical Association "Outstanding Practitioner Award."

Dr. Robertson was a member and served on the Board of Directors of the AETA. He was elected the 1989–1990 President of AETA. He served on the Board for the Society of Theriogenology from 1986 to 1992 and was President from 1991 to 1992.

Dr. Robertson dedicated his life to bettering his community and the world at large by improving the genetics of cattle and the quality of animal care and sharing his knowledge with the world. He was a true pioneer in assisted reproductive technologies and his work in embryo transfer was invaluable. His remarkable legacy will not be forgotten.

Introduction

The primary use of embryo transfer in cattle has been to amplify reproductive rates of valuable females. Ideally, embryo transfer can be used to enhance genetic improvement and to increase marketing opportunities with purebred cattle. Embryo transfer is especially useful with cattle because of their relatively low reproductive rate and long generation interval [1]. The success of embryo transfer depends on factors associated with the embryo, the recipient, and the embryo transfer technician, or an interaction among these factors. Once transferable embryos are collected from a donor cow, a decision is made as to which of the available recipients should receive embryos to achieve the greatest number of pregnancies [2]. Suitability of recipients is dependent on numerous management, nutritional, and estrous cycle control factors to ensure the presence of a functional corpus luteum (CL) at transfer. Although studies have focused on these factors, differences in techniques, sample sizes, and other elements have limited the applicability of the results of these studies. In many ways, management of the recipient is more critical to the success of an embryo transfer program than the donor, since the recipient is expected to conceive to the transferred embryo, maintain the pregnancy until full term, calve without assistance, and raise a calf of high genetic merit. This chapter focuses on recipient-related factors responsible for the success of an embryo transfer program.

Nutritional Management

Body Condition Score as an Indicator of Reproductive Efficiency

Insufficient intake of energy, protein, vitamins, and microminerals and macrominerals has been associated with suboptimal reproductive performance. Of these nutritional effects on reproduction, energy balance is probably the most important nutritional factor related to poor reproductive function in cattle. The metabolic use of available energy in ruminants for each physiological state is ranked, in order of importance, as follows: (i) basal metabolism; (ii) activity; (iii) growth; (iv) energy reserves; (v) pregnance maintenance; (vi) lactation; (vii) additional energy reserves; (viii) estrous cycles and initiation of pregnancy; and (ix) excess energy reserves [3]. Based on this list of metabolic priorities, reproductive function is compromised because available energy is directed toward meeting minimum energy reserves and milk production. Generally, beef cows do not experience a period of negative energy balance because they fail to produce the quantity of milk that dairy cows produce; however, beef cows need to be in sufficient body condition to resume estrous cycles after parturition and overcome anestrus, short estrous cycles, and uterine involution just to become pregnant every year.

Body condition score (BCS) is a reliable method for assessing the nutritional status of recipients. A visual BCS system developed for beef cattle uses a scale from 1 to 9, with 1

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

representing emaciated and 9 obese [4]. A linear relationship exists between body weight change and BCS, where an approximate 40-kg weight change is associated with each unit change in BCS. Managers of recipients should understand when cows can be maintained on a decreasing plane of nutrition, when they should be maintained on an increasing plane of nutrition, or when they can be kept on a maintenance diet. Understanding the production cycle of the cow and how to manipulate the diet will improve the ability of the recipients to conceive to the transferred embryo [5, 6].

Body condition score (BCS) at calving has been shown to be a more predictable indicator of the duration of postpartum anestrus than prepartum change in either weight or BCS [4, 7]. When cows were thin at calving or had a BCS of 4 or less, increased postpartum level of energy increased the percentage of females exhibiting estrus during the breeding season. BCS at parturition and breeding are the dominant factors influencing pregnancy success, although body weight changes during late gestation modulate this effect. However, altering poor body condition after parturition may reduce the negative impact on reproduction, but seldom overcomes or eliminates those negative effects. A study by Stevenson et al. [8] using blood samples at initiation of the breeding season to determine estrous cycling status demonstrated that only 47.2% of the cows were cycling at the onset of the breeding season. However, as BCS increased, the percentage of cows that were cycling also increased. It is important to note that when cows had a BCS of less than 4 at the beginning of the breeding season, only 33.9% had resumed their estrous cycles.

Prepartum Nutrition

The general belief is that cows maintained on an increasing plane of nutrition prior to parturition usually have a shorter interval to their first ovulation than cows on a decreasing plane of nutrition. Energy restriction during the prepartum period results in a low BCS at calving, prolonged postpartum anestrus, and a decrease in the percentage of cows exhibiting estrus during the breeding season [9]. Pregnancy rates and intervals from parturition to pregnancy are also affected by level of prepartum energy [9]. Conversely, when prepartum nutrient restriction was followed by increased postpartum nutrient intake, the negative effect of prepartum nutrient restriction was partially overcome; however, the effectiveness of elevated postpartum nutrient intake depended on the severity of prepartum nutrient restriction [7, 9]. The effect of BCS prior to calving also has implications for calf birth and weaning weights. When cows were fed to achieve a BCS of either 4 or 6 prior to calving, calf birth and weaning weights (with similar genetics) were greater for those cows at a BCS of 6 [10]. Despite the greater birth weights, there was no difference in calving difficulty, demonstrating the added advantage for recipients to wean calves with greater weaning weights. In addition, there tended to be an increased number of cows calving with a medium BCS that were cycling at the beginning of the breeding season and after a 60-day breeding season than cows in poor condition, resulting in a greater proportion of cycling cows at various stages of the breeding season [10].

Postpartum Nutrition

Numerous studies document that increasing nutritional levels following parturition increases conception and pregnancy rates in beef cows [4, 11]. Increasing the postpartum dietary energy density increased body weight and BCS, and decreased the interval to first estrus [7]. However, suckled beef cows in relatively poor body condition gaining in excess of 1 kg/day while consuming an 85% concentrate diet did not resume cyclic ovarian activity before 70 days postpartum [7]. Therefore, although an enhanced plane of nutrition after calving may partially overcome the negative effects of poor prepartum nutrition, the added stress and negative impact of suckling and lactation must be considered.

A major impact on postpartum fertility is the length of the breeding season. Having a restricted breeding season has many advantages, such as a more uniform and older calf crop, but most importantly a breeding season of 60 days or less increases the percentage of females cycling during the subsequent breeding season. If the breeding season is shortened, then all cows have a higher probability for pregnancy during the next breeding season. Strategic feeding to obtain ideal BCS can be achieved by understanding the production cycle of the cow. The period of greatest nutritional need occurs shortly after calving, when a cow is required to produce milk for a growing calf, regain weight lost shortly before and after parturition, and repair her reproductive tract to become pregnant within three months after calving. During this stage, a cow is usually consuming as much feed as she can, and attempting to adjust BCS at this time is often futile. Cows are usually grazing and tend to consume their full protein, vitamin, and mineral requirements; however, the grass is often lush with a high percentage of moisture, which can occasionally cause a deficiency in energy [12].

Estrous Cycle Control

Development of Estrus Synchronization Protocols

Factors such as nutrition, management, and inefficient detection of estrus affect the widespread use of embryo transfer in beef cattle operations. The most useful alternative for increasing the number of animals receiving embryos is to utilize protocols that allow for embryo transfer without the

need for estrus detection, usually called fixed-time embryo transfer (FTET) protocols. However, much of the research related to the systems currently used in embryo transfer programs was for fixed-time artificial insemination (TAI) rather than FTET. Transfer of embryos into estrus-synchronized cows has been most effective when embryos were transferred six to eight days after detected estrus or gonadotropin-releasing hormone (GnRH) injection [13]. Early estrus synchronization systems focused on altering the estrous cycle by inducing luteolysis with an injection of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) followed by estrus detection. Once systems involving a single $PGF_{2\alpha}$ treatment became successful, researchers focused on multiple injections of $PGF_{2\alpha}$ to further reduce days required for estrus detection [14, 15]. The next generation of estrus synchronization systems involved the use of exogenous progestins, such as an intravaginal controlled internal drug release (CIDR) insert or melengestrol acetate (MGA), which were used to delay the time of estrus following natural or induced luteolysis and extend the length of the estrous cycle [16, 17].

After the discovery of the wave-like pattern of follicular growth in cattle, scientists were able to embark on the third-generation systems of estrus synchronization [18]. Controlling follicular waves with a single injection of GnRH at random stages of the estrous cycle results in the release of a luteinizing hormone (LH) surge that causes synchronized ovulation or luteinization of dominant follicles [19–21]. Consequently, a new follicular wave is initiated in most (>60%) cows within one to three days after GnRH administration. Luteal tissue that forms after GnRH administration will undergo $PGF_{2\alpha}$-induced luteolysis six to seven days later [22]. A drawback of this method of estrus synchronization is that approximately 5–15% of cows are detected in estrus on, or before, the day of $PGF_{2\alpha}$ treatment, reducing the proportion of females that are detected in estrus during the synchronized period [23–25].

Advances in Protocols for Beef Cows

Preliminary studies identified significant improvements in fertility among cows that received MGA prior to the administration of $PGF_{2\alpha}$ compared with cows that received only $PGF_{2\alpha}$ [26]. When cows received a CIDR for seven days and an injection of $PGF_{2\alpha}$ the day before CIDR removal, estrus synchrony and pregnancy rates were improved [17]. In addition, when GnRH was given six or seven days prior to $PGF_{2\alpha}$, 70–83% of cows were in estrus within a four-day period [22].

The use of GnRH to control follicular wave emergence and ovulation and $PGF_{2\alpha}$ to induce luteolysis led to the development of the Ovsynch protocol for dairy cows [27]. Combining the second injection of GnRH with TAI (CO-Synch) proved to be more practical than estrus detection for beef producers because it had no negative effects on fertility [28]. However, a disadvantage of this protocol is that approximately 5–15% of suckled beef cows exhibit estrus prior to, or immediately after, the $PGF_{2\alpha}$ treatment [24]. Unless these cows are detected in estrus, they will fail to become pregnant to embryo transfer because of the lack of synchrony between the recipient estrous cycle and the age of the embryo. Therefore, the addition of a CIDR to a GnRH-based protocol can prevent the premature occurrence of estrus and result in enhanced synchrony between recipient estrous cycle and the age of the embryo. In the context of TAI, overall pregnancy rates were enhanced by the addition of a CIDR to a GnRH-based protocol (59 vs 48%, respectively). The CIDR delayed the onset of ovulation, resulting in more synchronous ovulation, and induced cyclicity in non-cycling cows [24]. Previously, the efficacy of these CIDR-based TAI protocols had not been evaluated concurrently with AI protocols requiring detection of estrus in suckled beef cows. Therefore, we implemented and coordinated a multistate, multilocation experiment to discern whether a GnRH-based with the addition of a CIDR protocol for TAI could yield pregnancy rates similar to protocols requiring detection of estrus [29]. Results demonstrated that the TAI protocols yielded pregnancy rates that were similar to the estrus detection protocol, even though 35% of the cows were in postpartum anestrus at the time of treatment.

A detailed version of current estrus synchronization and TAI protocols reviewed by the Beef Reproduction Task Force is available in Figure 84.1. Utilizing a similar protocol on recipients using FTET would be practical and effective in yielding high pregnancy rates in recipients.

Advances in Protocols for Beef Heifers

Early studies in beef heifers demonstrated that feeding MGA for 14 days followed by $PGF_{2\alpha}$ 17 days later was an effective method of estrous cycle control in heifers [16, 30]. However, when heifers were treated with $PGF_{2\alpha}$ 19 days after the 14-day MGA feeding period, there was no difference in fertility but estrus was more synchronous [31]. Following the success of this protocol, researchers began to include GnRH in estrus synchronization protocols for TAI. However, addition of GnRH to the above protocol failed to increase pregnancy rates following TAI in heifers [32]. Estrus synchronization using GnRH followed by $PGF_{2\alpha}$ successfully synchronized heifers, but the above MGA-$PGF_{2\alpha}$ protocol led to greater synchrony of estrus and therefore tended to be more effective [31].

Development of a TAI protocol in beefs heifers has not been as straightforward as in cows, especially considering that at the time of estrus synchronization the majority (>85%) of heifers have attained puberty [33]. The primary

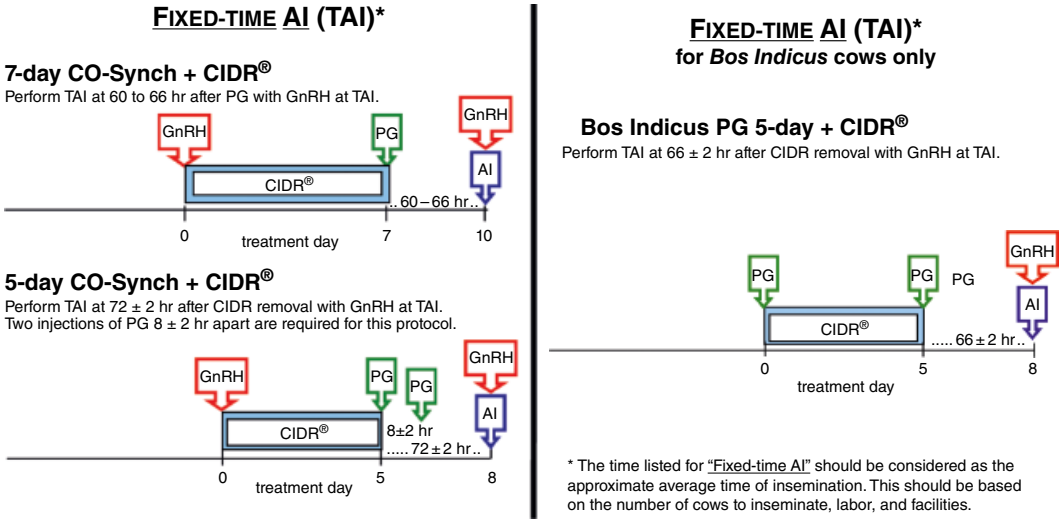

Figure 84.1 Current protocols for estrus synchronization and TAI of beef cows reviewed by the Beef Reproduction Task Force. Available at https://beefrepro.org.

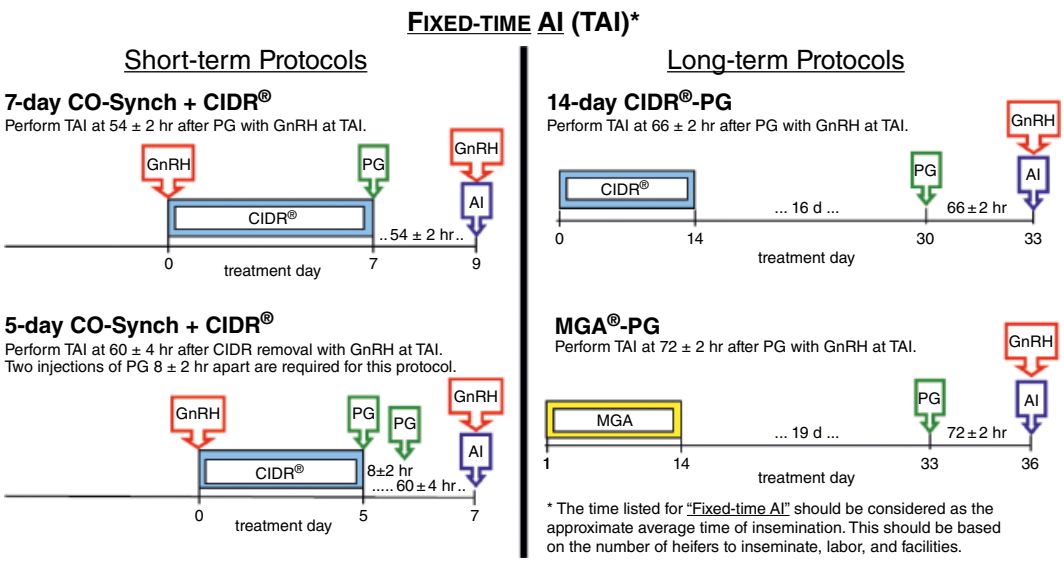

Figure 84.2 Current protocols for estrus synchronization and TAI of beef heifers reviewed by the Beef Reproduction Task Force. Available at https://beefrepro.org.

reason for failure of TAI in heifers appears to be the inability to synchronize follicular waves with GnRH. After an injection of GnRH at random stages of the estrous cycle, 75–90% of postpartum beef cows ovulated [34, 35], whereas only 48–60% of beef and dairy heifers ovulated in response to the same treatment [27, 36, 37]. We have found no difference in synchrony of estrus or pregnancy rate in CIDR-treated heifers whether or not GnRH is administered at CIDR insertion, suggesting that response to GnRH in heifers at CIDR insertion may be of limited value [33].

In a large multilocation study using GnRH, $PGF_{2\alpha}$, and CIDR, GnRH did not enhance pregnancy rates following estrus detection, but the addition of a CIDR to a GnRH-based TAI protocol yielded similar pregnancy rates to those utilizing estrus detection [33]. Nevertheless, a bewildering fact remains that the average pregnancy rate for these protocols ranged from 53 to 58%, whereas pregnancy rates in MGA (with $PGF_{2\alpha}$ administered 19 days after MGA removal) or long-term CIDR (with $PGF_{2\alpha}$ administered 16 days after CIDR removal) protocols followed by $PGF_{2\alpha}$ have been reported to range from 60 to 75% [23, 31, 33, 38]. A detailed version of current estrus synchronization and TAI protocols reviewed by the Beef Reproduction Task Force is shown in Figure 84.2. Utilizing a similar protocol on recipients using FTET would be practical and effective in yielding great pregnancy rates in heifer recipients.

Resynchronization of Estrus

Reinsemination of non-pregnant cows at the first eligible estrus can be facilitated by resynchronization of the estrous cycle [39], which would have wide application in intense embryo transfer programs. To most effectively condense the calving season, the second round of estrus synchronization needs to begin before the pregnancy status of the animals is known. Although resynchronization with a progestin increased synchronized return rates of non-pregnant females [40, 41], resynchronization with CIDR devices and estradiol cypionate or estradiol benzoate decreased subsequent conception rates to AI [40]. In contrast, further studies did not note a decrease in fertility when estrogens were utilized for resynchronization with a CIDR [42]. Furthermore, insertion of a CIDR for 13 days on the day of embryo transfer 7 days after estrus [43] or from 5 days after TAI until day 21 [29] was effective in resynchronizing estrus in non-pregnant cows, but insertion of a CIDR failed to enhance fertility compared to controls.

Recipient-Related Factors

Embryo Transfer Factors

The procedure of removing an embryo from its natural uterine environment, and in many cases freezing and thawing, increases the stress experienced by those embryos, resulting in a decreased survival rate following transfer. Results from our group (reference) show a decrease in pregnancy rate from 83% with fresh embryos ($n = 122$) to 69% with frozen–thawed embryos ($n = 326$) are similar to the 10–15% decrease in pregnancy rates reported previously [44, 45], which is similar to the difference in averages reported by the American Embryo Transfer Association (AETA) and the International Embryo Transfer Association (Savoy, IL). Results from two studies reveal that pregnancy rates among cows receiving a Grade 1 or Grade 2 fresh embryo [46, 47] were not different. Previous reports [2, 48–50] noted a decrease in pregnancy rate with each corresponding decrease in quality score.

Pregnancy rates have been shown to vary with the synchrony of the donor and recipient. Greater pregnancy rates were observed when recipients were in estrus coinciding with the donor or 12 hours before the donor. Pregnancy rates decreased when recipients exhibited estrus 12 hours after the donor [50]; however, other reports did not observe differences until 24 hours [45–47].

The variability of progesterone concentrations in recipients reflects a combination of different rates of CL development and the fluctuation of progesterone secretion during the early luteal phase. It has been suggested that the optimum circulating concentration of progesterone for establishing pregnancy ranges between 2.0 and 5.0 ng/ml [51]. However, a study has revealed that the minimum threshold progesterone concentration on the day of embryo transfer essential for the establishment and maintenance of pregnancy may be lower than previously reported, as there were no differences in pregnancy rates when progesterone concentrations were as decreased as 0.58 ng/ml or exceeded 16.0 ng/ml ($n = 448$) [47]. In another study, 8 of 177 pregnant recipients had concentrations of progesterone less than 0.5 ng/ml on days 10, 11, and 12 of the transfer cycle [52]. In addition, the diameter and volume of the CL differed among recipients that received embryos from 6.5 to 8.5 days after estrus [47], increasing as days after estrus increased. However, pregnancy rates did not differ among recipients receiving embryos 6.5–8.5 days after estrus.

A number of factors during the embryo transfer process have been reported to influence pregnancy success. Pregnancy rates have been inversely correlated with the time spent in the uterus during embryo transfer, where the least amount of time results in the greatest pregnancy rates [53, 54]. Furthermore, recipient movement while the embryo transfer gun is in the uterus increases the risk of damage to the endometrium, causing the release of $PGF_{2\alpha}$, which can hamper pregnancy success. When the prostaglandin synthesis inhibitor flunixin meglumine (FM) was administered at the time of embryo transfer, pregnancy rates were reportedly enhanced, but only when poorer-quality embryos were transferred [43, 55]. However, the United States Food and Drug Administration (FDA) has released a reminder that FM is only approved for intravenous use in cattle and extra-label drug use has resulted in increased residues found at slaughter. The site of embryo transfer has also been reported to influence pregnancy rates, where embryos that were transferred into the cranial part of the uterine horn tended to have greater pregnancy success when compared to those transferred to the middle and caudal third of the uterus [54]. Furthermore, transfers that are more difficult to perform tend to result in reduced pregnancy rates when compared to easier transfers [54].

General Recipient Considerations

Selection and identification of high-quality recipients is not simple. Many prefer the use of virgin heifers, whereas others choose cows with a known history of high fertility. When heifers are to be used as recipients, the selection criteria should be the same as for high-quality replacement heifers. Heifers need to be cycling, which can be assessed indirectly by using reproductive tract scores that are assigned based on the diameter and tone of the uterine

horns, as well as ovarian morphology (scale of 1 = reproductively immature to 5 = sexually mature) [56]. In addition, heifers need to be on an increased plane of nutrition, have an adequately sized and normally shaped pelvic canal, and have no history of receiving growth implants.

Lactating recipients have an advantage of a known reproductive history. Since the health of the calf is dependent on the recipient, records should be kept of calf health and weaning performance. Recipients that carry an embryo transfer calf to term but do not raise a normal calf to weaning should be reevaluated as a recipient prospect. Similarly, open cows with an unknown reproductive history need to be carefully examined prior to being included in a recipient herd or program [57]. The reproductive tract needs to be thoroughly examined via rectal palpation or transrectal ultrasonography for pregnancy or uterine anomalies such as fluid or fetal remnants, or evidence of metritis or endometritis, and the ovaries examined for normal follicular or luteal structures. In addition, recipients should have good teeth and eyes, a good udder, be less than eight years of age, and be structurally sound. Greatest fertility occurs in herds where handling facilities are designed to ensure that cattle are handled with minimum stress.

It is wise to keep the new arrivals separate from the breeding herd until sufficient time has elapsed for diagnostic screening tests to return and any incubating disease to become apparent. Many purebred producers and embryo transfer companies take blood samples to test for exposure to bovine leukosis virus (BLV), *Mycobacterium paratuberculosis* (Johne's disease), bovine viral diarrhea virus (BVDV), anaplasmosis, and *Neospora caninum*. Brucellosis testing or vaccination is no longer required in many areas, but it is prudent to test cattle from areas where the disease is present in wildlife. Many of these pathogens have been associated with decreased fertility by preventing fertilization or by causing embryonic death, fetal loss, or ovarian dysfunction [58]. A vaccination program to control livestock diseases is a common and proven practice. Conventional recommendations suggest that modified-live virus vaccines be given at least 30 days prior to breeding. However, recent research has shown that in previously vaccinated cattle, there are no detrimental effects of vaccinating cattle at the time of $PGF_{2\alpha}$ treatment or initial GnRH treatment [58]. Cattle with an unknown or questionable history of vaccination should receive primary and booster vaccinations at least 30 days prior to breeding [59].

Management after Confirmation of Pregnancy

Once the recipient is confirmed pregnant, she needs to be managed to remain pregnant. There are several environmental factors that cause abortion depending on the area of the country where the cow is maintained. Some of these include *N. caninum*, locoweed, ponderosa pine needles, fescue toxicity, nitrates, and mycotoxins and/or moldy feed. Handling stress has been shown to cause heifers to abort, but no reliable data have focused on the ideal interval after embryo transfer to transport recipients. However, pregnancy rates were lower in females that were transported between 8 and 33 days after AI as compared with those transported within the first 4 days [60]. Therefore it appears to be more desirable to transport recipients prior to embryo hatching than after hatching. Infectious agents (e.g. BVDV, infectious bovine rhinotracheitis, and, rarely, bluetongue virus) are also a threat to the developing fetus. Often it is not possible to diagnose the cause of abortions, but diagnostic success can be increased if the proper samples and history are submitted [61].

Biosecurity

To protect the herd from the introduction of infectious diseases that could cause abortion or reduce the value of the calves, a well-designed biosecurity program needs to be in place. This includes a test and quarantine program for all new cattle introduced into the herd. A commonsense program of single-use needles and rectal sleeves, disinfection of equipment between cows (drench applicators, tattoo pliers, and other instruments), external parasite control, the use of clean coveralls for employees and visitors as well as footbaths or shoe coverings, and not allowing equipment or clothing to be taken from one farm to another without first being thoroughly washed and disinfected can minimize risk of introducing pathogens onto a facility.

Pregnancy Diagnosis

Establishing a pregnancy diagnosis program allows for the detection of cows that are not pregnant and allows producers to make management decisions to increase reproductive efficiency, such as culling infertile recipients and resynchronizing recipients that are open. Knowing when cows conceive and when they will calve also helps concentrate calving supervision. Cows can be sorted into calving groups and managed to save on feed, labor, and veterinary expenses. Precalving vaccinations can be timed to ensure the most effective response. Also, avoiding overcrowding of calving pastures and/or calving cows on "fresh" pastures that have not been grazed by cows with calves has been shown to reduce calf morbidity and mortality as a result of infectious calfhood scours [62]. There are three main options to commercially diagnose pregnancy in cattle. Rectal palpation and ultrasonography are the most widely used methods for early diagnoses. Both techniques are

efficient but require a skilled technician and specific instruments and provide static information on pregnancy status at the specific moment of diagnosis. Rectal palpation is an accurate form of pregnancy diagnosis that can be performed after day 35 of gestation, whereas transrectal ultrasonography can be used to pregnancy as early as 26 days of gestation for heifers and 28 days for cows, with a high degree of accuracy [63].

Recent research has aimed to develop methods of pregnancy diagnoses that use measures of conceptus-specific markers in maternal blood as indicators of a viable pregnancy [64, 65]. After decades of research on potential biological markers of pregnancy, the measurement of pregnancy-associated glycoproteins (PAGs) in blood circulation has been established as the most reliable conceptus-derived marker for use in early pregnancy diagnosis in cattle and is commercially available for cattle producers. This test is commonly referred to as "the blood test." Produced by a specific cell population of the developing placenta, PAGs enter the maternal circulation as early as day 22–24 of gestation and reach levels currently acceptable for accurate pregnancy diagnosis at day 28. Today, commercial PAG testing is extremely accurate, providing 95–99% true positive (pregnant) reading, with false positive (reported as pregnant but actual non-pregnant) rates ranging from 1 to 5%. It is important to mention that some false positives may be due to embryonic mortality and not to test inaccuracy. Since the goal is for a producer to accurately determine non-pregnant cows, the blood tests are highly accurate and can serve as a reliable strategy to determine pregnancy in cattle. Tests currently available include BioPRYN (BioTracking LLC, Moscow, ID, USA), IDEXX Bovine pregnancy test (IDEXX Laboratories Inc., Westbrook, ME, USA), and DG29 pregnancy test (Genex Cooperative Inc., Shawano, WI USA). BioPRYN accepts blood samples from heifers 25 days post breeding and cows 28 days post breeding, IDEXX recommends day 28 blood or milk samples, and DG29 has been validated using day 29 blood samples.

Management for Efficient Recipient Utilization

Effective management of a recipient herd requires preparing the recipient to receive an embryo and identifying open recipients to be resynchronized and reused or inseminated. In any group of synchronized recipients, a small percentage will not be detected in estrus and not all detected in estrus will receive an embryo, due to either an asynchronous estrus or lack of a suitable CL at the time of transfer. If 80% of the synchronized recipients are detected in estrus and 90% of those receive embryos and 60% become pregnant, then less than 45% of any group of recipients will become pregnant. Therefore it is important to devise a strategy to resynchronize recipients as soon as possible.

In large herds with extended calving seasons, it is necessary to synchronize more than one group of recipients. Resynchronization strategies vary depending on the resources and capabilities of the ranch. With the use of ultrasonography, non-pregnant recipients may be confidently identified and resynchronized as early as three weeks after embryo transfer [66]. It is not recommended to transfer an embryo to a recipient more than twice in a given breeding season. Unpublished data from Granada BioSciences Inc. (Marquez, TX, USA) demonstrated that the pregnancy rate between recipients that became pregnant following one or two transfers was not significantly different, but less than 20% of the recipients that received a third embryo transfer became pregnant. However, a single report showed up to a 12% decrease in pregnancy rates for recipients receiving a second embryo transfer [67].

Many purebred producers contract with commercial cow-calf producers to use cows as recipients and purchase the weaned embryo transfer calf. Normally the cooperator synchronizes and observes cows for estrus, sorts recipients 6–8.5 days after estrus, and provides the labor to move the cows through the working facility for a technician to transfer embryos. The purebred producer pays the synchronization expenses and the embryo transfer technician, and pays the cow owner a premium for every embryo transfer calf weaned. This arrangement can be a win–win for both producers. However, there are issues that arise when first beginning this program, as not all commercial producers have the satisfactory management. Therefore a commercial producer already familiar with AI is a good candidate for such a program. It is essential that a producer has a good recordkeeping system, is able to weigh and identify each calf at birth, be comfortable with estrus detection, and have a good herd health program. The purebred producer may expect the cooperator to screen cows for the aforementioned diseases for biosecurity purposes.

American Embryo Transfer Association Survey

In 2011, we conducted a survey of all members of the AETA, regarded as leaders in embryo transfer of cattle in the USA. The goal of the survey was to assess the utilization of current embryo transfer practices, the perception by AETA members of each practice, and whether perceptions were supported by research. A total of 218 professional members received the survey, of whom 63 (29%) responded to the survey; 47 (75%) of the members who responded were certified AETA members, while 27 (43%) classified

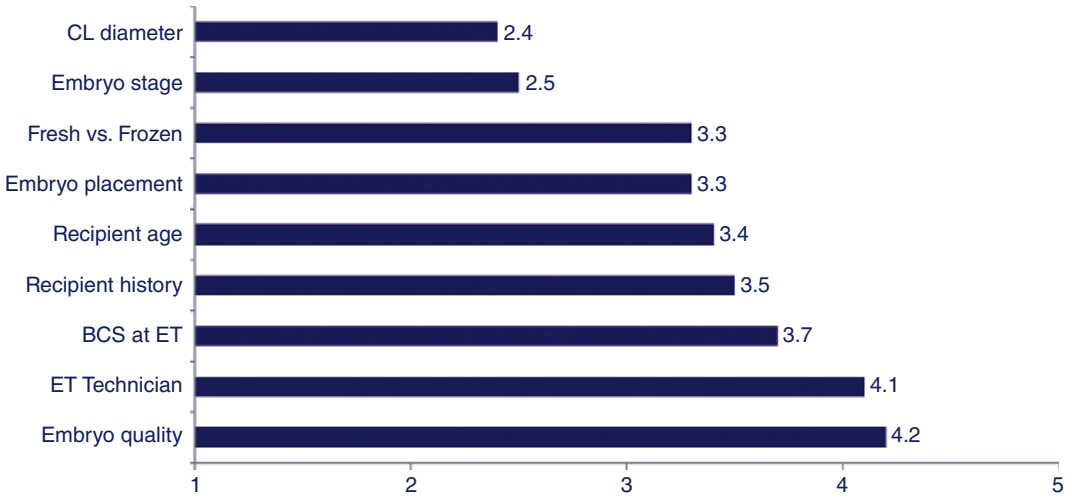

Figure 84.3 Perception of the relative impact on fertility of recipients to embryo transfer (1, least impact to 5, greatest impact). BCS, Body condition score; ET, embryo transfer.

their embryo transfer business as primarily beef cattle related, 13 (21%) as dairy cattle related, 21 (34%) as a mixture of beef and dairy, and one (2%) member was not cattle related. We asked the survey participants to rate their perception regarding several factors that could potentially affect the fertility of cows exposed to embryo transfer and the results are shown in Figure 84.3. Embryo quality was rated as the factor with the greatest impact on fertility. Quality grade of the embryo has a great impact on fertility. In a study comparing pregnancy rates of embryo transfer using embryos graded from 1 to 3 (1 being excellent and 3 being poor), recipients receiving Grade 1 embryos had greater pregnancy rates than recipients receiving Grade 3 embryos (56.1 vs 33.3%, respectively) [68]. Embryo transfer technician was rated the second most important factor affecting fertility of embryo transfer. Differences in pregnancy rates can be seen across embryo transfer technicians [69] and pregnancy rates have been inversely correlated to the time spent in the uterus during embryo transfer [54].

Recipient BCS at embryo transfer was rated of moderate impact on fertility and the effect of nutrition on the success of embryo transfer programs has been discussed in the section "Nutritional Management." Although rated as moderate, the use of fresh or frozen embryos as well as embryo stage at transfer and recipient history has a great impact on the fertility of embryo transfer programs [69]. The diameter of the CL is perceived as having a low impact on fertility of recipients of embryo transfer. In a study evaluating luteal characteristics and plasma concentrations of progesterone in pregnant and non-pregnant recipients, no differences were found in CL diameter, luteal volume, and plasma progesterone concentrations [47].

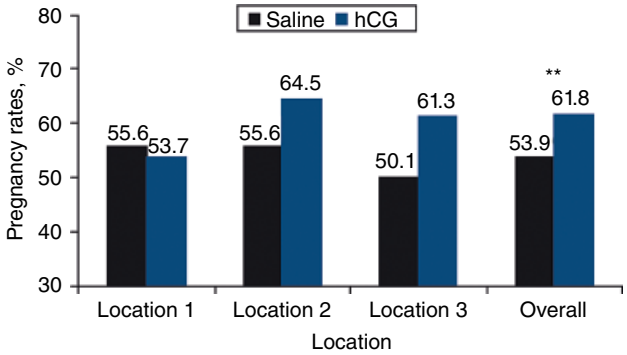

Figure 84.4 Effects of hCG 1000 IU at embryo transfer on pregnancy rates at day 33 (fresh and frozen embryos combined). **; hCG differs from saline, $P = 0.03$. *Source:* Adapted from [70].

Surprisingly, 61% of the survey participants claimed to have no experience with the use of human chorionic gonadotropin (hCG), while 23% claimed that the use of hCG is unsuccessful, and only 16% believed that the use of hCG is successful in embryo transfer programs. Nevertheless, our recent work [70] indicated that treatment with hCG at embryo transfer increased the incidence of accessory corpora lutea formation, increased progesterone in pregnant recipients, and increased transfer pregnancy rates. At three locations, purebred and crossbred Angus, Simmental, and Hereford recipients ($n = 719$) were assigned alternately to receive 1000 IU hCG intramuscularly or 1 ml saline (control) at embryo transfer. Pregnancy rates at the first diagnosis on day 33 were 61.8 and 53.9% for hCG and controls, respectively (Figure 84.4) and were 59.0 and 51.4%, respectively at the second diagnosis on day 68. In agreement with our findings, the use of hCG at embryo transfer also

increased pregnancy rates of Holstein recipient cows receiving FTET [71].

When questioned about the effects of FM on fertility of embryo transfer recipients, 53% of the survey participants claimed that the use of FM was not successful, 18% claimed to have no experience with FM, and only 29% rated the use of FM as successful in embryo transfer programs. In a study evaluating the effects of FM prior to embryo transfer, pregnancy rates were greater for recipients receiving an injection of FM. However, the results varied by location [43]. In another study, FM treatment improved overall pregnancy rates of recipients (65.3 vs 60.2% for FM and control, respectively) and the effects of FM appeared to be even more beneficial when transferring Grade 2 embryos [72].

Finally, we asked participants for their perception of the success of FTET programs; 73% claimed that FTET is successful, while 14% claimed that FTET is unsuccessful, and 13% had no experience with FTET. The use of synchronization protocols excludes the need for estrus detection and increases the number of animals receiving embryos. Most current FTET protocols are based on progestin-releasing devices combined with estradiol or GnRH, which control and synchronize follicular wave dynamics and ovulation. Conception rates to a single FTET have been reported to be similar to those after detection of estrus; however, pregnancy rates are higher because these treatments have increased the proportion of recipients that receive an embryo [68].

Conclusion

For an embryo transfer program to be effective, numerous factors need to be put in place to ensure success. Nutrition, estrous cycle control, and recipient management are all responsible for the success or failure in a given program. Producers, embryologists, veterinarians, and all members of the recipient management team need to be aware of the short- and long-term factors that contribute to recipients conceiving to embryo transfer, maintaining the embryo/fetus to term, delivering the calf without assistance, and raising and weaning a healthy calf.

Summary

A commercially viable cattle embryo transfer industry was established during the early 1970s. Initially, techniques for transferring cattle embryos were exclusively surgical. However, by the early 1980s, most embryos were transferred non-surgically. For an embryo transfer program to be effective, numerous factors need to be put in place to ensure success. Nutrition, estrous cycle control, and recipient management are all responsible for the success or failure in fertility for a given herd. Utilization of BCS is a practical method for determining nutritional status of the recipient herd. Prepartum nutrition is critical to ensure that cows calve in adequate body condition to reinitiate postpartum estrous cycles early enough to respond to synchronization protocols. Estrus synchronization for embryo transfer after detected estrus or for FTET are effective methods for increasing the number of calves produced by embryo transfer. In addition, resynchronization of non-pregnant females effectively ensures that a high percentage of recipients will return to estrus during a 72-hour interval and are eligible for subsequent embryo transfers. Many components need to be assessed to ensure that the recipient herd achieves its reproductive potential. These factors include assessing the merits of nulliparous, primiparous, or multiparous cows, ensuring that facilities allow for minimal stress, and that the herd health program is well defined and followed. Numerous short- and long-term factors contribute to recipients conceiving to a transferred embryo, maintaining the embryo/fetus to term, delivering the calf without assistance, and raising and weaning a healthy calf.

Introduction

Morphological evaluation of embryo quality is performed for three major reasons. The first reason is to differentiate between embryos and unfertilized ova. Careful evaluation of harvested embryos/ova is necessary to ensure that viable embryos are not discarded or, conversely, that unfertilized ova are not transferred or cryopreserved. The second reason is to determine if the developmental stage of the embryos is consistent with the expected developmental stage based on the days since estrus that the embryos were collected. There is often a high degree of variability in observed stage of embryonic development among embryos obtained during embryo recovery from a single donor female, and this variation in stage of development should be considered when selecting a suitable recipient female. The third reason is to enable technicians to have sufficient information on which to base the decision to transfer or to cryopreserve the harvested embryos. Poorer quality embryos that may result in pregnancies if transferred fresh usually do not survive the cryopreservation process.

Despite the importance of this topic, embryo evaluation is a difficult aspect of the overall embryo transfer process to learn, especially if attempting to self-train. Although this chapter will provide numerous helpful photographs of embryos and unfertilized ova, beginners would benefit from joining an experienced embryo transfer mentor for intensive and repetitive training sessions on morphological embryo evaluation. Proper training, proper equipment, and extensive experience are the three major factors affecting one's proficiency with embryo evaluation.

History of Bovine Embryo Evaluation

The very earliest stages of bovine embryonic development (the ovum and 2-cell embryo) were first described in 1931 by Hartman et al [1]. In the following decade two other research groups [2, 3] described and illustrated various stages of bovine embryonic development. These very early descriptions of embryonic development served as the foundation of the morphological embryo evaluation method that subsequently evolved and became widely used in the commercial bovine embryo transfer industry [4].

The morphological embryo evaluation method depends on the human eye to critically evaluate subtle differences among harvested embryos. During the early years of its use, the method was criticized as being too subjective, inconsistent, and prone to error. As a result, several alternative methods for assessing embryo quality were investigated for their potential to be less subjective and more consistent than morphological evaluation. Some of these methods included the ability of an embryo to continue its development during *in vitro* culture [5, 6], the dye exclusion test [7], measurement of embryonic metabolic activity [6], glucose uptake [8], live–dead stains [9], computerized image analysis [10], fluorescein diacetate vital stain [11, 12], DAPI (4′,6′-diamidino-2-phenyl-indole) staining for dead cells [13], and *in vivo* culture in rabbit oviducts [14].

Refinement of the Morphological Embryo Evaluation Method

Despite the numerous attempts to develop a more precise and predictable method to evaluate the viability of bovine

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

embryos, no methods have been devised that are considered better or more accurate than morphological embryo evaluation. This method is the preferred method of embryo viability assessment under clinical conditions because it is a relatively simple and fairly rapid technique for evaluation of bovine embryos.

After the early report on bovine embryo evaluation in 1976 by Shea et al. [4], three other landmark papers on embryo evaluation were subsequently published [15–17]. These practitioners and scientists described the criteria that are, for the most part, still used today as a general guideline for embryo evaluation and prediction of potential pregnancy. Linder and Wright [17] described numerous parameters commonly used for embryo evaluation, including stage of embryonic development and structural features such as embryo size and shape, presence of extruded cells or degenerated cells, color characteristic, number and compactness of the cells (also called blastomeres) that comprise the early embryo, integrity of the zona pellucida, and presence or absence of vacuoles within the cytoplasm of the embryonic cells.

History of the IETS Grading and Classification System

The International Embryo Technology Society (IETS) is an international organization that was born in 1974 in Denver, Colorado, USA. It was created by a group of US practitioners and scientists who recognized the need to share scientific discoveries. As the worldwide commercial embryo transfer industry grew, it became critical to develop standardized embryo nomenclature so that buyers and sellers of embryos knew precisely the stage and quality of embryos being marketed.

The IETS published in their manual [18] a recommended two-digit coding system to uniformly and systematically describe embryos and their characteristics. On completion of the morphological assessment of an embryo, it is assigned two numbers, separated by a hyphen, that correspond to the embryonic stage of development and embryo quality grade. The standardized coding system used to describe the stage of embryonic development ranges from 1 (an unfertilized oocyte) to 9 (expanding hatched blastocyst). The standardized code for embryo quality, based on morphological characteristics of embryos, is also numerical and ranges from 1 (excellent/good) to 4 (dead/degenerating). This IETS embryo grading and classification system must be used for international embryo trade, and because of this mandate most practitioners have adopted this system for everyday use. A more detailed description of the IETS embryo grading and classification system is discussed later in this chapter (see section "IETS Grading and Classification System").

The Importance of a Good Microscope

Before delving into the specific methodology used for morphological evaluation of embryos, it is important to remind readers that proper equipment is needed for accurate embryo evaluation. Although many beginners in embryo transfer are tempted to purchase an inexpensive microscope as a means to reduce start-up costs, doing so will likely create difficulties in finding and evaluating embryos. A poor-quality microscope can make it extremely challenging for a practitioner to tell the difference between an unfertilized ovum (UFO) and a compact morula. Similarly, a practitioner will be hampered by a poor-quality microscope when attempting to discern the various embryo quality grades.

Unlike semen evaluation, where a compound microscope is used, embryo transfer requires the use of a stereomicroscope. Stereomicroscopes, also called dissecting microscopes, are designed for use with three-dimensional specimens. Preimplantation bovine embryos, although microscopic in size, are round like a basketball and thus are best evaluated using a stereomicroscope.

There are several important features of a stereomicroscope that can directly influence one's ability to easily and accurately evaluate embryos. One important feature is the overall magnification. Overall magnification of a stereomicroscope is a function of the magnification of the eyepieces, objective lens, and zoom changer. For example, total magnification of a stereomicroscope equipped with 10× eyepieces, a 1× objective lens, and a 2× zoom changer would be approximately 20× ($10 \times 1 \times 2 = 20$). Many technicians prefer to search for embryos at a total magnification between 10× and 15×, but to effectively evaluate the fine details of an embryo and to identify any abnormalities, such as cracks in the zona pellucida, embryos should be observed under a good optical quality stereomicroscope with a magnification range that reaches at least 50×. It should be noted that the IETS-approved procedure for sanitary handling of embryos requires that embryos be inspected at a magnification of at least 50×.

Most embryo transfer technicians prefer that the eyepieces not exceed 10× in order to maintain an adequate field of view and image resolution. A microscope equipped with a diopter adjustment on one eyepiece (if not both) is very useful for compensating for differences in eyesight between a technician's left and right eyes. An adjustable binocular tube will also enable multiple technicians with varying interpupillary distances to use the same stereomicroscope.

A second important feature of a stereomicroscope for embryo handling and evaluation is the working distance (distance from the embryo to the objective lens). The working distance should be long to give maximal flexibility when searching for embryos, and the microscope stage should be large and free of obstacles such as stage clips, power buttons, or similar items that make sliding of Petri dishes on the stage difficult. A large and clear stage is important for providing adequate space to move Petri dishes and to operate the embryo handling device without accidently spilling the Petri dish and losing the embryos.

A third important feature of a stereomicroscope used for embryo evaluation is the illumination. The illumination should come from underneath the stage plate and it should be bright and uniform across the entire stage plate. A clear stage plate is needed; frosted stage plates are not suitable for embryo work. Brightfield illumination is standard for most stereomicroscopes, but darkfield illumination can be helpful when searching through "cloudy" fluids in a search dish.

Normal *In Vivo* Bovine Embryonic Development

In order to know whether embryos harvested from a donor have developed at the expected rate, it is important for technicians to have a good understanding of normal *in vivo* bovine embryonic development. The overall diameter of a bovine embryo is 150–190 µm (or about 15 times the size of white blood cells), which includes the zona pellucida thickness of approximately 12–15 µm [17]. The overall diameter of the zona pellucida-enclosed embryo remains virtually unchanged from the 1-cell stage of development until the blastocyst stage of development because blastomeres (individual cells of an embryo prior to cellular differentiation at the blastocyst stage of development) become progressively smaller with each cell division.

The zona pellucida is a translucent shell surrounding an embryo from the 1-cell until the expanded blastocyst stage of development. The zona pellucida functions as a physical barrier against pathogens, contains receptors for sperm, and blocks accessory sperm from reaching the ovum. Once an embryo reaches the expanded blastocyst and continues to grow, the embryo becomes so large that it ruptures the zona pellucida and "hatches."

During normal *in vivo* embryonic development, blastomeres go through a series of cleavage divisions. The ovum, after fertilization, divides and develops into a 2-cell embryo, the 2-cell develops into a 4-cell, the 4-cell into an 8-cell, and so on. When the blastomeres appear like a cluster of grapes and individual blastomeres cannot be differentiated, this stage of embryonic development is known as the morula stage. As the embryo further develops, it prepares to undergo its first differentiation event known as blastulation. Just prior to this differentiation event, cells of the morula "compact" and are allocated to the "inside" and "outside" parts of the embryo.

Once blastulation has occurred, the embryo is at the blastocyst stage of embryonic development. The blastocyst contains two populations of differentiated cells: an outer ring of trophoblast cells and an inner clump of cells known as the inner cell mass (ICM). The ICM will give rise to the fetus and most layers of the placenta, while the trophoblast cells will eventually form the outermost layer of the placenta. The blastocyst stage of embryonic development has another distinguishing feature, the presence of a blastocoele cavity. This fluid-filled cavity is surrounded by the trophoblast cells and grows progressively larger to help cause thinning of the zona pellucida prior to embryo hatching. Figure 85.1 illustrates the features observed in a blastocyst-stage bovine embryo, while Figure 85.2 shows the stages of bovine embryonic development.

IETS Grading and Classification System

Embryos are typically recovered six to eight days after the onset of estrus. Harvested embryos should be classified into groups based on their stage of embryonic development and quality grade. Table 85.1 illustrates the current IETS embryo evaluation system followed by a detailed description of these developmental stages. After a technician completes the embryo evaluation process, a two-digit code is assigned to each embryo. For example, a fair-quality early blastocyst would be denoted as 5-2. A blastocyst-stage embryo of excellent or good quality would be denoted as 6-1.

Stage of Embryonic Development

Stage Code 1 : 1-Cell

For any entity recovered on days 6–8 that is truly only a single cell, it is safe to assume that it is a UFO. However, a

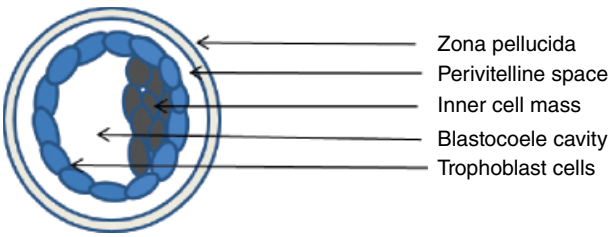

Figure 85.1 A blastocyst-stage bovine embryo.

Table 85.1 IETS recommended codes for embryonic stage of development and embryo quality grade.

Stage of embryonic development		Quality grade of embryo	
Code	**Stage**	**Code**	**Quality description**
1	Unfertilized	1	Excellent or good
2	2-cell to 12-cell	2	Fair
3	Early morula	3	Poor
4	Morula	4	Dead or degenerating
5	Early blastocyst		
6	Blastocyst		
7	Expanded blastocyst		
8	Hatched blastocyst		
9	Expanded hatched blastocyst		

challenging task for an inexperienced technician is to distinguish a UFO from a compact morula (stage code 4, see below). Discerning a UFO from other stages of embryonic development can also be difficult because not all UFOs have the same morphological appearance. Many "normal" UFOs have a perfectly spherical zona pellucida, perfectly spherical oolemma (also called the vitelline membrane), relatively uniform granularity in the cytoplasm, and a moderate volume of perivitelline space. However, other UFOs may show varying signs of degeneration including cytoplasmic fragmentation, which can lead to the illusion of a blastocoele cavity and/or appearance of cell division, and extreme condensation, which can lead to confusion with a compact morula.

Stage Code 2 : 2-Cell to 12-Cell

Cells of a preimplantation embryo prior to morphological and functional differentiation are called blastomeres. Any embryo recovered six to eight days after the onset of estrus

that contains 2–12 blastomeres is almost certainly dead or degenerate. Under normal conditions this stage of embryonic development is expected to be present in the oviduct (not the uterus) prior to day 5 of the bovine estrous cycle (day 0 = onset of estrus). Clearly, if a 2- to 12-cell embryo were somehow still viable, its development is severely delayed and it should not be considered for transfer or cryopreservation.

Stage Code 3: Early Morula

The term "morula" has its origin in the Latin word for mulberry. Embryos at the morula stage of embryonic development consist of a group of at least 16 cells. Although some individual blastomeres are easy to visualize, others are only partially visible as they are "hidden" by other blastomeres. This stage of embryonic development, like all stages of development discussed previously, is not well suited for cryopreservation.

Stage Code 4: Compact Morula

Individual blastomeres present in this embryo have coalesced to form a tightly compacted ball of cells. It is impossible to discern individual blastomeres at this stage of embryonic development. As a part of the compaction process, cells are allocated to the "inside" and also to the "outside" part of the ball of cells. The cells on the outside of the ball form tight junctions with one another in a contiguous ring. The cells comprising the embryo occupy approximately 60–70% of the space inside the zona pellucida (called the perivitelline space). As stated earlier, it is this stage of embryonic development that can be easily confused with a UFO.

Stage Code 5: Early Blastocyst

The most distinguishing characteristic of an early blastocyst-stage embryo is the presence of a small fluid-filled cavity known as the blastocoele. Several differentiated trophoblast cells will also be visible between the blastocoele cavity and the zona pellucida, although the ability to distinguish them from the cells of the ICM is quite limited at this stage. The cells comprising the embryo occupy approximately 70–80% of the perivitelline space. The zona pellucida is still the same thickness as the less developmentally advanced stages of embryonic development previously discussed.

Stage Code 6: Blastocyst

A blastocyst-stage embryo will have a clearly defined trophoblast layer, blastocoele cavity, and group of ICM cells, along with a normal-thickness zona pellucida. There will be little to no perivitelline space present except in cases where the embryo may be partially collapsed.

Stage Code 7: Expanded Blastocyst

The most distinguishing feature of an expanded blastocyst-stage embryo is an increase in its overall diameter, 1.2–1.5 times larger than its original diameter of 150–190 μm, coupled with a thinning of the zona pellucida to approximately one-third of its original thickness of 12–15 μm. Because of the large increase in the volume of the blastocoele cavity at this stage of embryonic development, no perivitelline space is present. Interestingly, expanded blastocyst-stage embryos frequently appear collapsed. This phenomenon is characterized by a partial loss of blastocoele cavity fluid and is believed to be a normal phenomenon that contributes to embryo hatching. The zona pellucida, once thinned, never regains its original thickness.

Stage Code 8: Hatched Blastocyst

Hatched blastocyst-stage embryos can be undergoing the process of hatching or may have completely hatched from the zona pellucida. Embryos at this stage may be spherical with a well-defined blastocele cavity or may be collapsed. Identification of this stage of embryonic development can be quite difficult if the embryo has completely hatched from the zona pellucida and has nearly totally collapsed because it can easily be mistaken for a piece of endometrial tissue. This stage of embryonic development is not eligible for international trade because the non-intact zona pellucida makes it impossible to wash the embryo in accordance with IETS procedures for sanitary handling of embryos [20].

Stage Code 9: Expanded Hatched Blastocyst

This stage of embryonic development is identical in appearance to a completely hatched stage code 8, except for being significantly larger in diameter. It is uncommon to recover expanded hatched blastocysts from bovine donor females unless flushing is performed more than eight days after the onset of estrus. This stage of embryonic development is not eligible for international trade.

Embryo Quality Grade

Embryo quality grade is determined by visual assessment of an embryo's morphological characteristics. Characteristics used to determine the quality grade of an individual embryo include uniformity of blastomeres (size,

color, and shape), presence of extruded cells, presence of dead/degenerating blastomeres, degree of cytoplasmic granularity, presence of cytoplasmic vacuoles, cytoplasmic fragmentation, and structural integrity of the zona pellucida.

Quality Grade Code 1: Excellent or Good

A quality grade 1 embryo has a symmetrical and spherical embryo mass with individual cells that are uniform in size, color, and density. The embryonic stage of development is consistent with that expected based on the day of the donor female's estrous cycle when the embryo was recovered. Irregularities (such as cytoplasmic vacuoles), if any, are relativity minor, and at least 85% of the embryonic cells are an intact, viable, and cohesive mass (i.e. no more than 15% of embryonic cells are extruded into the perivitelline space). The zona pellucida should be spherically shaped and smooth, with no concave or flat surfaces that might cause the embryo to adhere to a Petri dish or straw.

Quality Grade Code 2: Fair

Moderate irregularities exist in the overall shape of the embryonic mass or in the size, color, and density of individual cells comprising the embryo. Mild unevenness of cytoplasmic pigmentation within individual blastomeres (do not confuse this with translucency of the blastocoele cavity and darkness of the ICM cells of a blastocyst-stage embryo), "peppering" of cytoplasm within individual blastomeres, and/or a small number of vacuoles within the cytoplasm of blastomeres would be sufficient to warrant a quality grade 2 score. At least 50% of the embryonic cells should be an intact, viable, and cohesive embryonic mass.

Quality Grade Code 3: Poor

Major irregularities exist in the shape of the embryonic mass or in the size, color, and density of individual cells. Extreme unevenness of cytoplasmic pigmentation within individual blastomeres, significant "peppering" of cytoplasm within individual blastomeres, and/or large numbers of vacuoles within individual blastomeres are sufficient to warrant a quality grade 3 score. At least 25% of the embryonic cells should be an intact, viable, and cohesive embryonic mass. Multiple extruded cells of widely varying sizes, indicating a prolonged and persistent problem with the cohesiveness of embryonic blastomeres, would cause an embryo to be assigned a quality grade 3 score.

Quality Grade Code 4: Dead or Degenerating

Entities that are assigned a quality grade 4 score are nonviable and should not be transferred to recipient females or cryopreserved. Dead/degenerating embryos typically fall in this category because of extremely dark cytoplasm, nonintact cell membranes, and other significant defects. Because embryos typically are recovered on approximately day 7 of the estrous cycle, any embryo that has not advanced to at least the morula stage of embryonic development should be assigned an embryo quality grade 4 score.

Despite the strong correlation that exists between embryo quality grade and post-transfer pregnancy rate, some quality grade 1 embryos fail to produce a pregnancy after transfer, whereas some quality grade 3 embryos produce a higher than expected pregnancy rate. The *IETS Manual* [19] states:

> It should be recognized that visual evaluation of embryos is a subjective valuation of a biological system and is not an exact science. Furthermore, there are other factors such as environmental conditions, recipient quality, and technician capacity that are important in obtaining pregnancies after transfer of embryos.

Embryo Evaluation Procedure

During the recovery procedure, embryos are typically collected using an embryo filtration device that minimizes the volume of flushing medium through which the technician must search to locate the embryos. Some embryo filtration devices also serve as the embryo search dish, whereas other devices require that embryos be transferred from the filtration device to a Petri dish for searching. After embryos are recovered, they must be located in the recovery medium using a stereomicroscope typically under 10–15× magnification. Embryos are subsequently transferred to a Petri dish containing embryo holding medium, where they will be evaluated at a minimum magnification of 50× before being assigned the two-digit IETS code for stage of development and embryo quality.

As illustrated in Figure 85.2, the compact morula, early blastocyst, and blastocyst stages of embryonic development are the ones most commonly recovered on day 7 after estrus. The expanded blastocyst is typically recovered on day 8 but can sometimes be found after a day-7 embryo recovery. The zona pellucida, because of its translucency and ability to refract light, is the landmark structure that helps technicians identify embryos and ova during the search procedure. Once an embryo progresses to the

hatched blastocyst stage it may become harder to identify because it may have a collapsed appearance and, without the zona pellucida, it can easily be mistaken for endometrial cells or other cellular debris in the Petri dish.

Although each harvested embryo must be assigned its own two-digit code, there is great value in examining all harvested embryos/ova as a group. This comparative evaluation usually makes it easy for the technician to distinguish UFOs from embryos, as well as to compare embryos that are expanded and have a thinner zona pellucida with embryos that have not yet expanded.

A good predictor of an embryo's viability is its stage of development relative to what it should be on a given day after estrus. From a superovulated cow, one should expect variety in the stages of embryonic development recovered because there is variation in the time at which ovarian follicles rupture and release their ova. Similarly, one should also expect variation in embryo quality grade. It is not uncommon to obtain from the same donor female excellent quality embryos in addition to UFOs and degenerate embryos. Based on the American Embryo Transfer Association (AETA) survey report [21], the average number of viable embryos recovered from dairy donors was 5.7 (representing 56% of the total ova/embryos recovered) and from beef donors was 6.9 (also representing 56% of total ova/embryos recovered). The average number of degenerate embryos and unfertilized ova recovered was 1.6 (14% of total embryos/ova) and 3.1 (29% of total embryos/ova), respectively, from dairy donors and 2.0 (15% of total ova/embryos) and 3.5 (27% of total ova/embryos), respectively, from beef donors.

Practical Application of Embryo Evaluation Guidelines

To help technicians learn how to properly evaluate bovine *in vivo* derived embryos, Figure 85.3 depicts (using photographs of actual bovine ova and embryos) the range in embryonic developmental stage that may be obtained after performing a day-7 embryo recovery. A more developmentally advanced embryo (expanded hatched blastocyst) is shown in Figure 85.3b, although an embryo at this developmental stage is not usually expected on day 7. Many people find the side-by-side photos of actual specimens more helpful for learning embryo grading and classification than illustrations/sketches. In addition to the composite image in Figure 85.3 depicting the range in embryonic developmental stages, the figures in the remainder of this chapter show not only the principles of embryo grading and classification but also some of the common challenges faced by embryo technicians.

One important point to make before proceeding further is that although each stage of embryonic development is assigned a specific code, embryos are continually developing and are gradually transitioning from one stage of development to the next. As a result, many embryos may actually be between two different developmental stages at the time of recovery. Any time an embryo is making the transition from one stage to the next, it increases the likelihood that it may be called one developmental stage by one technician and a different developmental stage by another technician (e.g. stage 4 by some and stage 5 by others).

The following discussion of embryo evaluation is divided into sections on non-transferable quality embryos and transferable quality embryos.

Non-Transferable Quality Embryos

During the initial phase of the embryo evaluation process, most technicians segregate non-viable (non-transferable quality) ova/embryos from viable (transferable quality) embryos. Obviously, non-viable embryos should not be transferred to recipient females nor should they be cryopreserved.

Unfertilized Ova

Unfertilized ova collected six to eight days after the onset of estrus can have many different physical appearances (Figure 85.4). The three major keys to identifying a UFO are (i) the vitelline membrane (also called the oolemma) that surrounds the cytoplasm of the ovum is smooth and nearly perfectly spherical unless the ovum is fragmented or degenerate; (ii) the cytoplasm is granular and not cellular in appearance; and (iii) there is a moderate amount of perivitelline space (the space between the ovum and the zona pellucida), except in cases of degeneration.

As alluded to above, it can be frustrating to definitely determine the stage of development of ova that have undergone degeneration or fragmentation. Degenerate ova can, on occasion, appear very similar to a compact morula. Fragmentation, sometimes referred to as cytoplasmic blebbing, is a process during which some of the cytoplasm (which does not contain any chromosomes or chromosomal DNA) segregates itself from the ovum, resulting in a specimen that appears to be multicellular. Typically, the structure formed as a result of fragmentation is far smaller in size than would be expected for a blastomere of a 2-cell or 4-cell embryo. However, unless a fragmented ovum is exposed to a DNA-specific stain (e.g. bis-benzimide), one cannot determine with certainty if the entity is a stage code 2 embryo or a fragmented ovum. From a very practical

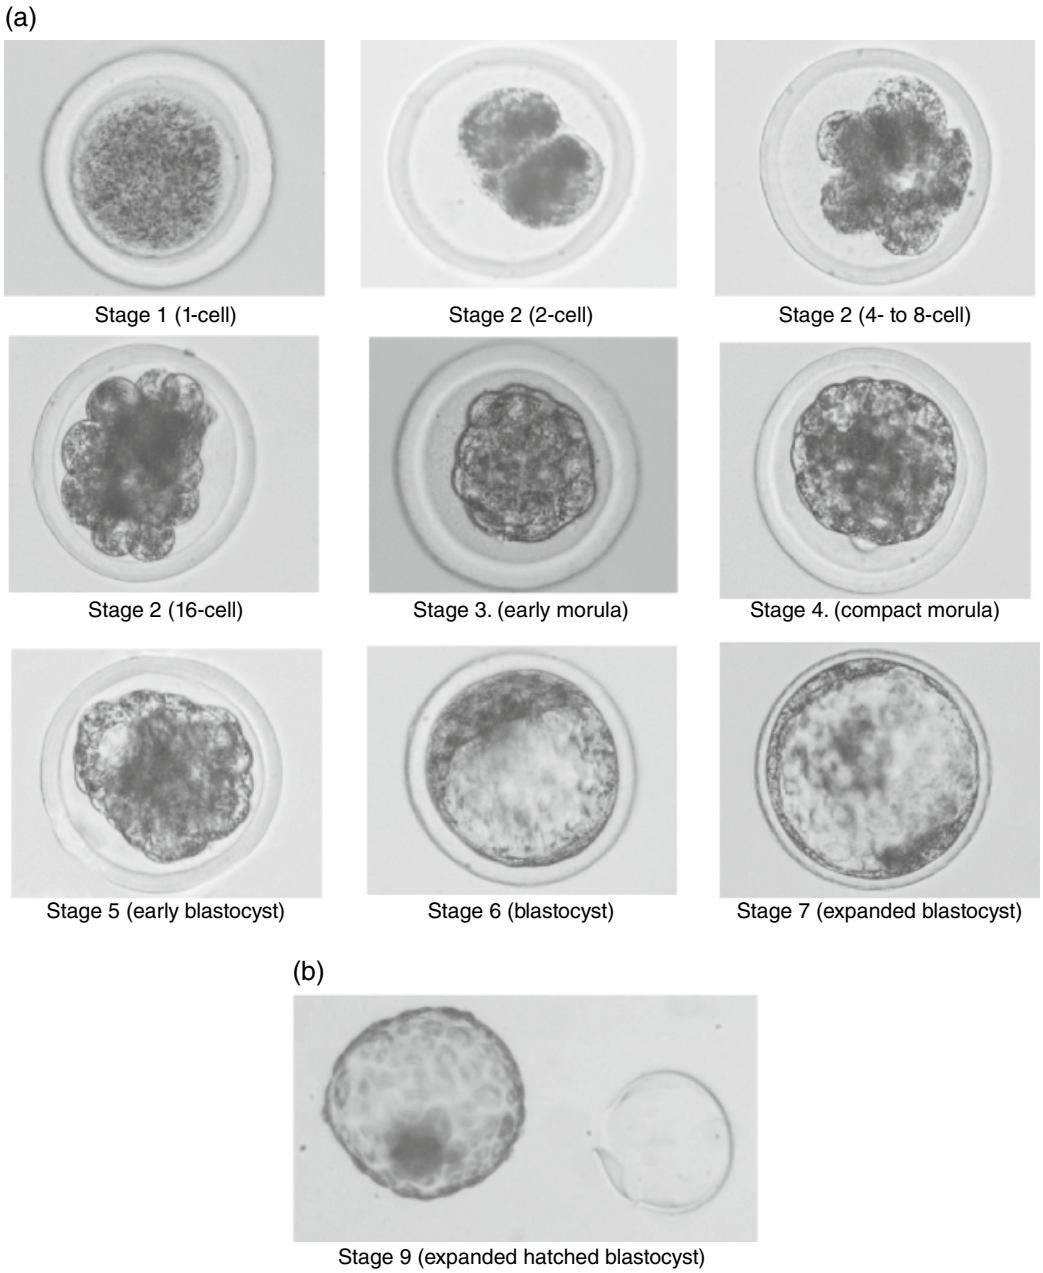

Figure 85.3 (a) Comparison of developmental stages of *in vivo* derived bovine embryos collected on days 6–8 after estrus. At day 7, a stage code 1 embryo is considered an unfertilized ovum and a stage code 2 embryo is considered dead or degenerate. (b) Expanded hatched blastocyst typically recovered on or after day 8 after estrus; note the empty zona pellucida on the right and the expanded embryo on the left. *Source:* Image b courtesy of Dr. Brad Lindsey.

perspective, however, the distinction between stage code 1 and stage code 2 is irrelevant because neither is suitable for transfer.

Dead or Degenerating Embryos

If embryos at stage code 2 are collected on day 7, the stage of embryonic development is not consistent with the expected stage of development. Therefore these embryos are classified as degenerate (quality grade 4) because they are severely retarded in their development. Degenerate embryos are ones that have been fertilized but which died some time during the developmental process.

An embryo could also be considered dead or degenerate if its blastomeres are not fused to one another (i.e. there is lack of tight cell junction formation between the cells of the embryo). Failure of blastomeres to develop in a tight and cohesive group, to compact, and to form tight cell

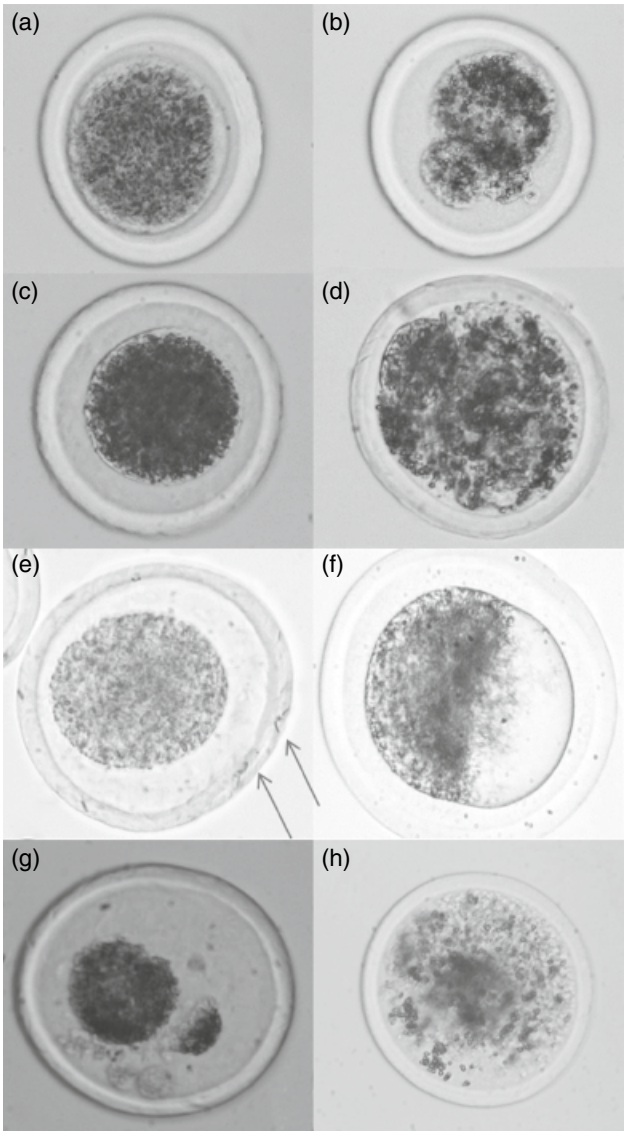

Figure 85.4 Unfertilized ova recovered non-surgically from superovulated donor cows six to eight days after the onset of estrus. Note the extremely wide variation in morphology which makes accurate identification difficult for inexperienced embryo technicians. (a) Unfertilized ovum with smooth vitelline membrane and granular cytoplasm that can be mistaken for a compact morula. (b) Fragmented unfertilized ovum. (c) Unfertilized ovum possessing dark cytoplasm and a smooth vitelline membrane; can be mistaken for a compact morula. (d) Degenerate unfertilized ovum. (e) Unfertilized ovum with light-colored granular cytoplasm; note sperm (arrows) attached to the zona pellucida. (f) Unfertilized ovum with smooth vitelline membrane; ovum is granular in one half and clear in the other half; can be mistaken for a blastocyst-stage embryo. (g) Fragmented unfertilized ovum. (h) Degenerate unfertilized ovum; note "loss" of vitelline membrane.

junctions is a sign that the embryo is in the process of degenerating or dying (Figures 85.5 and 85.6). Note in Figure 85.6 a compact morula (a) next to a degenerate/dead embryo (b).

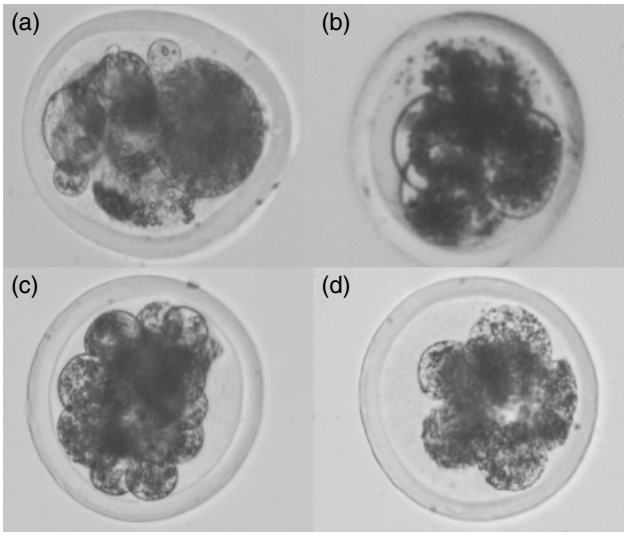

Figure 85.5 Degenerate bovine embryos collected on day 7: (a) and (b) are degenerate and are considered dead; (c) and (d) are not as developmentally advanced as expected for a day-7 embryo, and the cells are not fused tightly to one another, so are also considered degenerate.

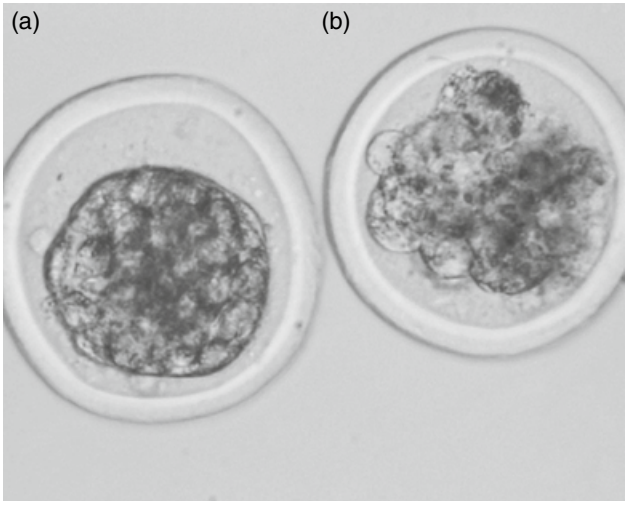

Figure 85.6 Day-7 compact morula (a) adjacent to a degenerate embryo (b).

Transferable Quality Embryos

Once a technician has discarded UFOs and non-transferable quality embryos, attention should be directed to the remaining embryos that are of transferable quality. In a perfect world, all transferable quality embryos would be quality grade 1. However, this is not the case. There are a number of "defects" in transferable quality embryos that can cause their embryo quality grade to be lowered to a quality grade 2 or 3. These "defects" are discussed in some detail in the following text.

What are the characteristics of a quality grade 1 embryo? In essence, it is the lack of "defects" that would lead to assignment of a quality grade 1. Although a number of quality grade 1 embryos have already been shown (e.g. Figures 85.3 and 85.6), the main emphasis in the remaining discussion will be on identification of the embryo "defects" that lead to assignment of lower quality grade scores. In many photographs, however, quality grade 1 embryos will be shown side by side with quality grade 2 and 3 embryos, as well as UFOs, for easy comparison.

A number of morphological characteristics of an embryo can be considered as a deviation from normal. These abnormalities can include irregular sizes of embryonic blastomeres, large and/or multiple vacuoles within the cytoplasm of embryonic cells, degeneration of one or more cells in the embryo, some cells not adhering to the other cells comprising the embryo (i.e. extruded blastomeres/cells), and a damaged or misshapen zona pellucida. Many viable embryos have some detectable morphological abnormality such as a small number of extruded cells. Embryo quality grading must consider not only the presence or absence of these abnormalities but also the extent/degree to which these deviations are expected to influence post-transfer embryo survival. Experience has shown, for example, that an embryo that possesses a few degenerate cells but which consists mostly of normal appearing cells has an excellent chance of establishing a pregnancy and producing a live calf.

Extruded Cells

One abnormality that occurs somewhat frequently during preimplantation embryonic development is failure of all cells of an embryo to continue developing. Ordinarily, all cells of an embryo adhere to and communicate with one another. However, in certain cases some cells do not participate with their cohorts in normal embryonic development. The cells that do not fully participate in embryonic development are known as extruded cells because they are not adhered to the rest of the embryo and are found in the perivitelline space. Extruded cells often detract from the developmental potential of an embryo, particularly when the cells are extruded early in the developmental process. Thus, the size and number of extruded cells directly impacts embryo quality grade.

Extruded cells typically do not divide, and the extrusion of cells from an embryo can occur at any developmental stage beginning at the 2-cell stage. As long as a substantial number of blastomeres within an embryo remain healthy, the embryo can produce a viable pregnancy even when extruded cells are present. The rate of pregnancy depends on the number and size of extruded cells. Several examples of embryos possessing extruded cells are shown in Figures 85.7–85.11. It should be noted that extruded cells in stage code 6 and 7 embryos get pressed against the zona pellucida and may not be obvious (Figure 85.11) or may lead to assignment of a lower than deserved quality grade score (Figure 85.9). Embryos should be rolled in the Petri dish to enable views from multiple angles.

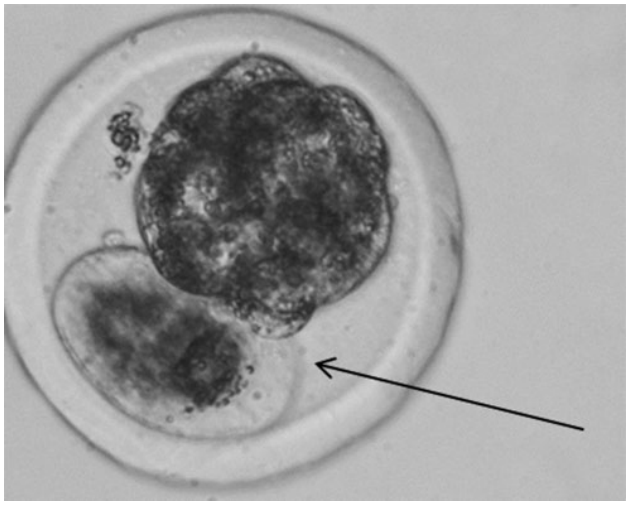

Figure 85.7 Grade 2 compact morula. Note one large blastomere (arrow) has stopped dividing, while others have formed a compact morula.

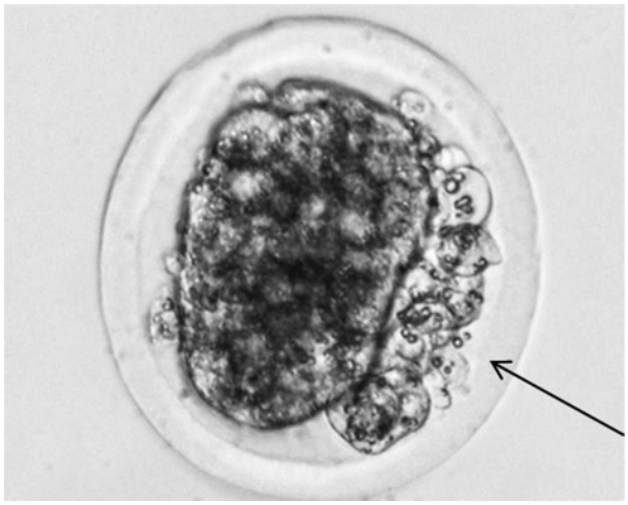

Figure 85.8 Grade 2 morula. Note several extruded blastomeres (arrow) to the right side of the embryo.

Misshapen or Flat Zona Pellucida

A zona pellucida is considered misshapen if it is not spherical or has a flat or concave surface that can cause the embryo to stick to a Petri dish or straw. This defect, by itself,

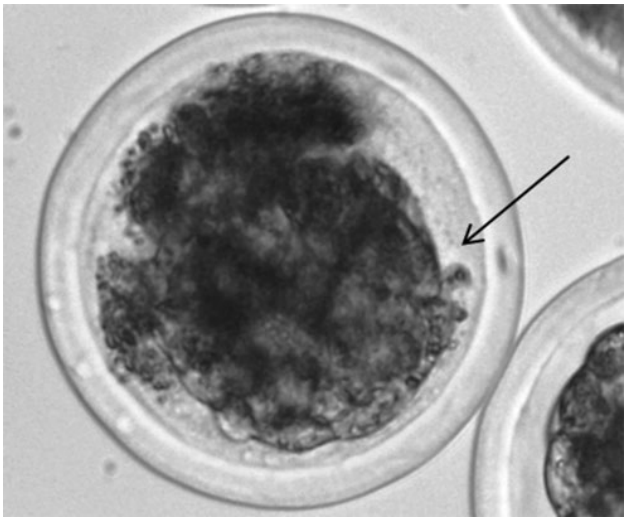

Figure 85.9 Grade 3 morula. Note embryonic cell mass on the right side (arrow) hidden by a large number of extruded cells in the upper left corner and left side. May be called grade 4 by some without rolling this embryo.

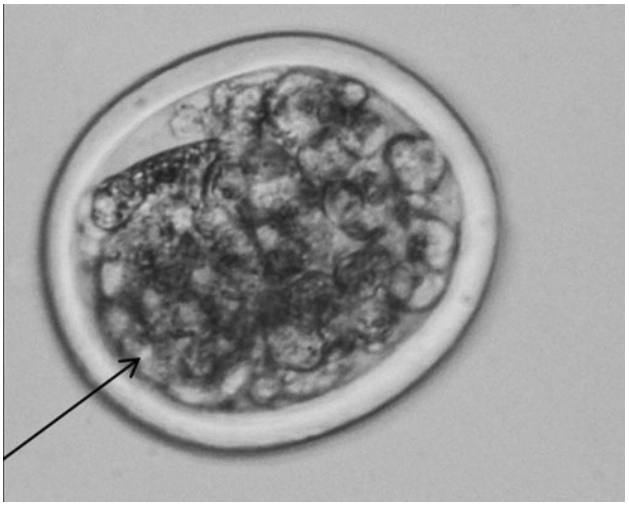

Figure 85.10 Grade 4 morula. Note the small group of cells on the left side (arrow) and very large number of extruded cells on the right. This embryo was identified as grade 4 by our laboratory but may be called grade 3 by others.

is sufficient to cause a lowering of embryo quality grade by one grade (e.g. from quality grade 1 to quality grade 2). Figure 85.12 depicts an early blastocyst-stage bovine embryo with a misshapen zona pellucida.

Lipids in the Cytoplasm

Although lipids are an essential component of cell membranes and must be present in viable embryos, some embryos possess an abnormal accumulation of lipid

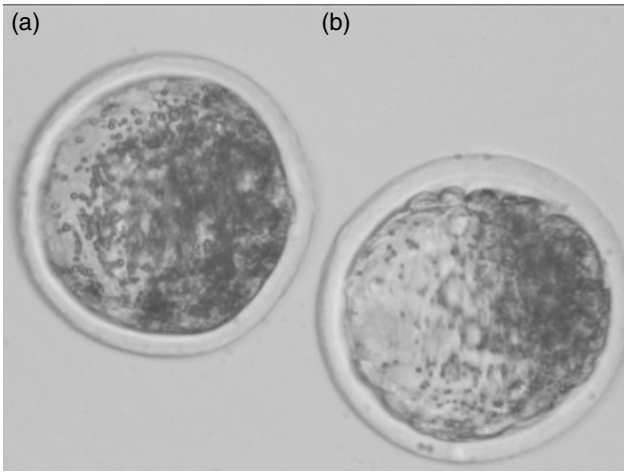

Figure 85.11 Embryos (a) and (b) are both IETS 6–1 embryos. Extruded cells in stages 6 and 7 embryos are often pressed against the zona pellucida and may not be obvious unless the embryo is collapsed. (a) It is difficult to identify this embryo as a blastocyst without rolling the embryo and having a good view of the blastocoele cavity which is obscured by the extruded cells on top. It could be easily mistaken for a degenerating unfertilized ovum.

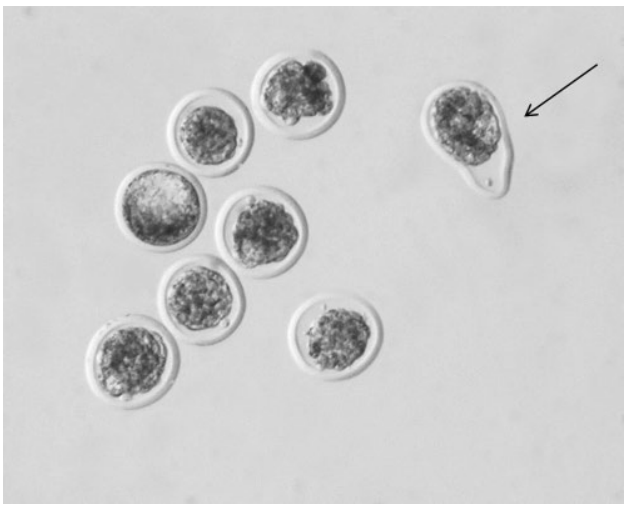

Figure 85.12 The arrow points to a day-7 grade 2 early blastocyst-stage embryo with a misshapen zona pellucida (50×).

droplets (also called vacuoles) within the cytoplasm of individual cells. Most technicians will lower the quality grade of an embryo that possesses more than a few small vacuoles. A high cytoplasmic lipid content may be a cause of decreased pregnancy rates after transfer of frozen–thawed embryos, especially with embryos from the Jersey breed of dairy cattle [22]. Figures 85.13 and 85.14 show the presence of vacuoles within individual cells of bovine embryos.

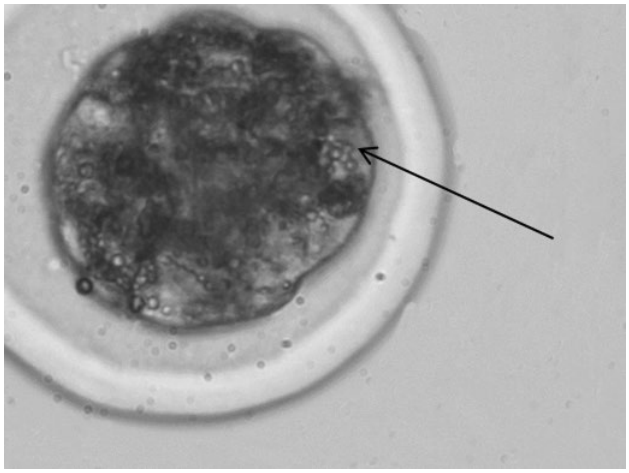

Figure 85.13 Grade 1 compact morula with vacuoles (arrow) in the cytoplasm.

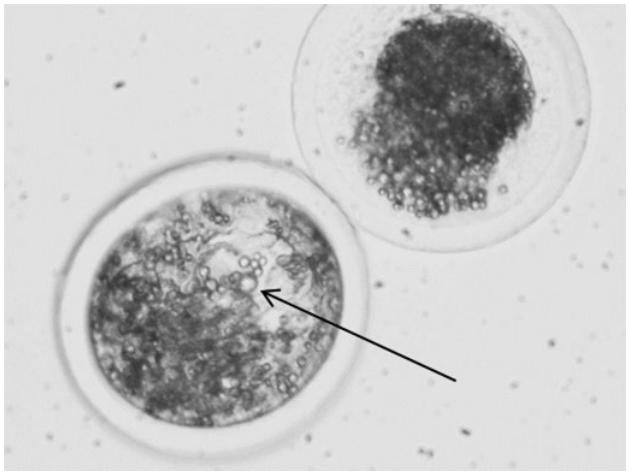

Figure 85.14 Grade 2 bovine blastocyst containing vacuoles (arrow) in the cytoplasm beside an unfertilized ovum. Note that it is difficult to identify the blastocyst embryo without rolling the embryo and having a good view of the blastocoele cavity. Could easily be mistaken for a degenerating unfertilized ovum.

Cracked Zona Pellucida

Typically, a cracked zona pellucida is found only in hatching blastocyst-stage embryos (stage code 8). However, some embryos can exhibit a cracked zona pellucida at earlier developmental stages, presumably due to the hydrostatic pressure placed on the embryo during the embryo recovery process (Figures 85.15–85.17). Although a cracked zona pellucida does not automatically lower the embryo quality grade, only embryos possessing an intact zona pellucida can be washed properly [20] and remain eligible for export. However, they can still be frozen for domestic use.

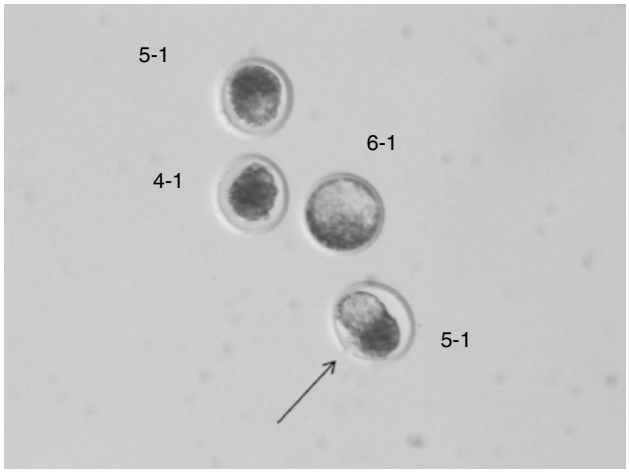

Figure 85.15 Collapsed early blastocyst with a cracked zona pellucida (arrow).

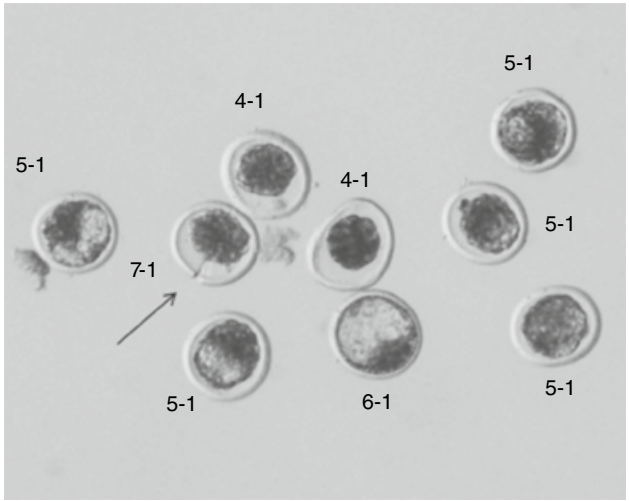

Figure 85.16 Day 7 group of embryos collected from a single donor. Note the embryo with a cracked zona pellucida (arrow) that could be either a morula or a collapsed blastocyst. The thinning of the zona pellucida and slightly larger overall diameter gives supporting evidence that it is a collapsed expanded blastocyst.

Irregular Shape of Cells Comprising the Embryo

An irregular shape of the group of cells comprising the embryo is commonly observed, especially in blastocyst-stage embryos when the blastocoele cavity is forming. Collapsing of the blastocoele cavity is considered a normal physiological process that does not automatically lower the quality grade, except in cases when the zona pellucida is also misshapen. Figure 85.18 depicts a group of embryos with normal and irregular shapes.

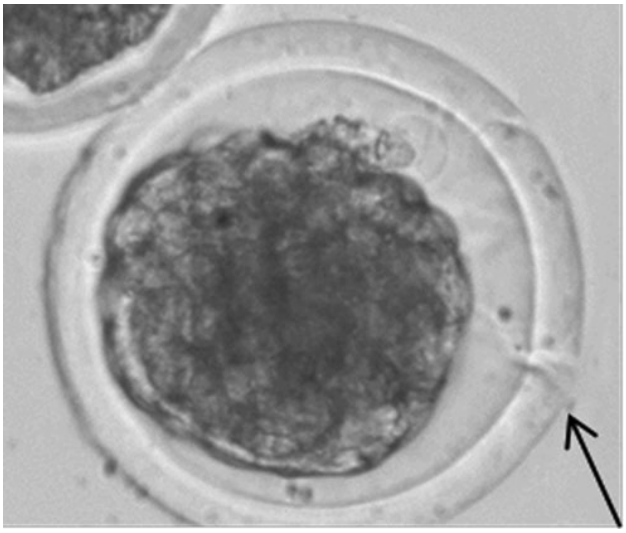

Figure 85.17 Day 7 compact morula. Note the crack in the zona pellucida (arrow).

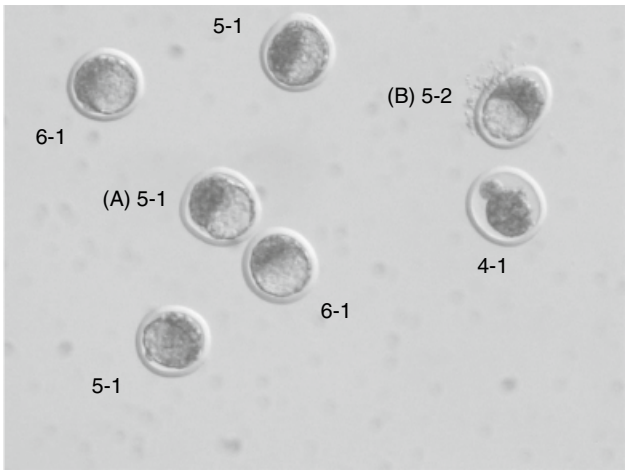

Figure 85.18 Day 7 grade 1 bovine early blastocyst (a) with slightly irregularly shaped cell mass. Day 7 grade 2 early blastocyst (b) with misshapen cell mass and zona pellucida.

Material Adhering to the Zona Pellucida

At the time of embryo recovery, it is not uncommon for some embryos to have material adhered to the outer surface of the zona pellucida. The adherent material may be mucus, individual cells, or a clump of tissue. Adherent material on the zona pellucida may be a sign of endometritis in the donor, cumulus cells that were not removed during normal gamete transport, or donor endometrial cells. Figures 85.19 and 85.20 depict bovine embryos with adherent material. The adherent debris can frequently be washed off the zona pellucida during the IETS-approved embryo washing procedure [20]. In some cases, it may be necessary to include washing in a 0.25% solution of trypsin. Washing embryos with an intact zona pellucida in accordance with IETS washing guidelines should remove the adherent debris, as well as most pathogens.

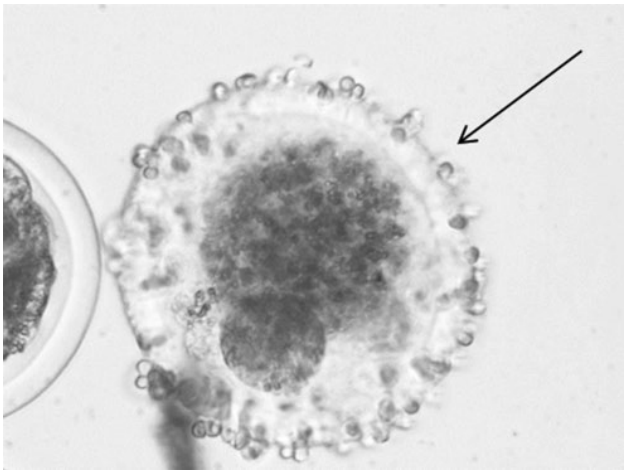

Figure 85.19 Fragmented unfertilized ovum. Note the white blood cells (arrow) attached to the zona pellucida.

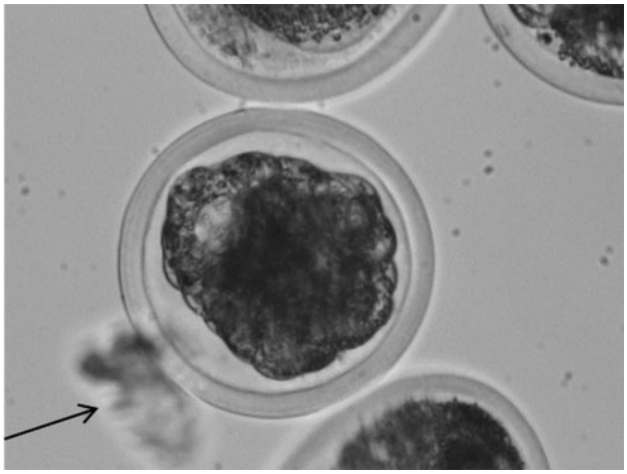

Figure 85.20 Day 7 early blastocyst (5-1). Note the endometrial cells (arrow) adhering to the zona pellucida. These cells must be removed prior to transfer or cryopreservation.

The presence of debris attached to the outer surface of the zona pellucida does not necessarily influence the assignment of an embryo quality grade. However, any embryo with adherent material is not eligible for commercial trade, either domestically or internationally.

Challenges to Accurate Embryo Grading and Classification

One very difficult task for technicians who are learning to grade and classify embryos is to properly distinguish between a compact morula and a UFO, two entities that

can look very similar in size, shape, and color. Figure 85.21 shows a group of compact morula and unfertilized ova side by side, and it is easy to envision how an inexperienced technician may inadvertently describe all these entities as either compact morula or unfertilized ova. This would be especially true when examining the specimens at a lower magnification or with a poor optical quality stereomicroscope. A more highly magnified view of an excellent quality compact morula and a UFO is shown in Figures 85.22 and 85.23. These are good examples of how these two stages of embryonic development are sometimes difficult to differentiate. As stated earlier, it is vitally important to be able to distinguish a compact morula from a UFO to prevent transfer (or cryopreservation) of a UFO and/or the disposal of a compact morula. With sufficient experience in grading embryos, it becomes easier to distinguish these two developmental stages.

Another common misclassification error can occur in instances when a portion of a UFO degenerates and becomes lighter, resembling the blastocoele cavity in a blastocyst-stage embryo (Figure 85.24). Experienced technicians will be able to distinguish the two by looking for the trophoblast layer which "surrounds" the blastocoele cavity in a blastocyst-stage embryo, as well as the ICM cells which are found only in a blastocyst.

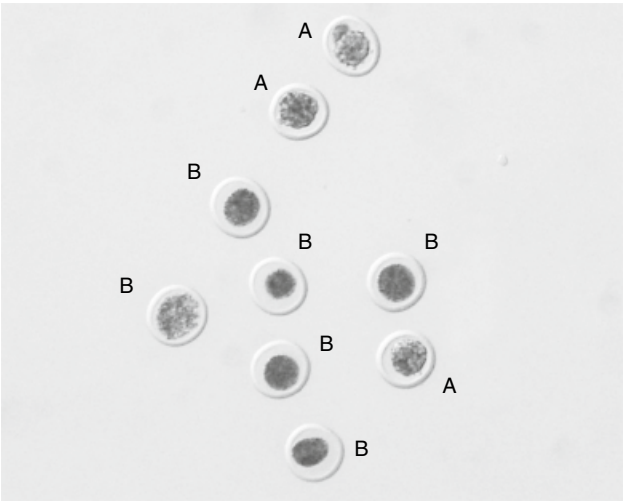

Figure 85.21 Group of compact morula (a) and unfertilized ova (b) recovered from a single donor cow on day 7. Note the similarity in diameter and sphericity between the compact morula and unfertilized ova. Unfertilized ova from this donor appear darker in color, and the vitelline membrane of each ovum is extremely smooth in contrast to the wavy edge of the compact morula.

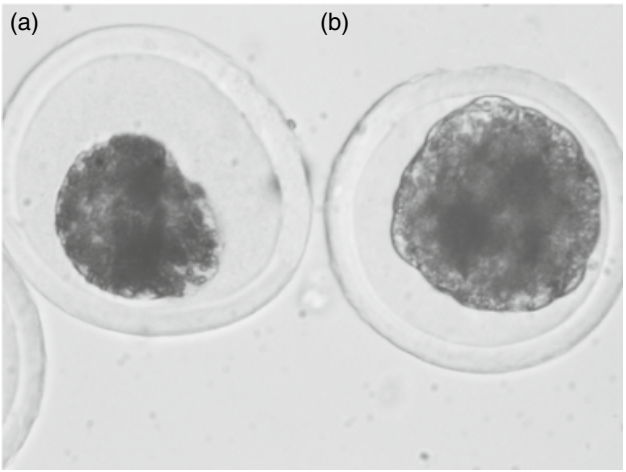

Figure 85.22 An unfertilized ovum (a) and excellent-quality compact morula stage embryo (b).

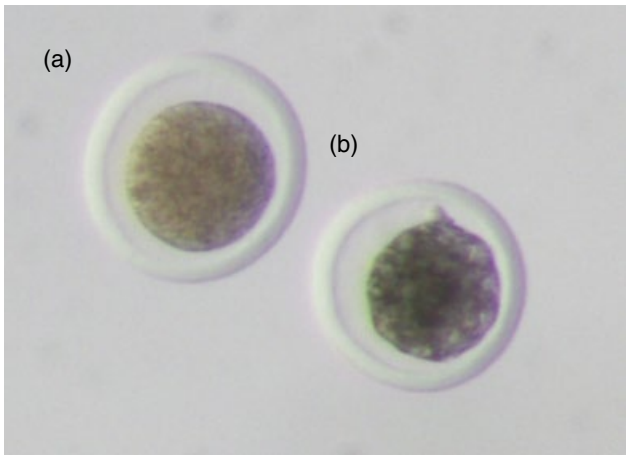

Figure 85.23 An unfertilized ovum (a) and excellent-quality compact morula stage embryo (b).

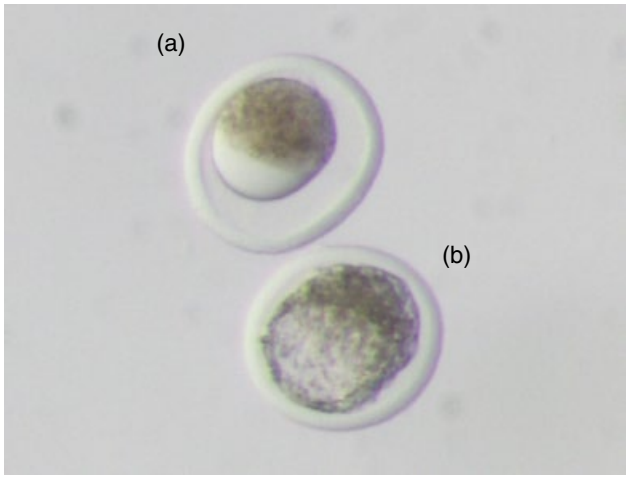

Figure 85.24 A degenerating unfertilized ovum possessing a translucent region (a) and an excellent-quality early blastocyst-stage embryo (b) with discernible trophoblast layer, blastocoele cavity, and inner cell mass cells.

Embryo Evaluation Tip

Although the potential exists for inexperienced technicians to make serious grading and classification errors, experienced embryo specialists seldom make such large mistakes. The most common disagreement among experienced technicians of embryo grading and classification is typically differentiating between excellent/good and fair and between fair and poor quality embryos. This is because of the subjective basis of the embryo evaluation procedure.

To avoid errors in classification and grading of embryos it is vitally important to "roll" the embryos in the Petri dish to enable the technician to thoroughly evaluate the entire surface of the zona pellucida as well as all sides of the cells that make up the embryo. This can be particularly important when donors yield a large number of ova/embryos in a wide range of embryo developmental stages and embryo quality grades (Figure 85.25). A very thorough visual appraisal will reduce the likelihood of embryo grading and classification mistakes.

Each embryo should be examined individually by focusing up and down, keeping in mind that the embryo is a three-dimensional object and that a single two-dimensional view is inadequate for proper evaluation. The embryo should then be rolled (with an embryo handling pipette or by gently and carefully swirling the medium in the dish) to enable the same embryo to be viewed from a different angle. Figure 85.26 consists of three panels (1, 2, and 3) which show the same group of eight embryos from three different angles. Note how different the embryos look in each picture, even though they are the same embryos. These three panels clearly help readers visualize the importance of rolling the embryos around within the Petri dish to enable correct identification of every detail of each embryo. Rolling the embryo and evaluating it from different angles is the key to proper embryo grading and classification.

The Effectiveness of Morphological Embryo Evaluation

Morphological embryo evaluation remains one of the most subjective aspects of the overall embryo transfer process. The photographs presented in this chapter were examined by several embryo specialists who, for the most part, agreed with the stage of development and grade assigned to each embryo. However, there were some mild disagreements over grades assigned to some embryos, and most of the disagreements were between quality grade 1 and 2 embryos. For a couple of the photographs one specialist called a quality grade 1 blastocyst-stage embryo a UFO. These discrepancies most likely occurred from that technician's inability to view the embryos through a stereomicroscope and to roll them around to see them from different angles.

Photographs can be great learning tools, but they are not equivalent to seeing embryos under the stereomicroscope and being able to roll them. One study [23] showed that agreement among six experienced embryo evaluators who viewed video images of embryos was higher for stage of embryo development (89.2%) than it was for embryo quality grade (68.5%). The inability to roll embryos within the Petri dish and to view them from multiple different angles undoubtedly contributed to this lack of agreement. Disagreement among evaluators on embryo stage of development may be attributed to embryos being between two developmental stages. Disagreement on embryo quality

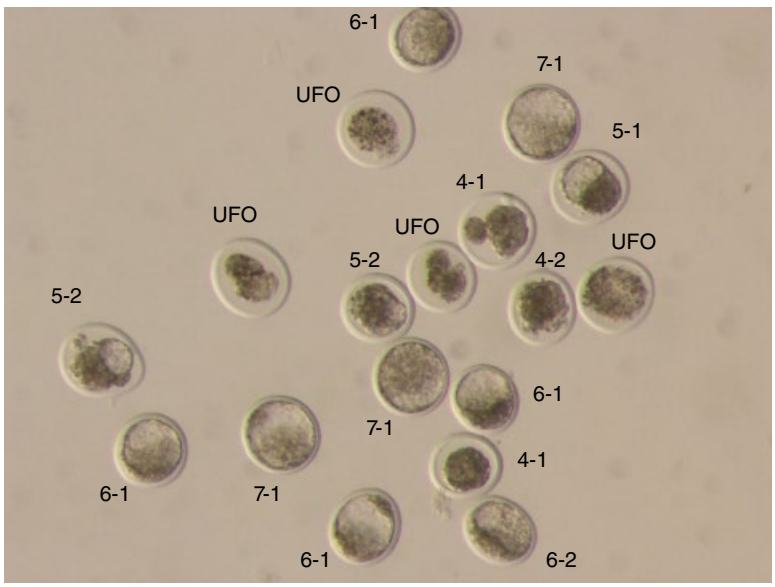

Figure 85.25 A group of 18 day-7 ova and embryos recovered from a single donor.

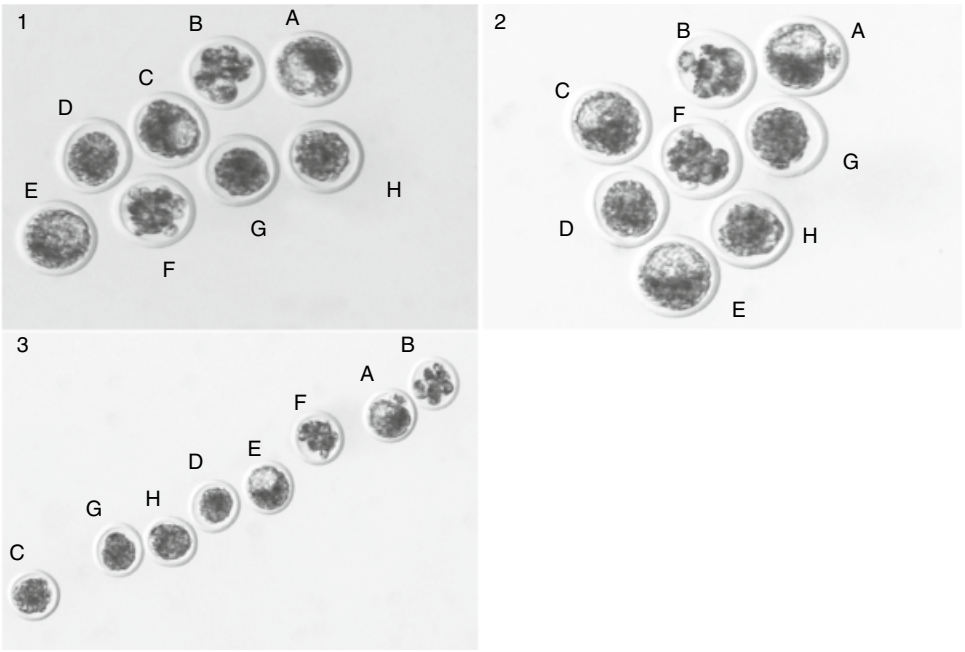

Figure 85.26 A group of eight ova/embryos collected on day 7 from a single donor cow seen from three different angles (panels 1, 2, and 3) after repositioning of embryos within the Petri dish. Note how different each embryo looks in each photo (e.g. embryo C), highlighting the importance of a thorough visual evaluation.

grading was higher when attempting to distinguish between good and fair quality embryos. This likely reflects differences in individual technician philosophies on embryo evaluation. Disagreement was lower when evaluating excellent and degenerate quality embryos. The higher rate of agreement when viewing excellent quality embryos (possessing few, if any, "defects") or degenerate embryos perhaps should not be surprising.

There are three key elements that contribute to successful evaluation of embryos: appropriate training, ample experience, and proper equipment. Appropriate training includes learning the correct morphology of embryos at different times after estrus and the significance of any deviations from normal embryo morphology. One must also learn how to maneuver embryos within a Petri dish in order to thoroughly examine them. Ample experience is gained by examining numerous embryos at all the different stages of embryonic development and different quality grades. Ideally, hundreds of embryos should be evaluated while under the guidance of a highly experienced embryo technician. Experienced personnel can evaluate more than 95% of ova/embryos accurately provided they have a suitable stereomicroscope. Proper equipment includes a good optical quality stereomicroscope of sufficient magnifying capabilities, appropriate embryo handling pipettes (or other handling devices), and satisfactory Petri dishes and embryo media.

Embryo transfer service providers routinely use the IETS embryo grading and classification system. Although this system is subjective, it has allowed practitioners and researchers to record data in a manner that lends itself to subsequent analysis. Although most large embryo transfer datasets originate from the commercial embryo transfer industry, a number of research studies have also contributed to the body of knowledge.

For example, embryonic stage of development has little influence on post-transfer pregnancy rate following transfer of fresh *in vivo* derived embryos to synchronous recipients if the embryos are IETS stage codes 4 (compact morula) to 7 (expanded blastocyst). This result has been obtained in both smaller-scale studies [24] and larger-scale studies involving retrospective analysis of multiple years of data obtained from commercial embryo transfer companies [25]. However, the latter study did document a lower pregnancy rate following transfer of hatched blastocysts (stage code 8).

Similarly, IETS stage code 4, 5, and 6 *in vivo* derived embryos survive the freezing and thawing procedures equally well (i.e. there is no difference in post-transfer pregnancy rate of embryos of the same quality grade). However, embryo quality grade is a critical factor that influences how well embryos survive the freezing and thawing process. Quality grade 1 and 2 embryos typically yield higher pregnancy rates than quality grade 3. One study [24] showed no difference in pregnancy rate among cows receiving grade 1 or 2 embryos (74.1 and 71.8%, respectively), whereas another study [16] showed that

quality grade 1 embryos had a greater probability to conceive (odds ratio 1.62) compared with quality grade 2 or 3 embryos. Conception rate of quality grade 1 embryos was reported as 76% for fresh embryos and 64% for frozen embryos [26].

Conclusion

The ability to accurately evaluate the developmental stage and quality of cattle embryos is critical to the success of an embryo transfer program. Careful examination with a stereomicroscope of ova/embryos recovered from donors is necessary to ensure that viable embryos are not discarded or that unfertilized ova are not transferred or cryopreserved. It is recommended that embryo evaluators undergo intensive and repetitive training and also that a consistent method be used for embryo evaluation. It is highly important to roll the embryos around within the Petri dish to accurately evaluate the entire surface of the zona pellucida as well as all cells comprising the embryo itself. During any given embryo recovery from a superovulated cow one should expect a range of embryo developmental stages and embryo quality grades. The best predictor of an embryo's post-transfer pregnancy rate is its embryo quality grade, with quality grade 1 embryos yielding higher pregnancy rates than either quality grade 2 or 3 embryos. Compact morula (stage code 4) through blastocyst (stage code 6) frozen–thawed embryos are expected to yield equivalent pregnancy rates when transferred to synchronous recipient females. Accurate record-keeping will allow embryo transfer service providers the opportunity to monitor their success and to identify any areas needing potential improvement.

Summary

Embryo transfer is a reproductive biotechnology that facilitates rapid genetic improvement in the dairy and beef cattle industries. An important determinant of the overall success of the embryo transfer process is the quality of embryos obtained from superovulated donor females. Although a variety of different methods have been used over the years to assess the quality of embryos, the only proven and industry-accepted method to assess embryo quality is morphological evaluation. The purpose of this chapter is to provide readers with the necessary information to enable accurate morphological assessment of bovine embryo quality. Although substantial experience is needed before one becomes proficient at this technique, it is an important skill to master because embryo quality is predictive of pregnancy rate obtained after transfer of embryos.

Control of Embryo-Borne Pathogens

Julie Gard

Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

In vivo derived (IVD), *in vitro* produced (IVP), micromanipulated, cloned, and transgenic embryos and oocytes are all vulnerable to contamination from numerous sources, including iatrogenic, the donor, the recipient, semen, culture, and washing media, along with animal source proteins utilized in the media. Bacteria, viruses, protozoans, and prions can result in a variety of negative effects on all types of embryos. Some of these pathogens can be very difficult to detect and may result in just slight decreases in overall embryo production, but others can have significant and often devastating effects on the clinical efficiency of embryo technologies. The epidemiologic adage that the agent, host, and environmental factors will combine to determine whether health or disease will prevail within a population of individuals resounds within the embryo production and transfer industry [1]. It is important to keep this axiom in mind when discussing embryonic pathogens. Three distinct generations of embryo technologies have been developed. With the application of each technology, there have surfaced critical challenges [2]. Each technology implemented imposes environmental changes allowing for the potential to either enhance or diminish the spread of infectious agents among susceptible animals via utilization of these technologies. Hence, it is necessary for these technologies to be extensively examined, as is done yearly by the Health and Safety Advisor Committee of the International Embryo Transfer Society (IETS) [2]. The World Organization of Animal Health (OIE) adopts the committee's recommendations on standards for embryo movement to minimize disease transmission and provide standard protocols and treatments to minimize pathogenic embryonic associations and the validity of experimental treatments currently utilized in embryo technologies to maximize viability and minimize embryonic loss. All areas are important to evaluate when controlling pathogens, but prevention through implementation of biosecurity is the foundation for prevention of all disease states.

The first two generations of embryo technologies, *in vivo* and *in vitro* embryo production, respectively, are widely utilized in commercial cattle production and in basic research. The Data Retrieval Committee of the IETS reported in the December 2018 Newsletter that in 2017 there were approximately 1 487 343 IVD and IVP embryos collected/produced that were available for transfer to other cattle. A total of 495 054 IVD embryos were collected and of these, 162 109 were transferred fresh and 244 178 were transferred frozen. Japan did not report production of IVD embryos in 2017, which most likely accounts for the IVD embryo numbers being decreased by approximately 100 000 [3]. There were 992 289 transferrable IVP embryos produced in 2017 with 757 652 of them transferred. Additionally, there were 500 808 IVP embryos transferred fresh and 256 844 transferred frozen [3]. As far as current numbers for cloned embryos, there were no reported numbers for 2018. There were 105 fresh transfers in 2006 according to the IETS 2006 Newsletter [4]. A number of companies produce cloned embryos, but the current numbers of cloned embryos produced are not accurately known. The USA is currently the largest exporter of embryos, exporting 41.7% of the 26 453 IVD embryos and 65% of the 6133 IVP embryos [3]. The embryo industry is strong and IVP embryo production is increasing every year. It has been estimated that the number of IVD and IVP embryos reported represents about 20% of the embryos produced worldwide [3]. Obviously, there is legitimate concern that due to the level of domestic and international embryo production, that transfer of embryos could facilitate broad distribution of pathogens, resulting in occasional transmission.

First Generation of Embryo Technologies

In vivo embryo production is considered the first generation of embryo technologies. The original techniques utilized in IVD embryos were developed more than 60 years ago, as detailed in a review by Betteridge [5]. These fundamental procedures are widely used in cattle production today and include superovulation of donors, non-surgical embryo collection, embryo cryopreservation, and non-surgical transfer of embryos to synchronized recipients [6]. The expansive implementation of these reproductive techniques represented a potentially significant environmental change, possibly increasing or decreasing the distribution of indigenous or foreign animal pathogens.

Numerous pathogens of cattle have been evaluated within the context of IVD production and transfer to determine if the techniques might diminish or enhance the normal spread of disease among populations of cattle [7–9]. The original hypotheses were that an intact zona pellucida would protect the early conceptus from infectious agents and that proper handling of zona-intact embryos was likely to reduce and often eliminate rather than enhance the spread of naturally occurring pathogens. There have been four primary strategies utilized to investigate these hypotheses [10]. Initially, zona pellucida-intact (ZP-I) embryos were exposed *in vitro* to a variety of pathogens. These pathogens were chosen due to the regulatory concerns surrounding them, such as institution of and/or current domestic disease control programs and/or international trade restrictions. For example, the OIE considers bluetongue virus (BTV) a reportable disease due to the socioeconomic concern and the major importance in the international trade of animal and animal products [11, 12]. Additionally, venereal, and transplacental transmission exists with most serotypes of BTV, and more pronounced clinical disease can be seen in cattle with serotype 8 [13–17]. Hence, the spread of BTV can be heavily influenced by human interventions that either prevent or facilitate the transmission pathways [18]. This emphasizes the necessity of these trials.

The first strategy consisted of embryos exposed to a pathogen of concern. Following the *in vitro* artificial exposure, embryos were washed with or without trypsin treatment and assayed for the presence of virus, either through implementation of an *in vitro* assay or transfer of embryos to disease-free recipients. The recipients and progeny were monitored closely for evidence of infection. The results of these experiments were promising in that the procedures employed for processing embryos seemed to provide a broad spectrum approach to prevention of spread of several important infectious agents [19, 20]. Additional trials were conducted to validate these embryo processing procedures within the context of normal embryo production and transfer protocols. In these studies, embryos were collected from diseased (acute or convalescent) donors, washed with or without trypsin treatment, and then either assayed for pathogens *in vitro* or transferred to disease-free recipients which, along with their offspring, were monitored for transmission of disease [7–10, 19–21]. The results of these studies served to certify that the embryo processing procedures that are now endorsed by the IETS [21] and recommended by the OIE (in their Terrestrial Animal Health Code, Chapter 4.8.5) [22] are effective widespread deterrents to the spread of certain infectious diseases which are categorized accordingly by the OIE [8, 13, 22, 23]. These procedures include the standard processing procedures for IVD embryos listed in the *IETS Manual* [21] and endorsed by the OIE, again as stated above [22], and the Food and Agriculture Organization (FAO) of the United Nations [24].

The following procedures are recommended:

1) Embryos should be washed at least 10 times with at least 100-fold dilutions between each wash, and a fresh pipette should be used for transferring the embryos through each wash.
2) Only embryos from the same donor should be washed together, and no more than 10 embryos should be washed at any one time.
3) Sometimes, for example when inactivation or removal of certain viruses, such as bovine herpesvirus-1 and Aujeszky's disease virus, is required, the standard washing procedure should be modified to include additional washes with the enzyme trypsin, as described in the *IETS Manual* [21].
4) The zona pellucida of each embryo, after washing, should be examined over its entire surface area at not less than 50× magnification to ensure that it is intact and free of adherent material [21, 24].

The protocol for washing and trypsin treatment for adherent viruses such as infectious bovine rhinotracheitis virus (bovine herpes virus-1), Aujeszky's disease, and vesicular stomatitis requires that the embryos be washed five times in phosphate-buffered saline to which antibiotics and 0.4% bovine serum albumin have been added, but without Ca^{2+} and Mg^{2+} (because they inhibit trypsin) [21]. Next the embryos should be put through two washes of trypsin of 60–90 seconds each, then again through five washes of saline containing antibiotics and 2% heat-inactivated serum (not bovine serum albumin) to inactivate the trypsin [21, 24]. The trypsin enzyme used to prepare the washes should have an activity such that 1 g will hydrolyze 250 g of casein in 10 minutes at 25 °C and pH 7.6 [21]. The sterile trypsin solution should contain a concentration of

0.25% trypsin in Hank's balanced salt solution without Ca^{2+} and Mg^{2+} [21]. There are ready-to-use solutions commercially available. After embryos have been washed, they should be microscopically examined over their entire surface area at no less than 50× magnification [21, 24]. Also, for purposes of disease control, only embryos that have an intact zona pellucida and that are free of adherent material should be transferred or cryopreserved [21–24].

Sources of Pathogens

Some areas of embryo production have seemed to receive adequate attention, while other important sources of pathogens in embryo production have received insufficient attention. These sources of pathogens are contaminated materials (reagents) of animal origin and diseased donors and recipients [6, 25, 26]. The term "materials of animal origin" embraces a variety of things, including supplements to media (e.g. fetal bovine serum [FBS] or bovine serum albumin), hormones that might be used to treat donors (e.g. pituitary-origin follicle stimulating hormone), and enzymes for treatment of embryos (e.g. trypsin). Detailed descriptions of the hazards associated with these products have been previously described [25–27]. To highlight some, bovine serum albumin is an unlikely source of pathogens because production protocols seem to preclude the survival of contaminants [28, 29]. However, on the other hand, FBS could be the source of adventitious bacteria, fungi, or viruses when adequate quality assurances are not in place [25, 30]. The most common contaminant in FBS is bovine viral diarrhea virus (BVDV) [25, 30–32].

A number of pathogens are known to be transmitted from mother to fetus via the placenta. These include BVDV, *Neospora caninum*, BTV, bovine leukemia virus (BLV), bovine herpesvirus (BHV)-1, and *Mycobacterium avium* ssp. *paratuberculosis* (Johne's disease) [13–17, 33–35]. Thus, a complete risk assessment should always give due consideration to the entirety of infectious agents capable of establishing transient, latent, or persistent infection of the donor and/or recipient, which can result in fetal disease. Often the disease may spread from the recipient to other animals through horizontal transmission. Otherwise, collection and transfer of embryos, albeit even pathogen-free embryos, could lead to the birth of diseased offspring, resulting from subsequent in utero infections.

As of 2019, the official biosecurity recommendations for international movement of embryos are outlined in Section 4.8.5 of the Terrestrial Animal Health Code under "Risk Management" [36]. These general strategies were developed to help ensure that the transfer of IVD embryos would not result in the transmission of infectious agents originating from donor animals [36]. Three general strategies are available [37, 38]. Each method represents a contrived environmental change intended to deter pathogen transmission. The preferred method in cattle is embryo processing (i.e. washing or trypsin treatment) [21] (as previously described in the section "First Generation of Embryo Technologies"), because it is relatively inexpensive and has been substantiated by a considerable amount of research to prevent the spread of a variety of viruses, bacteria, and bovine spongiform encephalopathy [8, 22, 36–38].

Other methods have been employed in cattle, which include donor testing and recipient quarantine and testing [37]. By testing donors for the presence of disease at the time of embryo collection, and again, weeks or months later (while embryos are held in the cryopreserved state), it can be confirmed that the donors are not a possible pathogen source. The testing of recipients following transfer of embryos and testing of offspring after birth function as bioassays utilizing the recipients and offspring as sentinel animals. However, this requires a lengthy quarantine of animals. Additional disadvantages are that these methods are expensive, multiple tests have to be conducted if there is a need to detect more than one disease, and multiple testing must be done to determine that accidental exposure did not occur during the quarantine period. Therefore, economically, the use of embryo processing is the preferred method for certifying the health of embryos. This method has greatly facilitated international trade in embryos because of the combination of animal welfare, disease control, and economic advantages [37].

Categorization of Pathogenic Agents of Embryos

In order to further facilitate international trade of embryos, an estimation, or categorization, of the known risk of transmission of a particular disease via embryo transfer (ET) is compiled by the OIE through the help of the Health and Safety Research Subcommittee of the IETS and is updated yearly [22, 23, 36]. The official categorization of diseases of embryos from one to four is detailed further in Article 4.8.14 which can be found by accessing Article 4.8.4 "Conditions applicable to the introduction of donor animals" in Section 4.8 of the Terrestrial Animal Health Code [22]. Categorization is currently under review by the IETS's Health and Safety Advisory Committee (HASAC) Research Subcommittee and some changes may occur in the coming years. As for now, Category 1 diseases are diseases or pathogenic agents for which sufficient evidence has accrued to show that the risk of transmission is negligible provided that the embryos are properly handled

between collection and transfer in accordance with the *IETS Manual* [21–24, 36]. The following diseases or pathogenic agents are in Category 1: BTV (cattle), bovine spongiform encephalopathy (cattle), *Brucella abortus* (cattle), enzootic bovine leukosis (cattle), foot and mouth disease (cattle), infection with Aujeszky's disease virus (pigs): trypsin treatment required, infectious bovine rhinotracheitis/infectious pustular vulvovaginitis: trypsin treatment required, and scrapie (sheep) [22].

The Terrestrial Animal Health Code 4.8.14 states that Category 2 diseases are those for which substantial evidence has accrued to show that the risk of transmission is negligible provided that the embryos are properly handled between collection and transfer according to the *IETS Manual* but for which additional transfers are required to verify existing data [22]. The following diseases are in Category 2: bluetongue (sheep), caprine arthritis/encephalitis, and classical swine fever. Category 3 diseases or pathogenic agents are those for which preliminary evidence indicates that the risk of transmission is negligible provided that the embryos are properly handled between collection and transfer according to the *IETS Manual* but for which additional *in vitro* and *in vivo* experimental data are required to substantiate the preliminary findings [22]. The following diseases or pathogenic agents are in Category 3: atypical scrapie, bovine immunodeficiency virus, bovine spongiform encephalopathy (goats), BVDV (cattle), *Campylobacter fetus* (sheep), foot and mouth disease (pigs, sheep, and goats), *Haemophilussomnus* (cattle), maedivisna (sheep), *Mycobacterium paratuberculosis* (cattle), *N. caninum* (cattle), ovine pulmonary adenomatosis, porcine reproductive and respiratory disease syndrome, rinderpest (cattle – eradicated), porcine circovirus type 2 (pigs), and swine vesicular disease [22]. Category 4 diseases and pathogenic agents as listed by the OIE in the Terrestrial Animal Health Code 4.8.14 and are those for which studies have been done, or are in progress, that indicate no conclusions are yet possible with regard to the level of transmission risk; or that the risk of transmission via ET might not be negligible even if the embryos are properly handled according to the *IETS Manual* between collection and transfer [22]. The following diseases or pathogenic agents are in Category 4: African swine fever, akabane (cattle), bovine anaplasmosis, BTV (goats), border disease (sheep), bovine herpesvirus 4, *Chlamydia psittaci* (cattle, sheep), contagious equine metritis, enterovirus (cattle, pigs), equine herpes virus 1 (equine rhinopneumonitis), equine viral arteritis, *Escherichia coli* 09:K99 (cattle), *Leptospira borgpetersenii* serovar *hardjobovis* (cattle), *Leptospira* sp. (pigs), lumpy skin disease, *Mycobacterium bovis* (cattle), *Mycoplasma* spp. (pigs), ovine epididymitis (*Brucella ovis*), parainfluenza-3 virus (cattle), parvovirus (pigs), Q fever (*Coxiella burnetii*), scrapie (goats), *Tritrichomonas foetus* (cattle), *Ureaplasma* and *Mycoplasma* spp. (cattle, goats), and vesicular stomatitis (cattle, pigs) [22].

Control of Viral Pathogens

Considerations of space preclude discussion of each disease listed in all four categories. Therefore the primary focus of the remainder of this chapter will be on BVDV, which is of great importance due to its tremendous economic impact on the cattle industry as a whole. This pestivirus, BVDV, is a Category 3 disease. It has the ability to diminish production through decreases in feed efficiency and milk production, and to cause early embryonic death, abortion, mummification, fetal abnormalities, diarrhea, pneumonia, and other various debilitating disease states [27, 39–46]. The economic impact of BVDV was evaluated in a study by Houe, who estimated BVDV losses to the cattle industry to be between USD $20 and 57 million per million calvings [40]. Hessman et al. investigated the economic effects and the health and performance of cattle populations after exposure to persistently infected (PI) animals [41]. They reported that for cattle with direct exposure to a PI animal, economic losses due to fatalities were $5.26 per animal and performance losses were much more significant at $88.26 per animal [41]. Also, due to the significant economic implications resulting from BVDV infections, a number of countries such as Denmark, Finland, Norway, Sweden, the Shetland Islands, and Slovenia have established eradication programs [27, 47–51]. Several countries are utilizing control programs and are moving toward implementation of eradication programs, while others, such as the USA, are leaving the individual states and specifically the producers within those states to set standards for BVDV control by the formation of voluntary control programs. Control of BVDV in the USA is further complicated by the existence of BVDV in the white tail deer population [52, 53]. Hence, the focus of most control programs is appropriate biosecurity including quarantine, testing, identification, and removal of PIs and prevention of PI formation.

Embryo Transfer as a Means of Controlling Pathogen Transmission

Historically, ET was utilized as a way to minimize disease transmission along with maximizing genetics [20, 54]. However, in the years following its inception, questions regarding the ability of embryos to transmit pathogens

surfaced. Numerous studies were performed that showed that ET was indeed a good way to prevent or minimize pathogen transmission if good quality controls and appropriate processing procedures were instituted [8, 20, 37, 38, 54–59]. However, there were some organisms for which prevention of pathogen transmission was not refutable and in some cases ET might plausibly serve as a mechanism for introduction of disease. The original placement of BVDV in Category 3 was based on a study conducted in 1982 [54]. This study validated the efficacy of embryo washing procedures for removal of virus after artificial exposure of embryos to a cytopathic isolate of BVDV [54]. Four later studies collectively produced five BVDV-free calves after transfer of washed or trypsin-treated embryos from PI donor cows [55–58]. While data from these four reports were limited, the results were encouraging. However, reports by Lindberg et al. and Drew et al. [60, 61] stimulated further investigations into the possibility of transmission of BVDV via ET due to seroconversion of heifers after ET and birth of a PI calf following ET, respectively. Contaminated FBS was thought to be the inciting cause of these infections. Hence, additional studies were necessary to determine if BVDV would remain associated with BVDV following standard IETS processing procedures for IVD embryos and whether this associated virus could be transmitted via ET.

So, further studies were performed which highlighted the variation in affinity between different strains of BVDV and the affinity of these strains for embryos [62, 63]. Some strains maintained association with embryos following IETS processing procedures, including when trypsin treatment was added to the processing procedures [62, 63]. These high-affinity strains became more of a concern when it was determined that the embryo-associated virus (EAV) was indeed infective in both *in vitro* and *in vivo* studies [63, 64]. Gard et al. (2009) [65] reported that 27% of IVD and 42% of IVP embryos had EAV following artificial exposure to a high-affinity strain of BVDV (SD-1, type 1a) following washing procedures in accordance with IETS (without trypsin). The range of the amount of EAV was 100–450 cell culture infective doses (CCID) to the 50% endpoint ($CCID_{50}$)/embryo [65]. In previous studies, EAV was also determined to be infectious in an *in vitro* culture (IVC) system and in an *in vivo* model through intravenous inoculation of embryos into virus negative and seronegative recipients [62, 64, 65]. An additional study was performed that utilized twice the amount of EAV known to be previously associated with individual IVD and IVP embryos following processing procedures [66]. This amount was then doubled (878 $CCID_{50}$/straw) to imitate what is commonly done in the ET industry, transferring two embryos simultaneously into one recipient, and in keeping with the worse-case scenario. It was found that all recipients of embryos and virus became viremic, and then seroconverted. There were six pregnancies at 30 days and only one at 60 days post transfer. However, all pregnancies were lost. The 60-day pregnancy was removed via colpotomy and tested for BVDV. The aborted fetus was found to have the same strain of BVDV, SD-1, as the infecting viral strain [66].

The finding that no BVDV-positive live offspring were produced in this study is similar to the results of the study by Bielanski et al. [67]. In this study, IVP embryos were exposed to non-cytopathic biotypes of BVDV for one hour, either type 2 strain (P-131) or type 1 strain (NY-1), and then washed in accordance with IETS guidelines (no trypsin treatment) then transferred to seronegative and BVDV-negative recipients. However, none of the recipients following intrauterine transfer of embryos exposed to the type 1 strain seroconverted, but of the 35 recipients receiving embryos exposed to the type 2 strain, 18 seroconverted (51%) and there were 11 pregnancies at 30 days post transfer. Of the 11 pregnancies only two resulted in live offspring. These two offspring were tested and determined to be BVDV seronegative and negative for antigen [67]. The infection may not have been recognized by the fetus and/or the virus was destroyed prior to development of immune competence so in fact no antibodies were formed by the fetus. The results of no detectable seroconversion from the type 1 strain and abortion due to the type 2 BVDV may be the results of mutations within the virus. In a study by Meyers et al., decreases in interferon production, abortion, and presence of virus in fetal tissues did not result when pregnant cattle were injected with two different mutant strains of virus [68]. Each of these mutant strains had mutations specifically affecting both the N-terminal protease, N(pro), and the deletion of codon 349, which abrogates the RNAse activity of the structural glycoprotein E(rns) [69]. However, decreases in interferon production, abortion, and presence of virus in fetal tissues did occur with wild-type viruses and in viruses in which only one mutation of either N(pro) or E(rns) occurred [68]. Therefore the establishment of persistent infections requires both N(pro) and E(rns). It is logical to ascertain that the type 1 strain utilized in Bielanski's study might have had mutations within these areas resulting in adequate interferon production and no fetal infection. Each specific strain may affect interferon production differently and therefore may or may not result in fetal infection and that fetal infection may or may not be fatal.

Thus, based on these studies and the variety of BVDV strains, it is still plausible that a PI could result via transfer of a contaminated embryo. The results from Gard's and Bielanski's studies show that some high-affinity isolates can result in viremia and seroconversion in susceptible

recipients followed by early embryonic death and abortion [66, 67]. The possibility of the development of a PI following transfer of contaminated embryos seems to be more likely to result from the viremia of the recipient (acute exposure) and shedding of virus to other gestating animals than from transfer of a contaminated embryo, based on the findings of these studies. However, additional studies involving naturally infected embryos with various strains of BVDV transferred intrauterine need to be completed in order to establish a thorough investigation of the ability of BVDV to be transmitted intrauterine and the potential for development of a PI calf. A thorough evaluation is important as the ability to transmit BVDV via an embryo would necessitate reevaluation of embryo health certification procedures along with implementation of additional regulations on embryos exported from BVDV-positive countries to those countries where BVDV has been eradicated.

Second Generation of Embryo Technologies

In vitro embryo production has been described as the second generation of embryo technologies and most of the essential components of this process in cattle have been developed and refined as these procedures have become adapted for commercial use [27, 38, 70]. Fundamental procedures currently used with *in vitro* production include superstimulation/superovulation of donor cattle, collection of oocytes via transvaginal follicular aspiration, *in vitro* maturation of oocytes (IVM), *in vitro* capacitation of spermatozoa, *in vitro* fertilization (IVF), IVC of embryos to blastocysts, and ET to a recipient [71]. This technology represents multiple changes in the animal breeding environment which provides opportunities for pathogens to enter, amplify, and be disseminated. Hence, there are a number of logical sources of pathogens in IVP embryo production. These sources include gametes and their associated fluids, somatic cells used in IVM, IVF, or IVC, and the materials of animal origin used to supplement maturation, fertilization, or culture media (e.g. FBS, bovine serum albumin, or follicle stimulating hormone [FSH]) [25].

Studies that surveyed for contaminants in *in vitro* embryo production laboratories have been conducted in a number of different countries such as Canada [69, 72], Denmark [73], France [7, 74], and the USA [70, 75, 76]. As expected, levels of bacterial contamination can be quite high – from 13 to 68% of samples when abattoir-origin materials are utilized in *in vitro* production systems [70]. Also, low to moderate levels of BVDV and BHV-1 have been found in abattoir-origin materials, with a range of one to 12% of samples testing positive for BVDV and zero to 12% of samples testing positive for BHV-1 [70, 76]. Luckily, the majority of IVP embryo production occurs without utilizing abattoir origin oocytes or uterine tubal cells. According to the Data Retrieval Committee of the IETS in 2017, only 1.2% of IVP embryos transferred were from abattoir-origin oocytes [3]. Additionally, in 2017, no IVD or IVP exported embryo was produced utilizing abattoir-origin oocytes [3]. However, there are other materials from the abattoir that are utilized in reproduction in cattle on a wide basis such as fetal calf serum and follicle stimulating hormone (FSH) that still have potential for contamination.

Since BVDV is widely distributed among populations of cattle and is known to result in severe respiratory, gastrointestinal, and reproductive disease, it has received the most attention by researchers [75]. In fact, all of the materials (animal products, ovaries, oocytes, follicular fluid, cumulus, uterine tubal cells, FSH, and serum) of animal origin that have been integral to IVF embryo production in cattle have been shown to contain BVDV when harvested from actively infected animals [75, 77]. This hazard is complicated by the fact that a proportion of animals infected by BVDV are asymptomatic [32, 40]. The PI cattle are often asymptomatic and, as stated, they serve as reservoirs for large quantities of virus [40]. Also, most of the field isolates of BVDV are noncytopathic and could cause unapparent persistent infections in donor animals from which semen, oocytes, and embryos are collected and from which laboratory cell lines are established and that are in co-cultures with oocytes and embryos [30, 77]. Finally, it is noteworthy that the cultures in each phase of IVF embryo production are ideally suited for replication of BVDV, providing adequate time and substrate as well as permissive cells for viral replication, such as the cumulus cells and spermatozoa. Therefore even a low level of contamination can be effectively amplified, leading to exposure of embryos to a high level of virus by the end of IVC. However, synthetic oviductal media have been developed to minimize contamination through use of animal origin products, but cumulus cells, semen, oocytes, and embryos will always provide a route for contamination in culture systems.

As with IVD embryos, it was originally hypothesized that the zona pellucida of IVF embryos would protect the developing conceptus from infections and, in fact, artificial exposure studies have demonstrated that an intact zona is an effective barrier that is seldom penetrated [78]. Nevertheless, it is clear that the processing procedures recommended for use on IVD embryos are not as effective for IVF embryos, since several pathogens such as BTV, BHV-1, foot-and-mouth disease virus, and BVDV have been shown to adhere more readily to the zona of IVF embryos [75, 76]. Furthermore, the presence of virus has been shown to result in reduced rates of maturation, fertilization, and development [75, 79–82].

Studies have shown that BVDV remains associated with IVP embryos after viral exposure and washing with or without trypsin treatment [67, 83, 84]. Infection of susceptible recipients was reported in Bielanski's study where 18 of 35 naïve recipients receiving embryos exposed to the BVDV type 2 strain seroconverted (51%) and only two of 11 pregnancies resulted in live offspring. These two offspring were determined to be negative for BVDV, which leads to the conclusion that the embryos with EAV underwent embryonic death [67]. Additionally, some interesting results were achieved in attempts to determine whether the amount of BVDV associated with individual embryos would constitute an in-utero, infective dose [85, 86]. The cumulative results of these *in vitro* studies evaluating risks of transmitting BVDV via ET of IVP embryos are somewhat contradictory. On the one hand, it is clear that multiple strains of BVDV will remain associated with IVF embryos after washing or trypsin treatment [85–87]. On the other hand, there appear to be innate deterrents to transmission of the EAV to permissive cells *in vitro* which mimics the environment of the uterus and uterine tube [85–87]. Additionally, media free of animal origin products are being produced and utilized that decrease the chances of entry of BVDV into the culture system, but one cannot ignore that there can be EAV. Obviously, resolution of these issues requires further studies.

Official recommendations for international shipment of IVP embryos in order to control the spread of disease are outlined in Section 4.9 of the Terrestrial Animal Health Code of the OIE [88]. Impediments to the establishment of universally recognized sanitary precautions for the production of bovine IVF embryos include lab-to-lab variability in techniques utilized, the comparative ease with which pathogens adhere to the zona pellucida, and the fact that raw materials, such as FBS, are collected from abattoirs [89]. It is apparent that mechanical washing and trypsin treatment of IVF embryos [83, 84] do not provide the same level of effectiveness when utilized for cleansing IVD embryos. However, these treatments have been shown to definitely reduce the level of contamination after IVF embryos following artificial exposure to some agents such as BHV-1 and BVDV [83, 84, 90]. Thus, as is the case with IVD embryos, further studies are necessary in order to complete the risk assessment which includes evaluating fully if the quantity of embryo-associated BVDV is sufficient to infect recipients and/or their fetuses after transfer into the uterus. Obviously, the strain of the virus seems to have a tremendous effect on the affinity of the virus for embryos and it is necessary to take this into account when assessing the true risk [63].

Third Generation of Embryo Technologies

The third generation of embryo technologies includes cloning, such as somatic cell nuclear transfer, and transgenics. These technologies specifically involve maturation and enucleation of oocytes, insertion of somatic cell nuclei, activation through chemical and/or electrical means, IVC, possibly cryopreservation, and non-surgical transfer. The same hazards that are associated with the second generation of embryo technologies apply directly to the third generation of embryo technologies with a few added caveats. These caveats include that the zona pellucida is either broken or removed, and the donor nuclei are harvested from additional cell lines. These cell lines utilized are often cultured for 8–16 weeks in order to allow for cellular amplification, and even longer if a transgene has been inserted. Additionally, the amplification procedures can allow for non-cytopathic BVDV replication and infection in these cell lines due to the use of animal origin materials such as abattoir origin oocytes and FBS utilized in formation and culturing of embryos. Logically, cloning has a much greater chance for contamination than IVD and IVP production.

The presence of non-cytopathic BVDV may be manifested in poor cloning efficiency and development, low pregnancy rates, early embryonic death, fetal wastage, and neonatal abnormalities. An example of the problems that might be associated with BVDV contamination in cloning systems is well documented in a report by Shin et al. 2000 [91].In this report, Shin described a high incidence of developmental failure in bovine fetuses that were derived by cloning using BVDV-infected cells. Specifically, a fetal fibroblast cell line was inadvertently infected with a non-cytopathic strain of BVDV. As a result of the infection an extraordinary amount of embryonic death and fetal resorption occurred with the use of this cell line [91]. In an additional study by Stringfellow et al. [92], screened samples sent to veterinary diagnostic labs revealed that 15 of 39 fetal fibroblast cell lines used in cloning research were positive for BVDV as determined by various assays including reverse transcription-polymerase chain reaction (RT-PCR). However, it was determined that only five of the 39 cell lines were actually infected with BVDV. Furthermore, three of these five lines were determined to not be infected at the earliest cryopreserved passage – hence leading to the conclusion that the cell lines became infected after culture in media containing contaminated FBS. Sequence comparison of the amplified cDNA from one lot of FBS confirmed that it was the source of infection for one of these cell lines [92]. Since BVDV was isolated from the remaining two cell lines at the earliest available passage, the fetuses

from which they were established could not be ruled out as the source of the virus. These studies highlight the additional concerns that cloning and transgenics pose and the greater potential for the production of contaminated embryos via the utilization of these techniques. Therefore excellent quality control is imperative in order to prevent embryonic pathogens and transmission of pathogens via ET to recipients. It is of major importance with all generations of embryo technologies and the needs increase with each subsequent generation.

The use of embryo technologies continues to increase in other species including swine, caprine, ovine, and equine, and wildlife as well. In 2017, 18 652 sheep, 3076 goat, and 20 459 horse IVD embryos were transferred. Additionally, there was an increase in equine IVP embryos with 14 788 embryos transferred [3]. Intracytoplasmic sperm injection (ICSI) continues to grow in the equine and bovine industries as well. During ICSI, the zona pellucida is punctured and a single spermatozoa is injected into the oocyte. Then the embryo is cultured in a similar fashion as an IVP embryo and finally the embryo is transferred. Good quality control and biosecurity are a must to reduce the chances of embryo and fetal mortality when using ICSI. Appropriate processing of oocytes and spermatozoa are crucial. Again, donors and recipients can be vectors of disease, and as is the case in cattle, there are a variety of pathogens that pose a concern and can result in embryonic and fetal mortality. A review by Givens and Marley [93] summarizes bacterial, fungal, protozoan, and viral causes of reproductive dysgenesis in cattle, sheep, goats, pigs, horses, dogs, and cats. This study illustrates how it is imperative to make prudent use of immunization and biosecurity protocols when incorporating embryonic technologies in order to minimize reproductive losses.

Experimental Treatments

The addition of antibiotics and antifungals to media significantly decreases problems with bacteria and fungi in culture. However, viral contamination poses a more complicated threat. A study looked at the addition of an antiviral substance, interferon-tau, to embryos in culture with BVDV and BHV-1. A significant decrease in the amount of BVDV in culture was seen but the same result was not observed for BHV-1 [94]. Additionally, other antiviral compounds such as DB606 (2-(4-[2-imidazolinyl]phenyl)-5-(4-methoxyphenyl)furan) have been shown to inhibit the replication of BVDV in bovine uterine tubal epithelial cells, Madin Darby bovine kidney cells, and fetal fibroblast cells, without negatively affecting embryonic development or future fertility of heifers derived from IVF embryos treated with DB606 [95, 96]. A study by Newcomer et al. [97] evaluated the scope of antiviral activity of another similar compound, 2-(2-benzimidazolyl)-5-[4-(2-imidazolino) phenyl] furan dihydrochloride (DB772), among diverse pestiviruses. Isolates of BVDV-2, border disease virus (BDV), HoBi virus, pronghorn virus, and Bungowannah virus were all tested for *in vitro* susceptibility to DB772 by incubating infected cells in medium containing various concentrations of DB772. It was found that DB772 effectively inhibits all pestiviruses studied at concentrations >0.20 μM with no evidence of cytotoxicity [97]. These compounds, DB606 and DB772, along with interferon-tau, show potential for minimization of viral pathogens, specifically pestivirus, in culture, which may result in their routine inclusion during culture of embryos and amplification of fibroblast cell lines for cloning and transgenics [96–98].

Emerging pathogens such as HoBi-like viruses (HoBiPeVs), which have also been called "atypical pestiviruses" and "BVDV-3," are of special concern since they cannot always be detected via testing for BVDV and BVDV vaccines may have limited efficacy against these viruses. These HoBiPeVs are found in multiple countries from Brazil to Asia and Europe. The use of contaminated FBS is implicated as the source through which HoBiPeVs have moved worldwide [99]. In Brazil, HoBiPeVs are endemic and account for 19.9% of the genotyped pestiviruses in 2018 [100]. Brazil has the biggest cattle herd and is still the largest producer of IVP embryos [3, 100]. Hence, HoBiPeV positive donor cattle can be seen as a significant source of contamination as well. Hence, efficacious antivirals would be beneficial in preventing EAV and possible transmission of HoBiPeVs since not much research has been completed involving bovine embryos and HoBiPeVs.

Human hepatitis C virus (HCV) is very similar to bovine pestiviruses. Pegylated interferon (PEG-IFN) and ribavirin have been considered the standard of care for HCV in humans but only have a sustained virologic response rate (SVR) and lack production of HCV RNA in 40–80% of patients depending on HCV genotype [101]. New antiviral drugs called direct-acting antivirals (DAAs) are now on the market and have SVRs as high as 60–100%. These DAAs target the non-structural HCV proteases NS3-4A and NSA5 or inhibit RNA-dependent RNA polymerase, and so they are termed protease inhibitors and inhibitors of HCV RNA-dependent RNA polymerase, respectively, which could be efficacious against HoBiPeVs [101]. Zika virus is another emerging disease that has looked to antivirals to inhibit the RNA-dependent

RNA polymerase to prevent severe repercussions of the virus on the embryo and fetus [102]. Zika virus is in the same family as BVDV and HCV, Flavivirdae [39, 40, 102]. Obviously, these new drugs regimens can have applications in human and bovine medicine. The use of antivirals would be extremely beneficial to counteract infectious virus on embryos, oocytes, and semen from animals that are potentially contaminated and where testing is not foolproof with these emerging diseases. More studies involving antivirals such as DB772, DAAs, and interferons are necessary to determine how efficacious these antivirals are at preventing detrimental effects of the virus on the embryo and prevention of disease transmission.

Summary

With the advent of synthetic media and antivirals, the embryo industry has made important strides in the prevention of transmission of diseases through ET. Continued evaluation of synthetic media and antivirals in culture systems for prevention of embryonic pathogens is imperative. These modalities might provide a reliable methodology to curtail infectious virus associated with embryos, oocytes, and semen in the future. However, proper biosecurity and quality control are always at the forefront of prevention of embryonic pathogens and should be the focus of standard operating procedures when utilizing any of the generations of embryo technologies.

Cryopreservation of Bovine Embryos

A. Lee Jones

UGA College of Veterinary Medicine, University of Georgia, Tifton, GA, USA

Introduction

Routine direct transfer (DT) of cryopreserved *in vivo* and *in vitro* derived cow embryos is not given a second thought today. It has become a common, integral part of genetic advancement and reproductive management of progressive beef and dairy herds. Data from the 2019 American Embryo Transfer Association (AETA) Statistics Committee reported that in 2018 of the 418 349 *in vivo* and *in vitro* derived embryos transferred in the USA (206 practitioners reporting), 179 810 (43%) were frozen [1]. Worldwide the percentage is much higher. Data from the International Embryo Technology Society (IETS) Data Retrieval Committee [2] indicates that of the 516 585 total *in vivo* derived embryos transferred worldwide in 2016, 321 022 or 62.1% were frozen, and 121 490 (37.2%) of the 326 623 *in vitro* fertilization (IVF) derived embryos transferred were frozen.

The convenience and success of transferring cryopreserved bovine embryos has made this routine practice possible. However, this has not always been the case. Prior to the development of reliable embryo cryopreservation techniques in the 1970s, transfer of cattle embryos from donors into recipient cows was limited to fresh recovered (not frozen) embryos transferred to available recipients on the premises or relatively close by. If more embryos were recovered than recipients were available for transfer, the remaining viable embryos were discarded [3]. In other cases, embryos would be chilled (4 °C) and personally transported in coolers on overnight commercial flights to other facilities where recipients were available. A reliable method of preserving cattle embryos was needed.

Modern embryo freezing technologies have evolved since the first reported successful transfer of frozen–thawed bovine embryos in 1973 [4] but didn't advance as quickly as developments for other procedures like embryo recovery and handling, transfer, superstimulation, and recipient management. Until the early 1990s glycerol was the most popular embryo cryoprotectant agent (CPA). While an improvement over previous systems, the main drawback of using glycerol as a CPA is that embryos had to be removed from the straws and glycerol removed from the embryo then reloaded into straws prior to transfer to recipients. In 1992, the method [5] referred to as direct transfer (DT) was introduced and was quickly adopted. Today in the USA almost 100% of the cryopreserved *in vivo* and *in vitro* produced embryos are frozen, thawed, and transferred using this method.

Cryopreservation

Cryopreservation of gametes and embryos is an essential procedure in advanced reproductive techniques for many species. Cryopreservation is the preservation of cells and tissues at subzero temperatures which essentially stops all biologic activity ("suspended animation") [6], preserving them for future use. Consequently, the viability of the preserved material after thawing is essential to the success of the procedure. Cooling mammalian tissues to extremely low temperatures exposes the cells to multiple risks: deleterious effects of cooling on cell functions and structures (chilling effects) [7], physical damage of cell membranes caused by transition of water to ice [6] (phase change transition), osmotic changes of cell dehydration, and exposure to CPAs [6, 7].

Most mammalian embryos are frozen in one of two methods: "slow rate freezing," equilibrium freezing prior to vitrification; or direct, ultra-rapid vitrification. The slow rate method allows for the embryo to equilibrate and

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

dehydrate prior to vitrification versus the direct vitrification process which does not include CPA equilibrium and cell dehydration. The equilibrium method of cooling includes slow, controlled reduction in temperature to allow extracellular ice crystals to grow and draw water from the cells without ice crystals forming within the cells. The slow rate of cooling is followed by vitrification (also referred to as plunging into liquid nitrogen [LN]) of the remaining intracellular water. The rate of cooling must be carefully controlled between 0.3 and 0.6 °C/minute [6, 7] to −30 to −32 °C. The remaining solute becomes more concentrated as more water molecules combine with the growing extracellular ice crystal. The hyperosmotic fluid outside the cells draws water from the cells, increasing the concentration of solutes and CPA within the cells. This also reduces the freeze point of the intracellular fluids which helps protect the cell from intracellular ice formation.

Vitrification is the rapid cooling of liquid into a "glass-like" state or the absence of crystal formation. During slow cooling, water molecules form a crystal structure as they rotate and form hydrogen bounds with four other surrounding molecules during the phase transition from water to ice. During vitrification, however, the freeze process is so rapid the molecules do not have the opportunity to form crystals. Vitrification is discussed in more detail in the section "Rapid Cooling."

Cryoprotectants

CPAs protect tissues and cells from injury caused by cooling to subzero temperatures and subsequent thawing. Embryos are placed into a hypertonic CPA solution (high concentration of CPA) to force water out of the cells, effectively dehydrating the embryonic cells prior to cooling. CPA compounds are either penetrating (act intracellularly) or non-penetrating (work extracellularly). Penetrating CPAs have small molecular weight and polar molecular structure similar to that of water so they readily cross embryonic cell membranes. For slow rate or conventional cryopreservation of bovine embryos, one of two penetrating CPAs are commonly used – glycerol or ethylene glycol (EG). Embryos are left in the CPA solution until they reach equilibrium [8]. As water leaves the cells, penetrating CPAs such as EG or glycerol enter the cell. EG reaches equilibrium in bovine embryos (5 minutes) more rapidly than glycerol (10 minutes) [8]. The high penetration and relatively low toxicity of EG make it especially favorable for DT applications [9].

Non-penetrating CPA compounds do not cross the cell membrane and work extracellularly. These compounds affect the osmolarity of a freezing solution and provide membrane-stabilizing properties. These compounds are generally sugars and include sucrose, galactose, and trehalose. These CPA compounds are not necessarily included in the freezing solutions utilized in slow-rate freezing but are frequently used to control the movement of water across the cell membrane after thawing (discussed in the section "Embryo Thawing"). Non-penetrating CPA compounds are commonly included in vitrification solutions. Freezing solutions used in slow-rate freezing commonly include only one CPA compound, though some practitioners do include sucrose with EG.

Modern freezing solutions for slow-rate freezing are typically commercially provided solutions. Penetrating CPA concentrations are normally 1.4 mol/l for glycerol or 1.5 mol/l for EG. The freezing solutions are hypertonic, causing cells to shrink on initial exposure but then slowly expand to their original size as the CPA enters the cells. Initially it was believed that this type of osmotic stress would reduce embryo viability and embryos were exposed to the CPA solutions in a stepwise manner. Empirical studies demonstrated that stepwise addition of CPA was not necessary. This is particularly true for EG. Embryos are placed in the freezing solution and allowed to equilibrate. Since 1.5 mol/l EG is not very toxic, equilibration times (5 minutes for 1.5 mol/l EG and 10 minutes for 1.4 mol/l glycerol [8]) are not critical and equilibration will continue while the embryos are loaded into 0.25-cc straws and during the first part of the cooling process. Embryos placed in a CPA solution will float because of the hypertonic nature of the solution and slowly sink as CPAs enter the cells. Normal practice is to start loading embryos as soon as they have settled to the bottom of the dish, with a minimum of 10 minutes of equilibration, before being placed in the embryo cooling chamber where they are held at −5 to −7.5 °C for 2 minutes before seeding (explained in the section "Ice Crystal Seeding").

Vitrification Solutions

In order for vitrification to occur at warm temperatures (20–25 °C), the CPA concentration must be higher than that described for slow-rate freezing. The majority of vitrification solutions used for bovine embryos consist of a combination of two or more penetrating CPAs and a non-penetrating CPA such as sucrose or trehalose. A typical vitrification solution for bovine embryos would consist of 15–20% EG, 15–20% dimethyl sulfoxide (DMSO), and 0.3–0.5 mol/l sucrose or trehalose. The combined concentration of EG and DMSO is at least three times the concentration of EG or glycerol used for slow-rate freezing. Extended exposure to these concentrations of CPAs can be toxic, so embryos are exposed to stepwise higher concentrations

and the exposure time to the final vitrification solution is limited to 40–45 seconds.

Rapid Cooling

In order for vitrification to occur at high temperatures, the cooling rate must be very rapid, in the order of 1000 °C/minute or greater. To achieve these rates of cooling, even by transfer directly into LN, the surface area to volume ratio must be greater than that of the 0.25-ml semen straw. One method of increasing surface area to volume ratio is the "open pulled straw" [10], which has been successfully used for the vitrification of bovine embryos. This is accomplished by gently heating the plastic semen straw and pulling it to yield a much smaller diameter and thus increasing the surface area to volume ratio. Additional methods of producing ultra-rapid cooling rates include the Cryoloop™, Cryotop™, and Cryoleaf™ [11]. These examples consist of various platforms or carriers that the embryo can be placed on in a minimal amount of vitrification solution. They create a high surface area to volume ratio and when placed directly in LN yield ultra-rapid cooling. All these carriers result in exposure of the embryo to LN, so once cooling is complete the embryo and carrier are placed in some sort of outer container that can be sealed. The same principle of high surface area to volume ratio that results in ultra-rapid cooling will result in ultra-rapid warming when placed in warm thawing solution. Thawing solutions will typically consist of a sucrose solution to ensure rapid heat transfer and control cellular swelling during removal of the CPAs.

Applications for Vitrification

Vitrification has been applied to the cryopreservation of human embryos and oocytes extensively, but far less for bovine embryos. At present there is no commercial application for cryopreservation of bovine oocytes and the value of vitrification for day 7 late morula or blastocyst stage bovine embryos has not been established. Vitrification has the advantage of not requiring a controlled-rate freezer and the freezing time for a single embryo is much less. However, the precise nature of the timing needed for vitrification requires that this procedure be conducted one embryo at a time. Because of this, when even a moderate number of embryos need to be processed, as much or more time will be required for vitrification compared with slow-rate freezing in which groups of embryos are frozen in a single cycle of a controlled-rate freezer. The precise nature of the timing and the handling procedures required during ultra-rapid cooling and warming during vitrification can result in variable success rates depending on the skill level of the person performing the procedure. There are very few data from controlled studies under practical conditions comparing success rates for vitrification compared with slow-rate freezing for late morula or blastocyst stage bovine embryos. Additionally, like embryos frozen in glycerol, thawing vitrified embryos requires removal of CPA and reloading into straws for transfer, making it less convenient than DT for bovine practice [12].

Embryo Selection, Handling, and Preparation

Once ova and embryos are removed from the reproductive tract of the donor cow they are placed in a commercially available isotonic holding media suitable to support embryo viability. If embryos are recovered from more than one donor laboratory, procedures should be in place to keep each sample separate from one another so that no embryos could be switched between petri dishes. This may include labeling all dishes with corresponding donor identification (both the dish and its cover should be identified) and embryo handling pipette tips should be changed between dishes. Ova and embryos are evaluated morphologically using a stereomicroscope with a minimum of at least 50× magnification and embryos and ova are segregated into unfertilized oocytes, degenerate embryos, and viable embryos. Viable embryos are further classified into grades one, two or three and degenerate embryos are classified grade four. The criteria for embryo grading, as well as the criteria for classification of embryonic stage, have been described in Chapter 9 of the *IETS Manual* [13].

Embryos are washed to remove any debris [13]. If embryos are intended for export the washing procedure should include two washes including trypsin. Chapter 6 of the *IETS Manual* covers sanitary handling of *in vivo* embryos in more detail. After sufficient washing, embryos are transferred into a CPA solution such as 1.5 M EG or 10% glycerol and individually loaded into 0.25-cc straws. The cotton/powder plug end of the straw is sealed when wetted by the fluid when the straw is filled during loading. The open end of the straw can be heat sealed or plugged and a label containing the registration numbers of the donor and sire, date of collection, breed, freeze code, and unique straw number is attached. Since embryo quality is a factor that varies considerably and has a major influence on the efficiency of cryopreservation, only grade 1 or 2 quality embryos are frozen. It is important to realize that many of the differences in morphological characteristics that constitute the embryo grading criteria are amplified by the freeze–thaw process. The freeze–thaw cycle can only be expected to reduce the number of viable cells, so these

characteristics that result in embryos being assigned lower grades are amplified by the freeze–thaw cycle. The pregnancy rate of grade 3 frozen/thawed embryos is typically unacceptably low. Embryos that have a damaged or missing zona pellucida also have reduced pregnancy rate following thawing and transfer.

Some practitioners fill the entire straw with 1.5 mol/l EG, while some load most of the straw with holding media and only the chamber containing the embryo with EG. There are numerous personal preferences to loading straws [14]. 0.25-cc straws can be inserted into the tip of a 1-cc tuberculin (TB) syringe for loading. The straw is rinsed to remove any fibers or plastic slivers before loading. A column of holding media or media containing 1.5 mol/l EG is aspirated followed by a short air chamber. The air chamber serves as a plunger and barrier to the cotton plug (if embryos contact the cotton plug they will not be expelled during transfer). Another short chamber of holding media is aspirated, followed by another air bubble; the embryo in EG is loaded into the straw, followed by another air bubble, and the rest of the straw is loaded with media. It is important that the air chambers be large enough to keep the chambers from mixing during freezing and thawing. The air chambers shrink during freezing and liquid expands so it is not uncommon for the chambers to move after the freeze–thaw process.

While stage of development is a factor in embryo cryopreservation for some species (human, pig, and horse, for example), embryonic stage is not a major factor for cryopreservation of bovine embryos within the context of normal embryo transfer. Differences in the ability to survive cryopreservation based on embryonic stage have been observed for bovine embryos [15], although all stages normally recovered from a day 7 (day 0 being observed or expected estrus) non-surgical embryo collection survive cryopreservation at an equal rate. A possible exception to this exists for hatched blastocysts, which have been observed to not survive cryopreservation well. Hatched blastocysts are not normally recovered at day 7 from cattle but are sometimes encountered when collection is delayed until day 8.

Embryo Freezing

The straws are placed upright (label end up and embryo in straw down) into a freezer chamber at −6 °C (range −5 to −7 °C) and held for two minutes prior to seeding (ice crystal formation; the instrument used to induce crystal formation should not be held near the embryo). The freeze program usually holds embryos at −6 °C for 6–10 minutes then cools at 0.5 °C per minute to −30 to −32 °C. Embryos are plunged into LN, packed into goblets labeled with the donor, sire, and date of processing information, and stored in an LN tank.

Currently, most practitioners freeze embryos in 1.5 M EG with or without sucrose which is the CPA used in the DT method of preserving embryos. No differences in pregnancy rates were observed between embryos frozen with or without supplemental sucrose in the CPA [14]. DT allows the embryo to be thawed, loaded directly into a transfer instrument, and transferred without rinsing the CPA or microscopic evaluation prior to transfer. Prior to the mid-1990s embryos were frozen in 10% glycerol. This method required embryos to be carefully deposited into a dish and moved through a series of dish wells containing decreasing concentrations of glycerol to remove the glycerol from the embryo, then microscopically evaluated for freeze/thaw damage prior to transfer. This procedure added time and required a clean "mini-lab" area on the farm to process the embryos prior to transfer. DT embryos are frozen and packed in yellow straws, goblets, and cane labels. Embryos frozen in glycerol are packed in white or clear goblets and white cane labels and should not be transferred in the direct method (personal experience).

It is critically important that embryos be handled with the utmost care. Embryos can be damaged or killed by mishandling, resulting in a reduced pregnancy rate. Embryos are susceptible to UV damage, chemicals (including osmotic changes), bacterial contamination, drastic temperature changes, and foreign materials (foreign bodies loaded and transferred with the embryo may result in a failed transfer). Implementing a total quality management (TQM) approach to embryo and laboratory hygiene to provide general cleanliness, aseptic techniques, and procedural consistency is critical to the success of an embryo production laboratory [13].

Ice Crystal Seeding

Aqueous solutions have a tendency to cool below their freezing point (undercool) before ice nucleation (freezing) occurs [16], which may result in spontaneous, uncontrolled ice formation including intracellular ice formation resulting in cell death. Control of when and where ice crystallization occurs is a necessary step in cryopreservation of bovine embryos. Ice crystal nucleation or "seeding" is intentionally inducing ice crystal formation in the extracellular media away from the embryo [6, 16, 17]. The straws are placed in the cooling chamber of the embryo freezer. After an equilibration period of two minutes in the chamber, ice crystal seeding is performed by touching part of the straw away from the embryo with metal forceps or a swab saturated with LN. Seeding induces ice crystal formation in the liquid in the straw and the ice formation spreads the length of the straw. As ice forms, water molecules are

removed from the liquid surrounding the embryos, increasing the solute and CPA concentration in the liquid around the embryo and drawing additional water molecules from the cells, which further dehydrates the embryo. The increasing concentration of CPA within the embryo reduces the freeze point of intracellular fluid [7], protecting the embryo from intracellular ice formation.

Embryo Packaging

The preferred package used for transferring and freezing embryos today is a 0.25-ml plastic straw [18]. The straws have an open end for loading and cloth wicks with a powder that seals the plug end when wetted properly. The ideal package containing the embryo should transfer heat and withstand changes in temperature from ambient room temperature to extreme cold storage (−196 °C) without damaging the container material and withstand rapid thawing from −196 to 30 °C. The package must remain intact and not allow any leakage of LN into the container. LN leakage may contaminate the contents of the straw and LN may vaporize quickly during thawing, potentially damaging the package and causing embryo loss. Semen and embryos are packaged in straws for convenience and efficiency of storage as well as ease of use in breeding and transfer pipettes.

Embryo Labeling and Record Forms

Confidence that given offspring resulted from the transfer of a specifically identified embryo is critical to the integrity of embryo transfer technology. Therefore accurate embryo recovery and labeling records are essential. Record forms have evolved to accommodate *in vivo* and *in vitro* embryo production as well as to transfer the information with embryos for international export. Chapter 9 of the *IETS Manual* [13] contains detailed information and instructions for proper labeling and record keeping as well as the proper forms (*ABC Embryo Certificates*) to provide a permanent record of the production, collection, and disposition of embryos.

The amount of information included on labels of cryopreserved embryos may vary. Minimal information should include the sire and dam of the embryo and the date the embryo was frozen. Additional information includes the practitioner or company conducting the freezing, breed of sire and dam, registration numbers, and the developmental stage and quality grade of the embryo at the time of freezing. The IETS provides "freezing codes" to its members that can be used to identify the practitioner or company conducting the freezing. This information should be printed directly on the label attached to the straw. Straw printing machines are available but not frequently used for embryos compared to semen straws because the information could be unique for each embryo. Information can be printed by hand but this can lead to legibility problems. One approach to labeling is to heat-seal a 0.5-ml straw to the 0.25-ml straw and apply labeling information on or inside the attached 0.5-ml straw. Another approach is the use of plastic identification and sealing rods. These rods attach to the end of a semen straw and can be used for labeling. In both of these approaches information can be printed on adhesive labels that can be wrapped around the labeling straw or plug. It is not recommended that labels be placed on the straw containing the embryo because this could interfere with the efficient transfer of heat during freezing and thawing. Another advantage of the approaches that place labeling information separate from the straw containing the embryo is that they provide a handle such that the information can be read without removing the straw containing the embryo from LN. Complete information about proper labeling of straws, goblets, and canes is provided by the AETA and can be found at https://www.aeta.org/docs/aetastrawlabel.pdf. Embryos frozen in EG are packaged in yellow straws. Non-DT embryos are in white. Embryos frozen by vitrification have blue labels or straws.

Embryo Thawing

Even though a slow rate of cooling is used in the early phase, a rapid rate of cooling is used in the final phase that results in vitrification of the remaining water in the cells. This results in a requirement for rapid thawing. If thawing is allowed to occur slowly, ice crystals will form during thaw and cellular damage will occur. Rapid warming is accomplished by transfer of the containers into warm (25–35 °C) water until all ice has thawed. It has been observed that if this rapid warming starts immediately from the liquid phase of LN there can be a high incidence of damage to the zona pellucida. Empirical studies have shown that if warming occurs in air for about 30 seconds before transfer to warm water, the incidence of zona pellucida damage is reduced. With this approach, warming through the critical temperature phase of above approximately −60 °C is still rapid and cellular damage due to ice crystal formation during thaw is avoided.

Often the thawing instructions are included at the bottom of the embryo processing certificate (*AC – Certificate of Embryo Recovery and Freezing* form). However, if the paperwork or other information is not available, the canes should be examined to make sure the embryos were frozen in 1.5 M EG designed for DT. If the embryos are not packaged in yellow goblets and straw labels or are not clearly labeled as DT they should not be thawed according to DT instructions. A commonly used procedure for thawing DT embryos is to air thaw for 5–10 seconds then submerse in 80–95 °F water for 15–20 seconds, wipe the straw dry, cut

the sealed end (the end opposite the cotton plug), load into a transfer pipette, and transfer into the recipient. A survey of embryo transfer practitioners in 1998 reported some variation of thawing temperatures with no differences in resulting pregnancy rates [14].

If embryos are frozen in glycerol the glycerol will need to be removed from the embryo prior to transfer. After thawing, the contents of the straw are carefully deposited into a petri dish and embryo(s) located and evaluated. During removal of glycerol, water enters the cells faster than glycerol exits and results in swelling of the cells. Cells are far less resistant to swelling than shrinkage and the degree of swelling that occurs with normal concentrations of glycerol can be very detrimental. Initially, this problem was circumvented by removal of glycerol by equilibration with stepwise lower glycerol concentrations. A number of approaches employing sucrose have been utilized, including a "one step" method using a 1-mol/l sucrose solution with an osmotic pressure equal to that of the freezing solution [19]. With this approach glycerol can leave the cells without water entering and no swelling occurs. After glycerol has been removed embryos can be placed in a physiological solution and water reenters the cells. Other approaches have utilized lower concentrations of sucrose [20], which can be removed in two steps. This approach prevents cellular swelling and also limits the degree of cellular shrinkage and dehydration. All these approaches have been successful in the preservation of viability of cryopreserved embryos but involve the movement of embryos between different solutions, requiring a certain degree of embryo manipulation skills and equipment between thaw and transfer. Sometimes the embryo has been severely damaged by the freeze/thaw process and judged unfit for transfer. It is not uncommon for the zona pellucida (clear envelope surrounding the embryo) to be fractured after thawing. As long as the cell mass is intact and resembles the description of the embryo prior to freezing the embryo should still be viable. The embryos are reloaded into straws with holding media, loaded into a transfer gun, and transferred into a recipient.

Transfer of Cryopreserved Embryos

The parameters for transfer of cryopreserved embryos to recipients are no different from those for transfer of non-cryopreserved or "fresh" embryos. Synchrony requirements between the donor and recipient estrous cycles are the same as for fresh embryos. This emphasizes the importance of including information concerning the stage of development on the labeling of cryopreserved embryos. If the embryonic stage is between a late compacted morula and a blastocyst, the assumption of a day 7 embryo is appropriate. Pregnancy rates for frozen/thawed embryos transferred to recipients 6.5–8.5 days after estrus are acceptable [21]. It is difficult to discuss expected pregnancy rates with any embryo transfer because there are so many variables. The same is true for the transfer of cryopreserved embryos. If high-quality day 7 bovine embryos are cryopreserved by the methods described here for slow-rate cooling, there should be an expectation of pregnancy rates very comparable to those expected for fresh embryos under the same conditions. The qualification of "high-quality embryos" is very important for cryopreserved embryos because the difference in pregnancy rates becomes significant for lower-quality embryos [22].

Embryo Freezers

There is a variety of embryo freezing equipment available, from inexpensive, manual machines that require constant manual adjustment and monitoring to more expensive, complex, computer programmed machines that require relatively minimal supervision. Freezing machines need to cool at the desired rate and the temperature in the freezing chamber should be monitored accurately. Some are designed to be used in LN (direct vapor or with the chamber suspended in nitrogen liquid) or an alcohol bath. Considerations for selecting equipment include reliability, ease of use and/or programming, number of straws or other types of containers, and whether equipment is portable or will remain in a laboratory. Regardless of expense and complexity, all equipment requires regular maintenance and supervision to ensure proper function. Be cautious of purchasing used equipment. Before purchasing, have the used equipment examined to make sure it is functioning properly and serviceable. A backup power source is essential. While some equipment has built-in battery backup, others may require some type of uninterruptible power backup source.

Managing the "Problem Donor"

Ky G. Pohler, Lohana Fernández, Rebecca K. Poole, Sydney T. Reese, and Gessica Franco

Department of Animal Science, Texas A&M University, College Station, TX, USA

Introduction

Genetic enhancement is a core motive for cattle producers, specifically seedstock producers. The bull can easily produce thousands of offspring through artificial insemination, and it has been, historically, more difficult to multiply the genetics of the female. These genetically superior females, or donor cows, are females whose oocytes or embryos are collected for transfer into a recipient cow in order to increase the number of offspring produced per donor. Genetics from females are mainly collected through one of two ways: ovum pick up (OPU) followed by *in vitro* production (IVP) of embryos or conventional embryo flush for embryo transfer (ET) [1]. In a conventional embryo flush, cows are inseminated following hormonal treatments to increase the number of ovulations per ovary in order to collect multiple embryos [2]. On the other hand, OPU can be utilized to collect oocytes from either exogenous hormone stimulated or non-stimulated donors [3]. Both techniques require investments of skill, time, and money; therefore selecting the ideal method that will provide the desired genetic enhancement can be a challenge. Criteria to select the correct protocol and approach for the donor cow includes factors such as age [4], subspecies (*Bos taurus* or *Bos indicus*) [5], body condition score (BCS) [6], and nutrition [7]. Donors' most common problem is being anestrous due to the presence of abnormal ovarian structures or the inhibition of hormones, which then would require individualized solutions [8]. Moreover, repeated exogenous ovarian stimulation by follicle stimulating hormone (FSH) can cause decrease in superovulatory response [9–14]. Variability in embryo quality and quantity is also one of the main problems found between donors and within the same donor. This chapter will discuss the factors that cause problems mentioned and management strategies to mitigate these challenges.

The Donor

Ovarian Dynamics of *Bos indicus* vs *Bos taurus*

B. taurus and *B. indicus* are subspecies of domestic cattle and have distinguishable physical characteristics with many physiological differences. *B. indicus* (zebu) cattle are known for their adaptation to tropical and subtropical climates [15], while *B. taurus* are more physically adapted to temperate climates [5]. In regard to reproduction, these subspecies have major differences in ovarian dynamics including follicular development and sensitivity to exogenous hormones that will affect ET and OPU outcomes. Understanding the physiology of each subspecies is essential to improve donor cow management.

Regardless of subspecies, cattle have a predominance of two and three follicular waves during each estrous cycle [16, 17]. Cows with two follicular waves will start the second follicular wave emergence later (day 9 or 10) than with three follicular waves (day 8 or 9) [18]. Considering that follicular wave pattern is repeatable within individuals [19] and that variability in treatments with exogenous hormones is dependent on the follicular stage [20], there is a need to synchronize emergence of a new follicular wave. The most common method to enhance superovulatory results is to synchronize the cow in order to coincide the initiation of exogenous superovulation treatment and wave emergence [18, 21], which will be addressed in the section "Variability in Response to Stimulation with FSH."

B. indicus cattle have greater small (<5 mm) antral follicle count [22] and greater percentage of oocyte recovery using OPU [23], even in the absence of superovulatory treatment [24]. When superovulatory protocols are used, *B. indicus* cows require lower quantities of gonadotropins to obtain the same number of oocytes recovered as *B.*

taurus [25]. *B. indicus* cows on average require 133–250 mg of FSH [26–31] while *B. taurus* require an average of 360–400 mg [27, 32]. Such response is due to the greater sensitivity to exogeneous FSH [15] suggested to be related to higher bioavailability of insulin-like growth factor 1 (IGF-1) in *B. indicus* follicles [33]; however, low quality oocytes remain problematic for donors of both subspecies. A better understating of oocyte quality will be addressed in the section "Variability in Embryo Quantity and Quality." Larger follicles have greater number of IGF-1 receptors regardless of breed [34–36] that aid in follicular growth [37] and oocyte maturation [38, 39]. *B. indicus* animals have smaller dominant follicles (10–14 mm) [16, 40–42] when compared to *B. taurus* (14–20 mm) [43, 44] which have higher concentrations of IGF-1. Nonetheless, *B. indicus* cows have a greater bioavailability of IGF-1 due to the elevated presence of the protein that degrades IGF-1 binding protein [33], indicating a potential mechanism for higher oocyte quality obtained from *B. indicus* cows compared to *B. taurus* [45], especially in tropical environments [46, 47]. Understanding ovarian dynamics such as follicular waves and most importantly characteristics inherent to subspecies like follicular size, oocyte quality, and sensitivity to exogenous hormones is key to utilizing and maximizing results from a hormonal or non-hormonal treatment involved in OPU and ET techniques.

Age

Cows are generally identified as potential donors when they have already produced a reliable reproductive and production record that demonstrates genetic superiority; however, there has been an increase in OPU and ET techniques performed in heifers selected for higher quality genetics. Nonetheless, in many cases, this decision comes later in life when the animal is older, leading to an interest in the association between age and donor quality which is often a negative relationship [48]. When making the decision to collect or flush a donor, the main objective is obtaining the greatest number of progeny in the shortest window of time to maximize lifetime productivity or to obtain superior genetics. In *B. taurus* beef cows 10 years of age and older, there is approximately a 20% decrease in the number of transferable embryos produced compared to younger cows [49]. Similar results were observed in Holstein and Charolais donors where total number of embryos and transferable embryos decreased as age increased [50, 51]. In contrast, others have reported no significant correlation between age and superovulatory response in Holstein, Simmental, and Angus breeds [51, 52].

Potential mechanisms of reduced embryo quality as age increases are yet to be established. Morphological abnormalities and differences in metabolic factors of the oocyte as age increases may contribute to future poor *in vitro* embryo development [53]. Another reason is attributed to the hormone concentrations before and during OPU in which younger animals had higher estradiol and lower progesterone levels [54]. High progesterone levels negatively affect follicle development in sheep [55], mice [56], and cattle [57] probably by the inhibitory effect on aromatase [58, 59]. On the contrary, older cows with lower progesterone levels before fertilization occurs have smaller ovulatory follicles and, thus, lower progesterone levels after ovulation and a decrease in embryo quality [4]. Moreover, oocyte abnormalities are higher in older cows due in part to a high incidence of failure to extrude the second polar body in the zygote (i.e. one-cell embryo) caused by impaired nuclear maturation [60, 61]. Lower oocyte quality due to an increase in age is also associated with a decrease in gene expression of the protein quality control system and genes related to mitochondrial activity [62]. Overall, in most cases, donor cows are older animals which can still produce good quality embryos and oocytes, indicating that age is not a decisive factor in the use of ET or OPU techniques; however, age can negatively impact oocyte and embryo yields.

Body Condition Score (BCS)

All living beings allocate available energy in a specific order, beginning with basal metabolism and growth, while estrous cyclicity and reproductive performance have the lowest priority [63]. BCS is a tool used to indicate the nutritional status of cows by visualizing the amount of fat and muscle in certain areas. Poor body condition will result in reproductive system quiescence to preserve proper function of other vital systems (the central nervous system, cardiovascular system, etc.). If donor cows are overfed and maintained at a high body condition this will normally negatively impact superovulatory response, decrease embryo and oocyte quality, and reduce pregnancy rates [64, 65]. High body condition decreases IGF-1 follicle concentrations [66], thus reducing the sensitivity of granulosa cells to exogenous FSH treatment and negatively affecting oocyte maturation [33, 67]. Moreover, cows with high body condition are predisposed to hyperinsulinemia and create an insulin resistance state, which impairs fertilization and embryo development [48, 68].

Produced by adipose tissue and increased by food intake, the hormone leptin is believed to be a key regulator of reproductive function. Increased circulating leptin has been positively correlated with luteinizing hormone (LH) pulses [69, 70] and leptin concentrations in follicular fluid [71]. Additionally, supplementing leptin to *in vitro*

maturation media increased subsequent blastocyst development and reduced cell apoptosis [72]. In spite of its advantages, higher body condition related to obesity and elevated concentrations of leptin can create a resistance to leptin in mice and women [73, 74]. Murine and bovine oocyte development and, thus, embryo yields *in vitro* are impaired by high levels of leptin [75, 76]. On the contrary, animals with low BCS have reduced plasma leptin levels [77]. Moreover, a decreased BCS and high energy requirements lead to a negative energy balance which increases non-esterified fatty acids (FAs) in the system [78], including in follicular fluid. Such levels may cause negative effects on oocyte maturation and thus on subsequent fertilization and embryo development *in vitro* [79]. In summary, ensuring good body condition in the donor cow will improve oocyte and embryo quality results; however, in cases where the animal is underweight, an OPU can be implemented and have better results than an ET.

Nutrition

Nutritional status will either positively or negatively affect reproductive performance, especially regarding the development and recruitment of follicles, and subsequent oocyte and embryo development. Thus, an animal's plane of nutrition must be intensely, yet carefully managed. In postpartum, lactating donor dairy cows, changes in metabolism and nutrient demands result in negative energy balance [80]. Energy deprivation reduces the concentration of IGF-1 and insulin by uncoupling of the growth hormone–IGF system, and reduces LH pulses, impairing follicle maturation and ovulation [81–83]. Moreover, excessive body fat mobilization is correlated with increase non-esterified FA and beta-hydroxybutyrate in follicular fluid [84, 85], which increases oocyte cell apoptosis and impairs early embryonic development [86–90]. Providing a diet with adequate energy concentration can overcome these endocrine changes and re-establish follicular fluid estradiol, improving oocyte quality during the postpartum period [91, 92].

Short- and long-term changes in energy intake affect superovulatory response in lactating and non-lactating donor cows. In lactating donor cows with lower body condition, increases in energy intake to levels higher than maintenance requirement elevate circulating insulin and IGF-1 [48, 68, 93]. These growth factors improve the effect of gonadotropins on follicular granulosa and luteal cells, enhancing follicle recruitment and steroidogenesis [38, 94]. In non-lactating donor cows with adequate or high body condition, however, high energy intake can increase catabolism of steroid hormones and high circulating concentrations of insulin and free FA derived from adipose tissue [68, 87, 95, 96]. High insulin and free fatty acid concentrations will most likely create an insulin resistance state and impair follicle stimulation response [48, 97, 98]. Overfeeding non-lactating cows or heifers, therefore, may reduce superovulatory responses.

Supplementation with fat, protein, and minerals can enhance oocyte and embryo quality. Results of fat supplementation in the form of FA are dependent on the lipid source (saturated or unsaturated) [99, 100]. Fat supplementation with unsaturated FA (not degraded in the rumen) as a major component can improve quality of *in vitro* produced bovine oocytes [101] and embryos [102], and porcine embryo viability after cryopreservation [103]. Bovine embryo quality is enhanced possibly by an increase in trophectoderm cells in the blastocyst stage [102]. Likewise, protein supplementation can improve reproductive performance; however, providing protein above nutrient requirements can lead to increased levels of urea (metabolite of protein digestion in the rumen) in the system [104, 105]. High levels of urea impair oocyte and embryo development by disrupting meiosis, as this also lowers oviduct and uterine pH, affecting embryo development and fertility [106, 107]. Mineral supplementation is a crucial yet often overlooked management tool that can affect embryo production. Recovery of cumulus oocyte complexes from donors supplemented with organic trace minerals improved subsequent *in vitro* embryo production when compared to those donor's receiving inorganic mineral sources [108]. Donors in good nutritional status and body condition, however, may not see an added benefit from organic trace mineral supplementation [109].

Adequate nutritional status can enhance reproductive performance in donor cows by improving embryo and oocyte quality. Managing high-energy diets must take into consideration the animal's metabolic status and body condition, with overfeeding constantly having detrimental effects. Supplementing FA or mineral is dependent on its source, while the negative effects of high-protein supplementation are related to urea circulating concentrations. In summary, donor cow's diets must be formulated to ensure a level energy balance combined with good body condition; moreover, it is important to supply nutrients that will optimize and meet the animal's requirements.

Problems Related to Donors

Anestrous Donors

Anestrous is a period where normal ovarian cyclicity ceases, causing an absence in estrus behavior. Heifers have a natural anestrous period until the onset of puberty and

pregnancy, which is also considered an anestrous stage [110, 111]. Naturally, cows experience a 40- to 60-day period of anestrous after calving [112–114] and management decisions can increase or decrease the length of this period. Additionally, significant research has evaluated voluntary waiting period (time from parturition to first insemination) management strategies in dairy herds to maximize reproductive efficiency [115, 116]. Extended postpartum anestrous can be attributed to two main causes: (i) uterine disease and infection and (ii) insufficient nutritional status prior to and post parturition. Uterine infections will increase the time required for complete uterine involution after parturition, in which the uterus shrinks back to its normal size [117]. Meeting nutritional requirements of the cow to prevent negative energy balance postpartum and ensuring a good BCS will aid in normal uterine involution and return to cyclicity by allowing the hypothalamus to resume its secretion of gonadotropin releasing hormone (GnRH) [118]. Considering the risk of long anestrous intervals and cyclicity failure, it is important to ensure proper management of the donor cows by maintaining good body condition at least one month prior to any ET or OPU procedure. If requirements are not met, deficiencies in protein quality, feed intake, and mineral, vitamin, and energy requirements must be addressed.

Persistent ovarian structures, including follicular cysts and corpus lutea, are a common cause of anestrous periods associated with a negative energy balance after parturition in high-producing dairy cows [8]. During the first cycle following parturition, 6–30% of dairy cattle will develop an ovarian cyst [119, 120]. A persistent follicle is considered cystic when it has a diameter greater than 17 mm and it persists for over six days [121]. Advances in technology, such as ultrasonography, allow visualization of follicular and luteal ovarian dynamics contributing to easier management of cows with persistent structures [122]. Symptoms of follicular cysts include altered estrous cycles and shorter intervals between estrus manifestation that aid in identifying problematic cows [123, 124]. Literature commonly characterizes altered LH release from the pituitary by GnRH as the main cause of an ovarian follicular cyst mainly due to a distorted feedback on the hypothalamus [8, 125–127]. Although cysts can undergo regression without interference, physical manipulation such as rupturing the follicle while performing a transrectal palpation or exogenous hormones such as GnRH or progesterone will eliminate the cystic follicle [128]. Performing a manual rupture of the cystic follicle should be carefully regarded as hemorrhaging may result [129]. Administration of GnRH will induce a surge of LH to cause ovulation of the cystic follicle [130]. Progestin devices have also shown to effectively regress follicular cysts, prevent future development of others, and return cyclicity in beef cows [119, 131, 132]. Alternatively, other data indicated that progestin-based estrus synchronization when used over long intervals of time may increase the risk of follicular cyst development as a result of the presence for longer periods of the dominant follicle [133]. Another solution for cystic follicles is treatment with human chorionic gonadotropin (hCG) [134] or addition of hCG to the synchronization protocol [135]. Treatment with FSH will not cause a regression of the follicular cyst but increases LH receptors that will aid in responsiveness of granulosa and luteal cells to induce ovulation [136].

Cysts can also be characterized as luteal cyst, with the main differences between them being the deficient luteinization process in a follicular cyst and wall thickness, with luteal cyst having a wall larger than 3 mm and it can be visibly seen in an ultrasound as a white or gray color [8]. Luteal cysts secrete progesterone in higher concentrations and are bigger in size than a follicular cyst [120]. These structures are corpus luteum (CL)-like in terms of production of progesterone and luteinized cells, so prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) administration results in the regression of luteal tissue [137, 138].

An inability to have follicles differentiate into a dominant follicle or anovulation of the dominant follicle can lead to an extended anestrous period. Treatment with progestins has shown to be advantageous with anovulatory or unresponsive ovaries. A progesterone releasing intravaginal device (PRID) is an exogenous, non-invasive way to administer therapeutic progestins. Such protocols normally utilize $PGF_{2\alpha}$ coupled with estradiol or GnRH doses in countries where estradiol is banned from use following progestin removal [113]. The mechanism of combining these hormones to aid in dominant follicle development is by suppressing ovulation with progesterone or maintaining an existing CL, then removing the negative feedback of progesterone and regressing the CL by administering $PGF_{2\alpha}$. The subsequent administration of GnRH or estradiol will induce a new follicular wave formation and, thus, a new dominant follicle and estrous cycle. A more overt or more strongly expressed estrus has been shown to be associated with higher embryo viability [139]. In general, an extended anestrous stage in cows can be prevented by ensuring good nutrition and adequate body condition. Moreover, impaired estrous cyclicity in donor cows caused by abnormal ovarian structures can be detected based on clinical signs or with an ultrasound examination and treated with exogenous hormones.

Repeated Superovulatory Treatments

Use of exogenous hormones to stimulate follicular development and growth in cows has been well documented [18, 140]. Superovulatory protocols can be performed every

30–40 days for ET with no detrimental effects on oocyte yield or quality [140, 141], but a decrease in response is observed after three to five sessions [52, 142–144]. Following repeated superovulatory procedures, the effectiveness of FSH stimulation will decrease, which can be explained, in part, by an alteration of the FSH receptor [9]. Therefore donors should be rested for an extended period, allowing the opportunity to carry a natural calf or to establish pregnancy and induce abortion.

In rats, cows, and pigs, a continuous dose of FSH results in desensitization of FSH receptors in granulosa cells [10–13, 145]. Treatment with exogenous progesterone and $PGF_{2\alpha}$ between superovulatory protocols may reduce detrimental effects of stimulation by preventing ovulation and inducing luteolysis [2]. Additionally, cows with low stimulatory response at the beginning of the treatment may be prescribed higher FSH doses in subsequent protocols to increase stimulation [146, 147]. Summarizing, detrimental effects on follicle stimulation response by repeated superovulatory treatments can be nullified by providing a resting period after three to five ET sessions, establishing pregnancy and inducing abortion, or with exogenous hormone treatment between superovulatory protocols.

Variability in Response to Stimulation with FSH

As previously mentioned in this chapter, FSH is the hormone responsible for the stimulation of recruitment and development of ovarian follicles. Due to the short biological half-life of FSH in the bovine circulatory system (approximately 4–6 hours), a typical superovulation protocol involves a series of 7–10 separate FSH doses administered at 12-hour intervals over a 4-day period [148, 149]. Typically, 72 hours after initiation of the superovulation protocol, $PGF_{2\alpha}$ is administered to induce luteolysis (regression of the CL) and enable onset of estrus (36–48 hours) and ovulation (24–36 hours) in donors [150]. The dose of FSH will vary based on product, body weight, stage of production, and the breed of the donor. Heifers and *B. indicus* cattle have a greater sensitivity to FSH and, thus, typically receive a lower dose of FSH for superovulation [21, 151]. While the dose of FSH varies, it is important to note that too much exogenous FSH negatively impacts the superovulatory response by causing the donor to produce the ovarian hormone inhibin, which will inhibit FSH production by the pituitary gland [152, 153].

Individual variation among donors in superovulatory response and the reasons for variation are not well understood. Previously mentioned intrinsic (e.g. age, genetic differences, BCS) and extrinsic (e.g. nutrition, hormone preparation) factors do influence the superovulatory response. The ovarian status (i.e. phase of the estrous cycle) of the donor at initiation of the superovulation protocol has been suggested to be a factor determining the superovulatory response [154]. There have been inconsistent reports on the effect of the presence of a dominant follicle at the time of initiation of the superovulation protocol on superovulatory response; however, multiple studies agree that the presence of a functional dominant follicle (i.e. diameter of >9 mm and stable diameter for less than 4 days) may be a limiting factor for superovulatory response [155]. One method to ensure the absence of the dominant follicle is ablation of the largest/dominant follicle prior to the superovulatory protocol [156, 157]. The results are inconsistent and this technique requires equipment and trained personnel for ultrasound-guided follicle aspiration. It is a common practice to initiate the superovulation protocol 8–12 days (i.e. mid-cycle) after natural estrus expression [18]. This is an ideal time for initiation because it encompasses the time of the emergence of the second follicular wave in cattle exhibiting two- and three-wave cycles [158, 159]. Moreover, many investigators have found a positive correlation between the number of small (2–4 mm) and medium (5–8 mm) antral follicles present on the ovary prior to superovulatory treatment and a better superovulatory response including the number of corpus lutea after superovulation and the number of transferable embryos recovered [160–162]. In contrast, others have not identified any correlation between the number of follicles and superovulatory response [163, 164]. Taken together, initiation of the superovulatory protocol during mid-cycle can be beneficial, and the quantity and quality of follicles that can respond to FSH is the primary reason for the variability of superovulatory response between individuals.

Variability in Embryo Quantity and Viability

The number of embryos recovered from a donor is directly dependent on the number of follicles that ovulate. While superovulation produces more follicles and thus more oocytes, the superovulation procedure may induce abnormalities in oocyte maturation, which negatively impacts proper fertilization and/or embryo development. This can result in the subsequent recovery of unfertilized oocytes or poor-quality embryos.

To understand the potential negative impacts of superovulation on oocyte maturation, it is important to know the normal morphologic changes occurring during oocyte maturation *in vivo*. Oocyte maturation begins prenatally, and oocytes must undergo two meiotic divisions (meiosis I and II) [165]. The oocyte is arrested at prophase I and will resume meiosis once the follicle reaches dominance [166]. The LH surge controls the process of oocyte maturation (i.e. nuclear and cytoplasmic maturation) and resumption

of meiosis, and the oocyte will arrest at metaphase II until fertilization [167, 168]. It has been demonstrated that superovulated cattle display abnormal oocyte maturation based on the stage of nuclear and cytoplasmic maturation and time at which the LH surge occurred. Hyttel et al. [169] found that 37% of oocytes collected from superovulated cattle were classified as having undergone abnormal oocyte maturation. This would increase the likelihood of recovering unfertilized oocytes or poor-quality embryos. Typically, fertilization rates are 85–95% in cows with a single ovulation and it has been shown that fertilization rates in superovulated cows are reduced to 65–70%, most likely due to the altered oocyte maturation and suboptimal oocyte quality [155]. Blondin et al. [170] conducted a study to establish an ideal superovulation protocol that would maximize the number of competent oocytes (i.e. those that had undergone proper oocyte maturation and subsequent embryo development) collected from Holstein heifers. Treatments included four versus six FSH doses, collecting oocytes via OPU either 33 or 48 hours following the last dose of FSH, and administering LH 6 hours before OPU or not. Collected oocytes were subjected to *in vitro* fertilization to assess oocyte competence and embryo production rates. Results indicated that six FSH doses and performing OPU 48 hours following the last FSH dose greatly improved embryo production; however, administration of LH was more beneficial when OPU was performed 33 hours following the last FSH dose (Table 88.1). Together this suggests that inducing a preovulatory-type follicular environment (i.e. OPU 48 hours following final FSH dose plus LH administration) allows for proper nuclear and cytoplasmic maturation and oocytes are developmentally competent, thus improving subsequent embryo development.

While the number of embryos produced from a donor is important, perhaps the most critical aspect relative to successful ET pregnancy establishment is the quality of embryos transferred. Embryo quality is determined by visual assessment of the morphological characteristics of the embryo and a grade is assigned (grade 1 = excellent or good, grade 2 = fair, grade 3 = poor, grade 4 = dead or degenerating) following International Embryo Transfer Society guidelines. Unsurprisingly, pregnancy rates are greatest when grade 1 embryos were transferred compared to grade 3 embryos (50–60 vs 30–40%, respectively) [171]. While advancements have been made to optimize superovulation protocols, the number of transferable quality embryos (grades 1 and 2) recovered from donors has seen little improvement. A recent study evaluated the effect of circulating progesterone (high vs low) during a traditional superovulation protocol on embryo quality [172]. While the total number of embryos recovered was reduced for low progesterone donors, the percentage of grade 1 embryos recovered was significantly increased for low progesterone donors compared to high progesterone donors (58.2 vs 37.3%, respectively). Moreover, high progesterone donors had a greater percentage of grade 3 embryos and unfertilized oocytes recovered. A few studies that have evaluated the role of progesterone during follicular development have found that low progesterone results in increased LH pulse frequency and estradiol concentrations, but did not affect oocyte competence [173–175]. It appears that the combination of the endocrine profiles associated with low progesterone during follicular development and FSH doses during the superovulation protocol improves oocyte competence and subsequent embryo development. Therefore it may be advantageous to utilize a low or subluteal progesterone protocol (i.e. administration of $PGF_{2\alpha}$ plus exogenous progesterone at the start of the superovulation protocol) for donors that repeatedly produce poor quality embryos.

Table 88.1 Effect of collecting oocytes via OPU either 33 or 48 hours following the last dose of FSH, and LH administration (with or without LH), with four or six FSH doses on *in vitro* embryo production.

	Treatment		Blastocyst rate (%)[a]	
Number of FSH doses	**33 vs 48 hours**	**LH administration**	**Day 7**	**Day 8**
4	33 hours	No	20	40
4	33 hours	Yes	54	67
4	48 hours	No	43	53
4	48 hours	Yes	41	54
6	48 hours	No	52	63
6	48 hours	Yes	63	80

Source: Adapted from [170].

[a] Blastocyst rate is the percentage of embryos produced from an inseminated oocyte.

An Alternative for the Problem Donor: *in vitro* Production of Embryos

In the early 2000s, IVP of embryos emerged as an alternative to superovulation for embryo production from donor females [176, 177]. There are some advantages to IVP, including subfertile and pregnant donors can still be subjected to OPU; donors can be subjected to OPU at frequent intervals to increase the yield of embryos produced; efficiently using sexed semen; and rapid utilization of multiple sires [178–180]. One major advantage of IVP is the ability to collect a greater number of oocytes without the dependency on exogenous gonadotropin stimulation. This advantage overcame one of the major issues of conventional ET, which is an inconsistency in ovarian response to superovulation. In *B. indicus* breeds, this advantage is even more pronounced because a greater number of follicles are present on the ovary throughout the estrous cycle [24]. It has also been shown that the antral follicle number plays a role in oocyte recovery [181].

With these advantages of IVP, a greater number of transferable embryos per donor can be generated through IVP than through superovulation over time; however, the efficiency of IVP is low, with only 10–40% of oocytes developing into transferable embryos [182]. Moreover, pregnancy rates are approximately 10% lower for IVP embryos compared to superovulation derived embryos [183] and pregnancy losses are greater for IVP embryos [184, 185]. Additionally, pregnancy establishment of IVP embryos is more embryo stage and quality specific than *in vivo* derived embryos. Greater pregnancy rates were achieved following transfer of expanded blastocysts (stage 7) compared to morula (stage 5) and early blastocysts (stage 6) [186, 187]. Furthermore, while both grade 1 (excellent embryo quality) and 2 (good embryo quality) embryos produced *in vivo* can be transferred with no differences in pregnancy rates, transferring grade 2 *in vitro* produced embryos will result in a greater chance of early embryonic loss during the first 14 days after transfer [188].

IVP of bovine embryos has gained worldwide interest, with 58% of the ET performed in 2017 being IVP embryos [189]. Regardless of the setbacks and hurdles that IVP systems pose, the benefits of utilizing this tool cannot be ignored. Specifically, with this technology, donors can produce more offspring each year than by conventional ET and problematic donors can be used. However, from a management perspective it is important to note that some cows respond well to OPU/IVP but not ET, and vice versa. Therefore identifying the ideal scenario for each donor will help to increase genetic proliferation.

Summary

In managing problematic donor cows, the practitioner must consider the interaction between factors that may affect superovulatory response to exogenous hormone stimulated or non-stimulated techniques, thus influencing embryo and oocyte quality and viability. Intrinsic factors such as subspecies (*B. indicus* vs *B. taurus*), age, and body condition and extrinsic factors like nutrition contribute to this response. Older cows and body condition at either extremes (too fat or too thin) will negatively impact oocyte and embryo quality, while subspecies influences the sensitiveness of the exogenous hormone treatment response. Most common problems related to donor cows are being in anestrous, lower response to superovulatory treatment after repeated protocols, variability in response to FSH doses, and embryo and oocyte inconsistency in quality and quantity (Table 88.2). Solutions to such problems vary according to the animal and cause of the problem;

Table 88.2 Definition, causes, and suggested solutions of problems related to problematic donor cows.

Problem	Definition	Causes	Suggested solution(s)	References
Anestrous donors	↓ normal cyclicity and estrus behavior	Cystic follicle Luteal cyst	Ablation, exogenous GnRH or hCG, progestins, synchronization protocols, $PGF_{2\alpha}$	[121, 128–132, 134, 135, 137, 138]
Repeated superovulatory treatments	↓ superovulatory response	↓ FSH receptor	Resting periods, progesterone, and $PGF_{2\alpha}$	[2, 52, 142–144]
Responses to FSH	Variable response to FSH treatments	Intrinsic and extrinsic factors	Initiate superovulation mid-cycle, ablation of dominant follicle, cow selection with ↓ antral follicles, IVP	[18, 156–162]
Embryo quantity and quality	Variable production of good quality embryos	FSH doses and various endocrine profiles	$PGF_{2\alpha}$ + exogenous progesterone at initiation of superovulation	[170, 173–175]

however, for anestrous cows a variety of exogenous hormone treatments can return and prevent acyclicity. The negative effect of repeated superovulatory treatments can be nullified by allowing the animal a resting period to carry a normal pregnancy. Moreover, variability to FSH treatments can be decreased by initiation of superovulatory treatment in mid estrous cycle, ablation of dominant follicle prior to treatments, or performing OPU and *in vitro* fertilization techniques. Lastly, variability in embryo and oocyte quantity and quality can be altered by a dose of $PGF_{2\alpha}$ and exogenous progesterone at initiation of superovulation treatments.

In Vitro Fertilization

John F. Hasler[1] *and Jennifer P. Barfield*[2]

[1] *Bioniche Animal Health, Inc., Laporte, CO, USA*
[2] *Department of Biomedical Sciences, Animal Reproduction and Biotechnology Laboratory, Colorado State University, Fort Collins, CO, USA*

Introduction

In Latin, *in vitro* means "in glass," and *in vitro* fertilization (IVF) is frequently used as a general term for the process of generating embryos outside of the body, which also includes *in vitro* maturation (IVM) and *in vitro* culture (IVC). Typically, these procedures are conducted in the sequence IVM–IVF–IVC to produce embryos exclusively *in vitro* (IVP). Glass is rarely used for *in vitro* procedures today, having been replaced by disposable plastics, primarily made from polystyrene or polypropylene.

In 1959, the rabbit was the first mammalian species in which live offspring were produced by IVF [1], followed by laboratory mice in 1968 [2]. Because the mouse was not a good model for cattle, the first successful IVF with cattle was in 1977 when sperm were capacitated in the oviduct or uterus of a cow or rabbit [3] and the first live calf born in 1981 when a four-cell embryo was transferred into the oviduct of a recipient cow [4]. The first calves produced entirely from IVM, IVF, and IVC were born in 1987 [5]. Since that time, research on *in vitro* procedures has grown dramatically. In addition, *in vitro* procedures are now being used commercially in conjunction with embryo transfer (ET) in a number of countries. In this chapter we intend to describe the most current techniques for oocyte collection, IVP of embryos, and the utilization of IVP embryos in the cattle industry. Some of the applications of IVF technology in cattle are listed in Table 89.1.

Collection of Oocytes

Originally, *in vitro* procedures in cattle were conducted primarily for research purposes and utilized oocytes collected from superovulated females. When collected from preovulatory follicles or oviducts 20–24 hours after onset of estrus, oocytes have already undergone maturation and are ready immediately for IVF, followed by an additional interval for IVC. Oocytes collected from slaughterhouse-procured ovaries require IVM; thus research utilizing these oocytes lagged until IVM techniques were improved. Today, ovaries from cattle slaughterhouses are used extensively as a source of oocytes.

Oocyte Collection from Living Cattle

The primary method of collecting oocytes from live cattle is aspiration of ovaries manipulated per rectum and guided by a vaginally inserted ultrasound probe and needle. Prior to the development of this technique, oocytes were obtained surgically through a flank incision [6] or laparoscopic procedures via the paralumbar fossa [7], though these approaches were expensive, inefficient, and risked the formation of adhesions with subsequent loss of fertility. The history of laparoscopic oocyte recovery is reviewed by Tervit [8].

The introduction of real-time transrectal ultrasonic imaging [9] led to the development of techniques for the repeated collection of oocytes from bovine females. Ultrasound-guided collection of oocytes via the paralumbar fossa was described in 1987 [10], and the first repeatable, efficient technique involving transvaginal ultrasound-guided aspiration was developed in 1988 [11]. This technique has become widely known as ovum pick-up (OPU) or transvaginal aspiration (TVA). An ultrasound transducer and an attached needle guide of the type used in cattle are shown in Figure 89.1. A diagram of how the transducer is inserted into the vaginal fornix so that a needle can be guided through the vaginal wall and into the ovary is also shown. Today a large number of appropriate

Table 89.1 Applications of IVF technology.

Commercial applications
Offspring from infertile cattle
Offspring from pregnant cattle
Offspring from young heifers prior to breeding age
Salvage of genetics from terminally ill/injured cattle
Efficient use of sexed semen
Use of resorted semen (frozen–thawed and sexed after thawing)
Use of multiple sires in a short period of time
Utilization of slaughterhouse-derived oocytes for production of research and/or inexpensive embryos
Research applications
Improvement of IVF technology
Improvement of IVC for cloning and transgenic procedures

ultrasound monitors and transducer/needle collection devices are available from different manufacturers for OPU.

The number of oocytes collected from a cow during a single session of OPU depends on a variety of factors. On the mechanical side, the vacuum pressure used to remove the oocyte from the follicle, the gauge of the needle [12], and the length of the bevel on the needle [13] all impact the number of intact cumulus-oocyte complexes collected. Frequency of collection is another factor. OPU can be performed once or twice a week on the same cow without the use of exogenous hormones. Studies have demonstrated no advantage of interval length for the number of oocytes retrieved per collection when three, four, or seven days were compared [14–16]. The ultimate goal is to generate embryos that can be transferred to recipients, and from that perspective there is evidence that a three- or four-day interval (8 oocytes per OPU) is better than a seven-day interval (5.5 oocytes per OPU) [17].

The number of oocytes collected per OPU can be increased by pretreatment of the donor with gonadotropins [18, 19]. In a very comprehensive comparison of different OPU intervals with and without follicle-stimulating hormone (FSH), Chaubal et al. [20] reported that the most productive protocol in terms of oocyte and embryo production involved dominant follicle removal, FSH treatment 36 hours later, and OPU 48 hours after FSH. This treatment was alternated weekly with simple once-weekly OPU. The OPU weekly session involving FSH averaged 10.6 oocytes and 2.4 blastocysts, while the alternating weekly OPU with no FSH averaged 4.6 oocytes and 0.9 blastocysts. The interaction of factors, including the frequency of OPU and the inclusion or absence of FSH stimulation, has been described in a number of studies, including some published in 2002 [21] and 2008 [22]. Since then, a number of publications have clearly demonstrated that the use of FSH prior to OPU increases the number of usable embryos at the end of IVP [22–28]. Also, a study in Japan [29] utilizing both Holstein cows and Japanese Black cows showed that a single injection of FSH or 4 injections at 12-hour intervals resulted in a higher percentage of both grade 1 oocytes than an injection of gonadotropin-releasing hormone (GnRH) or no pretreatment prior to OPU. Also, a single injection of FSH resulted in a higher proportion of blastocysts than the other treatments. Most surprising perhaps, the conception rate following ET was higher in the FSH

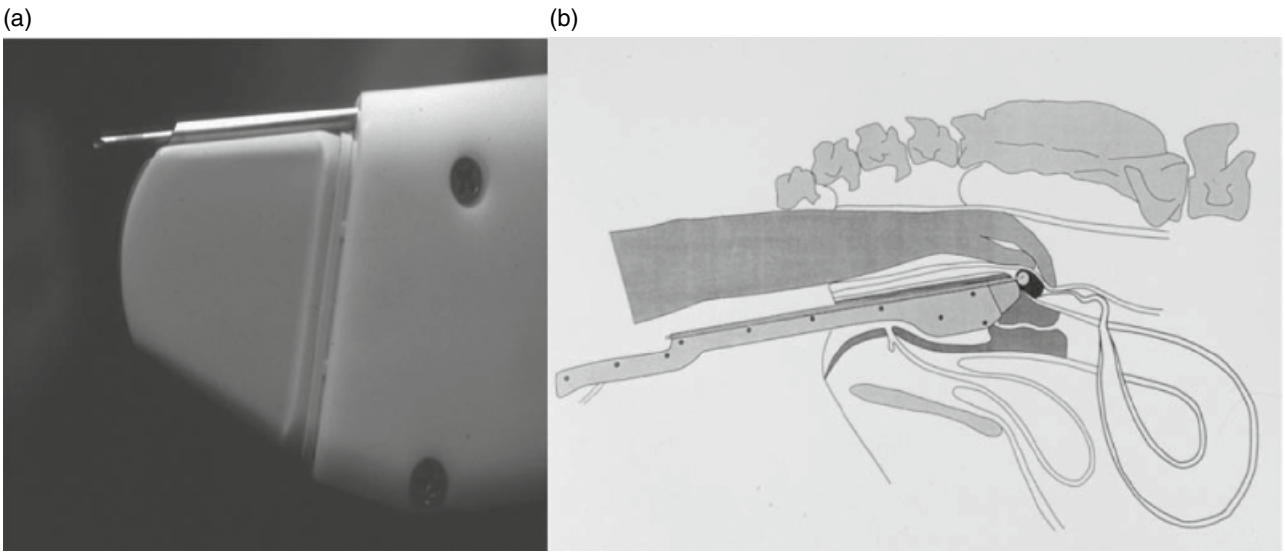

Figure 89.1 (a) Ultrasound transducer with oocyte aspiration needle protruding from needle guide. (b) Diagram showing position of ultrasound transducer pressed against vaginal fornix, with ovary manually manipulated per rectum and held up against vaginal wall.

pretreated donors. However, at least two studies failed to find an increase in the number of embryos produced as a result of FSH stimulation in non-lactating Holstein cows [29, 30]. Additionally, it has been shown that multiple injections of FSH were no more effective in increasing the number of embryos following OPU and IVP than when a single injection of FSH dissolved in 0.05% hyaluronan was used [31].

Breed of cattle also is an important factor. In South America (primarily Brazil) large numbers of oocytes are routinely collected with no FSH priming from Nelore cattle, an indigenous breed of *Bos indicus* origin known to develop higher numbers of follicles in each follicular wave than *B. indicus* females [32]. There are many unpublished reports of oocyte numbers following OPU ranging from several to more than 500 in these cattle. Furthermore, it was shown in Brazil that more embryos and pregnancies could be produced per unit time from *in-vitro* derived embryos compared to *in vivo* embryos derived from repeated superovulations [32]. In unstimulated *Bos taurus* cattle in the USA, low mean numbers of usable oocytes ranging from 4.1 to 5.3 were reported by Hasler et al. [33] and Looney et al. [34] from combined populations of dairy and beef breeds, including older females with a variety of fertility problems.

The concept of coasting can be defined as the time period between the cessation of FSH injection(s) providing stimulation of multiple follicles and the harvesting, usually via OPU of the oocytes. Much of the pioneering work involving coasting was conducted in Canada [21, 35]. In further work in Canada on this concept, "coasting" was also described as FSH "starvation" [36]. In this study the highest rates of blastocyst development *in vitro* were obtained when FSH support was discontinued for 44–68 hours and granulosa cell SMAD7 and mRNA were predictive of this period. The coasting procedure that is widely used today in the commercial IVP industry involves a range of approximately 30–44 hours between the last FSH injection and OPU. The use of FSH with a coasting period is now successfully employed in several commercial US bovine IVP businesses and has resulted in a mean of approximately 20 oocytes collected from *B. taurus* cattle once every two weeks (unpublished, courtesy of Trans Ova Genetics).

Age of the donor can also influence the number of oocytes recovered per OPU. Evidence in Holsteins suggests that a significantly higher number of oocytes can be collected in cows 6–9 years old than in cows 14–18 years old [16]. However, these were primarily cattle that were undergoing OPU/IVP due to previously existing fertility problems. Recent, unpublished data from a large commercial *in vitro* program involving reproductively healthy donors indicated little variation in recovered oocyte numbers up to age 13 and a steady decline from age 14 to 18 (unpublished, courtesy of Trans Ova Genetics). Interestingly, the developmental potential of oocytes was similar from all donor age categories in this program. In another study, young Holstein heifers aged 5–10 months tended to have significantly higher numbers of follicles, but the oocytes collected from these donors yielded fewer embryos reaching the morula and blastocyst stages [25].

A number of the factors involved in OPU/IVP cannot be covered individually without including more than one variable in the discussion. Although laparoscopic collection of oocytes was touched upon earlier in the section "Oocyte Collection from Living Cattle" and is no longer utilized in most commercial OPU/IVP programs, it is used in some programs for collection of oocytes from very young heifers. The increasingly important genomic value of young animals has led to a return to laparoscopic oocyte collection from heifers as young as two months of age [37].

There is considerable variation among donors in terms of oocyte production over time. For example, an 8-year-old Holstein donor, previously diagnosed as infertile, produced a total of 176 embryos from 167 collections by 23 different sires over a period of 167 weeks [16]. With repeated OPU collections, the mean number of oocytes decreased; however, the developmental potential of oocytes produced by OPU did not change. This clearly shows the potential for production of large numbers of embryos by OPU/IVP methods and the advantageous opportunity to use different sires weekly or even biweekly.

Oocyte Collection from Excised Ovaries

In addition to bovine oocyte retrieval by OPU, there are several situations in which oocytes are removed from excised ovaries. When cows develop terminal diseases or become crippled, ovaries can be removed via a flank laparotomy or through a vaginal incision and the oocytes recovered by follicular aspiration or slicing. Stringfellow et al. [38] reported collecting an average of 46 oocytes from 18 culled dairy cows by slicing the ovarian cortex. In a highly successful commercial program, Green and McGuirk [39] reported producing an average of 46 oocytes and 9 embryos per donor in more than 100 cases of chronically ill, injured, and senile cows.

Unpublished data from excised ovaries (author JFH) have supported successful IVP and pregnancy following transfer outcomes in many cases when ovaries were removed from crippled or "down" cows and shipped to an IVP center. In some cases, these ovaries were shipped in a warm insulated container by overnight express. Ovaries shipped at higher temperatures, including body temperature, or cooled, often did not result in the successful

production of embryos. In contrast to these results, a study in China [40] showed that a storage temperature of 15 °C for a three- to four-hour period significantly improved the quality and developmental competence of oocytes used for somatic cell nuclear transfer. The authors attributed the improvement to alleviation of stresses on the oocytes compared to those stored at 25 or 35 °C.

Oocyte Collection from Slaughterhouse-Procured Ovaries

A large source of oocytes is ovaries from cows processed in slaughterhouses. All follicles between 3 and 8 mm in diameter are aspirated and the collected oocytes used to generate IVP embryos. In a mass-production system using ovaries from the slaughterhouse, Lu and Polge [41] reported producing more than 200 000 *in vitro* derived blastocysts from approximately 700 000 oocytes in two years. Although this program is no longer in operation, it demonstrated the potential for production of IVP embryos from cattle after slaughter. Reports indicate that as many as 100 and 200 oocytes sometimes can be harvested from one pair of *B. taurus* ovaries [41]. In Japan, ovaries from individual Kobi cows are procured at the time of slaughter and sent to an IVP lab for processing. Later in the same day, carcass values of the individually identified cattle determine which oocytes are retained and processed through the entire IVP procedure. In addition to their commercial value, IVP embryos are produced in universities and labs around the world as a valuable source of material for bovine reproduction experiments [42].

Media

Once oocytes are collected, they are cultured in a series of media that support IVM, IVF, and *in vitro* development. In general, there are at least six different media utilized for the production of *in vitro* embryos. Most of these media are not commercially available and must be produced in the laboratory, though some commercial media systems exist. All of these media have common components, which are briefly reviewed here, followed by specifics about media used during specific stages of development.

Water

Pure water is the single most abundant component of all media used for all types of embryo procedures. In fact, water quality might be considered the single most important component of embryo media. What constitutes pure water and how best to produce it has been thoroughly reviewed [43].

Salts

A number of salts, such as sodium chloride and potassium phosphate, are used in the preparation of virtually all media that are utilized for IVP. These components and, in fact, all chemicals used in media preparation should be reagent quality and whenever possible they should be certified as having been "mouse embryo tested."

Energy Sources

Glucose, fructose, and/or pyruvate are often included in media as energy sources. It is well established that optimal glucose levels for bovine embryos must be low, around 0.5 mM, during early embryonic development. Once the late morula stage is reached, however, higher glucose levels are desirable, and most ET media contain approximately 2.0 mM glucose.

Macromolecules

Macromolecules include serum, bovine serum albumin (BSA), hyaluronic acid (HA), and synthetic molecules such as polyvinyl alcohol (PVA). The most important reason to include a macromolecule in IVP media is the surfactant properties of these molecules, which reduces the chances that embryos will float or stick to equipment, pipette tips, straws, and Petri dishes. More specifically, serum contains a wide range of components that are beneficial for embryo development, such as proteins, growth factors, vitamins, minerals, and energy substrates, and it is well established that serum promotes blastocyst development [44]. Serum and BSA also provide a number of physical properties, including chelation, colloidal osmotic regulation, and pH regulation. Unfortunately, the inclusion of serum during IVC has been associated with a high degree of abnormal pregnancies and offspring, often referred to as large offspring syndrome (LOS) [45–48]. (Editor's note: also see Chapter 71.)

PVA primarily is used as a surfactant in flushing and holding media that are formulated to include no components of animal origin. These media have been used on hundreds of thousands of bovine donors with highly satisfactory results, based on extensive, repeated sales and verbal expressions of satisfactions from a large number of bovine and equine ET practitioners (unpublished, courtesy of Bioniche Animal Health, Inc.).

HA is a glycosaminoglycan that is present in follicular, oviductal, and uterine fluids [49]. Embryos have been shown to have surface receptors for HA, and it is involved in the regulation of gene expression, cell proliferation, and cell differentiation. Addition of HA to bovine embryo

culture systems improves development to the blastocyst stage, increases hatching rates, and improves cryotolerance [50–53]. The traditional source of HA has been cock's combs, but it can be produced biosynthetically in a *Streptococcus equi* fermentation that does not contain any products of animal origin.

Amino Acids

The addition of all 20 essential and non-essential amino acids to embryo culture systems is almost universal. The role of certain individual amino acids and also that of all 20 combined in the development of embryos, and enhancing their viability was reviewed by Gardner [54]. When serum is absent from culture media, the inclusion of amino acids substitutes for some of the benefits that serum provides.

Antioxidants

Antioxidants reduce the formation of damaging free radicals in media. Glutathione, BSA, ascorbic acid, and catalase are frequently used as antioxidants in embryo media.

Chelators

Chelators are chemicals that bind heavy metal ions. In a perfectly pure medium, there would be no need for chelators, but there is always a chance that traces of heavy metals can enter the formulation via water or reagent salts. Transferrin, BSA, and ethylenediaminetetracetic acid (EDTA) all function as chelators.

Osmolytes

Osmolytes are organic compounds that play a role in maintaining the volume of cells and organelles within cells as well as fluid balance. When cells swell due to external osmotic pressure, membrane channels open and allow efflux of osmolytes, which carry water with them, restoring normal cell volume. Glycine is an osmolyte and the smallest of the so-called non-essential amino acids that are usually added to culture media and to some formulations of holding and cryopreservation media. The physiological basis for the osmolyte properties of glycine in embryo culture was described in detail by Steeves et al. [55].

pH and Buffers

The intracellular pH (pHi) of *in vitro* derived bovine embryos is 7.2, as measured with a pH-sensitive probe [56]. This study also demonstrated that bovine embryos in culture recovered after being subjected to an acid pH more readily than from a basic pH. In fact, pHi was decreased only to approximately 7.8 when embryos were subjected to a pH above 8. In a classic study, Kane [57] showed that the highest percentage of rabbit blastocysts that hatched during IVC was in the range of 7.2–7.4, with a precipitous decline when pH was below 7.0 or above 7.8. Most bovine IVP media are in the 7.3–7.4 range, except for fertilization media which are generally 7.5–7.6.

Phosphate buffered saline (PBS), which has been widely used for *in vivo* derived (IVD) embryo recoveries, contains phosphate as a buffer. Although phosphate is not a particularly effective buffer, the inclusion of either serum or BSA adds additional buffering capacity to PBS. IVP media, on the other hand, are normally maintained in an incubator with a 5% CO_2 atmosphere. The inclusion of bicarbonate in these media provides a stable pH due to the equilibrium that is established between the bicarbonate and the CO_2. When media based on this system are removed from the incubator, however, the pH rapidly decreases and will reach an unacceptable level of acidity within a few minutes in air. As a consequence, the media used for rinsing ova/zygotes between IVP steps and for holding them in the air prior to transfer or cryopreservation contain 3-(4-morpholino)propane sulfonic acid (MOPS) or 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) zwitterionic buffers.

Osmolarity

The optimum osmolarity for maintaining bovine embryos during IVP procedures is approximately 275 mM, which also is true of other species such as the rabbit, rat, and pig [58]. On a practical basis, bovine, and probably equine embryos are not adversely affected by exposure to osmolarities ranging from 250 to 300 mM for relatively short periods. Research has suggested that a total osmolarity between 250 and 270 appeared to be optimal when bovine *in vitro* derived embryos were cultured in potassium-supplemented simplex optimized medium (KSOM) [59].

An important consideration when adjusting the osmolarity of media is the issue of what molecules are added or reduced in order to raise or lower osmolarity. The most abundant salt in all media utilized in IVF procedures is NaCl, but it had been shown to be detrimental to bovine embryo development at concentrations above 95 mM [59]. Thus, the benefit of having osmolarity below 300 mM in most studies likely is due to lowered Na^+ as opposed to lowered osmolarity per se (oviduct fluid is >300 mM).

Maturation

Much of the success of embryo IVP depends on the quality of the starting material, the oocyte. Photomicrographs of the four basic categories of freshly collected oocytes are shown in Figure 89.2. Oocytes in these four categories have greatly different potentials for maturation and development into embryos, ranging from type 1 with the best potential to type IV with almost zero potential [16]. Table 89.2 demonstrates the potential for these oocytes to be fertilized, develop to blastocysts, and result in pregnancies.

An oocyte that is considered competent for IVP is referred to as "matured." Maturation involves a series of events that begin in fetal life with the initiation of meiosis. At birth, oocytes are arrested at the diplotene stage while continuing to grow and they do not become meiotically active again until puberty, when they are exposed to preovulatory surges of the gonadotropins luteinizing hormone (LH) and FSH which induce changes in gene expression as well as in morphological and physiological features of the theca, granulosa, cumulus, and oocyte compartments of the ovarian follicle. A subset of oocytes is continually recruited to proceed with meiosis during each estrous cycle, only to arrest at metaphase II, the stage at which they are ovulated. The changes that occur between the diplotene and metaphase II stages of arrest are considered maturation [61].

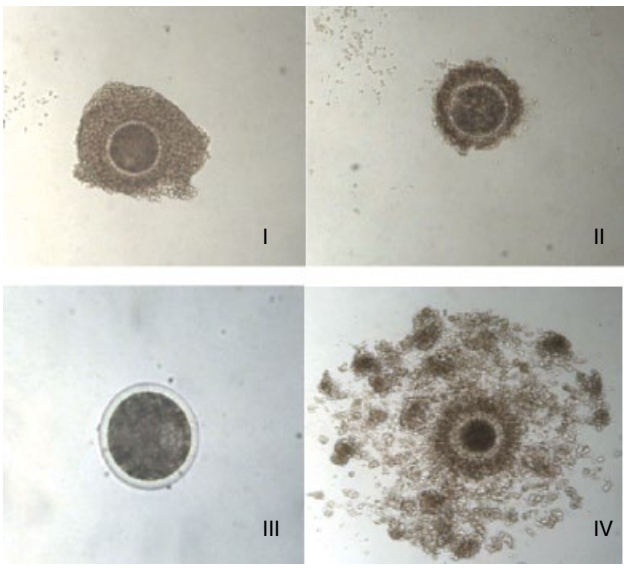

Figure 89.2 Types of bovine oocytes collected from cattle ovaries prior to IVM. I, >4 layers of cumulus; II, 1–3 layers of cumulus; III, nude oocyte with no cumulus; IV, expanded cumulus. *Source:* Reproduced with permission from [60].

IVM of immature oocytes occurs by a different mechanism than *in vivo* matured oocytes. Removal of an oocyte from the inhibitory follicular environment followed by favorable culture conditions results in spontaneous maturation without the physiological series of events that occur *in vivo*, though some morphological changes can be observed (e.g. expansion of cumulus cells) [62]. *in vitro* conditions simulate some of the physiological changes with the addition of hormones, including LH, FSH, and 17β-estradiol, which are typical of the preovulatory follicle, and growth hormones or epidermal growth factor [63].

The way in which oocytes are collected and their maturation status dictate how they must be handled after collection. Immature oocytes can be collected from unstimulated cows undergoing OPU every three to seven days, irrespective of the stage of their estrous cycle; however, it is also possible to time aspiration after ovarian stimulation and injection of LH or GnRH so that one collects mature oocytes. These *in vivo* matured oocytes do not require further maturation *in vitro*, though some period of time in maturation medium prior to fertilization may be beneficial. Oocytes aspirated from ovaries collected from cows processed in slaughterhouses are primarily from follicles 3–8 mm in diameter and the resulting cohorts of oocytes vary in their maturational status. Even so, the majority of these oocytes can achieve maturation during a 24-hour period of IVM.

While many oocytes do reach metaphase II after a maturation period, research indicates there may be an asynchrony in nuclear and cytoplasmic maturation of oocytes *in vitro*. Studies to balance this asynchrony have

Table 89.2 Potential for fertilization and embryonic development in different types of immature bovine oocytes.

Oocyte type	Cumulus	No. of oocytes	Percentage cleaved	Percentage blastocysts	Percentage hatched
I	>4 layers	571	65^{a}	29^{a}	19^{a}

^{abc} Values within a column with different superscripts differ significantly ($P < 0.025$).

attempted to delay nuclear maturation by addition of meiotic, protein synthesis, or phosphorylation inhibitors to the maturation medium to allow more time for cytoplasmic maturation. Early indications were that this can improve maturation rates as well as embryo production rates, though results from replication experiments have been varied [64].

Other avenues of research to improve IVM and subsequent embryo development or quality involve modifying maturation media with antioxidants (e.g. cysteamine) [65], amino acids (e.g. L-carnitine) [66], hormones (e.g. thyroid hormone) [67], or maturing oocytes in a co-culture system with theca cells but no hormonal supplementation [68], to name a few. Additionally, the effects of the maturation environment on epigenetics and genomic imprinting in the IVP embryo continue to be of interest.

Fertilization

Once IVM is complete, oocytes are ready to be fertilized. This involves the co-incubation of oocytes with spermatozoa and is generally done in a four-well dish, but also can be done in a microdrop under oil. Most labs allow for 18 hours of co-incubation, even though the majority of fertilization events will be complete by 12 hours of co-incubation.

Upon ejaculation, spermatozoa are motile but not capable of fertilizing an oocyte. The changes that a spermatozoon must go through before it is capable of fertilizing an oocyte are collectively called capacitation. Even though this process was discovered in 1951 by Chang [69] and Austin [70], the molecular mechanisms of capacitation remain unclear. Capacitation generally occurs in the isthmus of the oviduct, although in some species it may begin in the cervix where cervical mucus facilitates the removal of sperm surface proteins. The challenge for those performing IVF is to mimic these conditions by providing spermatozoa with an environment that supports capacitation. Temperature is a critical factor for successful capacitation. Evidence in sheep and pigs suggests that capacitation is most efficient at body temperature rather than at 37 °C, the temperature to which many incubators are preset (reviewed in [71]). This may be associated with the physical state of membrane lipids outside of physiological conditions. In cattle, IVC is typically done at 38.5 °C, including the fertilization process.

Media have been developed to support capacitation *in vitro*. The medium in which sperm and oocytes are co-incubated is generally slightly higher in pH (7.5 vs 7.3 in the maturation and culture media, respectively). A basic medium that can be used is Tyrode's or Krebs-Ringer's solution supplemented with an energy source (glucose, lactate, and pyruvate) and albumin [71]. The primary capacitation agent added to fertilization media is heparin, which is thought to assist in the removal of seminal plasma components from the sperm surface by binding to proteins and stimulating the efflux of cholesterol and phospholipids [71, 72]. Other capacitation agents include caffeine, an inhibitor of phosphodiesterases; bicarbonate, which induces pKa-dependent changes in lipid architecture; adenosine, which interacts with membrane receptors and increases intracellular cyclic adenosine monophosphate (cAMP) and reactive oxygen species (ROS), such as superoxide anion, hydrogen peroxide, and nitric oxide, which activate membrane targets to trigger intracellular mechanisms including protein tyrosine phosphorylation [72].

The majority of spermatozoa used in bovine IVF are frozen–thawed. The cryopreservation process induces changes in bovine spermatozoa that resemble capacitated spermatozoa. They have elevated intracellular calcium, a net loss of plasma membrane proteins, and an increase of ROS [73]. These sperm also require a shorter exposure to and lower doses of capacitation agents than fresh spermatozoa, which are ideal for IVF. In a well-managed IVF laboratory, fertilization rates with frozen spermatozoa can average 80% or higher.

The most common method for preparing spermatozoa for fertilization is by centrifuging spermatozoa through a density gradient. This discontinuous gradient is prepared with a sperm tyrode albumin lactate pyruvate (TALP) solution mixed with Percoll® (Sigma) in different proportions. The most common gradient is a 45% Percoll mixture layered on a 90% Percoll mixture. The semen or contents of a thawed straw of semen are layered on top of the gradient and centrifuged at 800g for a time dependent on the volume of the column through which the sperm must travel. This isolates intact sperm at the bottom of the centrifuge tube. An alternative method for isolating intact sperm is a "swim up," which involves layering a medium over the contents of a thawed straw and allowing the spermatozoa to swim up into this medium, where they are aspirated off after a period of time.

Today, the use of spermatozoa that have been sorted via a laminar flow device, based on whether they carry an X or Y chromosome, is an important part of commercial bovine IVP, particularly in the dairy industry [74]. The accuracy of the semen sorting process is approximately 90%. In a number of studies, there was no difference in pregnancy rates between dairy cows receiving IVP embryos produced with sexed or traditional semen. However, a small but significant increase in pregnancy loss of IVP-sex sorted embryos compared to cows that had been artificially inseminated with traditional semen has been reported [75].

Starting in 2014, Sexing Technologies, the Navasota, Texas-based company responsible for providing a major share of sexed semen, announced a new sorting process termed SexedULTRA™ [76]. Higher pregnancy rates when this product was used in artificial insemination (AI) have been reported, but no definitive improvements in IVF are as yet available.

In some cases, frozen semen is sorted for sex after thawing and used to fertilize oocytes immediately after sorting. This is called reverse sorting and has resulted in *in vitro* blastocyst production and pregnancy rates that are comparable to rates obtained with fresh sexed semen and better than sexed semen that was frozen after sexing (unpublished, courtesy of Trans Ova Genetics) [77].

In Vitro Culture of Embryos

The IVC of bovine embryos is the last step in the IVP process and involves approximately six days of culture from the 1-cell zygote stage following IVF to a blastocyst-stage endpoint.

In the past, one of the most common media for culturing bovine embryos was variations of Tervit's [78] original synthetic oviduct medium (SOF), supplemented with amino acids and, in some cases, low levels of serum [51, 79–81]. SOF-based culture may involve one medium formulation for the duration of IVC or a two- or three-step "sequential" system in which the medium formulation changes at certain points in the culture period. Sequential systems are based on an attempt to mimic the physiological changes that *in vivo* zygotes encounter as they move down the oviducts and into the uterus during the first six or seven days of development. The volume of medium used in IVC systems also varies, with some laboratories culturing embryos in microdrops as small as 25 µl under a layer of oil, and ranging up to 500 µl in each well of a four-well dish with or without an oil layer. More sophisticated culture systems have been developed, such as microfluidic IVC [82] and single embryo time lapse culture systems, but these are not widely used at this time. Some IVC systems are conducted in an incubator atmosphere of 5% CO_2 in air; however, there is significant evidence that in the absence of co-culture, bovine embryos develop better in a 5% CO_2, 5% O_2, and 90% N_2 atmosphere [83, 84].

In the past, most commercial IVP involved the use of co-culture systems that included a monolayer of somatic cells. Cell types that have been used in the successful co-culture of bovine embryos include primary cells from oviducts (bovine or porcine), mouse oviductal ampullae, cumulus, granulosa, and uterus, as well as established cell lines such as buffalo rat liver (BRL), and Vero cells. These cells have been combined in co-culture systems with a number of different media, including TCM-199, Menezo's B2, and Ham's F-10.

Co-culture systems are not widely used today, as most laboratories have largely pursued investigating IVP systems based on "defined" media formulations. Defined media are those in which all of the components are known and, as a consequence, products such as serum and BSA are not included. It should theoretically be possible for a defined system to be exactly replicated in any laboratory at any time. Also, the use of defined systems is essential for understanding and optimizing the culture requirements of pre-implantation embryos. However, only moderately successful rates of blastocyst production have been reported with the use of chemically defined, protein-free media [85, 86]. Some very comprehensive reviews have been written on this subject [87–90].

Commercial ET/IVP businesses are primarily concerned with efficiently and predictably producing as many viable embryos as possible. Consequently, BSA (semidefined media) and, in some cases, moderate levels of serum (non-defined media) are frequently added to various media, including IVC media. Addition of high concentrations of FCS (10% or greater) has been associated with lipid accumulation in the embryo, which decreases cryotolerance, and with the production of large calves, though lower concentrations (<5% or less) of FCS may mitigate these effects while still enhancing embryo production. Timing of supplementation with fetal bovine serum (FBS) or preparation of the FBS may also influence embryo production results [91], though for practical as well as animal welfare reasons alternatives to FBS are being researched [92, 93]. In addition, non-defined systems may involve co-culture in which any of a number of different somatic cells is included in the system. These systems can be difficult to reproduce because of variations among batches of commercially available cells or a lack of "immortality" when some cell types are cultured through multiple generations in IVP laboratories.

Continual efforts to improve IVC and results post transfer involve supplementing media with components found *in vivo*. There is evidence that a variety of factors can improve embryo development as well as establishment and maintenance of pregnancy. For example, insulin-like growth factor-1, colony stimulating factor 2, and hyaluron are found in the female reproductive tract and when added to IVC media are reported to enhance embryo survival post transfer (reviewed in [94]). There is an extensive body of literature on supplements and/or additives that may improve embryo development rates *in vitro*.

Numerous qualitative and quantitative differences between *in vivo* and *in vitro* produced embryos have been

described in detail for cattle and other species [16]. There is evidence that IVP embryos have fewer cells and lower proportions of inner cell mass (ICM) cells to trophoblast cells than *in vivo* embryos at the same stage of development and this variation can be related to different culture systems [95, 96]. However, total cell counts do not necessarily reflect the overall integrity and viability of preimplantation IVP embryos. Van Soom et al. [97] used differential staining to show that although embryos produced in Menezo's B2 medium had higher cell counts than embryos of the same age produced in TCM-199, the B2 embryos had a larger range of variation in the number of ICM cells. The additional cells in the embryos produced in B2 were mainly trophoblast. Including serum can also increase cell numbers, but there is evidence that this may decrease the embryo's ability to survive cryopreservation [98]. Thus, one should not choose an IVC medium strictly on the basis of increasing cell numbers in embryos.

In addition to differences in cell numbers, the rate of embryonic development varies among IVC media [99–101]. It is clear that within a given IVC medium, faster developing embryos frequently are of higher quality based on cell number [102], end-stage of development [103], and pregnancy rate after transfer [33].

A study that utilized fluorescence in-situ hybridization showed that a high proportion (72%) of bovine embryos cultured in a Menezo's B2 co-culture system were mixoploid (being composed of polyploid and diploid cells), compared to 25% of blastocysts developed *in vivo* [104]. Of the total number of *in vitro* embryos, 17% contained more than 10% polyploid cells. In contrast, all of the *in vivo* embryos contained less than 10% polyploidy cells. The authors of this study offered a hypothetical link between the polyploidy in *in vitro* embryos and the possibility of polyploidy placental cells developing from them, leading to overactive placentas that in turn are responsible for large calves (see section "Pregnancies and Offspring").

A summary and illustration of early embryo development in the IVP process compared to *in vivo* embryo development is provided in Figure 89.3.

Cryopreservation of IVP Embryos

Cryopreservation of bovine embryos is routinely done in research and commercial IVF laboratories around the world. Traditional slow-freeze cryopreservation has been used extensively with IVP embryos, with pregnancy rates up to 50–55% in large-scale trials [33, 105]. Pregnancy rates with frozen–thawed IVP embryos have been lower, and thus globally most IVP embryos are transferred fresh (73.2%) compared to only 39.9% of IVD embryos in 2018 [106]. As the number of IVP embryos generated annually continues to rise and exceed the number of *in vivo* produced embryos (1 029 400 IVP compared to 469 967 IVD in 2018) [106], improving cryopreservation of bovine IVP embryos will continue to be an important area of research.

A rather unique finding was reported in a paper from Japan in which bovine IVP embryos were successfully held for seven days at 4 °C in a HEPES-buffered medium [107]. This approach eliminated the need for cryopreservation and the authors opined that embryos could be held and transported for up to seven days with a high pregnancy rate following transfer into recipients.

The most common protocol for slow-freeze cryopreservation of bovine oocytes involves cooling and holding the

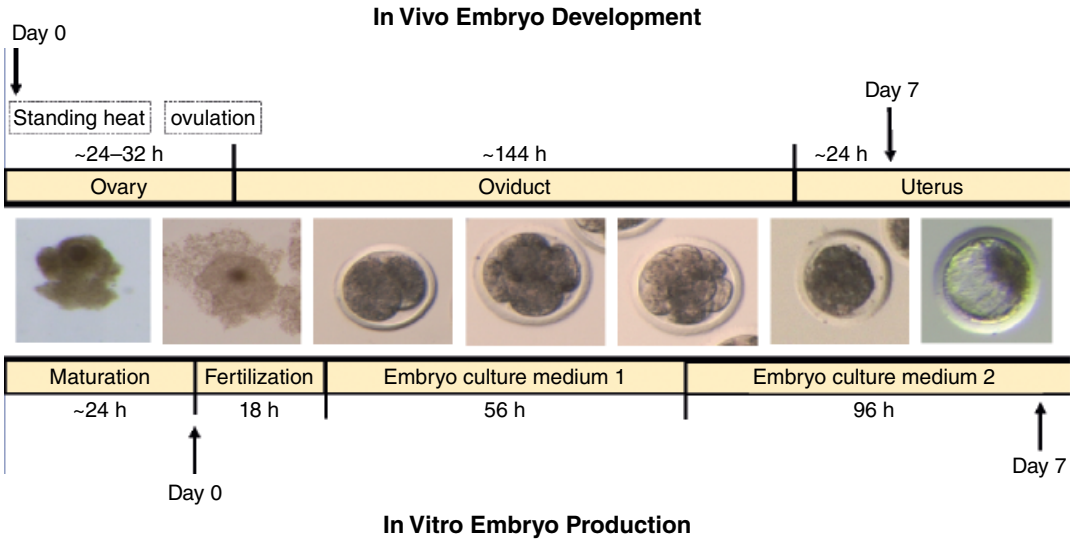

Figure 89.3 Comparison of early embryo development *in vitro* to *in vivo*.

embryo at −6 °C, during which time the straw containing the embryo is seeded, followed by a decrease to −32 °C at 0.3–0.6 °C per minute and plunging the straw into liquid nitrogen. Bovine embryos are typically frozen in a solution containing 1.5 M ethylene glycol and 0.1–0.5 M sucrose. The use of ethylene glycol as the cryoprotectant allows one to transfer the embryo to a recipient directly from the straw, whereas other cryoprotectants such as glycerol must be removed via dilution of the freezing medium prior to transfer [108]. Other cryoprotectants that have been used to freeze bovine embryos include dimethyl sulfoxide (DMSO), propandiol, methanol, various sugars, and combinations of these [109].

There are several factors that influence embryo survival post thaw, including stage of development. Morulae and blastocysts survive the freeze–thaw process better than earlier-stage embryos, but even the day of blastocyst development can impact post-thaw survival. Pregnancy rate following transfer of IVF blastocysts frozen on day 7 was 42%, but dropped to 20% for blastocysts frozen on day 8, with a higher incidence of early abortions and dystocias [33]. The quality of the embryos also impacts post-thaw results. Pregnancy rates for frozen–thawed bovine embryos by grade were reported by Hasler et al. [33]: grade 1 – 63%, grade 2 – 57%, grade 3 – 44%, and grade 4 – 36%.

There has been extensive research conducted on the effects of cooling and warming rates on embryos of a variety of species. In one study, bovine embryos were cooled at 0.3, 0.6, 0.9, 1.2, or 1.5 °C/min and warmed either rapidly in a 35 °C water bath (warming rate >1000 °C/min) or slowly in 25–28 °C air (<250 °C/min) [110]. The best treatment was cooling at 0.3 °C/min with rapid warming; 42.1% of the morulae developed into hatching blastocysts. These results indicate that the survival of IVP bovine morulae and blastocysts is improved by very slow cooling, but slow warming was deleterious to morulae and blastocysts even when coupled with very slow cooling.

Vitrification is an alternative to slow-freeze cryopreservation that involves ultra-rapid cooling, resulting in a glass-like state rather than ice formation. Since its introduction as an effective embryo cryopreservation method in 1985 [111], vitrification has been used primarily for research. Limitations of vitrification include toxicity from exposure to high concentrations of cryoprotectants, damage caused by osmotic shock, the need for highly skilled technicians, and the lack of a convenient direct transfer method. Researchers have attempted to improve vitrification of bovine embryos by manipulating culture or vitrification media [112, 113], delipidation of embryos, and/or altering plasma membrane composition [114, 115], as well as reducing free water in embryos by either predehydration or reduction of the blastocoele cavity prior to cryopreservation [116]. Despite these challenges, vitrification has proven more effective for embryos sensitive to cryopreservation, such as IVP embryos [117]. Another advantage of vitrification is that it does not require expensive cell freezers used for slow-freezing procedures and the equilibration and subsequent cryopreservation take less time per embryo. In addition, studies have shown that slow-freeze cryopreservation may induce changes in expression levels of genes involved in development in the preimplantation bovine embryo when compared to vitrified embryos [118], though further research is needed. Vitrification combined with an in-straw dilution would provide an alternative to slow-freeze cryopreservation of embryos produced *in vitro* or *in vivo*.

IVP embryos have been produced from vitrified bovine oocytes, but embryo production rates remain low [119]. Most protocols involve vitrification of mature oocytes (in metaphase II) as this has been more successful than vitrification of immature oocytes; however, damage to the spindle and microtubule network as well as the cytoplasmic membranes remains a problem [115].

Transfer of IVP Embryos

In most cases, IVP embryos are transferred in the same manner as IVD embryos. Once removed from the incubator, IVP embryos are usually transferred immediately, whereas IVD embryos can be held without loss of viability at room temperature for up to 24 hours prior to transfer.

Pregnancy rates of IVP embryos are consistently lower than IVD embryos. Significantly lower pregnancy rates were achieved, in order, by IVD frozen, fresh IVP day-7, fresh IVP day-8, frozen IVP day-7, and (lowest) frozen IVP day-8 embryos [33]. With regard to stage of development independent of age and grade, the transfer of large numbers of IVD embryos showed that early blastocysts (EB) and mid-blastocysts (MB) resulted in higher pregnancy rates than morulae (M), expanded blastocysts (XB), or hatched blastocysts (HB) [120]. Transfer of grade 1 day-7 embryos at the EB, MB, or XB stages results in higher pregnancy rates than transfer of corresponding day-8 embryos.

Synchrony of recipient cows to embryo development is an important factor for the establishment of pregnancy. For IVP embryos, day 0 is considered to be the day of IVF, while in cattle, including ET recipients, day 0 commences when the cow is in standing estrus. With regard to ET, zero synchrony traditionally refers to the transfer of an embryo into a recipient of the same day, e.g. transfer of a day-7 embryo into a recipient that was in estrus 7 days earlier. Minus 1-day synchrony is the transfer of an embryo to a recipient that was in estrus 1 day earlier than the age of the embryo,

e.g. a day-7 embryo transferred into a cow that was in estrus 6 days prior. While this is the convention, it is misleading because ovulation in the recipient occurs approximately 12 hours after the end of estrus which lasts on average 18 hours (day 0 begins at the onset of standing estrus), while fertilization *in vitro* occurs within hours. Consequently, if an IVP embryo is designated as day 7, it is actually one day older than a day-7 IVD embryo [33, 121]. Pregnancy rates reflect this asynchrony. When day-7 embryos were transferred into day-6 recipients, pregnancy rates were 50.3%, compared to 55% for day-7 and 58% for day-8 recipients. Further support is provided by data based on more than 10 000 transfers from Trans Ova Genetics showing pregnancy rates of 42, 50, and 49% when day-6, -7, and -8 recipients, respectively, were used for day-7 IVP embryos (personal communication). To avoid decreased pregnancy rates, the use of day-6 recipients should be avoided whenever possible.

Commercial production of bovine embryos via IVP is now successful in a number of laboratories around the world. BOVITEQ Inc. (Quebec, Canada) [122] and Trans Ova Genetics (Sioux Center, IA, USA) [123] and Em Tran, Inc. (Elizabethtown, PA, USA) [33] either have been in the past or are currently operating commercial ET companies that have successfully produced OPU/IVP derived pregnancies from infertile donors. In addition, Trans Ova Genetics, Sexing Technologies, and Ova Tech in the USA and BOVITEQ in Canada are currently producing large numbers of IVP embryos from healthy cattle.

The trend in the international production of IVP and IVD embryos on a biyearly basis between 2000 and 2018 is shown in Figure 89.4. It is clear that *in vivo* production, involving the number of embryos produced by superovulation and collection via "flushing," is decreasing, whereas there has been a rather dramatic, steady increase in the numbers of IVP embryos. Initially, more IVP embryos were produced in Brazil than in any other country. One company, *In Vitro* Brazil, reported the transfer of more than 200 000 IVP embryos in 2012. In 2007 it was estimated that superovulation/flushing represented only 9% of the ET work in Brazil, while OPU/IVP provided 91% of the embryos (unpublished, courtesy of *In Vitro* Brazil). Although such a large difference in how embryos are produced is not true in every country, the increased emphasis on OPU/IVP versus superovulation/multiple ovulation embryo transfer (MOET) is evident worldwide, as shown in Figure 89.4.

There has been especially dramatic growth of OPU/IVP in the USA in recent years, along with a decline in the traditional MOET. The number of actual collections for these two technologies is shown in Figure 89.5.

In the Netherlands, IVP embryos have been produced from oocytes obtained by OPU from young, reproductively healthy donors and transferred on-farm around the country [124]. In Japan, the production of IVF-derived embryos from slaughterhouse ovaries has been commercialized, and in some cases very large numbers of embryos have been produced. Kuwayama et al. [125] described the production of more than 150 000 frozen IVP embryos in a one-year period from more than 21 000 ovaries of Japanese Black cattle.

Today, much of the OPU/IVP industry is driven by the increased sophistication and accuracy of genomic analysis of individual animals, especially in breeds in which a great deal of information is available from the contribution of individual bulls. Genomics has had a profound effect on the selection of individual animals that enter OPU/IVP programs. This trend and the reasons for it have been

covered in a number of reviews including [126–128]. The importance of genomic value has probably been the main reason that the overall application of superovulation/MOET has decreased, while OPU/IVP has increased in dairy donors since 2000 [129]. (Editor's note: see Chapter 76.)

Pregnancies and Offspring

Problems with pregnancies resulting from bovine IVP embryos have been described by a number of authors [16, 47, 80, 124, 130]. One of the more obvious problems is larger-than-normal calves at birth, referred to as LOS. Some of the problems associated with this syndrome are shown in Table 89.3.

A number of reports indicate that the average birth weights of IVF calves are heavier than those of AI calves [124, 131, 132]. Furthermore, Farin and Farin [130] showed that seven-month fetuses derived from IVC embryos were heavier than those from *in vivo* embryos. Other studies indicate that serum, co-culture, IVM–IVF, and uterine environment are all capable of influencing fetal development in sheep. These studies have primarily been done with sheep because the high maintenance costs and longer gestation period make the bovine a more expensive model for studying the effects of *in vitro* procedures on subsequent offspring. Nevertheless, the findings that lambs from *in vitro* cultured embryos exposed to serum can be up to 20% heavier than control embryos could be of significant consequence to the cattle industry [133]. Longer gestations have also been noted but are not correlated with the weight of the offspring [133–135].

Table 89.3 Aberrant characteristics associated with the LOS syndrome of IVP bovine pregnancies and calves.

Large calves
Increased gestation length
Decreased intensity of labor
Increased rate of abortions
Increased rate of congenital malformations
Increased rate of perinatal mortality
Increased rate of hydroallantois in recipients

Because serum has been implicated as a cause of higher birth weights of *in vitro* derived lambs (reviewed in [45]), its use in bovine IVC systems has received a good deal of attention. Deletion of serum during the first four days of co-culture failed to decrease the incidence of problems with IVP derived pregnancies and calves [46], whereas Agca et al. [136] showed that birth weights and gestation lengths were normal for a relatively small number of calves resulting from embryos cultured in serum-free CR1aa [137]. Another study comparing pregnancies resulting from co-cultured embryos versus those produced in SOF containing BSA showed that the use of SOF resulted in lower birth weights and easier calvings [80]. Unfortunately, comprehensive data regarding late-term pregnancies, incidence of

dystocias, and calf normalcy are not available from the large commercial *in vitro* programs currently in business.

Higher-than-normal abortion rates, ranging from 8 to 47%, during the first two trimesters of pregnancy were reported for *in vitro* derived bovine pregnancies [33, 138–140]. In contrast, abortion rates of 5.3% from 2 to 7 months [141], 4.7% from 2 to 6 months [120], and 4% from 40 to 250 days [142] for bovine *in vivo* ET pregnancies were reported.

Perinatal and neonatal losses have also been reported as higher in recipients carrying *in vitro* derived fetuses compared to AI or *in vivo* embryo pregnancies [33, 124, 143, 144]. There was no difference in the incidence of calf loss at birth between calves produced in the TCM-199 and B2 co-culture systems at Em Tran. However, the overall loss at birth of the IVF calves was 14.9% (205/1376), which is higher than the 9% loss reported for *in vivo* ET [141].

Increased incidence of hydrallantois was diagnosed among pregnant Holstein recipients carrying IVP derived fetuses (1%; 34125). A frequency of 1% is substantially higher than the cited frequency of 1 per 7500 calvings reported in non-IVP pregnancies [145].

Finally, although the data were not quantified, it was reported that labor often was not clearly pronounced in the Holstein heifers used as recipients for IVP embryos [16]. As a result, these recipients often were not observed in labor, and calvings frequently went unassisted, resulting in increased perinatal losses. However, when calves were delivered by scheduled cesarean section, the survival rate was close to 98%.

A number of reports show that male bovine IVP embryos grow more rapidly than female embryos during the first seven to eight days in IVP [146–149]. Bovine IVP embryos are usually transferred on day 7 or 8 and the most advanced embryos are usually selected because they tend to be more viable [33]. The percentage of male calves born following transfer of IVP embryos has been reported as 60% [138], 62% [140], and 53.4% [16]. The 53.4% was based on more than 2000 IVP calves and fetuses and differed significantly ($P < 0.001$) from 50% and also from the 51.1% males reported for 1751 calves produced from transferred IVD embryos [141] and the 50.5% of 24 000 Holstein AI-produced calves that were males [150].

Summary

IVF has come a long way since 1959 when the first IVF mammal was produced, and is now a growing component of the bovine ET industry. Media systems continue to be improved to more closely mimic the *in vivo* environment, resulting in better quality embryos. This, coupled with the introduction of sexed semen to the IVP process, and the availability of very comprehensive genomic values, has enhanced the value of IVP embryos, particularly in the dairy industry. Additionally, cryopreservation techniques have been greatly improved for IVP embryos, making on-farm transfers very convenient and facilitating the storage and shipment of these embryos.

Cloning by Somatic Cell Nuclear Transfer

J. Lannett Edwards, F. Neal Schrick, and Jessica L. Klabnik

Department of Animal Science, University of Tennessee, Knoxville, TN, USA

Introduction and Brief History

In 1997 Dr. Ian Wilmut and coworkers [1] startled the world by announcing the birth of Dolly, the first ever clone (i.e. genetic replica) of an adult mammal (Figure 90.1). Because doing so was thought to be biologically impossible, the announcement of Dolly's birth reverberated around the world, capturing the attention of scientists and conjuring up outlandish visions from the lay public. Fascination with Dolly, continuing even today, stems from her unexpected origin. Dolly originated from a mammary cell derived from a six-year-old adult ewe. The mammary cell's nucleus was transferred into an oocyte whose nuclear DNA had been previously removed (i.e. enucleated). The brief electrical pulses used to achieve that end were all that was needed to initiate embryonic development, highlighting the important fact that a spermatozoon is not needed for this type of "asexual" reproduction.

Ability to clone by nuclear transfer was not novel to Dolly. In fact, numerous clones were produced pre-Dolly using totipotent or pluripotent cell types comprising the early embryo. The first successful production of embryonic derived clones by nuclear transfer was in amphibians in 1952 [2]. Thirty-one years later McGrath and Solter [3] announced embryonic cell cloning of mice. Soon thereafter came embryonic cloning of sheep [4], cattle [5], rabbits [6], and pigs [7]. Global failures using other differentiated, highly specialized cell types gave credibility to the long and widely held dogma that it was biologically impossible to clone adult mammals by nuclear transfer. An initial hint that this dogma would not withstand the test of time came with the reporting of the births of Megan and Morag in 1996 by Dr. Wilmut's group (Dr. Keith Campbell as lead author) [8]. Unlike all the other clones that had been born up to that time, these cloned sheep were obtained after performing nuclear transfer using a cultured cell line that was embryonic in origin but had been passaged up to 6–13 times in the laboratory (i.e. number of times the cell line was subcultured to produce a larger number of cells from the initial number harvested). Because cells were serum starved before nuclear transfer, success at producing cloned offspring was attributed to the use of quiescent-induced cells (i.e. non-proliferating and induced into G_0 of the cell cycle). Subsequent cloning successes using established cell lines from mammary (i.e. Dolly), fetal, and embryo cells after inducing cells into a quiescent state (Table 90.1) reinforced this notion.

Although it was later shown that inducing cells into quiescence before nuclear transfer was not required, Dolly's birth continues to serve as a reminder that the impossible is possible assuming a willingness to persevere while thinking "outside the box." The list of adult animals cloned using different cell types and cultured cell lines for nuclear transfer now includes, but is not limited to sheep, cattle, mouse, goat, pig, gaur, mouflon, rabbit, cat, horse, rat, African wild cat, sand cat, mule, banteng, deer, dog, ferret, wolf, buffalo, camel, and Spanish ibex (Figure 90.2). Realizing what can be done in one species is likely possible in others, the list of species that will be cloned will continue to grow. In 2018, macaque monkeys were added to the list. Use of cumulus cells to derive nuclear transfer clones from adult females yielded two live births that were short-lived [9]. Because clones may be constructed using a variety of different body cell types, cloning by nuclear transfer is appropriately termed somatic cell nuclear transfer (SCNT).

Procedures Involved

The SCNT procedure is remarkably similar in the numerous species that have been cloned to date, highlighting the relevance of the procedural steps depicted in Figure 90.3.

Although any/all are important to obtain viable offspring, success is ultimately dependent on reprogramming somatic nucleus to allow for proper embryo development. The cell type of choice is an oocyte arrested at metaphase II (MII). An oocyte at this stage of meiotic arrest has within it the majority, if not all, of the key critical components to direct early embryo development.

Collection of somatic cells from the animal to be cloned (i.e. somatic cell donor) is an important first step in SCNT. In cattle and other species, adult animals have been cloned using a variety of different diploid ($2n$) cell types including, but not exclusively, fibroblasts obtained from various sources, granulosa cells from antral follicles, and cumulus cells, along with cells originating from mammary tissue, muscle, oviduct, uterus, and other sources. From a practical viewpoint, the relative ease of obtaining skin-derived fibroblasts using a simple biopsy instrument makes this cell type a logical choice to use for cloning adult males and females. Ovarian/granulosa cells are also easily obtained from mature females using the same ultrasound-guided transvaginal aspiration equipment used for ovum pick-up (OPU) in cattle. Regardless of origin, cells obtained from somatic cell donors may be utilized soon after collection, or more often cultured for some time in the laboratory before being frozen for later use. Inducing quiescence in somatic cells using serum starvation or other approaches is not required to obtain cloned offspring. Before SCNT is to be performed, cells are dispersed into a single cell suspension. A trypsin-based solution works well with most somatic cell types. In cases where outcomes are less than expected for a certain somatic cell donor (i.e. embryo development or pregnancy outcomes less than expected after performing SCNT) effort to establish a new cell line, rather than switching cell type, may be beneficial.

When SCNT is to be performed, oocytes must be collected. In cattle, pigs, sheep, goats, and horses, abattoir-derived ovaries provide an abundant and affordable supply of oocytes. In cases where it is important to control the genetic and/or maternal background of the females providing oocytes to reprogram somatic nucleus, OPU procedure provides a means for collecting smaller/limited numbers of oocytes from live animals. There is no doubt that risks exist when oocytes and other biological materials from non-verified sources are used for *in vitro* production of embryos [10, 11]. However, being mindful of the importance of biosecurity along with effort to use source-verified materials, ensure proper oocyte and embryo handling, and disease testing whenever possible and relevant are important steps to minimize inherent risks.

After collection and extensive washing, cumulus oocyte complexes must be matured *in vitro*. In most maturation

systems, the majority of oocytes will have matured and progressed to MII by 18–20 hours after placement into maturation medium. Ability to remove associated cumulus with ease and visually identify those that have extruded a polar body provides a greater level of control for selecting MII oocytes.

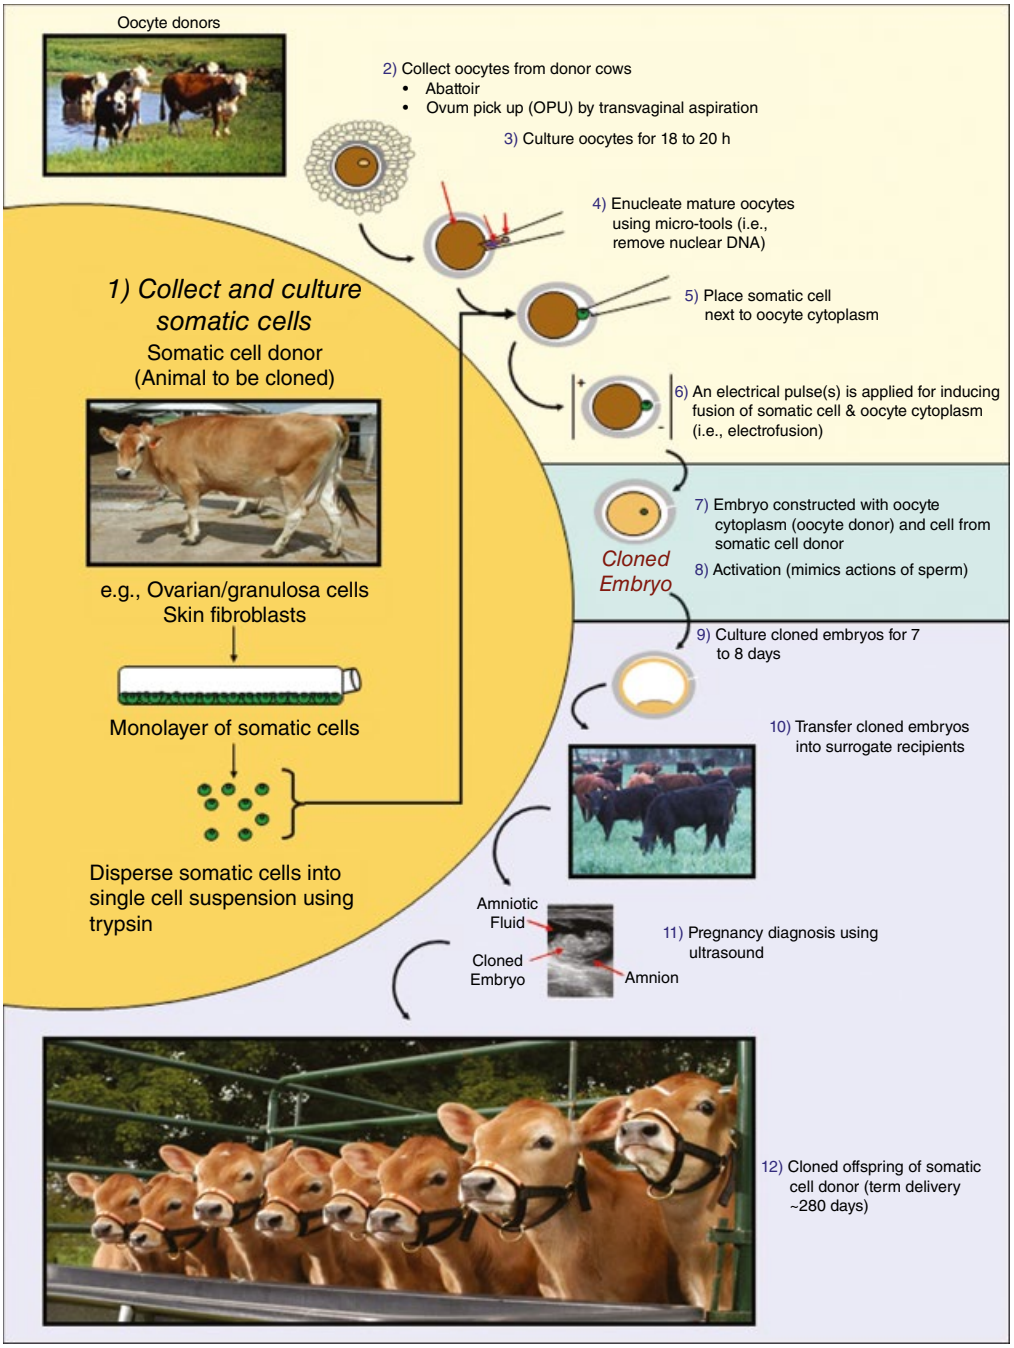

Figure 90.3 Different SCNT steps for cloning adult animals. Although the schematic depicts efforts to clone a cow, SCNT procedures are similar across species (1). The first step involves collection of cells from the animal to be cloned (somatic cell donor) (2). Oocytes are collected from other cows (3). Oocytes may be matured *in vitro* (4). DNA is removed from an oocyte using microtools (5). A somatic cell is placed beside the bag of oocyte cytoplasm (6). Exposure of the oocyte cytoplasm and somatic cell to an electrical current will induce the majority to fuse (7), effectively constructing a 1-cell cloned embryo (8). Electrical induction of fusion of the oocyte cytoplasm with somatic cell may be sufficient to activate the cloned embryo to begin development (9). Cloned embryos may be cultured in the laboratory for a defined period of time (10). Thereafter, embryos must be transferred to surrogate recipients for continued development (11). Ultrasound is useful for determination and monitoring of resulting pregnancies (12). A few of the cloned embryos will develop to term, resulting in the birth of live offspring.

The next and perhaps more labor-intensive step of the SCNT procedure involves the removal of maternal (nuclear) DNA from MII stage oocytes using microtools (Figure 90.3). Addition of a microfilament inhibitor (i.e. cytochalasin B) to the holding medium relaxes the cytoplasm, allowing mechanical removal via aspiration of 5–15% of the oocyte's cytoplasm containing the maternal (nuclear) DNA. Doing so is important to minimize the incidence of lysis that

would otherwise occur without the addition of a microfilament inhibitor. Addition of a DNA-specific fluorescent dye (i.e. Hoechst stain) to the holding medium allows verification that the oocyte's nuclear DNA was successfully removed. Taking effort to restrict/limit exposure of ultraviolet light to the microtool containing maternal DNA that was removed is important to avoid issues/harm related to exposing mitochondrial DNA, organelles, and other essential cytoplasmic components.

The next challenge of the SCNT procedure is transferring the nucleus from a cell obtained from the somatic cell donor (i.e. animal to be cloned) into the "bag" of oocyte cytoplasm that resulted after enucleation of MII chromatin. In most species, mice being an exception, this is achieved by electrical-induced fusion. To this end an intact somatic cell is mechanically inserted into the perivitelline space (available space between the zona pellucida and the enucleated bag of oocyte cytoplasm) using microtools. The resulting "couplet" (bag of enucleated oocyte cytoplasm and somatic cell) is aligned between two electrodes and briefly pulsed with an electrical current. In cattle, 2.2 kV/cm for 40 μs induces >70% of couplets to fuse. Applying an electrical current in this manner induces pore formation in the respective membranes of the two cell types. Electrofusion as a means of transferring the somatic nucleus into the bag of oocyte cytoplasm depends on continuing direct contact between the somatic cell and the oocyte cytoplasm. Depending on the extent to which membranes intermingle, fusion may occur. Within minutes of introducing the somatic nucleus into the bag of oocyte cytoplasm, the nuclear membrane breaks down and the chromatin condenses. Successful fusion of this couplet effectively constructs the equivalent of a 1-cell embryo.

In some cases, the electrical pulses utilized to transfer the somatic nucleus into the enucleated oocyte cytoplasm is also sufficient to "activate" components in the oocyte cytoplasm which is critical to initiate embryo development. Some laboratories prefer the use of different chemical combinations to achieve this end (i.e. calcium ionophore and/or different kinase inhibitors). Regardless of how one chooses to "jump start"/initiate embryo development, the ultimate challenge of activation protocols is to mimic the developmentally important processes occurring after fertilization. Note the deliberate use of the word "mimic" because the spermatozoon is *not* required for this type of asexual reproduction. After activation and depending on the species, cloned embryos may be transferred into ligated oviducts (preventing entry into the uterus of temporary recipients; this is what was done for Dolly) or the uterus (pigs), or cultured in the incubator for a period of time required for development to the compact morula or blastocyst stage (cattle). Cloned bovine embryos develop to the blastocyst stage at an equivalent rate to those undergoing *in vitro* fertilization (Table 90.2).

Because of the incredible effort to produce an SCNT embryo and pregnancy, outcomes are less when *in vitro* derived embryos are frozen, and morula-/blastocyst-stage SCNT embryos should be transferred into surrogate recipients without delay. Embryo transfer utilizes the same approach as is done when transferring other *in vitro* or *in vivo* derived embryos. In cattle, effort should be taken to transfer embryos before or during the early stages of blastocoele expansion, otherwise the expanding blastocoele that is extruding through the holes in the zona pellucida resulting after insertion of microtools to enucleate the oocyte or insert somatic cell into perivitelline space may be problematic (Figure 90.4). Extensive extrusion resulting from the expanding blastocoele through a hole in the zona pellucida has been likened to a "figure 8"

Table 90.2 Developmental potential of SCNT cow clones (constructed with ovarian/granulosa cells and skin fibroblasts) or *in vitro* produced embryos using *in vitro* fertilization.

(Figure 90.4). The potential for extrusions of this type to become pinched/broken off during or after transfer into the uterus may explain why on occasion cloned pregnancies result in twins after the transfer of individual cloned embryos. Depending on the level of difficulty during transfer, potential for damage increases when transferring embryos in the process of expanding. Because pregnancy outcomes after the transfer of one or two embryos do not differ, effort to transfer a single embryo is helpful to minimize complications associated with twinning. To avoid issues with the aberrant hatching of SCNT embryos, earlier stage embryos should be transferred (i.e. compact morula- or early blastocyst-stage embryos). When doing so, embryos should be stage-matched with the uterus (i.e. compact morulae would be transferred to day-6 recipients, not day 7 or 8). Depending on the cell line, it is reasonable to expect day-28 pregnancy rates in cattle approaching 50% after the transfer of single SCNT embryos, as indicated by the presence of an embryo proper with heartbeat (Table 90.3). A limited number of cloned embryos resulting in a confirmed pregnancy will progress to term and result in the delivery of live offspring.

Applications

Success in cloning sheep, cattle, pigs, and goats confirms the usefulness of SCNT for clonal expansion of agriculturally important food-producing animals. Additional efforts of producers to cross their best clonal lines to create new genetic combinations are imperative for making genetic improvements while maximizing genetic diversity. It is worth restating that SCNT clones are merely genetic replicas of existing individuals. Relevant for the few clones that could eventually enter the food chain, compositions of their meat and milk products are indistinguishable from those that are derived from conventionally bred animals [14, 15]. The US Food and Drug Administration (FDA) confirmed that there are no unique risks with meat or milk products from clones or their progeny [16], affirming safety for consumption of food-derived products [15].

The usefulness of SCNT to restore endangered or even extinct species is closer to being realized. Initial reports described efforts to preserve the last surviving cow of the Enderby Island cattle breed [17] and the cloning of a wild ox (guar bull) which was on the verge of extinction [18]. In these and others instances, oocytes within a given species are not available for SCNT. Reprogramming a somatic nucleus from an endangered species is accomplished by transferring to an enucleated oocyte obtained from a different species. Outcomes of interspecies SCNT are less than those expected for same species SCNT [19]. Depending on species-specific differences, incompatibility of mitochondrial and nuclear genome along with other things beyond the scope of this chapter may continue to be problematic.

Use of SCNT is commercially available for individuals seeking to clone companion animals. "To clone or not to clone" depends on expected outcomes. In instances where genetic background of a given animal is not known or

[a] MHC class I haplotypes (AH) carried by the SCNT donor cell lines were determined by MHC class I microarray typing and genomic MHC class I sequencing.

[b] Day-28 pregnancy rates following transfer of a single SCNT embryo to each recipient were not significantly different for the two groups ($P = 0.80$).

[c] Pregnancy losses for class I homozygous and heterozygous SCNT cell lines were compared for three time periods: days 28–90, days 28–200, and day 28 to term. For all three time periods, pregnancy loss was significantly different at $P < 0.001$ (chi-square test).

limited, SCNT may provide an opportunity to produce a genetic replica of an existing individual. However, in instances where intent is to use technology to "replace" a deceased companion, outcomes of SCNT will be less than expected. For instance, identical twins (i.e. nature's truest form of clone) are genetically identical but phenotypically different because of environmental influences.

Cloning by SCNT for the purpose of producing genetic replicas of existing individuals is collectively referred to as "reproductive" cloning. Because SCNT could be used for cloning humans, the moral and ethical issues of its use have been, and will continue to be, debated by various governments worldwide. While the majority would agree that cloning humans for reproductive purposes should be banned, the usefulness of the technology for therapeutic purposes remains contentious. Therapeutic cloning refers to the use of SCNT to reprogram patient-derived somatic cells to provide a source of patient-derived stem cells that could be used for the regeneration of tissues afflicted by a disease or injury. Use of patient-derived stem cells would obviate concerns related to tissue or cell rejection. Contentious aspects of SCNT for this purpose relate to destroying resultant embryo to harvest stem cells for patient/donor use.

Ability of SCNT to utilize somatic nucleus to construct an embryo also allows for cell-mediated transgenesis [20]. Its use for producing transgenic animals (a.k.a. genetically modified organisms) is dependent on inserting a foreign gene of interest into the somatic cell nuclear genome *before* SCNT is performed. Use of a transgenic cell line in SCNT effectively increases the efficiency of producing transgenic farm animals to 100%. Mindful of this and that somatic cells can be easily cultured in the laboratory, genetically modified, and tested before nuclear transfer, makes SCNT the preferred approach for producing transgenic farm animals [20]. The ability to produce transgenic farm animals to serve as bioreactors for the production of pharmaceuticals or possibly serving as organ donors for the human population has created a new form of "pharming" with unlimited potential benefit for human health. Transgenic animals also provide a means in agricultural and biomedical disciplines to study genes involved in a variety of biological and physiological systems.

Challenges Associated

A major limitation of SCNT to clone agriculturally important food-producing animals and other species continues to be the inefficiency in producing live offspring. Dolly was one of 277 cloned embryos that developed to term (0.3% efficiency) [1]. "Millie," a clone of an adult Jersey cow produced in the laboratory of the authors Edwards and Schrick, was just one offspring that resulted after 95 attempts (1.1% efficiency). The US Food and Drug Administration (FDA) conducted a detailed assessment of the potential hazards and risks to highlight the magnitude of inefficiencies that continue to be problematic in food-producing animals such as cattle, sheep, pigs, and goats [15]. Data provided by numerous academic and private laboratories around the world emphasize that, regardless of species or somatic cell type, deaths of cloned embryos and fetuses occur throughout pregnancy. Complications occurring later in pregnancy pose significant risks to the surrogate recipient. Moreover, an unusually high proportion of cloned offspring that are born are larger than normal and die soon after birth.

Development of cloned bovine embryos during the first 29–32 days parallels development of embryos produced after *in vitro* maturation, fertilization, and culture (IVMFC) to the blastocyst stage (Figure 90.5 and Table 90.3). However, similarities beyond this time period end abruptly. Depending on the cell line, embryonic deaths (defined by the absence of a heartbeat and detachment of placental membranes [24]) may occur in up to 100% of cloned pregnancies between about 30 and 90 days of pregnancy (Table 90.3 and Figure 90.6). Without ill effects on the dam, pregnancy losses in cattle of this magnitude during this time period are significantly higher than those expected after breeding by natural service (2–10%) [25] or after development using IVMFC procedures (16%) [21, 22]. Detailed efforts examining placentas from cloned embryos between days 40 and 50 of gestation showed that a high percentage were hypoplastic or partially developed with rudimentary cotyledons [24] (Figure 90.7). Placental insufficiency likely explains much of the fetal losses occurring during this time period. Although the basis for placental insufficiency is not entirely understood, immune-mediated rejection related to inappropriate expression of trophoblast major histocompatibility complex (MHC) class I antigens may be problematic [26]. While other efforts did not provide evidence to support abnormal expression of MHC class I on the trophoblast of cloned fetuses [27], it is interesting to note that the two cell lines used extensively in our laboratory (Edwards/Schrick) and shown to produce a substantial number of successful pregnancies were both derived from MHC homozygous cows [13] (Table 90.3). In contrast, the cell lines resulting in a high degree of fetal losses were from MHC heterozygous cows, suggesting some degree of incompatibility.

The incidence of spontaneous abortions increases during the second trimester of cloned pregnancies. Complete macroscopic and histopathologic examinations of aborted fetuses reveal few abnormalities. However, placentas are oftentimes grossly abnormal with a marked reduction in

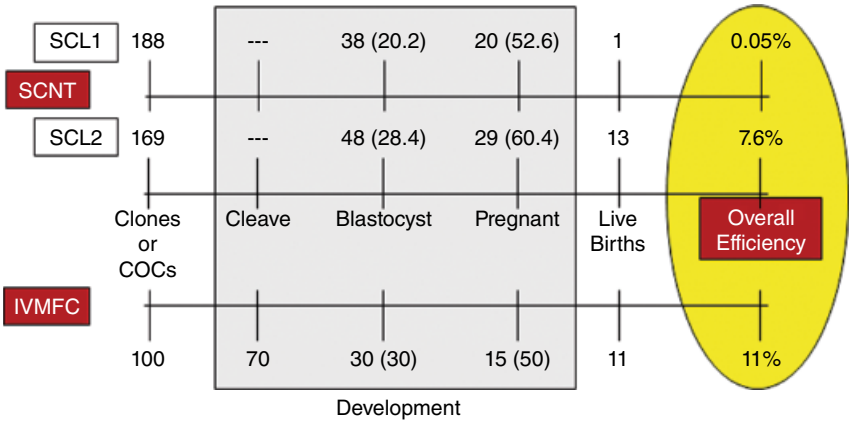

Figure 90.5 Comparison of overall efficiency of SCNT using different somatic cell lines (SCL1 vs SCL2) with IVMFC procedure to produce offspring. Numbers presented for SCL1 and SCL2 represent actual numbers obtained using two different cell lines. Numbers of cumulus–oocyte complexes (COCs) presented for IVMFC were derived from our own experience and volumes of data presented by Dr. John Hasler in published literature [21–23]. Shaded areas highlight time periods with similar development for SCNT and IVMFC embryos (i.e. up to ~29 days in gestation with pregnancy rates approximating 50%).

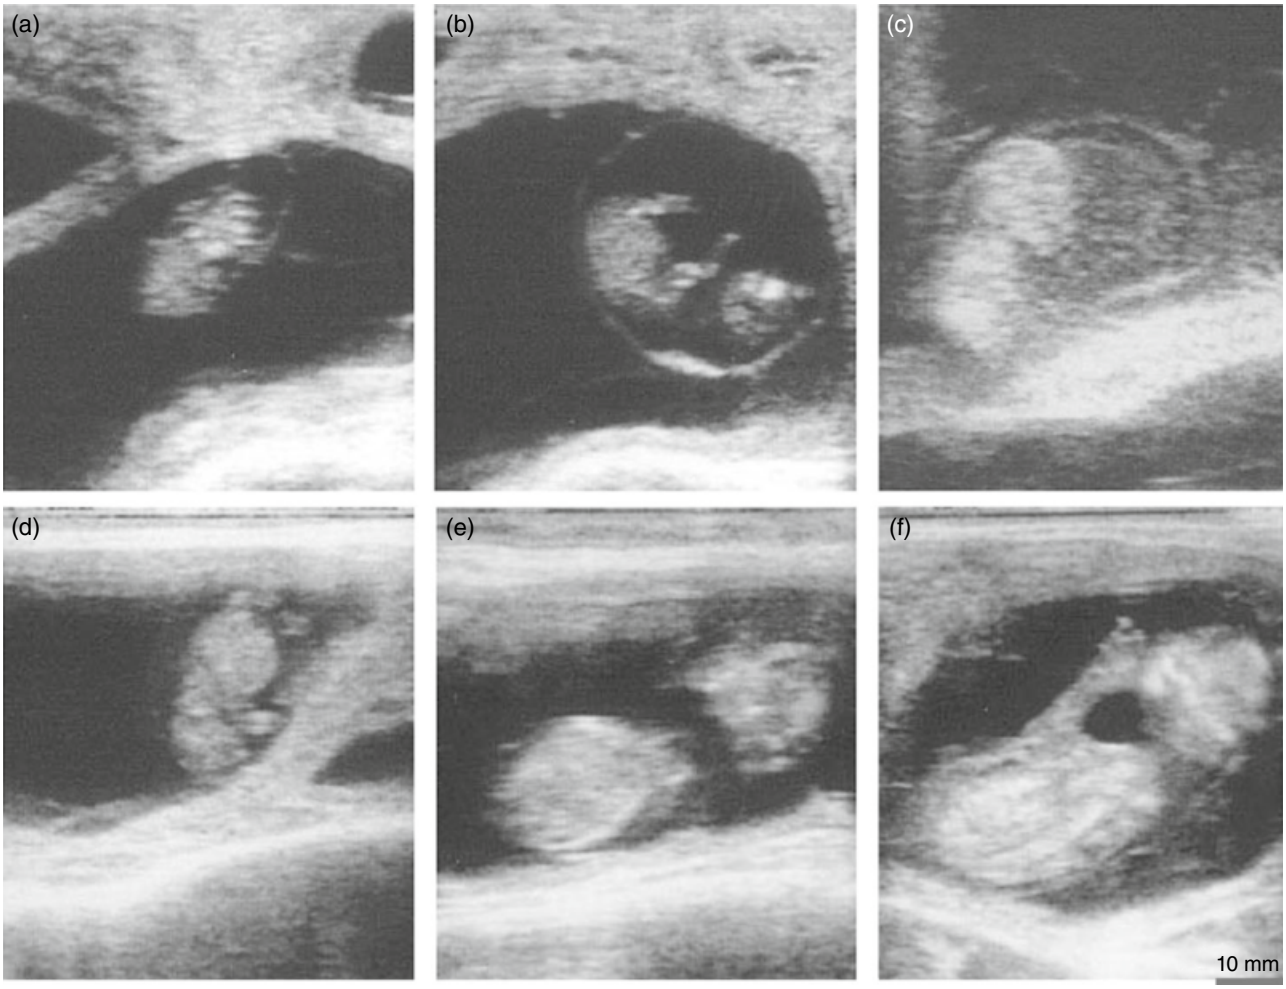

Figure 90.6 Comparison of development of non-viable (a–c) and viable (d–f) SCNT fetuses using transrectal ultrasonography at days 45 (a, d), 55 (b, e), and 65 (c, f). The non-viable fetus was alive at day 45 (heartbeat detected) and dead at day 55 (no heartbeat). At day 65, increased echogenicity of amniotic fluid was apparent as the fetus degenerated. Crown–rump lengths (cm) for the non-viable and viable fetuses at each stage were, respectively, 3 vs 2.8, 3.7 vs 5.7, and 3.7 vs 7.5. *Source:* [24], with permission from Wiley-Blackwell. Image kindly provided by Dr. Jonathan Hill at the University of Queensland.

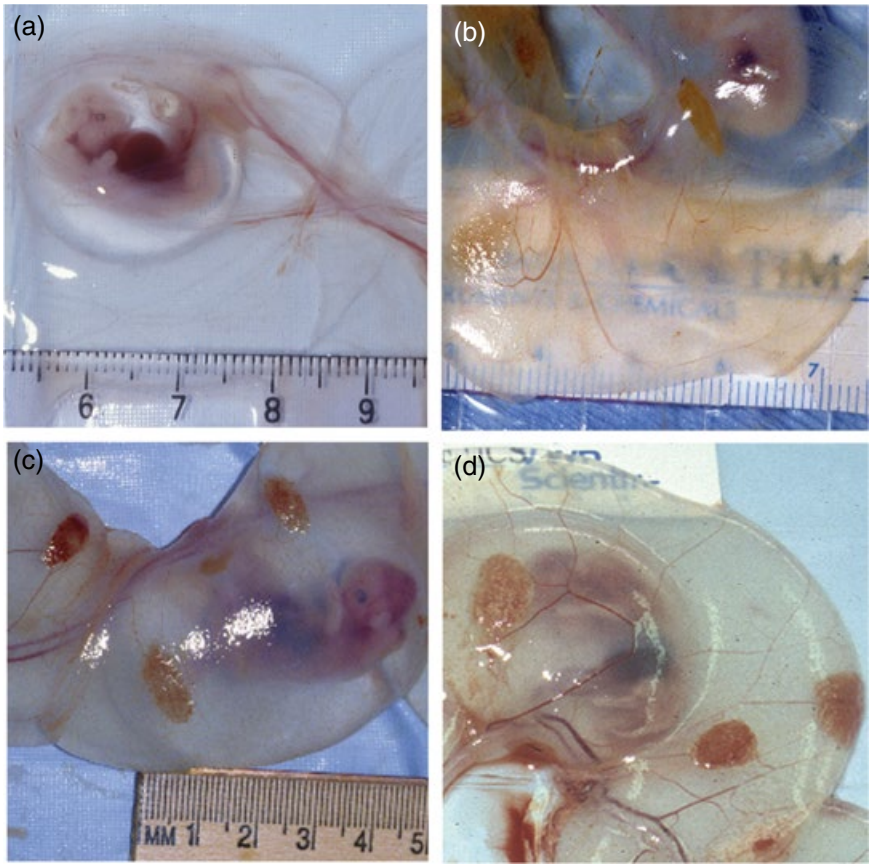

Figure 90.7 Each observed SCNT placenta could be grouped as hypoplastic (a, day 40), partially developed with a reduced number of rudimentary cotyledons (b, day 45), or essentially normal (c, day 50). A control placenta is included for reference (d, day 53, placenta from an IVMFC derived fetus). *Source:* [24], with permission from Wiley-Blackwell. Image kindly provided by Dr. Jonathan Hill at the University of Queensland.

fetal cotyledons (occasionally fewer than 20 compared with the expected 70–120) [15] (Figure 90.8). Fetal membranes are generally thickened and edematous.

Pregnancy losses during the third trimester, especially between 200 and 265 days (term is 280 days), are more challenging. Many of the fetal losses occurring during this time relate to an increased incidence of the dropsical condition hydrops. Excessive accumulation of fluid may occur in different parts of the placenta (hydrallantois and/or hydramnios) [28] and/or fetus (hydrops fetalis). Incidence of hydrops as high as 86% has been reported with SCNT pregnancies with varying levels of severity [15]. In our experience, 58% of established pregnancies developed hydrops; 37% of the hydropic pregnancies were severe enough to warrant euthanasia of the surrogate recipient. Incidence of hydropic SCNT pregnancies is much higher than what may be expected in pregnancies resulting from conventional breeding (1: 7500) [29] or from IVMFC procedures (1: 158) [23].

In moderate to severe cases of hydrops, the abdomen becomes noticeably distended from the excessive accumulation of fluids (Figure 90.9a). Uterine rupture and other

Figure 90.8 SCNT fetus aborted during second trimester. Placenta was thickened and edematous with about 14 fetal cotyledons.

harmful complications to the surrogate recipient may be problematic in rapidly developing cases, warranting immediate euthanasia [28]. Attempts to "rescue" the fetus by emergency cesarean section often prove futile as the fetus is often already dead. Even if delivered early enough, neonatal care is inadequate to sustain the life of those neonates delivered at the time when most cases of hydrops are diagnosed. Marked reductions in numbers of placentomes of varying sizes, along with marked hypertrophy of many cotyledons, are evident with cloned placentas. Often there is an increased incidence of adventitial placentation and severe edema in the intercotyledonary placental membranes (Figure 90.9d). Most fetal abnormalities are consistent with consequences related to hydrops and placental insufficiency. Fetal anasarca with generalized edema and marked edema of the umbilicus is usually present (Figure 90.9e). Amniotic squames and meconium are generally present in the lungs of late-term fetuses, indicating some degree of stress in utero before death. Because of the poor prognosis for the fetus and possible harm to the surrogate recipient, termination of a hydropic pregnancy is most often warranted after initial diagnosis. Some of the cattle producers interviewed for the FDA risk assessment [15] indicated that they began monitoring surrogate recipients closely for developing signs of hydrops as early as 150 days into gestation.

While clones may die immediately or soon after birth (within about 48 hours), survival rates up to 50–70% are obtainable. Survival is related to birthweight to some extent (Figure 90.10). In the sample data provided in Figure 90.10, the majority of Jersey cloned calves surviving (L, live) weighed about 39 kg or less at birth. Jersey clones

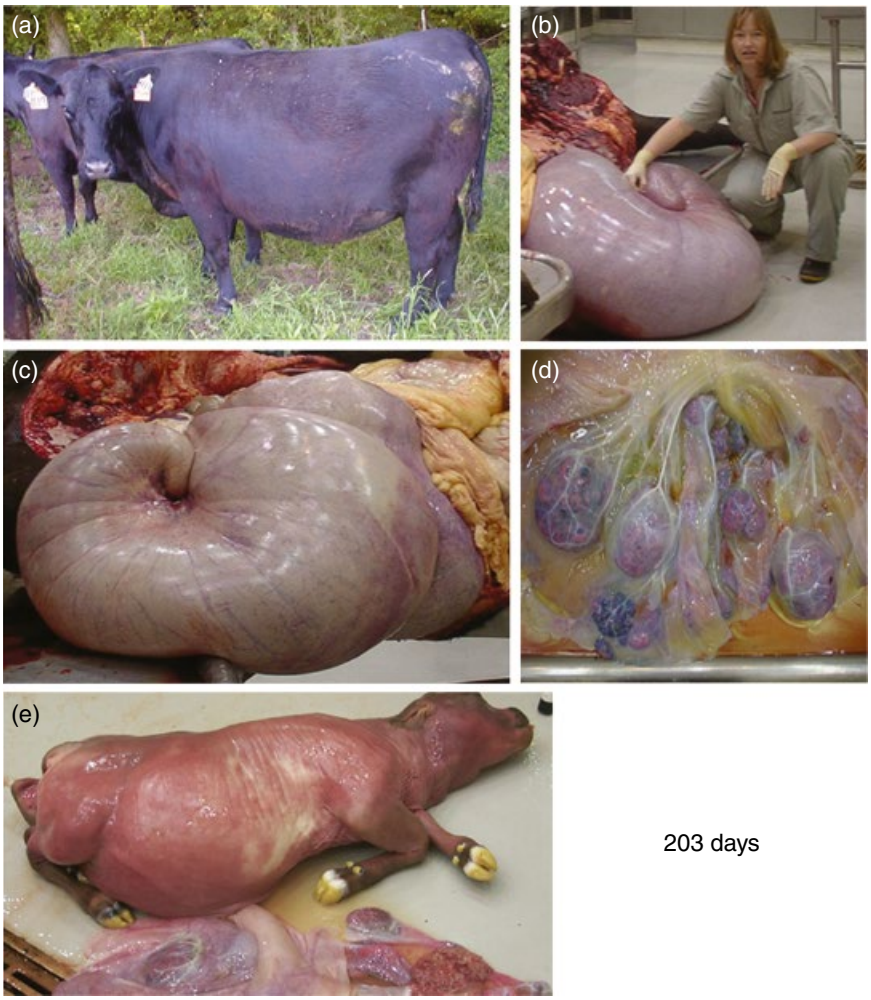

Figure 90.9 (a) Hydropic surrogate recipient at 203 days of gestation. (b) After euthanasia; ovary is located on the tip of the first uterine horn (indicated by individual's hand). (c) Clearer image of hydropic uterus; the fetus is located in the uterine horn behind the first one. Figure 90.10 Representative image depicting survival for SCNT clones of Jersey cows (L, live; D, dead; E, euthanasia) considering birthweight and placenta (H, hydropic; N, no obvious signs of hydrops).

weighing 40–45 kg died at birth, and at times thereafter. Of the few cloned embryos that develop to term, calves are typically larger at birth, with some exhibiting clinical signs associated with "dummy calf" syndrome. Reported incidence of cloned calves exhibiting large/abnormal offspring syndrome varies considerably, ranging from 8 to 100% [15]. In our experience and others [15], large calves are slow to stand, have difficulty with regulating body temperature, have a weak sucking reflex, and their umbilicus is often enlarged and edematous with a patent urachus. Some have deformities in limbs related to tendon contracture, have disproportionate or immature organ development, and may be more susceptible to infections. Calves exhibiting clinical signs of large/abnormal offspring syndrome are intensively monitored and may be provided with therapies to treat a whole plethora of complications, including but not limited to lung dysmaturity, pulmonary hypertension, respiratory distress, hypoxia, hypothermia, hypoglycemia, metabolic acidosis, enlarged umbilical veins and arteries, and/or the development of sepsis in either the umbilical structures or lungs. Few survive, despite extraordinary efforts to intervene.

Complications in cloned calves may not be evident for several months, with the majority of deaths occurring by six months of age [15]. In those exceeding six months of age, surviving clones may appear "normal" and "healthy" until some unexpected pathology presents itself. We had three clones die at 7.5, 8, and 9 months of age, while two others died at 1 and 2.5 years of age. Although different pathologies were noted, several died or were euthanized after periodic episodes of scours unresponsive to treatment. A few but documented instances of sudden death in clones without any ill effects in the non-clones housed in the same environment makes for good discussion whether death was attributable to the animal being a clone or merely a victim of its circumstances.

Fortunately, most of the healthy-appearing clones from otherwise normal pregnancies exhibit normal growth and development. To date, numerous clones have been bred and have given birth. Dolly gave birth to six lambs (Bonnie was the first, born in 1998, twins followed the next year, with triplets the year after that; Figure 90.11). Unfortunately, Dolly was diagnosed with Jaagsiekte sheep retrovirus (JSRV) as were other sheep at the Roslin Institute. She was euthanized in 2003 after developing viral-related lung tumors according to the Roslin Institute.

Like cattle, much of the SCNT losses occurring in other species are attributable to early embryonic and fetal losses. Fortunately, complications related to hydrops and large/abnormal offspring syndrome are not problematic in goats or the majority of other species cloned to date. In pigs, litter sizes ranging from zero to eight are possible

Figure 90.11 Dolly with Bonnie, her first-born lamb after being mated to a small Welsh Mountain ram. *Source:* Image and permission to reproduce were provided by the Roslin Institute, University of Edinburgh.

after the transfer of more than 100 one-cell cloned embryos into the uterus of surrogate recipients [15]. While a few abnormalities have been noted, most pig clones are smaller, not larger, at birth when compared to those derived from natural mating or IVMFC procedures [15]. Success with cloning horses using SCNT was realized and numerous clones using adult somatic cells have been produced. Although the incidence of embryonic and fetal losses parallel those occurring in cattle (75–100% loss may be incurred depending on cell line), pregnancies and offspring in the available literature are without complications related to hydrops and large/abnormal offspring syndrome [30, 31]. For the most part, placentas appear "normal" at term, with some foals having an enlarged edematous umbilical cord.

Although SCNT in the dog is remarkably similar to what has been done in cattle and other species (Figure 90.12), inability to mature appreciable numbers of oocytes *in vitro* warrants use of *in vivo* matured oocytes [33]. Aside from dogs being monoestrus, the fact that oocytes undergo maturation in the oviducts after ovulation, which may occur over a time period of 48–72 hours, poses a unique challenge related to controlling stage of maturation utilized for SCNT. With success after transferring cloned embryos to the oviducts, much of the inefficiency related to SCNT in dogs has been related to early embryonic and fetal losses. Placental issues may be problematic with cloning of dogs. As observed in cattle, heavier placentas were associated with lower survival rates [34]. Different pathologies have been noted in non-surviving cloned fetuses and offspring, including increased muscle mass [35].

Potential Factors Contributing to the Inefficiency of Cloning by SCNT

Mindful of the physical insult inherent in the SCNT procedure and the complexity of factors within the oocyte's cytoplasm that are "expected" to reprogram a somatic nucleus, it is truly remarkable that any clones develop into healthy offspring. Some of the procedural aspects related to the extensive micro-manipulations required to construct cloned embryos using oocytes and somatic cells are not ideal (see Figure 90.3). Removal of nuclear DNA from the oocyte typically involves the physical removal of 5–15% or more of the cytoplasm while exposing it to an otherwise "noxious" chemical. Verification of this process may expose the cytoplasm to ultraviolet light, which has been shown to alter membrane integrity, increase methionine uptake, and alter protein synthesis and mitochondrial activity [36]. To transfer the somatic cell nucleus into the bag of oocyte cytoplasm generally involves electrical-induced fusion or microinjection. No matter how careful, some degree of membrane lysis occurs with either procedure. Furthermore, a variety of protocols have been described for activating cloned embryos, with the majority involving exposure to otherwise noxious chemicals. It is also important to note that SCNT typically involves the transfer of a somatic cell nucleus into an ooplast (enucleated oocyte) obtained from a nondescript female not from the somatic cell donor. This results in embryos with nuclear DNA from the somatic nucleus but mitochondrial DNA (mtDNA) from the "foreign," non-autologous oocyte cytoplasm. Resulting embryo is not a "true" clone like identical twins; rather it is chimeric at the mitochondrial level (i.e. mtDNA heteroplasmy).

Moreover, culture of cloned embryos from *in vitro* matured oocytes before transfer into surrogate recipients is not without ill effects. Like SCNT, complications inherent to the production of embryos using IVMFC procedures include alterations in gene expression in early embryos and fetuses [37], increased abortion rates (~16%) [22], abnormal placentas, increased incidence of hydrallantois (~1%) [21], heavier fetuses, dystocia, large/abnormal offspring syndrome, and mortality rates (~15%) [21–23, 38–41], albeit at a much lower rate (see Chapter 71). The specific SCNT factors exacerbating problems inherent to IVMFC procedures are poorly understood. However, stark differences in the ability of certain cell lines to produce live offspring after nuclear transfer, approaching values derived from IVMFC procedures (see Figure 90.5), implicate improper or incomplete reprogramming of the somatic nucleus by the oocyte cytoplasm. To this end, genomic methylation status in cloned blastocysts often resembles that observed in somatic cells, which would explain the aberrant expression of developmentally important genes observed in cloned embryos and fetuses [42, 43].

Summary

Cloning by SCNT defies basic principles in developmental biology. Eventual improvements related to increasing the number and survival rates of cloned embryos, fetuses, and offspring are imperative for fully realizing SCNT applications for animal agriculture and human medicine. Because of the complexity involved with the construction of an embryo, using nothing more than a somatic nucleus and the cytoplasm of an oocyte, it is likely that many more years of effort will be required to understand the process well enough to improve outcomes.

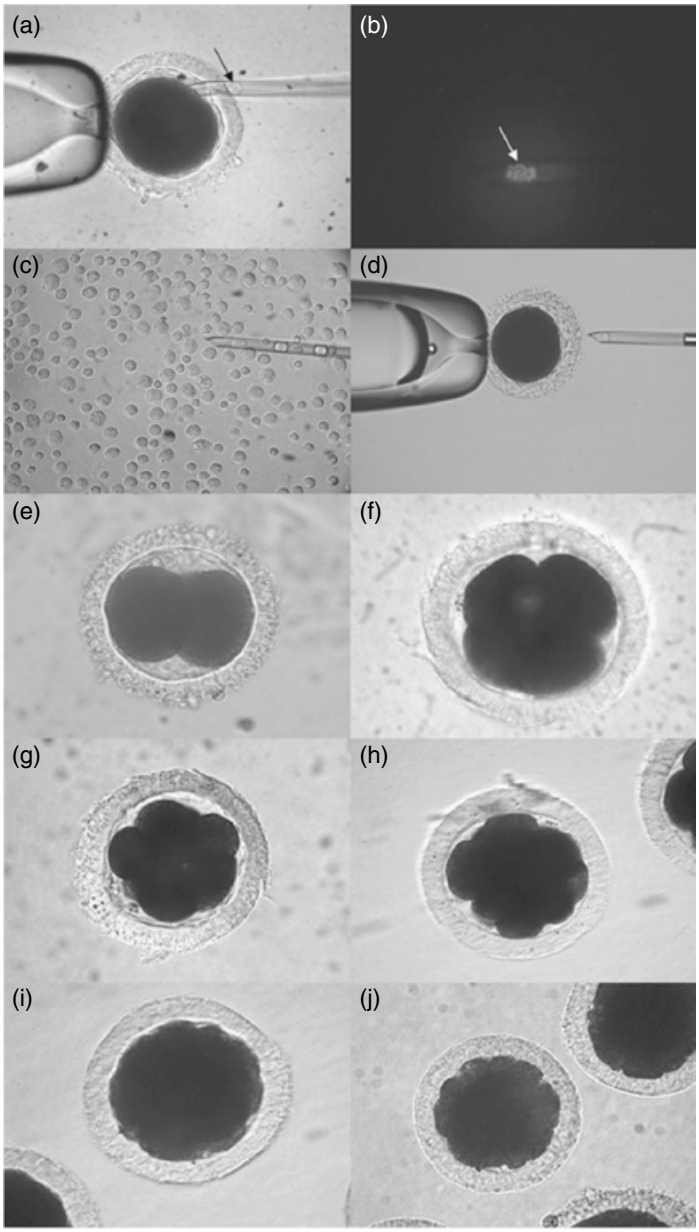

Figure 90.12 Representative image depicting SCNT procedure and *in vitro* embryo development for cloned dogs. The first polar body (a, arrow) and oocyte nucleus (b, arrow) are removed in *in vivo* matured oocytes using an aspiration pipette. Enucleation may be confirmed by nuclear staining (b, arrow). Somatic cells are aspirated into a micropipette (c) and placed into the perivitelline space of an enucleated oocyte (d). Fused couplets are activated and cultured for seven days. Cloned cleavage stage embryos: 2-cell (e), 4-cell (f), 8-cell (g), 16-cell (h), 32-cell or morula (i, j). *Source:* Reproduced from [32], with permission from Elsevier.

Application of CRISPR-Cas9 Technology in Bovine Reproduction

Vanmathy Kasimanickam

Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, WA, USA

Introduction

Genome manipulation was first made possible in the 1970s when *Escherichia coli* was first manipulated to produce somatostatin, a therapeutic protein, by fusing this gene to the *E. coli* beta-galactosidase gene on a plasmid and transforming it into *E. coli* [1]. Clustered regularly interspaced short palindromic repeats (CRISPR)-Cas9 technology is now a unique tool that can precisely change an organism's DNA. Precision genome editors are new genome editing tools that enable one to rewrite genes, making targeted changes to an organism's DNA by deleting, inserting, or modifying sections of DNA sequences with unprecedented specificity. Genome editing is currently unraveling its benefits in wide areas of science and medicine, although there are ethical, social, and legal challenges associated with its application. Advances in gene editing technologies from transgenesis and gene silencing to precision gene editing tools (zinc-finger nuclease [ZFN], transcription activator-like effector nuclease [TALEN], and CRISPR) put us at the dawn of a new revolution in life sciences.

Basics of the Genome

A genome consisting of DNA (RNA in RNA viruses) is the blueprint of life and heredity, and the instructions needed for an organism to grow, develop, survive, and reproduce are written in the genome. Mammalian body consists of trillions of cells which are divided into somatic cells and gametes. Somatic (autosomal) cells have a diploid number of chromosomes, whereas gametes comprise a haploid number of chromosomes. In the event of fertilization, two gametes, one from the dam and one from the sire, unite to form a zygote. A zygote's genome is a combination of a male and a female gamete DNA, and initially quiescent but contains all the genetic information necessary to form a new individual. The mammalian genome is comprised of billions of nucleotide base pairs, and a sequence of nucleotides constitutes a gene that encodes the synthesis of a functional gene product, either RNA or protein. A set of genes is responsible for a genotypic trait and the genotypic trait interacts with the environment to produce a specific observable phenotypic characteristic. Numerous studies have been carried out to elucidate gene function; however, elucidation of genes and their function is far from our understanding because genes are differentially expressed in a temporal and spatial manner. Modern genome editing technologies take a leap toward endogenous genome modification with the ability to rapidly and economically introduce sequence-specific alterations into the genomes of a broad spectrum of cell types and organisms, which gives rise to several opportunities to increase production and reproduction efficiency, to produce disease-resistant animals, and to generate climate-tolerant animals in livestock species.

History of CRISPR Technology

The underlying molecular mechanism of the CRISPR-Cas9 system was highlighted by a group of researchers at the University of California-Berkley and the University of Vienna in 2012 [2]. From the fact that in bacteria and archaea, CRISPR-associated systems provide adaptive immunity against viruses and plasmids by using CRISPR RNAs to guide silencing of invading nucleic acids of viruses [3–9], the researchers explained that this system can be used in prokaryotic cells to produce programmable precise double-strand breaks at any specific DNA site by

Companion website: www.wiley.com/go/hopper/bovine

combining an RNA guide with an endonuclease protein, CRISPR-associated (Cas)9 nuclease. Simultaneously, the investigators filed a patent for the methods and applications of this RNA-directed site-specific DNA modification. Concurrently, another group of researchers from the Broad Institute of MIT and Harvard University demonstrated that the *Streptococcus pyogenes* CRISPR system can be heterologously reconstituted in mammalian cells, including in several human cell lines, to facilitate highly efficient genome editing [10]. A patent application was also filed from the Broad Institute of MIT for invention of mammalian genome editing using CRISPR-Cas9 technology. Legal battles around these patents from these two groups of researchers have attracted media attention and made the CRISPR fantasy in recent years [11–13].

The simple, albeit elegant, machinery of the CRISPR-Cas system has become the technology of choice in various biotechnological applications including genome editing, gene therapy, and elucidation of gene function. With the accuracy and flaws in techniques, and ethical and social implications from the public, CRISPR-Cas9 technology and its applications are being progressed rapidly. The CRISPR-Cas9 system has two crucial molecules, Cas9 and guide RNA (gRNA), that can generate an accurate change in DNA. The endonuclease protein Cas9 acts as a pair of "molecular scissors" that can sever two strands of DNA at a specific location in the genome in order to delete or insert fragments of DNA. The gRNA is a small piece of predesigned RNA sequence (about 20 nucleotide bases long) situated within a longer RNA scaffold. The RNA scaffold binds to the targeted DNA, and the predesigned sequence guides the Cas9 enzyme to the right part of the genome and to cut at the correct targeted site. The gRNA consisting of complementary nucleotide bases is precisely designed to identify and bind to a specific targeted sequence in the DNA. The gRNA will theoretically bind to the target sequence only, but not to any other region in the genome.

Other Main Gene Editing Tools

Zinc finger proteins contain many finger-like structures linked via small peptide linkers in a tandem fashion. These proteins' tandem arrangement and their ability to recognize a wide variety of DNA sequences made them attractive to be bioengineered to design novel DNA-binding peptides/proteins. Zinc fingers are short stretches of amino acids folded into an ααβ compact structure with the help of a Zn ion. The Zn ion links the α-hairpin and β-helix in a tetrahedral fashion with the two conserved cysteine and two histidine residues. Although Zn metal is not directly involved in DNA-binding activity, it is critical for stability of the ααβ architecture of the zinc finger domain [14]. These bioengineered zinc finger DNA-binding proteins were used for targeted editing of the genome by creating double-strand breaks in DNA at user-specified locations [15, 16]. Gene editing using ZFNs was many times more efficient in gene targeting and gene alteration via mutagenic DNA repair compared to conventional homologous recombination-based gene targeting. A milk protein, β-lactoglobulin (BLG) which is a primary milk allergen, is found in cow milk but not in human milk. Recently, BLG gene-free cows were generated using ZFN mRNA contributions [17]. In this study, primary female bovine fetal fibroblasts were transfected with designed BLG-ZFN mRNA, and BLG bi-allelic knockout cows were generated by somatic cell nuclear transfer (SCNT) [17].

Initial technologies such as ZFNs and TALENs suffer from lower specificity due to their off-target side effects. Many possible off-target genomic sites, based on high-sequence similarity to on-target sites, were identified in ZFN-mediated genome editing in human-induced pluripotent stem cells [18]. Another study targeting endogenous human chemokine (c-c motif) receptor 5 (CCR5) and vascular endothelial growth factor A (VEGFA) genes identified nine off-target sites by CCR5-induced changes and 31 off-target sites by VEGFA-induced alterations in cultured human cell lines [19]. Assembling zinc finger domains to bind a precise extended stretch of nucleotides with high affinity is not straightforward [20]. Bioengineering ZFNs to specific targets is difficult and time consuming. In addition, multiplex genome editing has been performed in only a few models using ZFNs and TALENs [21]. Further, the main obstacle was to develop a simple but effective delivery method for these proteins (ZFNs and TALENs) to enter the host cell compared to small gRNAs in the CRISPR-Cas9 system. Overall, CRISPR-Cas9 technology seems to provide better efficiency and feasibility, with greater suitability for multiple clinical applications.

Customized DNA-binding domains engineered using TALEN repeats were widely used in genome editing. TALENs consist of an engineered array of TALE repeats linked to the FokI nuclease domain. TALENs have been used to create site-specific DNA double-strand breaks in various organisms and cell types for directed genome editing [22]. Myostatin gene-edited cattle and sheep were produced by zygote injection of engineered TALEN mRNA [23] and they had advantages over the traditional process that involves generation of a knockout cell line using homologous recombination and SCNT into oocytes. Application of SCNT requires a high-level of technical expertise, reliable supply of oocytes, and many recipient animals. Myostatin knockout bovine fetal fibroblasts were obtained using TALENs and in which myostatin-TALEN vector was constructed and transfected into bovine fetal fibroblast cells.

Sequencing confirmed the knockout efficiency for TALEN-myostatin pairs and the efficiency was 20% [24]. In another elucidation, codelivery of myostatin and TALENs induced highly specific and efficient gene disruption in a variety of mouse, human, and bovine cells. This specific combination of myostatin and TALENs seemed to be very functional, based on sequence analysis and makes the application possible in many other mammalian species in the future [25]. One transgenic cow with site-specific marker-free *Sulfolobus solfataricus* β-glycosidase (LacS) was produced with a long-term purpose of generating cows producing low-lactose milk [26]. Site-specific integration of the LacS gene was mediated through TALEN-mediated microhomologous end-joining. The TALENs vector that targets the cow's β-casein locus, LacS gene expression vector that contains TALEN reorganization sequence, and microhomologous arms were constructed and cotransfected into bovine fetal derived skin fibroblasts. Positive cell clones were used as donors for SCNT and resultant embryos were transferred into recipient animals. LacS knockin rate in TALEN-treated cattle fetal fibroblasts was 0.8%. The blastocyst rate following SCNT was 27%, the three months pregnancy rate was 20%, and one transgenic female calf was born [26]. The prion protein (PRNP) gene that encodes prion protein was deleted by transfection of plasmids that encode TALEN pairs into bovine fibroblasts and the propagated cloned cells were used for SCNT [27]. Resultant blastocysts were confirmed to have deletion of the PRNP gene. TALEN-stimulated homology directed repair introduced a mini-gene donor construct, an 11.5-kb insert at the bovine albumin locus in primary bovine fibroblasts to create genetically modified cattle as a biopharming source of recombinant human serum albumin in the future and resulted in a targeting efficiency of 11%. Moreover, these manipulated fibroblast cells were used as nuclear donors in SCNT and developed to at least the blastocyst stage [28].

Although ZFNs and TALENs were used in the past for targeted genome editing, CRISPR has captured the attention of the research community, primarily due to its lower cost than TALENs and other genome-editing tools. Donor structure is simple and smaller in the CRISPR-Cas9 system (RNA–DNA) compared to donor structures in ZFNs and TALENs editing tools (protein-DNA) and this structure facilitates easier delivery of the CRISPR-Cas9 system into target cells. Versions of gRNA can be easily designed for any specific targets [29]. TALENs require complex cloning methods, whereas in CRISPR-Cas9 application, genes can be easily retargeted by standard cloning methods and oligo synthesis in most scenarios. Large-scale library preparation has not been performed using ZFNs and TALENs [30]. Although the techniques using ZFNs and TALENs have been improved by booming biotechnologies, and these methods are still being applied in certain situations, the CRISPR tool seems to be a game changer at present time pending discovery of another new technology, probably whole genome editing, to completely create synthetic animals and humans.

Reproduction and CRISPR-Cas9 Technology

Reproduction is the fundamental biological process by which organisms maintain their generations. Natural mutations in the DNA or RNA nucleotides, genes, or chromosomes can occur randomly, and these mutations may be beneficial or harmful with regards to inheritance and evolution. Gene editing is an intended genetic mutation in which DNA is inserted, deleted, modified, or replaced in the genome of a living organism. Whether it is a natural gene mutation or an intended change made in the gene, the reproductive process is critical to propagate the desired alteration in a population. DNA constructs harboring homologous stretches were able to enter, interact, and eventually integrate at the target site of the genome by the endogenous homologous recombination machinery in a variety of cells. Although gene editing by conventional homologous recombination has been successful in various somatic cells, DNA editing using conventional recombination techniques has been virtually unfeasible in germline, zygotes, embryo, and embryonic pluripotent cells. Nevertheless, discovery of novel and highly efficient DNA editing tools such as CRISPR-Cas9 technology has simplified genome editing in zygotes, germlines, and pluripotent stem cells.

Pronuclear and cytoplasmic microinjections of CRISPR ribonucleoprotein targeted tyrosinase gene by electroporation into murine zygotes were highly efficient, simple, and cost-effective, and facilitated indel mutations, exon deletions, point mutations, and small insertions [31]. To investigate the function of the pluripotent octamer-binding transcription factor 4 (OCT4) during human embryogenesis, the CRISPR-Cas9 system was used to manipulate OCT4 and this system efficiently and specifically targeted the gene encoding OCT4 in diploid human zygotes. Blastocyst development was compromised in OCT4-deleted zygotes [32]. Proto-oncogene, c-KIT, encodes the receptor tyrosine kinase and was better targeted using CRISPR-nuclease than utilizing CRISPR-mRNA in marmoset embryos, and mosaicism was avoided when the CRISPR-nuclease system was applied [33]. RNA-guided Cas9 nuclease genes efficiently facilitated genome editing in zebrafish embryos in a simple and robust manner when ETSRP, GATA4, or GATA5 genes were targeted. The Cas9-gRNA system induced target-specific indels in F0 mutants comparable to mutants produced with TALENs and ZFNs

in zebrafish embryos, making it feasible to generate heritable F1 mutants using the Cas9-gRNA system [34]. A protocol for microinjection of the CRISPR system into one blastomere of two-cell embryos was established to generate viable chimeric founder mice with a heritable embryonically lethal mutation to elucidate function of VIRMA and DPM1 genes [35]. Targeted deletion of the OCT4 gene was created by direct injection of the CRISPR/Cas9 reagent into bovine zygotes and disruption at the bovine OCT4 locus arrested embryonic development at the morula stage and hindered blastocyst formation [36]. When the FGF10 gene that encodes fibroblast growth factor 10 was targeted through microinjection of TALEN and CRISPR-Cas systems into one-cell mouse embryos, the resultant F0 phenotype from FGF10-deficient embryos had limb-defect. The CRISPR-Cas system produced limb defects with strikingly higher efficiency compared to the TALEN system [37].

Although scientists are successful in gene editing in mammalian zygotes and early embryos, the studies battle with manifold complexities of DNA repair in zygotes and early stages of embryonic development such as mosaicism and off-target effects. Many factors such as gRNAs, local chromatin effects, competition between Cas9 and endogenous transcriptional regulators, and epigenetic factors shape the success of gene modification in zygotes and early embryos. CRISPR-Cas9 is not immediately degraded after cutting and repairing the genome at the targeted site and may continue to slice off-target locations until its complete degradation. Synthesis of Cas9 protein from plasmids can lead to high enzyme concentrations, high levels of off-site targeting, and residual activity following desired gene manipulation. As an alternative, purified recombinant Cas9 protein can be directly injected into oocytes, zygotes, and embryos which may enhance specificity while shortening enzymatic exposure time, thus lessening off-site targeting. Also, limiting the CRISPR-Cas9 reagents or introducing an adjacent silent mutation effect in the donor DNA may prevent off-target and residual effects. Timing of editing in the embryo cannot be monitored and any editing that occurs after the first cell division is very likely to produce mosaicism in edited embryos.

Simultaneous injection of sperm and CRISPR reagents can reduce the level of mosaicism compared to the level that happens when the CRISPR reagent is injected after fertilization. The zygote will have more time to edit and complete repair before the first division when CRISPR component is micro-injected before fertilization. However, there will be residual activity later in the embryo if editing on one or both alleles is unsuccessful before the first cell division. Paternal and maternal chromosomes may be edited at various rates in the early embryo and repaired using different mechanisms. The paternal genome appears to be more efficient in gene editing than the maternal genome [32]. One allele sometimes remains to be unedited immediately after the first cell division. Alternative strategies might be to develop new protocols to edit germline cells before fertilization. In humans, gene repair in gametes or preimplantation embryos would reduce the risk of producing mutant embryos, thereby increasing numbers of embryos available for transfer and eliminating the need to dispose of a mutant embryo that is considered a potential life in some societies. Therefore germline gene therapy is more ethically acceptable to some families.

The CRISPR-Cas9 system was used to mutate an EGFP transgene and endogenous CRYGC gene in mouse spermatogonial stem cells (SSCs) without any off-targets. Mutated SSCs were transplanted into seminiferous tubules of infertile mouse testes to undergo spermatogenesis. Round spermatids were injected into mature oocytes to produce heterozygous offspring and these offspring displayed the corresponding mutant phenotypes [38]. The CRISPR-Cas9 provided a platform to generate targeted germline mutations in rat SSCs and to elucidate details of spermatogenesis in rats. In that study, EPSTI1 and ERBB3 genes were targeted to be modified, altered spermatogonial cells were transplanted into recipient rat testis to regenerate spermatogenesis, and pure non-mosaic mutant progenies were produced [39]. TALEN and CRISPR-Cas9 produced ROSA26 that is unrelated to spermatogenesis, and STRA8 that is indispensable to spermatogenesis, genes deleted mouse spermatogonial cells. Upon transplantation into a recipient testis, ROSA26 targeted cells produced competent sperm whereas STRA8 targeted cells showed defective spermatogenesis [40].

The CRISPR-Cas9 was used to manipulate the genome in zebrafish oocytes. Injecting oocytes in advance with predesigned CRISPR-Cas9 components and incubating them in oocyte incubation medium significantly improved efficiency of genome editing and germline transmission by *in vitro* fertilization in zebrafish compared to conventional methods. This novel strategy not only provided an efficient gene editing alternative but also generated heritable mutants in zebrafish [41]. The CRISPR-Cas9 targeted PDX1, a critical gene for pancreas development in sheep oocytes. Microinjecting CRISPR-Cas9 components in metaphase II oocytes was found to have reduced lysis, improved blastocyst rate, and increased the number of targeted biallelic mutations, and had similar degree of mosaicism compared to zygote microinjection of the same components. Also, a dual sgRNA system achieved complete PDX1 disruption and mutated fetuses with disrupted pancreatic development [42]. The CRISPR-Cas9 system can produce corrected mature sperm and oocytes that can be used to produce disease-free individuals. It has also been efficiently

applied to produce synthetic gene drives in populations to control genetic and vector-borne diseases. Safe applications of CRISPRs in reproduction can guarantee a huge reduction in genetic as well as vector-borne parasitic diseases in humans and animals.

The Cattle Industry and CRISPR-Cas9 Technology

In the cattle industry, selective breeding plays an important role in breeding superior males and females to produce progeny with specific characteristics or traits. The main goal of selective breeding is to reduce production costs and increase output values. Selective breeding started in the 1950s, to improve growth and conformation traits. Later, feed efficiency characteristics were paid attention to. Reproduction, meat quality, health, and behavioral traits were of interest in the 1990s in selective breeding programs. Current breeding programs also intend to select traits involved in longevity, metabolic disorders, infectious diseases, and climate tolerance. In the past, traditional selection was performed based on pedigree charts and phenotypes. A new development in genomics facilitated genotyping of animals. Single nucleotide polymorphisms (SNPs) and genome wide association studies helped to predict a phenotype associated with an SNP. Animals can be genotyped early in life, which can result in acceleration of genetic gain [43, 44].

In selective breeding, precise targeting of a trait is impossible. Selective breeding is a relatively slow and expensive process since it depends on natural selection and reproduction processes. Selective breeding can also result in harming animals. For example, selection to increase milk production in cattle resulted in discomfort for the animal because of the weight of huge udders and frequent milking. This caused inflammatory and metabolic diseases. Belgian Blue cattle are the result of selective breeding and in these cows the myostatin gene is mutated from the wild type, resulting in extreme muscle production [45, 46]. These cows have problems with calving and 80% of the calves are born via cesarean section. CRISPR-Cas9 is one of the modern gene editing tools; it simply speeds up selective breeding and the producer can choose exactly what genes need to be manipulated from a "catalog" of desirable traits, including reproductive traits in the cattle industry.

Japanese Black cattle, a beef breed in Japan, are known for the high quality and distinctive marbling characteristics of their meat. Several years of selective breeding not only generated this beef breed with high quality and very palatable meat, but also resulted in accumulation of recessive mutations that cause genetic diseases. CRISPR-Cas9-assisted genome editing corrected isoleucyl-tRNA synthetase (IARS) syndrome which is a recessive disease in Japanese Black cattle caused by a single nucleotide substitution [47]. In this study, CRISPR/Cas9, donor DNA containing a codon for the correct amino acid, and a green fluorescent protein were introduced into bovine fetal fibroblast cells isolated from a homozygous mutant calf. Enriched recombinant cells with the repaired allele were cloned to produce SCNT embryos. Twenty-two cloned blastocysts were transferred to recipient cows, with the success of five viable fetuses at days 34 and 36. Further fetal genomic DNA analysis exhibited the correct repair of the IARS mutation without any other abnormal DNA footprint [47].

Disbudding of calves (destruction of the cells that produce horns before they grow and attach to the skull) is a routine practice in the US dairy cattle industry to prevent injury to other animals and handlers, reduce feeding trough space, and diminish aggressive behaviors. However, the procedure of disbudding/dehorning is a painful process for the cattle and an unpleasant task for the personnel. Therefore alternative, more humane solutions including precision gene editing and breeding have been sought to flawlessly integrate the polled trait into high genetic merit dairy cattle. In this instance, the horned gene is replaced with a naturally occurring polled gene to produce naturally hornless calves, considering animal well-being and health.

A bovine POLLED allele was introgressed into fibroblasts obtained from horned bulls using TALENs to introduce a hornless phenotype into dairy bulls, and two hornless dairy bulls were subsequently produced by cloning [48, 49]. Following this gene editing task, a recent study [50] investigated genomic and phenotypic analyses of offspring produced by crossing one of the hornless bulls with horned cows to determine whether the polled genome edit was passed on to offspring. The genome-edited dairy bull had the homozygous dominant POLLED allele whereas horned cows had the homozygous recessive allele. Six heterozygous polled calves were born and all were healthy and phenotypically unremarkable. These calves are apparently the first reported offspring of a genome-edited bull. However, based on whole genome sequencing of all animals using an Illumina HiSeq4000, it has been revealed that two calves inherited the naturally occurring hornless allele and four calves additionally inherited a fragment of bacterial DNA, known as a plasmid, used to stimulate homologous directed repair while delivering the hornless trait to the bull. This fragment of bacterial DNA had integrated alongside one of the two hornless alleles in the bull. Although plasmid integration can be screened and the genome-edited hornless bull that inherited only the naturally occurring allele without any remnant of plasmid

DNA can be selected, the US Food and Drug Administration (FDA) may consider these bulls and offspring as genetically modified organisms since they contain foreign DNA, bacterial plasmid DNA. New alternative methods that no longer use foreign DNA sequence in the donor template to deliver the hornless allele should be sought to fulfill the regulatory guidelines.

The CRISPR-Cas9 system was used to elucidate the function of POU domain, class 5, transcription factor 1 (POU5F1) in bovine embryos [36]. POU5F1 encodes a transcription factor containing a POU homeodomain that has critical roles in maintaining stem cell pluripotency and embryonic development. In this study [36], a synthetic gRNA targeting bovine POU5F1 exon 2 along with Cas9 protein were microinjected into the cytoplasm of bovine zygotes. Targeted mutation of embryonic POU5F1 exon 2 was highly efficient, with large deletions, resulting in a complete knockout rate of 86 and 78% bi-allelic deletions. Upon further observations of CRISPR-induced POU5F1-altered and control bovine embryos, it was concluded that POU5F1 expression is required for blastocyst and expanded blastocyst formation but not for development to the morula stage [36]. Single Cas9 nickase (Cas9n) created a single strand break and inserted a gene, the natural tuberculosis resistance-associated macrophage protein-1 gene, at a selected locus in bovine fetal fibroblast cells, albeit with some off-target effects. Subsequently, embryo transfer followed by SCNT generated transgenic cattle with increased resistance to tuberculosis [51].

Fertility is a key component of modern cattle production systems. Reproductive traits are multifactorial in nature and largely influenced by multiple genes and environment. In the past, intensive selective breeding for production traits negatively influenced fertility traits such as ovulation, estrus expression, fertilization, and embryonic survival. With the capability of CRISPR-Cas9-mediated multiplex gene editing, multiple genes and several traits can be precisely and simultaneously targeted, avoiding these negative additive effects.

Limitations of CRISPR-Cas9 Applications

Although the CRISPR-Cas9 system is currently the method of choice for genome editing in animals, it also comes with some technical limitations. Several parameters that control efficiency of CRISPR-Cas9-mediated targeted deletion, insertion, and alteration are yet to be completely understood. Unfortunately, a challenging technical limitation – presence of more than one genotype which is called genetic mosaicism – in an individual following microinjection of CRISPR into zygotes is commonly seen [52–55]. This limitation is sometimes overlooked and occasionally impeded targeted mutagenesis by its direct application into embryos. Early microinjection (10 hours post insemination [hpi]) of the CRISPR-Cas9 system into zygotes and microinjection of the CRISPR-Cas9 system into oocytes before fertilization (0 hpi) significantly reduced the rate of mosaicism compared to the standard 20 hpi protocol group [56]. Promoting Cas9 degradation by combining Cas9 with ubiquitin reduced genetic mosaicism in non-human primate embryos and enhanced precision genome editing [57]. Wild-type Cas9 compared to other variants, and pronuclear injection of the CRISPR-Cas9 system compared to cytoplasmic injection reduced the rate of mosaicism in mice zygotes [58].

There are numerous disease-causing single-gene mutations in humans and animals and these gene mutations can be often corrected using CRISPR-Cas9 applications in human zygotes. The Cas9-sgRNA complex creates a DNA double-strand break at the targeted site that stimulates the endogenous DNA repair system, resulting in targeted genome modifications. Even though CRISPR-Cas9 offers a tangible potential to correct genetic defects in humans and animals, effectiveness of correcting genetic defects via CRISPR technology in mammalian zygotes has not been completely elucidated apart from its merit and ethics. Homologous directed repair efficiency is found to be variable. The CRISPR-Cas9 system had the ability to cleave the endogenous β-globin gene in tripronuclear human zygotes, although homologous recombination directed repair lacked efficiency. Several edited embryos also had mosaicism, and off-target cleavage was apparent in some of these zygotes [59]. Moreover, the endogenous Δ-globin gene which is like the β-globin gene competed with exogenous donor oligos to function as the repair template, resulting in untoward mutations. Naturally occurring CCR5Δ32 allele was successfully replaced in early human 3PN embryos by co-injecting Cas9 mRNA, gRNAs, and donor DNA. However, in the edited embryos containing the engineered CCR5Δ32 allele, function of the other alleles at the same locus could not be completely regulated because of untoward indel mutations [60]. To address off-target effects, untoward mutations, and mosaicisms the CRISPR-Cas9 system and protocols of gene editing should be continuously improved. Single-point mutations, in which one single nucleotide base is added, deleted, or altered in the DNA, are commonly seen in genetic diseases affecting humans and animals. A pristine gene editing technique known as prime editing can rewrite the DNA by only severing a single strand to insert, delete, or replace a base, and is being tested in human and mouse cells [61]. This prime editing tool has a catalytically modified Cas9 fused to an engineered reverse transcriptase and programmed with a prime

editing guide RNA (pegRNA). This tool can specifically target the single point mutated site and encode the desired edit better than the existing genome-editing approach of CRISPR-Cas9 that performs a double strand cleavage.

Despite these limitations, CRISR-Ca9 has several advantages. Gene editing is more efficient using CRISPR-Cas9 compared to other major applications. The protocol is very simple and relatively inexpensive. Furthermore, sensitivity is high as CRISPR-Cas9 has sequence-specific gene targeting. Multiplexed genome editing is possible with application of CRISPR-Cas9 as multiple sgRNAs of several genes can be targeted simultaneously [62]. With the use of the CRISPR-Cas9 tool, the disadvantages of current selective breeding programs can be addressed. As well, CRISPR-Cas9 technology could be used in combination to complement current breeding programs to address these negative factors and to increase reproduction and production efficiencies and farm profits. Regardless, a stringent approval process for gene-edited animals and animal products, and public perception may restrict the use of targeted gene editing.

US Regulation of Gene-Edited Food Animals

Millions of naturally occurring DNA variations are seen in a population of a given animal species. These variations occur at a slower rate and allow breeders to select a desirable variation for selective breeding. Sometimes these naturally occurring variations happen incorrectly and result in an undesirable trait. However, nobody controls naturally occurring mutations in plants and animals and no regulatory agencies appraise them before they come to market. In contrast, discovery of new gene editing tools now allows us to precisely introduce the useful genetic variation into agricultural breeding programs and propagate the desirable trait significantly faster. Nevertheless, regulations come into effect when gene editing technologies are used to generate a genetic variation regardless of its benefit. The US Department of Agriculture (USDA) considers gene-edited plants and crops as being like plants and crops produced through conventional breeding techniques. Therefore gene-edited plants do not require additional regulatory oversight prior to commercialization as opposed to genetically modified organisms that contain exogenous genes from other species such as bacteria. With this regulatory protocol, USDA supports innovation when there is no risk present in the products. However, due to the complicated framework in the USA, the FDA plays a role in regulating animals and animal products for human consumption, has stringent guidelines in evaluating gene-edited animals and animal products, and undertakes mandatory premarket evaluation for all food animals whose genomes have been intentionally altered using modern molecular technologies, including gene editing technologies [63, 64]. The FDA views these products as new animal drugs requiring regulatory oversight. This rigorous regulation goes against the already developed US biotechnology policy that regulatory oversight should be triggered by unreasonable risk in the product and not by the fact that an organism has been modified by a process or technique. Regulations on gene-edited food animals and animal products by the FDA do not fulfill the purpose of biotechnology and advancement. Therefore harmonizing the regulations associated with gene editing in food species is critical to allow both plant and animal breeders access to advanced gene editing tools to introduce beneficial sustainability traits like disease resistance, climate tolerance, and attributes to improve food quantity and quality within US agricultural breeding programs.
