Figure 40.12 shows a normal estrus uterus in cross-section. The uterus is most heterogeneous at this point. Varying amounts of anechoic mucus are present in the uterine lumen. The large difference in acoustic impedance between the dense endometrium and the fluid mucus often creates specular reflection artifacts on the inner wall of the endometrium. The endometrium thickens to about 2.5 times its normal volume under the

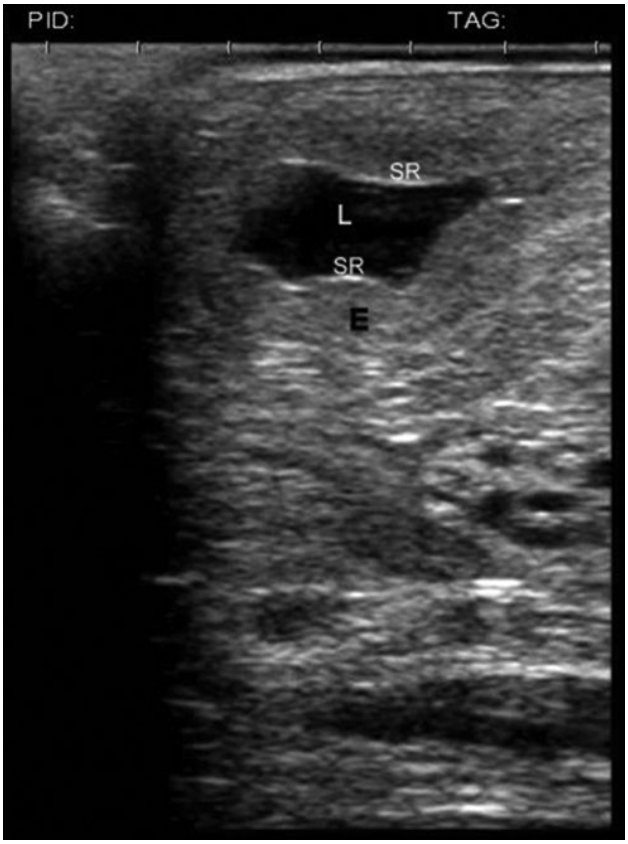

Figure 40.12 Estrous uterus in cross-section: lumen (L), endometrium (E), specular reflection artifacts (SR).

influence of estrogen. When measured in cross-section at about 2 cm from the internal uterine body bifurcation, the endometrial thickness has been shown to increase to about 9.4 mm in estrus from 6.9 mm in diestrus [32]. A mature follicle is still present until ovulation at approximately 12 hours after the end of standing heat. Sometimes a portion of the follicular fluid is not expelled during ovulation. In these cases it is difficult to determine if ovulation has occurred. A small heterogeneous CL may still be seen throughout proestrus and estrus.

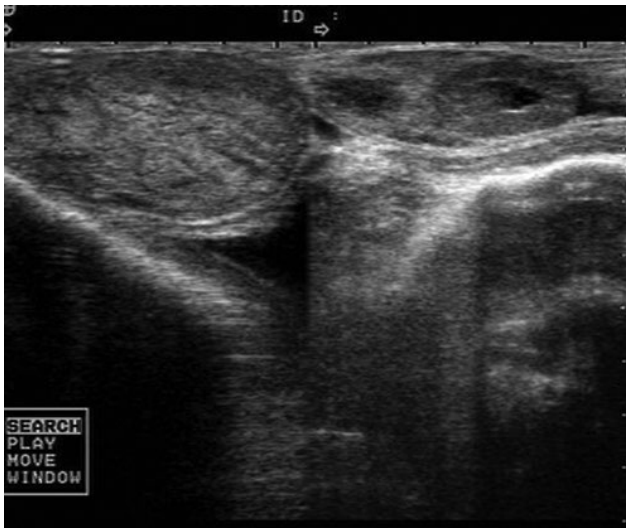

Figure 40.13 Split screen image of diestrous uterus in longitudinal section on the left and ovary with CL on the right.

Metestrus

After ovulation a new wave of small follicles (<8 mm) develops. In the first day or two of the cycle these small follicles are all that is visible on the ovaries. By day 2 or 3 a small heterogeneous CL becomes visible, often with an anechoic fluid-filled cavity. Occasionally the cavity is filled with very hyperechoic material, probably clotted blood.

Diestrus

Figure 40.13 shows a normal diestrus uterus and ovary. During diestrus the uterus is homogeneous and a medium shade of gray. There should be little or no fluid in the lumen. The CL will also be homogeneous and a medium shade of gray. The CL may or may not have a fluid cavity. Figure 40.14 shows three corpora lutea in heifers seven days after standing estrus. Despite their different appearances these are all normal corpora lutea for that stage. About 80% of corpora lutea have a cavity at some stage in development, usually early [33]. The cavity may be filled with clear fluid (Figure 40.14b), probably due to incomplete expulsion of follicular fluid during ovulation. Dense material in the cavity (Figure 40.14c) may be clotted blood remaining after ovulation. The fluid cavity tends to fill in over time, but may persist into pregnancy. A mature CL with a fluid cavity may also have bright specular reflection artifacts where the dense, fully developed luteal tissue meets the clear fluid cavity (Figure 40.15). These artifacts are less evident in less

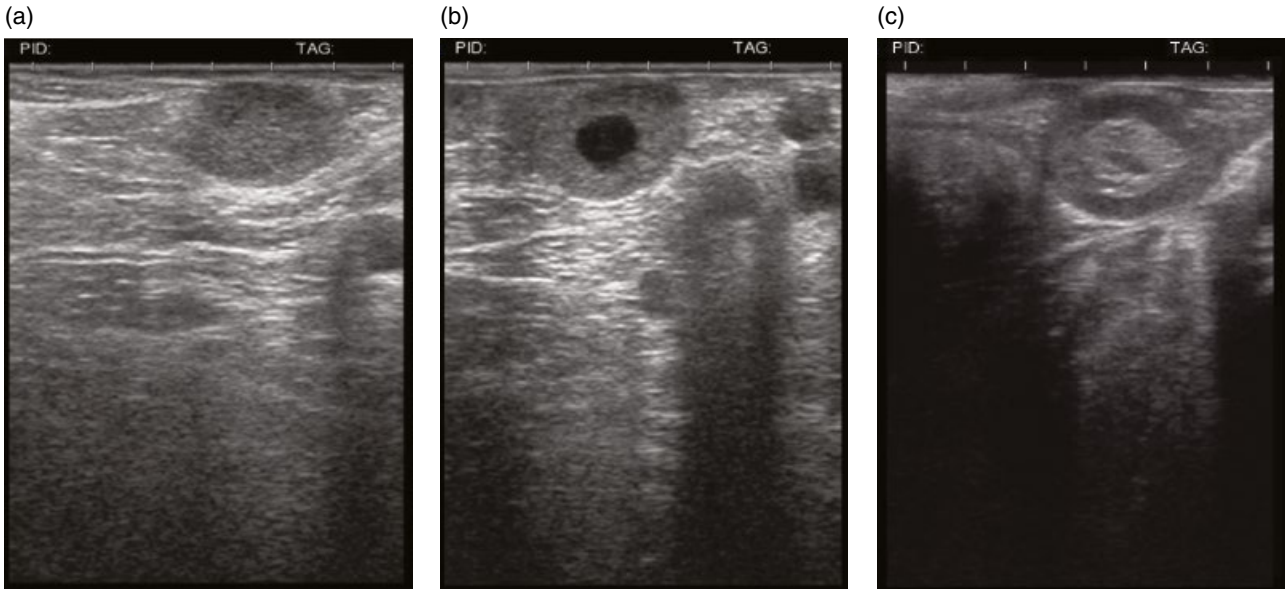

Figure 40.14 (a) Solid CL seven days after estrus. (b) Cavitary CL seven days after estrus. (c) Cavitary CL with dense center seven days after estrus.

Figure 40.15 Mature cavitary CL with specular reflections.

mature cavitary corpora lutea (Figure 40.14b) because there is not yet adequate acoustic mismatch for them to occur. Specular reflection artifacts are discussed further in the section on "Artifacts." Follicles ranging in size from 2 to 20 mm may be present depending on the stage of follicular wave cycles.

Pregnancy

Before 21 days of gestation the uterus and ovaries look much as they do in diestrus. A small amount of fluid may be visible in the uterine lumen at 21–23 days of gestation. The embryo is difficult to see under field conditions until at least 24 days. The gravid uterus does not have a thickened endometrium as in estrus. Specular reflections are either not present or much less pronounced than in estrus. The CL is usually solid at this point, but may be cavitary.

Ovarian Pathology

Anovulation

Wiltbank et al. [34] have classified ovulation failure into four basic categories. Ultrasound can assist in determining the category of ovulation failure.

Anovulation with Follicle Growth Only to Emergence

The term "static ovaries" has been used to describe conditions in which follicles grow to emergence (about 4 mm) but do not mature further to ovulatory size of 8 mm or more. On ultrasound examination this condition resembles early metestrus, with many small follicles, no follicles over 4 mm, and no visible CL. A second examination a few days later is required to differentiate this condition from metestrus. According to Wiltbank, this type of anovular condition is rare except in extreme malnutrition and possibly in Zebu cattle.

Anovulation with Follicle Growth to Selection but not Ovulatory Size

This type of follicular growth pattern is typical in the postpartum period. There is no CL and the ovaries are small, but frequent ultrasound examinations reveal that follicles grow up to 8.5 mm in a dynamic wave pattern.

Anovulation with Follicle Growth to Ovulatory or Larger Size (Follicular Cysts)

Follicular cysts have been defined as thin-walled fluid-filled follicular structures greater than 22 mm in diameter [35]. A follicular cyst (Figure 40.16) is differentiated from a cavitary CL, luteal cyst, or luteinizing follicular cyst (Figure 40.17) by the absence of a visible luteal rim. Follicular cysts are benign in most cases, with luteal structures and follicular waves developing normally on the same or contralateral ovary. Benign cysts can persist throughout several cycles and into pregnancy. Ultrasound is far superior to manual palpation for diagnosis of benign versus pathologic follicular cysts because it is more capable of identifying luteal tissue within the fluid-filled structure or the presence of a small CL elsewhere [36, 37].

Thorough ultrasonographic examination of both ovaries is essential to properly classify follicular cysts. If luteal tissue is detected the cyst is benign. Figure 40.18 shows a large ovary with several follicular cysts and a normal CL at 5 o'clock. If no luteal tissue is seen, a second examination must be performed in about 5–14 days to determine if a CL has developed. If not, the cyst is likely preventing normal cyclicity.

Follicular cysts have traditionally been treated with GnRH. Following treatment, most follicular cysts luteinize rather than ovulate. In these cases, examination seven days later will reveal that the original thin-walled structure has developed a thicker rim of luteal tissue (Figure 40.17). This large soft structure will still feel like a follicular cyst on manual palpation, but the luteal tissue is clearly seen with ultrasound. Alternatively, the cyst may remain but another, smaller follicle may be induced to ovulate. In this case the original follicular cyst will still be seen after seven days, but a

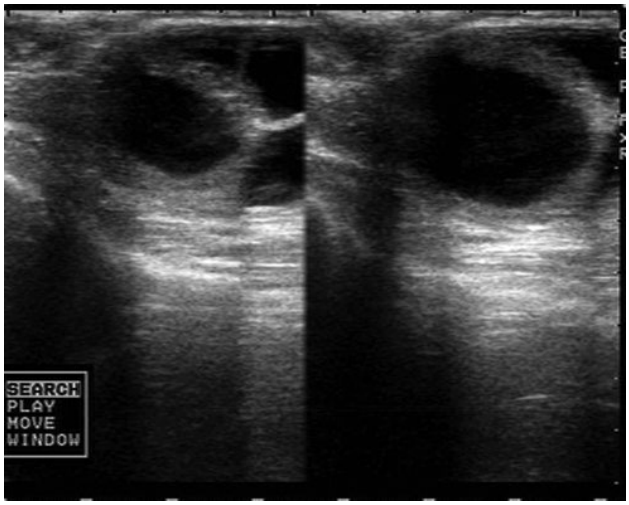

Figure 40.16 Multiple follicular cysts.

Figure 40.17 Luteinizing follicular cyst.

small CL will be evident elsewhere. It has been demonstrated that the presence of progesterone improves conception rates to the Ovsynch synchronization program [38]. Hence animals that respond to GnRH treatment by producing luteal tissue may be started on this protocol with good success.

Another common treatment for follicular cysts is progesterone supplementation in conjunction with the Ovsynch synchronization protocol at the time of diagnosis.

Figure 40.18 Benign follicular cysts with CL.

Progesterone supplementation adds expense and inconvenience. In some countries it is not permitted or requires substantial documentation. For these reasons, ultrasound diagnosis is very helpful to limit progesterone supplementation only to cystic cows that do not produce luteal tissue in response to GnRH treatment.

Anovulation in the Presence of Luteal Tissue

Prolonged luteal function prevents ovulation at normal intervals. Various papers define prolonged luteal function differently. Proposed definitions include, but are not limited to, the persistence of the CL with milk progesterone above 3 ng/ml for more than 30 days [39], or milk progesterone above 3 ng/ml for at least 19 days [40]. Frequent multiple ultrasound examinations or progesterone tests are required to confirm persistent luteal function. Because the Ovsynch protocol works well in the presence of progesterone, it is more important to identify the presence of a CL rather than attempting to identify if it is persistent.

Other Ovarian Pathologies

Ovarian pathologies other than the above anovular defects are rare in cattle. Granulosa cell tumors are sometimes

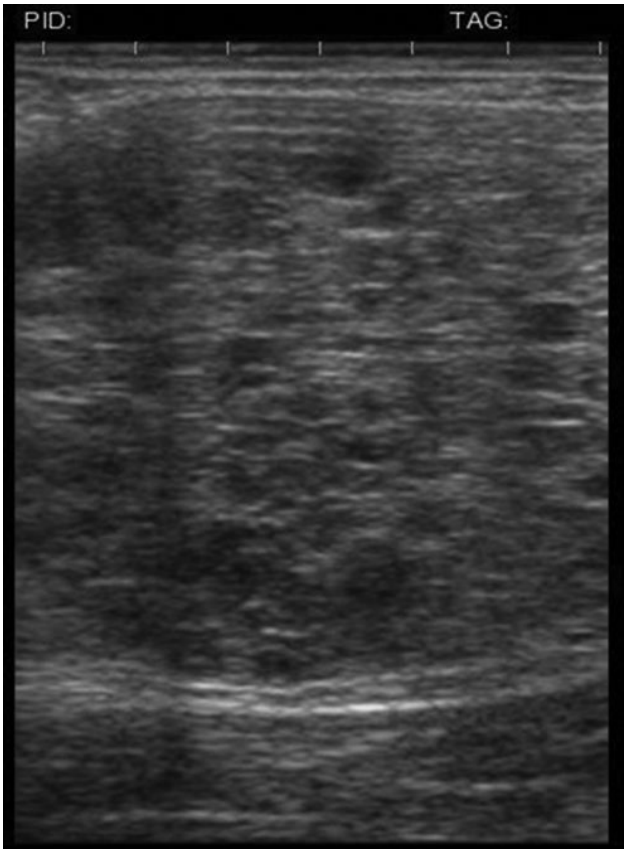

Figure 40.19 Granulosa cell tumor.

seen (Figure 40.19). The ovary is very large. The hyperechoic areas are specular reflections between the vasculature of the tumor and the denser surrounding tissue.

Synchronization Protocols

When cattle are presynchronized with prostaglandin (Presynch) before beginning Ovsynch, all normal cycling animals should have a CL when the first GnRH injection (G1) is scheduled. An examination of ovaries at this time will reveal if presynchronization was successful. If many cows do not have corpora lutea at this time, the protocol has failed and the reason must be found. Poor compliance, poor cow health, low body condition scores, and nutrition problems are all possible reasons for failure.

It has been shown that the presence of a CL and the availability of an ovulatory size (≥8 mm) follicle at G1 improve conception rates for Presynch/Ovsynch [38]. This study is summarized below:

- For cows with a CL and ovulation to G1, the conception rate was 42.2% when pregnancy examination was performed at 38 days.
- For cows with a CL and no ovulation to G1, the conception rate was 37.7%.
- For cows with no CL and ovulation to G1, the conception rate was 27.6%.
- For cows with no CL and no ovulation to G1, the conception rate was 15.4%.

Ultrasound is very sensitive for identifying the presence of a CL, including very early metestrus corpora lutea and regressing proestrus corpora lutea. These very early and late corpora lutea are probably not producing progesterone in adequate levels for optimal conception rates to Ovsynch. Therefore it has been suggested that a cutoff size be used to determine if a CL is functional. Bicalho et al. [37] found that ultrasound was nearly 90% sensitive and specific for identifying a CL producing more than 1 ng/ml blood progesterone if a 2.2-cm cutoff size was used. Palpation, by contrast, was 33–60% sensitive and 77–93% specific for identifying blood progesterone greater than 1 ng/ml, varying among palpators.

Ovsynch works best from days 5 to 10 of the cycle when some early corpora lutea may not yet be 2.2 cm in diameter. Therefore this author uses a minimum cutoff size of 1.5 cm if the CL appears to be a typical early diestrus CL (see section on "Normal Ovarian Structures Throughout the Estrous Cycle"). If the CL appears to be regressing during proestrus, it is more desirable to wait until 5–10 days after ovulation to begin the Ovsynch protocol.

Based on the findings in the study by Galvão et al. [38], the presence of a functional CL was more important than ovulation to G1. However, some ultrasonographers [41] feel it is also of value to identify the presence of a potentially ovulatory follicle greater than 8 mm. Given that it is difficult to assess if follicles of this size are normal, persistent, or atretic, this author relies more on the presence of a CL of appropriate size and stage.

Uterine, Cervical and Vaginal Pathology

Metritis, Endometritis, and Pyometra

Clinical and most subclinical uterine infections can be diagnosed with ultrasound. Field ultrasound units can visualize 2 mm of fluid, far less than detected by manual palpation. Ultrasound can also evaluate the character of the fluid based on echogenicity. In most cases of metritis/endometritis, echogenic purulent material can be seen in the uterine lumen. This fluid may be any shade from light gray to very bright white depending on its density. Intraluminal fluid in cases of pyometra is usually voluminous and of medium echogenicity (Figure 40.20).

Figure 40.20 Pyometra.

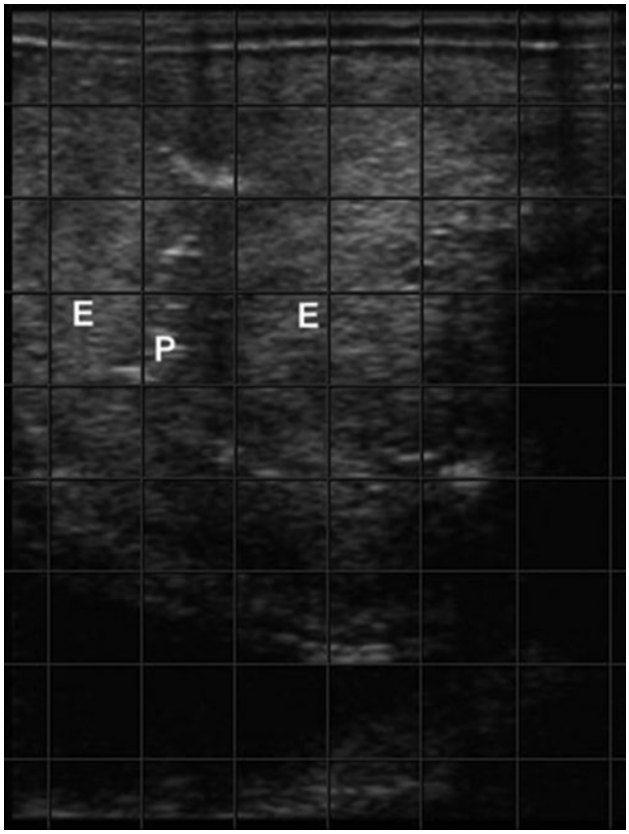

Figure 40.21 Subclinical metritis: endometrium (E), purulent material (P) in lumen.

Cases of chronic subclinical metritis/endometritis usually have little intraluminal fluid of higher echogenicity (Figure 40.21). The ultrasonographer should be careful not to confuse small volumes of echogenic intraluminal fluid with specular reflections due to estrus (Figure 40.12). When fluid is not detected, increased endometrial and cervical thickness may be used to evaluate endometritis in the early postpartum period [42]. The ultrasonographer should keep in mind that endometrial thickness is also increased in estrus and must perform a thorough examination of both ovaries and uterus to make a differential diagnosis.

Mucometra

Mucometra is an accumulation of sterile anechoic or slightly echoic fluid in the uterine lumen not associated with pregnancy. Specular reflections may or may not be present. The endometrium is not thickened as it is in estrus. Mucometra does not appear to be related to ovarian structures. The ovaries may have follicular cysts, normal corpora lutea, or no significant ovarian structures. It is critical to confirm the absence of an embryo or fetus in cases of mucometra. When in doubt the ultrasonographer should perform a second examination a few days later to confirm the diagnosis. Mucometra in heifers may be related to the presence of a complete hymen or other congenital blockage of the tubal portions of the reproductive tract. The cause in adult cows is unknown.

Lymphosarcoma

Uterine lymphosarcoma is identified by very firm thickening of the uterine wall that may be localized or throughout the entire uterus. The affected uterine tissue (Figure 40.22a) looks like the tissue of a lymph node (Figure 40.22b).

Abscesses

Uterine, cervical, or vaginal abscesses can be caused by difficult parturition, rough assistance during parturition, or trauma from artificial insemination. They can be distinguished from metritis, cervicitis, or vaginitis by the presence of a capsule around the purulent material (Figure 40.23). Uterine abscesses have a poor prognosis for future fertility. Cervical abscesses may or may not be of concern. Careful ultrasound examination can determine if the abscess extends into the cervical lumen or is entirely outside it. If the latter, the

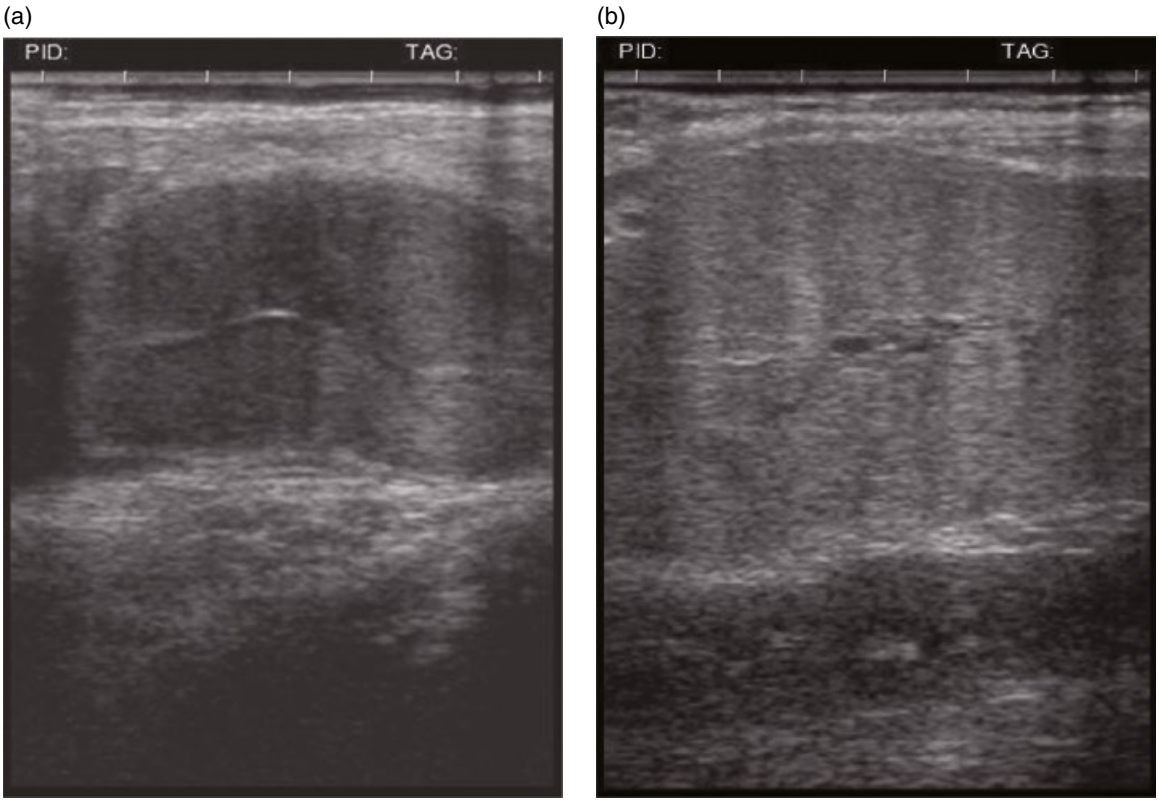

Figure 40.22 (a) Uterine lymphoma. (b) Pelvic lymph node.

Figure 40.23 Uterine abscess: capsule (C), purulent material (P).

prognosis for future fertility and parturition is good. Vaginal abscesses generally do not cause difficulty unless they are large enough to interfere with breeding or parturition.

Vaginitis

The normal vagina presents as a thin white line representing the confluence of opposite sides of the vaginal wall. In cases of vaginitis echogenic material is visible in the vaginal vault and the vaginal mucosa is thickened. Unless echogenic material is also present in the uterus, the prognosis for fertility is fair to good if a protective sheath is used on the insemination gun at breeding. Vaginitis may be primary or caused by urine pooling (UP) (Figure 40.24).

Vaginal Urine Pooling

Urine is usually less echogenic than purulent material, but is often mixed with purulent material when accumulated in the vagina (Figure 40.24). As with vaginitis, prognosis for fertility is fair to good if there is no abnormal fluid in the uterine lumen and a protective sheath is used on the insemination gun at breeding. UP may be accompanied by cystitis.

Pneumovagina

Gas in the vagina or elsewhere presents as a reverberation artifact (Figure 40.25) (see section "Artifacts").

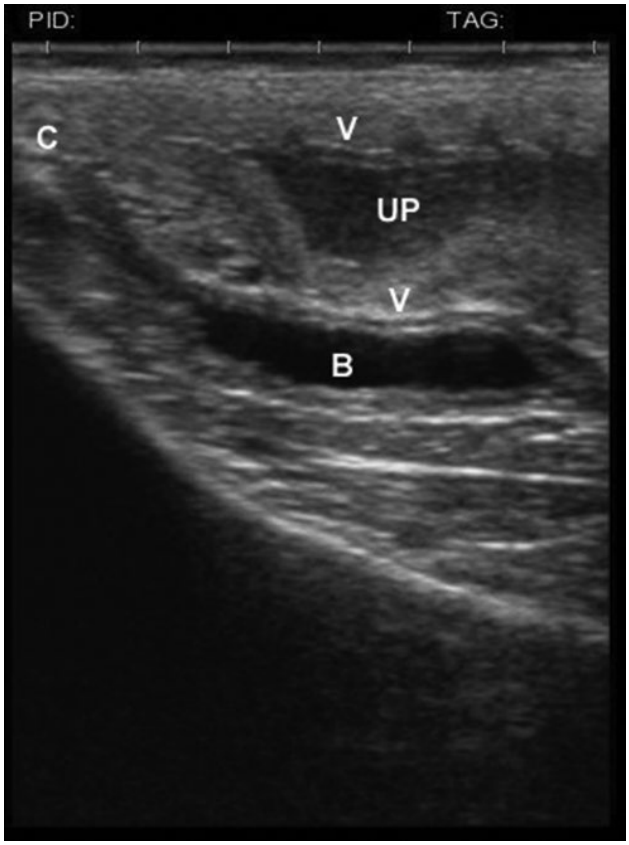

Figure 40.24 Vaginitis due to urine pooling: vaginal walls (V), urine pooling (UP), bladder (B).

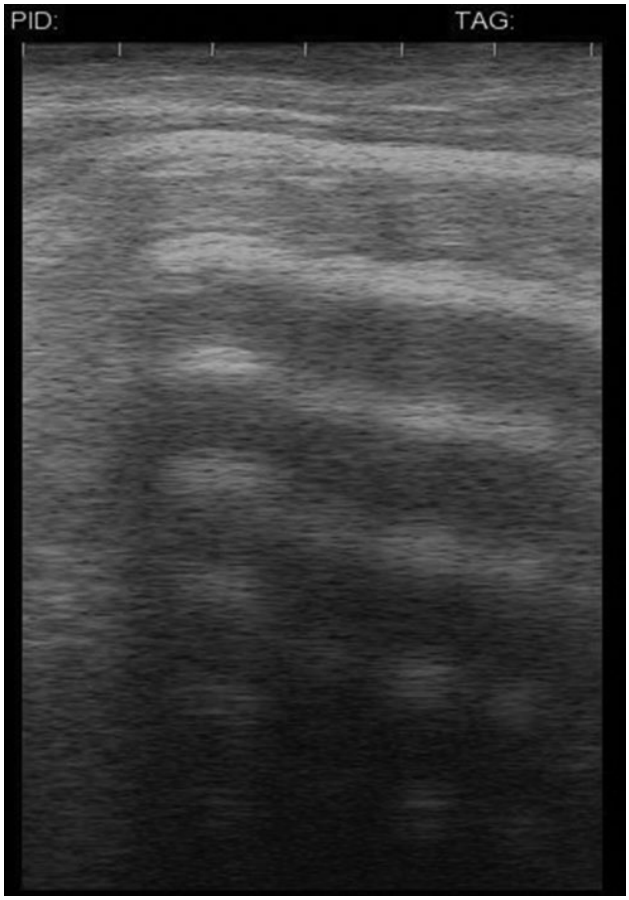

Figure 40.25 Reverberation artifact due to pneumovagina.

Embryo Transfer

Donor Evaluation

Donors should be assessed for uterine health and ovarian function before beginning the superovulation protocol. If the cow is examined during follicular recruitment, it may be possible to predict the response to future superovulation. Cows that recruit large numbers of follicles at the beginning of each follicular wave can be expected to produce more follicles after treatment with follicle-stimulating hormone (FSH) [43, 44].

It is usually not necessary to examine the donor cow on the day of insemination unless very rare or expensive semen is to be used. In those cases it is helpful to know if enough ovulatory size (≥8 mm) follicles are present to warrant insemination. Care must be taken to scan gently over the ovaries without manipulation or pressure. It is possible to rupture small follicles or even remove the ovary from the ovarian bursa with rough handling.

On collection day, ultrasound is much more useful than manual palpation for counting the number of corpora lutea [38]. Small corpora lutea, cavitary corpora lutea, and corpora lutea imbedded deep in the ovary can be seen. Figure 40.26 shows two sections of the same ovary. Note the solid corpora lutea in the first section and the cavitary corpora lutea or unovulated follicles in the second section. The ultrasonographer should keep in mind that some cavitary corpora lutea will have very thin walls and may be difficult to differentiate from unovulated follicles [45]. When these fluid-filled structures are seen the cow should still be flushed. It is very possible that more embryos than expected will be retrieved.

Recipient Evaluation

Recipients should be evaluated for uterine health and ovarian function prior to beginning estrous synchronization. This is more important for adult cows than for heifers due to increased risk of uterine or ovarian pathology in parous animals.

It is critical that ultrasound is used to identify corpora lutea before embryo transfer (Figure 40.14). Because ultrasound is much more accurate than manual palpation for identifying small or fluid-filled corpora lutea [37, 45], more animals will be used. Almost 100% of corpora lutea in recipients are diagnosed with ultrasound, but only 80% with manual palpation. Maintaining open animals is costly, so it is imperative to identify all appropriate recipients. Examination for uterine health should

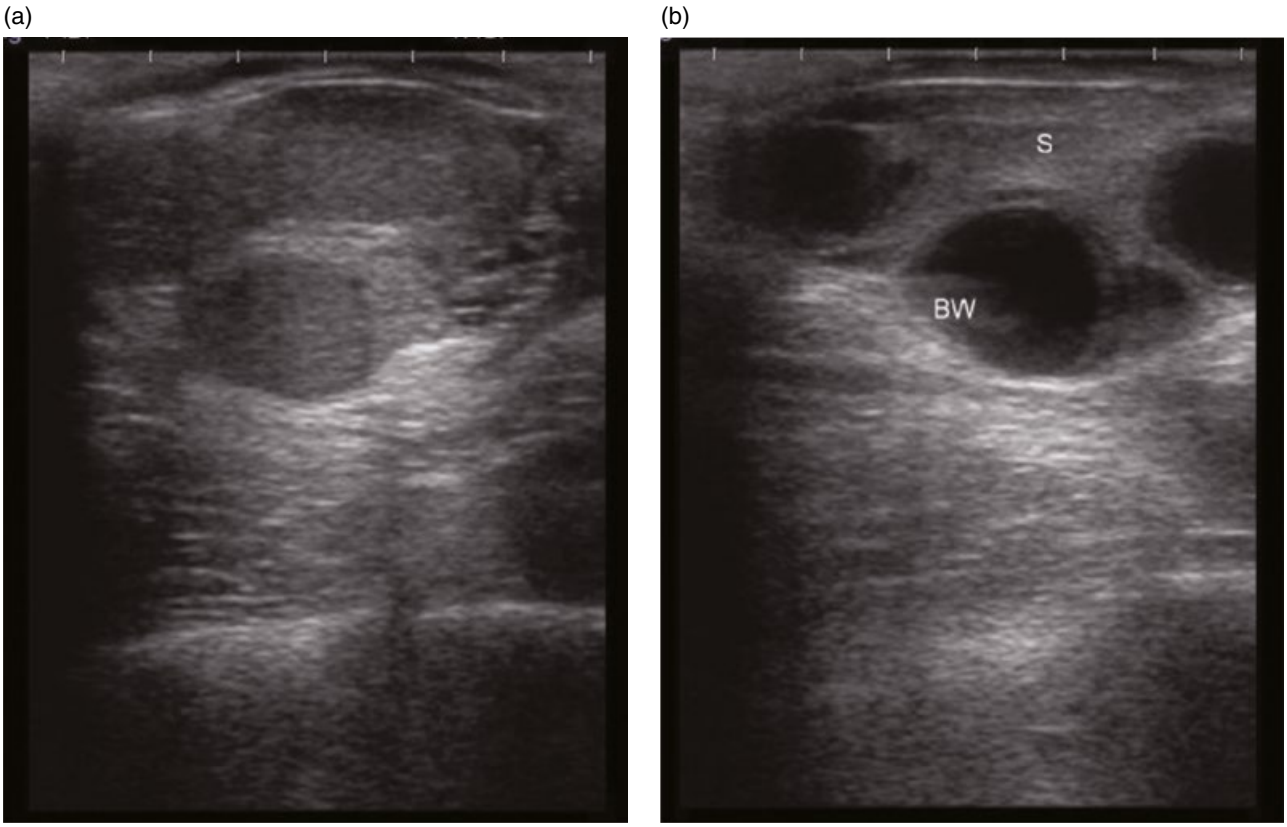

Figure 40.26 (a) Multiple corpora lutea on embryo flush day. (b) Cavitary corpora lutea or unovulated follicles on embryo flush day: ovarian stroma (S), beam width artifact (BW).

also be performed at this time, especially if not evaluated prior to synchronization.

Pregnancy examination of recipients can take place at any stage comfortable for the ultrasonographer. I have noted that some frozen embryo pregnancies appear one day smaller than fresh embryo pregnancies. Also, some *in vitro;* fertilized (IVF) embryos appear one day larger. This is of no concern as long as the embryo is viable and large enough to be detected on the day post-transfer chosen for examination. Twins are rare in embryo transfer pregnancies, but are at high risk for loss when they occur. Twins may be due to splitting of the embryo, intentional transfer of two embryos, or insemination of the recipient during estrus prior to embryo transfer.

An ideal time to perform pregnancy examination is at 21 days after transfer (28 days in embryonic development). At this stage open animals with no pathology can immediately receive an embryo if the CL is appropriate. In dairy animals, this is probably more effective in heifers than adult cows. Adult dairy cows often do not have typical 21-day estrous cycles [46], so may not be at the correct stage of luteal development.

Recheck pregnancy examinations after 60 days of gestation should always be performed due to the high value of most embryo transfer and IVF pregnancies. Fetal gender determination and evaluation for fetal anomalies can also be done at this time.

Ovum Pick-Up

Collection of ova for IVF is done with a guided needle attached to a transvaginal ultrasound transducer. A curvilinear transducer is usually used, but a standard linear rectal transducer can be adapted for the purpose if attached to a special introducer containing the guided needle.

Embryonic and Fetal Anomalies

Embryonic and fetal anomalies are rare but of great importance. Depending on the anomaly, it may be desirable to monitor the pregnancy, abort the pregnancy, or take special precautions at parturition. Most anomalies are best seen at about 50–90 days, when the fetus is developed enough to resemble a small version of an adult bovine, but not too large to reach for a thorough examination. A few abnormalities can be detected earlier.

Abembryonic Vesicle

Figure 40.27 shows a 35-day embryo that is outside the AV. Such embryos rarely survive even if they have a heartbeat on the day of first examination. Recheck examination usually reveals an empty amniotic sac or complete lack of uterine contents.

Schistosomus Reflexus

Note the fluid-filled fetal stomach (FS) outside the body cavity in Figure 40.28. In most cases the spinal column (SC) is severely bent, sometimes into a "V" shape.

Fetal Ascites

Note the fluid within the peritoneal cavity in Figure 40.29. In a normal fetus the abdominal organs should completely fill the cavity with no visible fluid. In some cases there is also fluid around the heart or lungs. Careful assessment should be made to differentiate fetal ascites from a dead fetus with fluid accumulation (see Figure 40.3a).

Figure 40.27 Abembryonic vesicle.

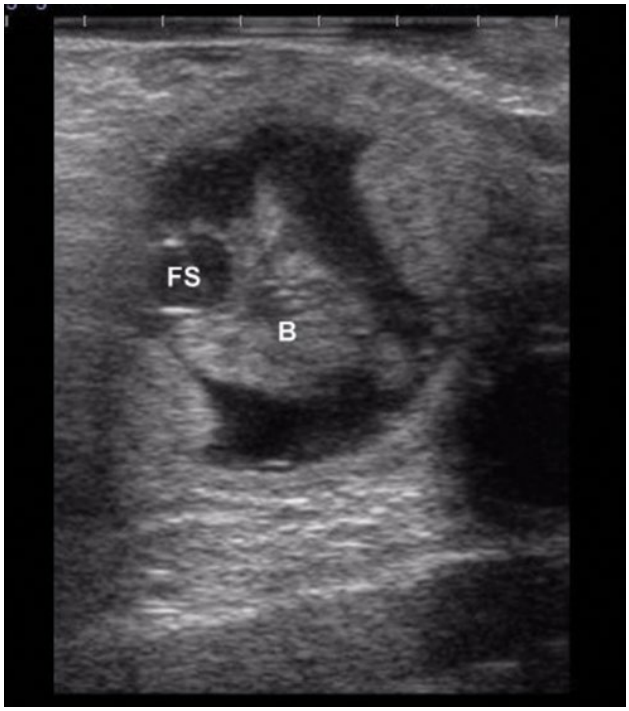

Figure 40.28 Schistosomus reflexus: fetal stomach (FS), fetal body (B).

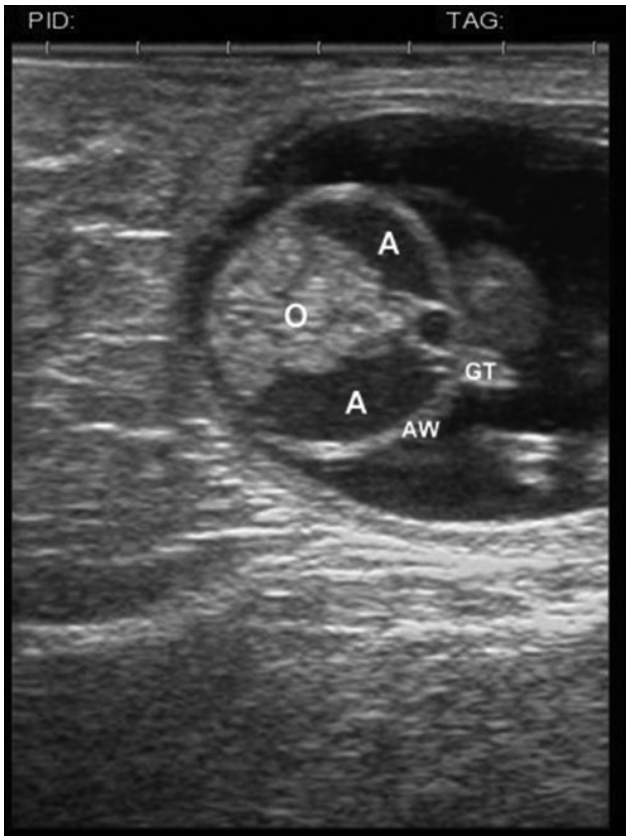

Figure 40.29 Fetal ascites: abdominal organs (O), ascites (S), abdominal wall (AW), male genital tubercle (GT).

Fetal Anasarca

Compare the fluid under the skin in fetal anasarca (Figure 40.30) with the fluid within the abdominal cavity as in fetal ascites (Figure 40.29). Follow-up of fetal anasarca sometimes reveals that the fluid is no longer visibly present. In other cases there is no change or fetal death occurs.

Umbilical Hernia

Figure 40.31 shows the fetal chest to the left of the screen and a large umbilicus to the right. The umbilicus contains tissues of various densities probably representing abdominal structures. Not shown in this view is the absence of the fluid-filled FS within the abdomen.

Amorphous Globosus or Acardiac Twin

The round structure to the right of the normal fetus in Figure 40.32 is likely a ball of fetal tissue sustained by the circulatory system of its live twin. These anomalies usually do not grow large so are rarely a problem at parturition. They have no gender so are not of concern for freemartinism.

Conjoined Twins

Figure 40.33 shows a fetus with two heads. Conjoined twins are very rare and must be differentiated from normal twins lying close together.

Figure 40.30 Fetal anasarca: skin (SK), fluid (F), head (H), spinal column (SC).

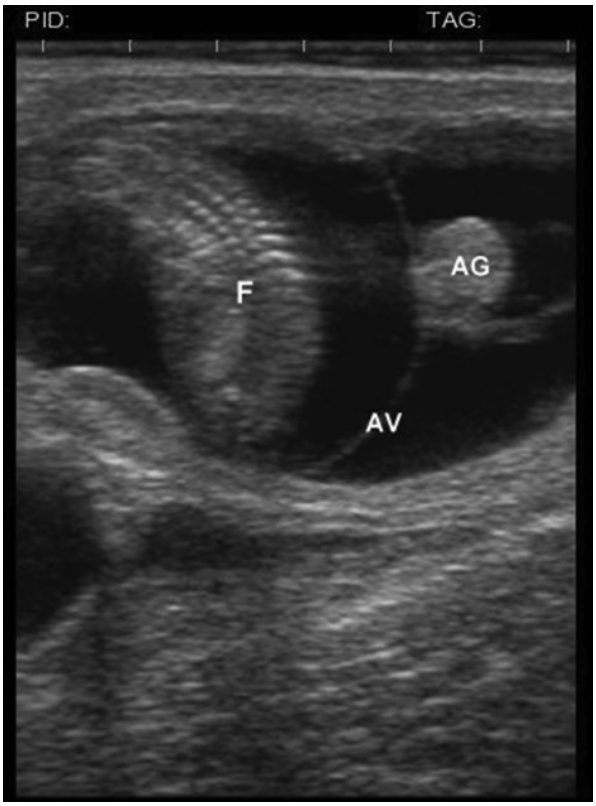

Figure 40.32 Amorphous globosus: normal fetus (F), amorphous globosus (AG), amniotic vesicle (AV).

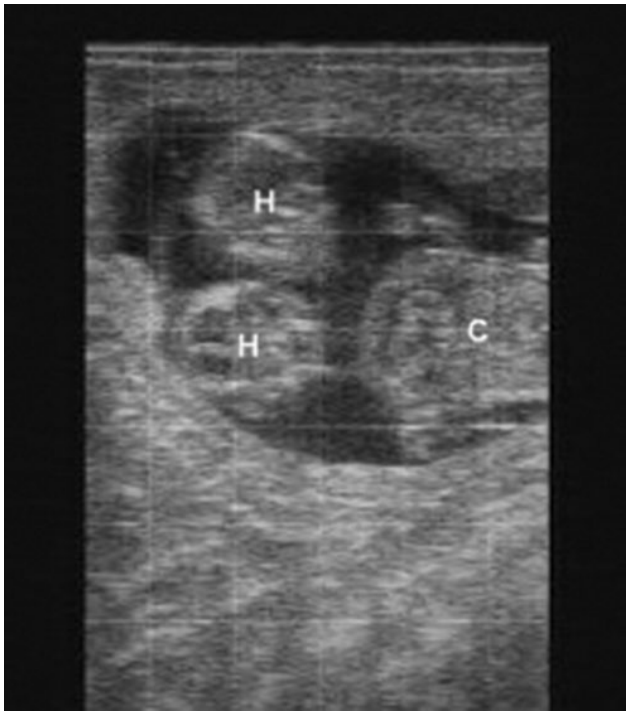

Figure 40.33 Conjoined fetus with two heads: heads (H), chest (C).

Artifacts

It is important to recognize common artifacts in order to avoid misdiagnosing them as normal structures or pathology. When identified properly artifacts are often helpful in evaluating the reproductive tract. For a more complete description of artifacts and their interpretation refer to Ginther [1].

Specular Reflection Artifacts

These common artifacts occur when two interfaces of very different densities are aligned horizontally to each other and perpendicular to the ultrasound pulse. They are most often seen when a fluid-filled structure is adjacent to denser tissue. They appear as thin bright horizontal lines of varying lengths. Figure 40.12 shows specular reflections between the turgid uterine tissue of a cow in estrus and the clear fluid in the lumen. Figure 40.15 shows specular reflections in a cavitary CL. Figure 40.19 shows many small bright specular reflections representing the confluence of the tissue and the fluid-filled vasculature of the granulosa tumor.

Reflection and Refraction Shadows

Fluid reflects and refracts ultrasound waves just as the surface of a lake reflects and refracts light waves. When the ultrasound beam is either refracted at an angle into the fluid or reflected away from the fluid, it is not echoed back to the transducer. Hence no image will be seen below the point of reflection/refraction. This artifact is commonly seen at the lateral edges of fluid-filled structures (Figure 40.34).

Beam Width Artifacts

When one ultrasound beam passes through two tissues of different densities at the same depth, a beam width artifact is produced (Figure 40.34). Two echoes reach the transducer at the same time, but only one is read. These artifacts are most common on the lateral walls of fluid-filled structures and cause the sides of the structure to appear more echogenic than the contents. Figure 40.34 shows beam width artifacts between the endometrium and fluid contents of a gravid uterus. Beam width artifacts are most obvious when using ultrasound machines with poor lateral resolution.

Beam width artifacts are also common on the edges of follicles or follicular cysts (Figure 40.26b). In these cases the artifact may be mistaken for luteal tissue. In the uterus they may appear to be abnormal contents in the lumen. In either case a slow scan throughout the structure will help differentiate the artifact from actual tissue.

Reverberation Artifacts

Repeated echoing of ultrasound waves between two strong interfaces creates reverberation artifacts. One interface is

Figure 40.34 Reflection/refraction artifacts (R), beam width artifacts (BW), enhancement artifact (E).

usually the rectal wall/transducer. The second interface is usually gas or bone. Each time the wave is echoed it is reduced by attenuation. Hence each reverberated echo is weaker than the previous one. Also, the time delay between echoes results in each later echo being seen farther down on the ultrasound screen. The resulting image on the screen consists of equidistant, increasingly smaller, parallel artifacts. Figure 40.25 shows the reverberation artifact caused by pneumovagina.

Mirror Image Artifacts

Mirror image (MI) artifacts are a type of reverberation artifact. They are most common when the pelvic bone lies below the structure being examined. Figure 40.35 shows a 60-day pregnancy with a false "twin" in MI below the pelvic bone. Understanding MI artifacts helps avoid mistaking one structure for two.

Blockage Shadows

Material dense enough to block or attenuate the ultrasound beam causes blockage shadows. Most obvious are shadows caused by bone, as in the "prison bar" artifacts shown in Figure 40.36. Less dramatic shadows can be caused by manure between the transducer and rectal wall leading to a poor-quality dark image.

Enhancement Artifacts

Enhancement artifacts are a function of machine settings. Because ultrasound beams are attenuated over time and distance, it is necessary to increase the gain (volume) at deeper levels so that similar tissues at various depths from the transducer appear the same. However, when less echogenic material such as fluid is near the face of the transducer the beam is not attenuated and structures below the fluid appear brighter than they should. Figure 40.34 shows enhancement below the fluid-filled uterus. Gain controls can be manipulated to reduce enhancement artifacts if desired by the ultrasonographer.

Crystal Defects

Crystal defects are seen as black vertical lines extending vertically from the transducer face (Figure 40.37). They can be differentiated from shadow artifacts or reflection/refraction artifacts because they always stay in the same location on the monitor and always begin at the face of the transducer.

Figure 40.35 Mirror image artifact: fetus (F), pelvic bone (PB), mirror image (MI).

Figure 40.36 Prison bar artifacts.

Figure 40.37 Crystal defects.

They may be caused by broken crystals in the transducer or by broken wires connecting the crystals to the power source in the unit. Loss of a few crystals may not be noticed, but loss of many will greatly reduce image quality.

The Future

Technologies used in human medicine are being adapted to veterinary use. Three-dimensional ultrasound has been described in mares [47] and may have advantages over two-dimensional imaging for identifying fetal anomalies and for fetal aging. Color Doppler ultrasound has been studied extensively in horses and, to a lesser extent, in cattle [48]. It is currently feasible to use color Doppler ultrasound to assess fetal viability in cattle. In the future it may be possible to use blood flow changes in ovarian structures and the uterus to more accurately assess stage of the estrous cycle and predict ovulation. Some field ultrasound units already come equipped with color Doppler capabilities in addition to standard B-mode ultrasound.

Other Uses

Ultrasound has many uses outside the scope of this chapter. Ultrasound of the male reproductive organs has been well described [49]. Other organ systems can be assessed with ultrasound for diagnosis or prognosis of disease [50].

Beef Herd Health for Optimal Reproduction

Terry J. Engelken and Tyler M. Dohlman

Department of Veterinary Diagnostics and Production Animal Medicine, Lloyd Veterinary Medicine Center, College of Veterinary Medicine, Ames, IA, USA

Introduction

A recent analysis of cow-calf enterprise profitability indicates that there is more variation in production costs than income among Kansas beef producers [1]. However, reproductive efficiency is still the most important output parameter affecting the financial health of these operations. While there are many reasons for suboptimal reproductive performance and calf survival, infectious disease is a major contributor and often plays a pivotal role. Reproductive disease may manifest itself in a number of ways, depending on the pathogen involved. Early embryonic death, late-term abortion, "weak calf syndrome," and delayed conception are all common clinical scenarios. However, the end result is that the operation will have fewer kilograms to market from weaned calves. It is critical that the veterinary practitioner be able to understand the relationship of these infectious agents with the risk of exposure, timing of gestational loss, herd diagnostic information, and herd productivity. Only then can comprehensive immunization programs be constructed for the entire operation that will minimize losses associated with reproductive pathogens.

Utilization of Diagnostics

It is critical that diagnostic information be utilized in the construction of the herd health program. The selection of vaccines to be used in a program depends on the presence of a particular pathogen in the herd or geographical area, its risk of introduction into the herd, and an individual producer's cattle working schedules [2]. It is important to determine the category or period of reproductive loss since reproductive pathogens have a tendency to occur within specific stages of gestation. Classically these categories have been defined as early gestational, mid gestational, late gestational, and periparturient (Table 41.1). Determining when gestational losses occur is the first step in understanding the etiology of these losses and represents the starting point for building the vaccination program.

Utilizing diagnostic tools in cases of abortion can be very helpful and can be very frustrating due to diagnostic limitations and challenges. In cases of abortion, an etiologic diagnosis is identified less than 50% of the time [3]. However, several diagnostic advances, through conscious efforts by diagnostic laboratories, have been made to improve detection of certain pathogens [4]. Even though an etiologic diagnosis can be challenging, infectious agents causing abortions can be identified. Table 41.2 highlights the multiple pathogens that have been associated with bovine abortions, the gestational period they normally affect, and common diagnostic procedures used to identify their presence [2, 5–9]. Some pathogens are considered common reproductive agents and some are rarely identified. In addition, certain pathogens can be more prevalent in certain geographical areas [3].

Diagnostic laboratories have different capabilities in handling an abortion case. As a practitioner, it is prudent to have a close working relationship with your laboratory. Diagnostician consultations are sometimes necessary to develop a systematic approach for abortions. Appropriate tissues and bodily fluids samples are more useful than others are and comprehensive submissions are valuable.

Adequate information, including herd history, with complete submission to a diagnostic laboratory is the most important step to a definitive diagnosis [4]. An abortion work-up can be costly and sometimes unrewarding. It is in the best interest to provide the diagnostic laboratory with the required information to minimize cost and maximize diagnostic success. Even though infectious agents comprise

most of the reported etiology, practitioners, producers, and diagnosticians have to be aware that abortions are not limited to infectious agents [9]. Non-infectious causes, such as environment, toxins, nutrition, and genetics, have to be considered as possible sources of reproductive failures.

Serologic sampling can be utilized in diagnostic work-ups for abortions, but the results should always be interpreted with caution. Single serum samples have little to no value when diagnosing causes for abortions. It is difficult to differentiate the titer values based on vaccine and natural exposure to certain agents/antigens. However, a lack of titer in abortions may rule out certain causes.

Paired serum samples have also demonstrated limited value. Many of the bacterial and viral pathogens that cause abortion may infect the fetus or placenta long before the abortive event occurs. This lag time between infection and abortion may prevent the practitioner from detecting the rising or falling titers associated with the initial infection. This leads to the collection of two "convalescent" serum samples that will fail to detect the increase in antibody titer, if it indeed occurred. This is especially true when only affected females are sampled at the time when the abortion is noted. Overall, the time of seroconversion is dependent on the exposure of the agent and the amount of immunity established prior to the breeding and throughout gestation. Paired sera are much more useful when used as part of a complete diagnostic work-up that includes samples from the placenta, fetus, and fetal fluids.

Serologic profiling is one option to optimize the use of serologic testing. The basis of serologic profiling is analyzing titers from affected/aborted and non-affected dams over the same time period [4]. It is unclear how many samples are needed, but some suggest that the same number of affected and non-affected animals, preferably at same stage of gestation and age, is adequate [5]. In herds with chronic gestational losses, serum may be collected and frozen from a statistically relevant number of cows for future testing as needed. These frozen samples may be collected as the females are processed prior to breeding and/or at the time of pregnancy examination. Then, as fetal loss is detected, banked serum samples can be submitted along with acute and convalescent samples to provide a clearer serologic picture of the affected animals and their normal cohorts. This should give a more complete picture of when seroconversion occurred and what pathogens were involved.

In some cases, all samples will have elevated titers due to endemic infections of specific agents. For example, in herds endemically infected with bovine viral diarrhea virus (BVDV), all animals may have seroconverted yet have no clinical evidence of etiologic diagnosis of abortions [10]. In some instances, fetal/precolostral serology may be beneficial. Fetuses must be immunocompetent for specific agents (*Toxoplasma gondii*/*Neospora caninum*/BVDV/infectious bovine rhinotracheitis [IBR]/*Brucella*) to produce serologic evidence in fetal fluids [3, 4, 11]. However, in some cases of premature placental separation, maternal serum antibodies may "leak" into the fetal circulation and give a false positive result on serology. While serology may be valuable in certain circumstances, the interpretation of these results should be carefully assessed as it relates to the entire diagnostic work-up and clinical signs in the herd.

Designing Herd Vaccination Protocols

While vaccines represent an important tool in protecting reproductive performance, they tend to be somewhat underutilized in beef herds (Table 41.3). When designing protocols to immunize the beef breeding herd against reproductive pathogens, there are several other important factors to consider. The potential at-risk level of the herd should be considered not only from the entry of potential pathogens, but also from the standpoint of the current disease level in the resident herd, different management groups on the ranch, breeding animal movement, and the potential side

Table 41.3 Use of reproductive vaccines by cow/calf operations.

Type of vaccine	Use in weaned heifers (%)	Use in pregnant heifers (%)	Use in cows (%)
IBR	19.4	11.9	24.6
BVDV	25.1	13.7	28.1
Campylobacter	12.6	10	19
Leptospira	19.9	15.1	37.1
Brucella abortus	14.8	2.8	1
Histophilus somni	9.3	5.3	7.9
Neospora	–	0.4	0.3
Tritrichomonas	0.7	0.9	1

Source: Based on [12].

effects of the immunizing agents [2]. While complete protection against every pathogen in every individual is not realistic, the goal would be to minimize the number of susceptible animals in the population. This should prevent epidemic outbreaks of reproductive disease as well as the establishment of chronic endemic losses in the cow herd.

While veterinarians and producers often think of individual vaccination protocols for different management groups on the ranch, it is the author's belief that vaccination programs should be viewed as a continuum. For example, if producers are developing their own replacement heifers, the suckling calf vaccination program should be viewed beyond the summer grazing season and fall weaning events. This vaccination program should be constructed to take into account the probability that these young heifer calves will join the replacement pool, become pregnant, and eventually become a productive member of the mature herd. The suckling calf protocol should be designed to prepare the calf for post-weaning disease challenges and increase the calf's response to subsequent reproductive vaccination. Research has clearly shown that calves vaccinated at an early age will mount a cell-mediated immune response that will enhance the calf's ability to respond to subsequent vaccination or disease challenge [13, 14]. This approach will maximize protection against reproductive pathogens and minimize the potential for any negative vaccine side effects associated with the prebreeding vaccination of seronegative females [15–17]. These side effects may include multifocal areas of ovarian necrosis, hemorrhage and inflammatory cell infiltrate in the ovary, and the development of cysts in the corpus luteum. These lesions are transitory in nature but can result in decreased reproductive performance in the short term.

Other factors to consider in vaccine selection include fetal protection and duration of immunity. Recent advances in vaccine technology and diagnostic testing have allowed vaccine manufacturers to document the ability of their products to prevent disease organisms from spreading to the placenta and fetus following maternal infection. Challenge studies using virulent BVDV, IBR, and *Leptospira borgpetersenii* (serovar *hardjo*) have shown that fetal protection against pregnancy wastage, BVDV persistent infection (PI), and leptospiral renal colonization and urine shedding are possible following vaccination [18–22]. While both modified-live viral and killed virus vaccines have demonstrated fetal protection against BVDV, typically modified-live vaccines provide better protection and a longer duration of immunity [23–25]. Studies have also shown that this protection can last for one year or longer following vaccination of animals of various ages [18, 20, 26]. The concepts of fetal protection and duration of immunity are especially important for beef operations as they are more likely to come in contact with adjacent herds and may only be handled for vaccination once per year.

Before constructing any vaccination program for a cow/calf operation, the potential risk for exposure of the herd to a particular pathogen through herd additions or herd contact with clinical or inapparent carriers of a pathogen should be evaluated. The epidemiological terms "open," "closed," and "modified open" have been used to describe the potential risk level of a given herd [2]. When assessing the need for vaccination, factors such as risk-level management, the magnitude and etiology of previous reproductive losses, herd working patterns and animal management, and the producer's long-term goals should all be considered. Once this information is collected and evaluated, recommendations concerning the use of specific vaccine antigens, the type of vaccine needed, and the frequency of vaccination can be constructed to fit within the confines of the total ranch management plan [2].

First Level: Closed Herd Vaccination

Closed herds run a relatively low risk of disease introduction due to the fact that there is limited movement of breeding animals on and off the operation. These operations develop their own replacement females and have little to no contact with adjacent herds. The primary potential source for disease introduction would be in the form of venereal disease from the addition of breeding bulls. There is also the potential of exposure to leptospiral serovars from domestic livestock and wildlife populations in the area. This type of management will create a herd that is highly susceptible to viral and bacterial reproductive diseases but does so at a very low level of risk for disease introduction [2].

Adequate quarantine protocols and facilities are important for all operations, but this is especially true for closed herds. While the risk of introduction of viral reproductive pathogens is very low in these herds, it can be devastating if it occurs. Therefore quarantine procedures must prevent nose-to-nose contact between new arrivals and the resident cow herd for a minimum of 30 days. This time period should allow animals that are shedding IBR virus following recrudescence or undergoing acute BVD to clear the viremia and stop shedding prior to introduction with the resident herd [27]. Individual animals can also be vaccinated appropriately as they enter and again as they leave the quarantine pens to ensure that herd immunity is maintained and the resident herd protected. This time frame also ensures that all diagnostic screening performed on arrival, such as testing for BVD-PI or *Tritrichomonas foetus*, will be completed and test results returned to the practitioner prior to the animal being released from quarantine. An additional step to enhance biosecurity would be to screen

culled animals annually to gain insight as to the level of seroconversion that is occurring in the breeding herd [2]. Effective quarantine procedures not only help prevent disease introduction but also will enhance the effectiveness of the vaccination program [28].

Vaccination of closed herds should center on pathogens that are difficult to control through biosecurity measures alone. Annual boosters with multivalent products containing *Leptospira* and *Campylobacter fetus* subsp. *venerealis* should be utilized in all breeding females on the ranch [2]. Depending on the normal working patterns on the ranch and the anticipated timing of disease exposure, these vaccine antigens may be given before breeding prior to bull turnout or in mid gestation at the time of pregnancy examination (Table 41.4). While *C. fetus* vaccination would be most effective if given before breeding, it is commonly given in concert with the *Leptospira* serovars in mid gestation since it is unlikely the herd would be handled an additional time. Herd bull vaccination schedules should match the antigens and timing of the female group that they will be turned in with.

Replacement heifers represent the highest at-risk population for reproductive pathogens, both viral and bacterial [2]. The antigens given to these heifers during the suckling calf and weaning phases should prepare these females to respond adequately to the reproductive vaccines given just prior to the first breeding season. This prebreeding vaccination can be administered 30–45 days prior to breeding as the final selection for the breeding pool takes place (Table 41.4). Since these heifers will have had previous vaccine exposure, are relatively stress-free, and are not pregnant, they make the ideal candidates to utilize modified-live IBR and BVDV vaccines. This will enable the herd to maximize protection and minimize potential vaccine side effects [2, 17].

Second Level: Modified Open Herd Vaccination

Modified open herds represent a moderate risk level for disease introduction and should be considered partially susceptible to viral diseases at all times. These herds are best described as those in which the addition of new animals takes place on a limited basis (herd expansion or replacement with purchased additions), or individual animals move in and out of the herd (to livestock shows or exhibitions), or there may be adult animal-to-animal contact with adjoining herds [2]. It is imperative that newly introduced replacements, whether raised or purchased, carry a high level of protective immunity to the most common viral pathogens. Addition of replacements of this type will lessen the need to rely on annual viral vaccination of the resident breeding herd. Well-designed quarantine protocols are important for modified open herds as well.

Table 41.4 Example vaccination program based on risk management concept.

Closed herd
Adult (female and male)
Campylobacter: prebreeding
Leptospira: prebreeding or mid-gestational period
Replacements (prebreeding)
IBR and BVDV: MLV s.c.
Campylobacter: prebreeding
Leptospira: prebreeding or mid-gestational period
Brucella (optional): 4–10 months
Modified open herd
Adult (female and male)
Campylobacter: prebreeding
Leptospira: prebreeding or mid-gestational period
Replacements (non-pregnant, prebreeding)
Brucella: 4–10 months
IBR and BVDV: MLV s.c.
Campylobacter
Leptospira
Replacements (pregnant before introduction)
IBR: killed virus s.c. or i.n.
BVDV: killed virus s.c.
Campylobacter
Leptospira
Open herd
Adult (non-pregnant females, 30–45 days prebreeding)
IBR and BVDV: MLV s.c.
Pregnant females and bulls
IBR: killed virus s.c. or i.n.
BVDV: killed virus s.c.
All adult animals
Campylobacter: prebreeding
Leptospira: prebreeding or mid-gestational period
Replacements (non-pregnant, prebreeding)
Brucella: 4–10 months
IBR and BVDV: MLV s.c.
Campylobacter
Leptospira
Replacements (pregnant before introduction)

IBR, Infectious bovine rhinotracheitis; BVDV, bovine viral diarrhea virus; MLV, modified live virus; s.c., subcutaneous; i.n., intranasal.

Yearling replacement heifers represent the main concern for building an immune base within modified open herds. The prebreeding vaccination should include IBR, BVDV, the appropriate *Leptospira* serovars, and *C. fetus* (Table 41.4). These heifers are not pregnant, so it would be preferable to take advantage of the longer duration of immunity provided by modified-live viral vaccines. BVDV types 1 and 2 should be included in the vaccine to ensure a higher level of heterologous protection against strain variation [24, 29]. Whether these heifers are home-raised or purchased, it is important to emphasize the use of vaccines that have been proven to provide fetal protection.

If producers are purchasing pregnant replacements or additions, killed or intranasal combinations of IBR and BVDV provide the best alternative to avoiding the negative side effects of modified-live virus vaccination [2]. This is especially important if the vaccination history of these animals is undocumented prior to their arrival (Table 41.4). Following calving, modified-live viral vaccines may be used before breeding in subsequent years. There are modified-live vaccines that are labeled to be used in pregnant females. However, it is critical that the label directions on these vaccines are followed with regard to the timing and the number of doses given before breeding while the females are not pregnant. This is essential to avoid vaccine-induced pregnancy wastage. As in closed herds, annual vaccination for *Leptospira* and *Campylobacter* is conducted in all adult replacement females and in bulls [2].

Third Level: Open Herd Vaccination

Open herds represent the greatest challenge to a vaccination program since these operations have the highest risk for the introduction of both viral and bacterial reproductive pathogens [2]. These pathogens are typically introduced via animal movement on and off the ranch. This movement typically occurs via the routine purchase of replacements, via direct contact or commingling of the breeding herd with stressed high-risk stocker or feeder calves, or through the sale barn purchase of orphan calves for the purpose of grafting onto a lactating female in the resident herd. These purchased replacements may be heifers or mature cows and can be pregnant or open. The main issue with these purchased females is that the practitioner and producer typically know nothing about their previous vaccination or disease history. Proper quarantine protocols and disease screening at arrival are absolutely critical components to minimize disease risk in this type of herd.

The primary emphasis of the vaccination program for open herds centers on the addition of viral components to maintain a high level of collective herd immunity to these pathogens. This will require annual viral vaccinations in the breeding herd, while continuing annual vaccination against the common bacterial pathogens [2]. A modified-live viral vaccine would be most commonly used 30–45 days prior to the start of the breeding season in open cows. In those situations where the breeding herd is only vaccinated at pregnancy examination (mid gestation) or the herd has a prolonged calving season, the use of an annual killed virus vaccine may be the only option (Table 41.4).

The use of viral vaccines in replacement females should follow the same guidelines as those for the modified open herd. This will minimize the risk of introducing susceptible females into the herd, help establish an immune base for the operation, and ensure that the subsequent pregnancy is protected [2]. Depending on the source of breeding bulls in these herds and the risk of venereal disease introduction, *T. foetus* vaccine could be considered in these heifers and cows. However, a critical review and meta-analysis of the efficacy of *T. foetus* vaccine indicated that while there may be a small positive effect on decreasing abortions in vaccinated heifers, there was no effect on decreasing the infection rate or the risk of being open [30].

The delivery of vaccines for *Leptospira* and *Campylobacter* will be the same in open herds as was described for closed herds (Table 41.4). All adult females, replacement females, and herd bulls will receive these antigens at least annually [2]. These may be given before breeding or at mid gestation, depending on the normal working patterns associated with the ranch management.

Summary

The process of designing immunization programs for beef cattle operations must take into consideration factors such as traffic patterns on and off the ranch, normal handling times, the pregnancy status of the animals to be vaccinated, historical disease patterns, and the relative risk of disease introduction. The goal of the immunization program should be to increase the level of collective herd immunity by minimizing the number of animals that are susceptible to reproductive disease. This not only will prevent epizootic outbreaks of pregnancy wastage, but also should control chronic endemic disease. Our ability to better understand the relationship between reproductive pathogens and the bovine reproductive tract has enabled vaccine manufacturers to provide products that ensure fetal protection and a long duration of immunity, while minimizing negative vaccine side effects. The end result is that the practitioner can provide the client with cost-effective vaccine options to help ensure optimum reproductive performance.

Dairy Herd Health for Optimal Reproduction

Joseph J. Klopfenstein

Large Animal Clinical Sciences, Carlson College of Veterinary Medicine, Oregon State University, Corvallis, OR, USA

Introduction

The modern dairy farm is an extremely complex system. Optimal productivity and profitability are dependent upon an interaction of genetics, health, nutrition, reproduction, environment, and management [1, 2]. Good reproductive efficiency, in turn, has a positive impact on animal health. Farm profitability depends upon maintaining dairy cows in the most productive and profitable portion of their lactation curve, returning them there as soon as possible and maximizing the number of lactations in a cow's lifetime [3]. This concept is illustrated in Figure 42.1.

The goal of a modern reproductive herd health program is to maximize reproductive efficiency, that is – to establish a voluntary waiting period (VWP), then to achieve pregnancy as soon as possible after the commencement of the breeding period. Four main factors influence efficiency: the VWP, insemination rate, pregnancy per artificial insemination (AI), and pregnancy loss [4]. The metric best used to evaluate the efficiency of a reproduction program on a dairy farm is the 21-day pregnancy rate (or risk) and is calculated retrospectively:

$$\text{Conception Rate}\left(\text{CR}\right) \times \text{Insemination Rate}\left(\text{IR}\right)$$

This calculation includes only cows eligible to become pregnant once a program is established. Achieving good conception rates depends upon a healthy, properly involuted reproductive tract, a cow in positive energy balance, a fertile ovum, and good AI technique (or a fertile bull). Insemination rate (also referred to as heat detection rate or AI submission rate in some sources) depends upon good heat expression and detection. Many reproduction programs utilize hormonal manipulation of the estrus cycle to synchronize ovulation and insemination, thereby eliminating heat detection as a variable. In this circumstance, insemination rate depends upon excellent compliance with the breeding management program. This simplified description of a reproductive herd health program illustrates the complexity of interactions on a dairy farm where reproduction is involved. It is the role of the reproductive herd health program to monitor and manage these variables to maximize reproductive efficiency. Due to the relationship of biological and management factors that determine when cows become pregnant following the end of the VWP and whether or not pregnancy is maintained, a reproductive program needs to integrate the principles of theriogenology and herd health in order to optimize reproductive performance. This chapter gives an overview of certain health events on a dairy, how they impact reproduction on a herd level, and the development and implementation of herd health programs.

Ketosis and Diseases of Transition

Ketosis, defined as an elevated level of ketone bodies (e.g. betahydroxybuterate [BHBA]) in the bloodstream, occurs when the cow is unable to adapt adequately to a state of negative energy balance [5]. Cows are most at risk during the periparturient period when dry matter intake is low and energy demands from a rapidly growing fetus prepartum or increasing milk production postpartum require body energy stores to be utilized, increasing body condition loss. Ketosis is classified as clinical when characterized by decreased milk production, inappetence, and unthriftiness. Identification of subclinical ketosis (SCK) occurs by measuring an increase in blood ketone (primarily BHBA) levels without observed clinical signs.

The effect of ketosis on individual animal reproductive performance has been demonstrated [5]. Cows that exhibit SCK

early in lactation (less than day 16 postpartum) have reduced fertility at first service and were less likely to become pregnant by 150 days in milk [6]. Studies by Walsh et al. identified a threshold for herd levels of ketosis that affect clinical disease, production, and reproduction. In one study, the median time to pregnancy for cows above the threshold for SCK (BHBA ≥1000 mmol/l in week 1 and ≥1400 mmol/l in week 2 postpartum) was 130 days. Median days to pregnancy was 108 days in cows that never experienced SCK. In addition, first insemination pregnancy rate/AI was reduced by 2% in cows that were ketotic in week 1 postpartum and 3% for those ketotic in week 2 for each 100 mmol/l increase in BHBA [7]. Another study established a herd alarm level for elevated BHBA or non-esterified fatty acids (NEFA). Herd pregnancy rate was found to be reduced by 1.2% in herds when 15% of prepartum animals were found with NEFA ≥0.27 mEq/l and was reduced 0.8% in herds where 15% of prepartum animals had BHBA ≥12 mg/dl. Herd pregnancy rate was reduced 0.9% in herds where ≥15% of postpartum animals had BHBA ≥12 mg/dl [6]. In addition, clinical and subclinical ketosis have a significant downstream effect on transition diseases that can affect reproductive efficiency such as metritis, endometritis, mastitis, immune suppression, and displaced abomasum [6, 8]. Hypocalcemia can also predispose periparturient animals to immune suppression and has been associated with increased incidence of retained placenta and metritis. Hypocalcemia can also lead to increased days to cyclicity and, potentially, increased days open [9]. Managing intake, mineral status, and energy balance through strategies such as proper ration balancing, improved feedbunk access, minimizing pen moves, and reduction of overcrowding are critical to maintaining body condition and achieving maximum reproductive efficiency [8].

Mastitis

Mastitis occurs when inflammatory changes occur in the bovine udder, most commonly because of an invasion by an infectious bacterial organism. Mastitis may be defined as clinical (changes in the character of the milk and/or udder with or without systemic signs) or subclinical (elevated somatic cell counts above 150 000 cells/ml without a change in milk character) [10]. Mastitis is the most common and costly infectious disease of dairy cattle according to survey data of dairy producers [11]. Although estimates of the cost of mastitis on a case basis include the value of herd removals resulting in lost pregnancies [12] or assumptions of an effect on pregnancy rate [13], there is little research to demonstrate the effect of the disease on herd-level reproductive efficiency. However, we can infer its effect on the herd using studies evaluating the influence on individual animal reproductive performance.

Most studies of the effect of mastitis on fertility compare a clinical mastitis event with reproductive performance. Indeed, Hudson and his group found that a clinical mastitis event shortly before or after breeding has a significant effect on fertility [14]. Fuenzalida et al. found that in cows with chronic clinical mastitis (that is, clinical mastitis occurring prior to insemination and continuing through the period of breeding risk), clinical mastitis (disease occurring anytime during the breeding risk period), and subclinical mastitis, the odds of pregnancy are 0.56, 0.67, and 0.75, respectively, compared to cows without mastitis [10]. The period of breeding risk was defined as 3 days prior to 32 days post insemination. Subclinical mastitis seems to have variable results on fertility. Peake did not find a negative effect, whereas Hudson found that subclinical mastitis had a significant effect on the likelihood of an insemination to be successful. His work showed that the odds of a service leading to a pregnancy were decreased by around 18% where a cow exhibited a somatic cell count (SCC) of between 200 000 and 399 000 cells/ml within 32 days of insemination and the odds were decreased by almost 26% when the animal's SCC was >399 000 cells/ml during the same time period [15]. A high proportion of clinical and subclinical mastitis occurs during the first two months of lactation, which overlaps with the interval most producers select as their VWP. It is imperative that producers and herd health veterinarians focus on mastitis control during this period to maximize fertility.

Lameness

Lameness is among the most common [11] and costly [16] diseases of dairy cattle, affecting welfare, productivity, and reproductive performance [17]. Although the diagnosis of lameness is somewhat subjective and determining the severity of the disease depends upon observer bias, the majority of studies show that lame cows resume postpartum cyclic activity more slowly and, once cycling, have poor estrus expression and reduced fertility. Peake and colleagues

found that lame cows diagnosed by a herd veterinarian had 6 more days to the first luteal phase and 9 more days open than herdmates that were not lame. In the same study, cows identified as clinically lame by producers had 6 more days to first service and 43 more days open than their sound herdmates [15]. This study also revealed that lameness in combination with other stressors such as body condition loss and increased SCC have a synergistic effect on the time to an animal's first luteal phase. Morris and colleagues in a UK study supported these findings. This group found that 50% of lame cows either did not ovulate or did not respond to hormonal ovarian stimulation at all during the postpartum period (30–80 days post calving) [18]. Delayed cyclicity and subfertile animals affect herd pregnancy rate during the critical breeding period, negatively impacting herd economics and reproductive success [19].

Heat Stress

Another stressor affecting both expression of estrous and fertility is heat stress. Heat stress occurs when external environmental forces act upon an animal and generate an increase in body temperature enough to evoke a physiological response [20]. Heat stress on livestock is normally measured using the temperature humidity index (THI) which is a calculated value incorporating the combined effects of environmental temperature and relative humidity [21]. A THI of 72 is most commonly used as the upper limit of a diary cow's thermoneutral zone [20, 22, 23], but studies range from 70 to 75 [21]. THI is applied most accurately as a daily average rather than as a measurement at any point in time.

Heat stress causes negative energy balance through reduced feed intake and unique metabolic adaptations, affecting reproductive performance in a similar manner to negative energy balance during the periparturient period [23]. Direct effects on the reproductive tract also affect fertility. Heat stress can affect the reproductive performance of both males and females [22]. It reduces the duration and intensity of estrus behavior [20, 22], and ovulations without estrus signs can occur [24]. Heat may cause physical lethargy and decreased dry matter intake, leading to altered hormone production and thus estrus behavior [20]. Studies have identified effects on fertility such as impaired oocyte quality and embryo development, increased embryonic mortality, endometrial dysfunction, impaired steroidogenesis in ovarian follicles and corpora lutea, loss of normal follicular dominance patterns, and reduced uterine blood flow [25–27]. Schüller [28] showed that even in temperate climates, cows were 61% less likely to become pregnant if a cow was exposed to a THI of ≥73 from 21 days to 1 day prior to breeding. Morton et al. demonstrated that the effects of heat stress on reproduction can be cumulative, particularly from day 35 prior to service to day 6 after service [25]. There is some evidence that embryo technologies such as embryo transfer may have the potential to improve fertility since fertilization and early embryo development are bypassed, which are stages of increased thermosensitivity [4]. These data show that producers must employ heat stress mitigation throughout the hot season even in temperate climates to maximize reproductive performance.

Prevention of Infectious Disease

The effects of infectious viruses and bacteria on the health and reproductive performance of dairy cows are well covered in other parts of this text. The role of the herd health advisor should be to design an effective biosecurity and vaccination program to maintain the health and productivity of the herd. When designing an effective vaccination protocol, this author employs a system similar to that designed by James S. Cullor and Anne M. Nelson at the University of California in the 1990s called Dairy Breakthrough Management (BTM). This system, influenced by the US Food and Drug Administration (FDA)'s hazard analysis critical control point (HACCP) program and other management materials, uses a 12-step approach to design protocols that are consistent and workable, and that ensure buy-in by all members of the management team on a dairy.

BTM and similar systems are designed to anticipate an outcome and identify those steps where control can be applied and that are essential to prevent the outcome being undesirable (for example, disease, abortion, or infertility due to an infectious disease). These steps, called *critical control points*, are assigned monitoring procedures, critical limits, and corrective actions if the identified critical limits are exceeded.

In general, using this approach, the process to design an effective vaccination protocol may look like this:

1) Perform a hazard analysis
   a) What is the goal of the program?
      i) Prevent respiratory, digestive, or other disease?
      ii) Protection of conception?
      iii) Fetal protection?
   b) What is the current program?
      i) Is compliance adequate?
      ii) Is it accomplishing the stated goal or goals?
   c) To what disease risks are the animals exposed?
      i) What is the current state of disease on the dairy?
      ii) Are animals of unknown disease status being brought onto the farm?
      iii) Is natural breeding employed?

   d) Are there management factors or other stressors that may affect response to the program?
      i) Is nutrition adequate?
      ii) Is stocking density appropriate?
      iii) Is concurrent stress from lameness or other factors present?
2) Assemble a management team to design the new program
   a) Ownership or upper management
   b) Herdsman
   c) Veterinarian
   d) Anyone who will be handling or administering the vaccines
3) Identify the desired outcome
4) Discuss the current work flow situation
5) Identify critical control points
   a) Examples:
      i) Is the vaccine properly stored, mixed properly if required, and promptly administered?
      ii) Is there an adequate inventory management program in place so the farm does not run out?
      iii) When are animals handled?
      iv) How many vaccines are in the protocol? How many will be given concurrently?
      v) Is the right product going to the right animals?
      vi) Is the vaccine administered by the appropriate route?
      vii) If boosters are required, are they being given correctly?
6) Write the protocol
7) Decide what should be monitored and set action points
   a) Is disease incidence under control?
   b) When to reorder if inventory gets low
   c) Does the inventory match the number of doses that should have been administered?
8) Develop a record keeping system.

Although the system described here is for the development and implementation of a vaccination protocol, the same approach may be useful for development of other treatment protocols, management protocols (such as a managed breeding protocol), and standard operating procedures on a dairy farm.

Developing and Implementing Reproductive Herd Health Programs

The definition of a reproductive herd health program has changed significantly since the 1960s when producers and veterinarians became more proactive in their approach to reproduction. During this period and throughout the 1970s, veterinarians and dairy producers developed routine scheduled visits designed to identify non-pregnant animals and re-enroll them into a reproductive management program. The advent in the 1990s of hormonal manipulation of the estrus cycle, synchronization protocols, and advanced reproduction and production data management programs facilitated the evolution of modern reproductive herd health programs. During this time, veterinarians coined the term "production medicine" to recognize the interrelationships health, reproduction, and management have on dairy farm profit. Today's production medicine veterinarian employs a holistic view of the dairy farm – incorporating nutrition, health maintenance, reproduction management, genetics and genomics, youngstock management, economics, employee training, and protocol development. Each area of this complicated system must be monitored and managed to maximize production, reproduction, and farm profit.

In the latest National Animal Health Monitoring System (NAHMS) dairy management survey, over 85% of dairy farms surveyed used veterinary services for reproductive management [11]. Reproductive efficiency has a major impact on farm profit, animal health, and replacement inventory [3]. Shortening the calving interval reduces the average days in milk for the herd, resulting in more cows in the early, more profitable part of their lactations [4]. The cost of a day open increases with greater calving interval, with estimates ranging from USD $1.25 at 90 days to $2.75 at 201 days in milk. It can vary, however, from $0 to $6.00 based on a variety of factors [4]. Shorter lactations also promote animal health and welfare by maintaining animals in more optimum body condition. Progressive dairy producers will challenge veterinarians to design a reproductive herd health program that meets the farm's objectives in these key areas.

Setting Goals

A wise colleague once told this author that he made much more progress in his herd health programs once he stopped telling producers what to do and began asking them about their goals (W.M. Hilton, personal communication). For veterinary recommendations to be successful, advice should meet three criteria [29]:

1) Advice should be based on scientific evidence.
2) Advice should be effectively communicated.
3) Advice should build on the goals of the producer in order to take advantage of their motivation to implement change.

Unfortunately, too often the goals of dairy farmers and their advisors do not match. In a study from the Netherlands, 16 of 22 farmer : veterinarian combinations did not match in their primary goal for the farm. In general, veterinarians overemphasized production and udder

health and farmers more often prioritized cow fertility [29]. Goal setting is an integral part of modern management programs like the previously mentioned BTM. Dairy farmers and their advisors should routinely have a frank conversation about farm goals to ensure that each understands the priorities that the producer has for the farm's herd health and reproduction programs.

Determining the Ideal VWP

The first component of herd reproductive efficiency is the establishment of an appropriate VWP. The VWP is defined as the time a dairy farmer is willing to wait after parturition before cows are eligible for insemination, normally reported in days [30]. The goal of the VWP is to improve conception rate at first service by allowing time for uterine involution and clearance, improved energy balance, and the return of normal cyclicity [4]. The ideal VWP for an individual herd is partly determined by reproductive efficiency represented by the herd pregnancy rate and partly by the anticipated optimum time for the establishment of pregnancy [3, 4]. In general, cows with lower milk production, poor lactation curve persistency, and a lower 21-day pregnancy rate require a shorter VWP, while herds with higher producing cows, persistent lactation curves, and a high 21-day pregnancy rate could benefit from a longer VWP [3, 4].

In an economic analysis, Ribeiro and colleagues looked at two periods (110 and 130 days) for optimum days to pregnancy after calving. They found that in herds with poor 21-day pregnancy rates (<15%) these goals could not be met, even if breeding commenced immediately after calving. In herds with 21-day pregnancy rates >22.5% the goals could be met with VWP of between 60 and 98 days [4]. The most recent averages for >9800 dairy herds on Dairy Herd Improvement Association (DHIA) records from the USA that are processed at the Raleigh, NC testing center were for an average VWP of 59.4 days and a 21-day pregnancy rate of 19.2%. Average days to pregnancy was 148.9 days (DairyMetrics, Dairy Records Management Systems [DRMS], Raleigh, NC). One should also consider individual cow factors such as parity, milk production, and persistency of lactation when establishing the length of the VWP. A longer VWP does not necessarily result in a longer calving interval if conception rate to first AI is good [4].

Strategies to Increase Insemination Rate

The second component of reproductive efficiency is to maximize insemination rate once the VWP has passed. Insemination rate is dependent upon cows in estrous being delivered for breeding. Traditionally this was accomplished by observing estrus behavior, and this is still the system used by just over half of dairy producers for first service [11]. However, whether or not cows are inseminated in this system is based on the efficiency of estrous detection, which is low in most herds. External factors such as increasing heat stress, herd size, animal density, and confinement housing on concrete, as well as individual animal factors discussed previously can affect estrus expression [4]. The majority of dairy farms are now using technologies such as timed AI (TAI) programs and activity monitors to increase insemination rate at some point during the breeding period [11].

The advent of luteolysis and subsequent ovulation from the use of exogenous prostaglandins in the 1970s improved reproduction management in dairy cattle, although timing of estrus expression using this system is variable dependent upon external factors and individual animal status [4]. The development of TAI programs in the 1990s further improved insemination rates by synchronizing ovulation and insemination. These programs are particularly effective in herds where heat detection is a challenge and they provide a significant economic benefit over heat detection alone [4]. Designed initially as programs intended to increase insemination rates, newer methods of TAI incorporate knowledge about bovine reproductive biology, hormonal manipulation, and oocyte and embryo quality to improve conception and pregnancy retention [4].

Among the dizzying array of TAI program options, herds that employ a strategy of TAI for first insemination (no matter which specific protocol) coupled with estrus detection experience the lowest median days to pregnancy and more profit per cow [31]. In a simulation evaluating reproductive performance and economics of 10 different breeding programs by Galvão et al., the highest 21-day cycle pregnancy rate was obtained when cows were subjected to a TAI program with 95% compliance of treatments for first insemination followed by estrus detection at 60% efficiency with 95% accuracy. It was demonstrated that the greatest improvement in economic return in the simulation was in those herds that previously had poor compliance of treatments [31]. It follows that optimal reproductive efficiency and herd economics occurs in herds that incorporate an effective and compliant TAI protocol for first service followed by estrus detection, and that efficient and accurate detection of estrus activity remains an integral part of successful dairy reproductive performance.

Automated estrus detection systems are increasingly in use by dairy producers [11]. These systems generally work by measuring a cow's activity via a neck-mounted activity meter or a leg band with a pedometer and generating a notification when an increase in activity exceeds a designated threshold as determined by computer algorithms [32]. Studies have indicated that automated systems can identify

as many as 80% of cows in estrous accurately [32, 33]. Limitations on this technology include multiparous cows, lame cows, cows with low body condition score (BCS), and cows with purulent vaginal discharge. These animals tend to exhibit poor activity [32]. Sensitivity of detection can be influenced by such activities as being on pasture, pen moves, hoof trimming, and other management events that may increase measured activity. Although economic analyses do not necessarily show an economic advantage to these systems [34], automated systems will likely become more common in an industry with progressively restricted access to pharmaceuticals.

As recently as 2014, a NAHMS survey [11] found that over half of dairy operations in the USA incorporated natural service with bulls somewhere in their breeding program and 10% used bulls exclusively [11]. Days to pregnancy and 21-day pregnancy rate may be improved in bull-bred herds over herds that employ AI [35]. However, a 2010 economic analysis found that cows in herds enrolled in a TAI program enjoyed a benefit of nearly $38.00 per pregnancy over cows in herds that employed natural service when pregnancy rate and VWP were standardized. This advantage depended on the cost to feed bulls, semen price, and genetic merit of semen [35]. Natural service may be an option for those producers who lack the management ability, resources, or labor to manage an effective AI program, but it is not the most effective strategy to maximize reproductive efficiency, genetic advancement, or economic performance of dairy herds [3].

Managing and Monitoring Fertilization Failure and Pregnancy Loss

Recognizing and monitoring pregnancy per AI and pregnancy loss is a vital component of reproductive efficiency. A review article by Wiltbank and colleagues summarizes studies involving pregnancy loss outside of that caused by infectious disease [27]. The authors identified four distinct periods of risk and described the herd health effects that influence the loss of the conceptus during these periods.

Period one includes fertilization and the first week of pregnancy. In thermoneutral conditions in healthy cows with high-fertility semen, fertilization failure occurs in 10–20% of inseminations. Factors involved in increased fertilization failure include improper AI technique, inflammation and the presence of inflammatory cells in the uterus, poor quality semen, and heat stress. Once fertilization occurs, increased degeneration of embryos in the first week can occur because of the ovulation of larger, possibly persistent follicles due to inadequate circulating P4 during follicular development. One theory holds that these larger follicles may be a response to increased body condition loss [36]. One way synchronization protocols can increase embryo quality and survivability is by ensuring that smaller, less persistent follicles are presented for fertilization [27].

The second critical period occurs from day 8 to 27 and may result in 10–50% of pregnancy losses. Three important factors occur during this period. The first factor is the growth of the embryo and development of the trophoblastic tissues. This factor may again be associated with low circulating P4 levels. Nutritional support of the dam is vital; interestingly, three amino acids identified as limiting for milk production (lysine, methionine, and histidine) are those that exhibit the greatest increase in the uterine environment during embryo elongation. In addition, body condition loss can affect P4 levels, as described previously. The second factor is maternal recognition of pregnancy. Occurring at day 16 in the bovine, maternal recognition is especially dependent upon proper embryonic development, as described above. The third factor is the suppression of the maternal immune system, requiring a healthy maternal immune system and immunological diversity. Heat stress can also affect embryonic degeneration during this critical period.

Period 3 is days 28–60 of gestation. This period may account for around 12% of pregnancy losses. This period is especially important to monitor for reproductive efficiency as evaluation for pregnancy normally occurs around days 28–30, and therefore losses during this period may occur after pregnancy diagnosis. Risks for pregnancy loss during this period include increased body condition loss, anovulation at the end of the VWP, reduced P4 circulation during dominant follicle growth, the presence of uterine disease or non-uterine disease such as mastitis, and nutritional factors such as vitamin E/selenium deficiency.

Critical period 4 occurs from day 60 to day 90 after insemination. This period accounts for 1–3% of pregnancy losses. Up to 75% of losses during this period may be due to twin pregnancies, especially those occurring in the same uterine horn. Proper maternal nutritional support is also critical during this period [27].

Evaluation for Pregnancy Status

Reproductive efficiency depends upon early pregnancy evaluation and, if the cow is not pregnant, re-enrollment into the breeding management program. The ideal test for pregnancy should have a high sensitivity and specificity, be cost effective, simple to perform under field conditions, and supply results at the time of the test [37]. Direct transrectal palpation of the reproductive tract is the oldest and most well-established method. Experienced palpators are highly accurate at 30 days and above after insemination.

Transrectal ultrasound may be used to diagnose pregnancy as early as 26 days, but sensitivity below 30 days is decreased due to pregnancies normally lost after this point. Diagnosis at this early date is more accurate when a fetal heartbeat is visualized [37]. Due to the number of pregnancies that are normally lost after this point, as mentioned above, programs that include pregnancy testing at day 28–30 should include re-evaluation later in gestation.

A commercial test for pregnancy-associated glycoprotein-B has been available since the 1990s for the diagnosis of pregnancy in cattle. The test is highly sensitive, but specificity varies from 83 to 97% depending upon the study and the methodology [37, 38]. With this test, blood samples are submitted for evaluation and results are not normally available cowside. In the future, in-line testing of pregnancy-associated proteins and glycoproteins in milk may supply dairy producers with immediate, day-to-day pregnancy status in their animals [37].

Monitoring Health Effects on Reproduction

Accurate and consistent records are essential for proper management of health and reproduction. According to the 2014 Dairy NAHMS survey, a record-keeping system is in use to track individual animals by 95.0% of all operations and 100.0% of large operation [11]. Many smaller dairy farms cling to a paper-based system, but the majority (94%) of large operations use a computer-based system. As performance and reproduction have advanced through the implementation of synchronization protocols, monitoring compliance and outcomes via records systems have become important metrics in their success (Dr. Mark Kirkpatrick, Zoetis Animal Health, personal communication). A more detailed description of record-keeping systems and records analysis is found in Chapter 45 of this text.

These powerful systems may be employed in the monitoring of the effects of herd and individual animal health on reproductive efficiency. Often, producers take advantage of the flexibility of these programs to define disease conditions or use farm-specific or vague definitions (e.g. "SICK") or conditions based on the farm-specific treatment employed. Disease definitions within records systems should be standardized to enable more effective and consistent monitoring by producers, veterinarians, and advisors. Kirkpatrick [39] argues that disease monitoring be standardized with the definition of nine clinical diseases of economic importance: milk fever, retained placenta, metritis, ketosis, displaced abomasum, lameness, clinical mastitis, pneumonia, and digestive disease. Producers can quantify these conditions' effects on profitability and reproductive efficiency by evaluating:

- The proportion of animals affected with a specific condition removed from the herd by 30 days after onset.
- The proportion of affected individuals dead by 30 days after onset, to judge the lethality or severity of the condition.
- The effect on milk yield associated with the condition.

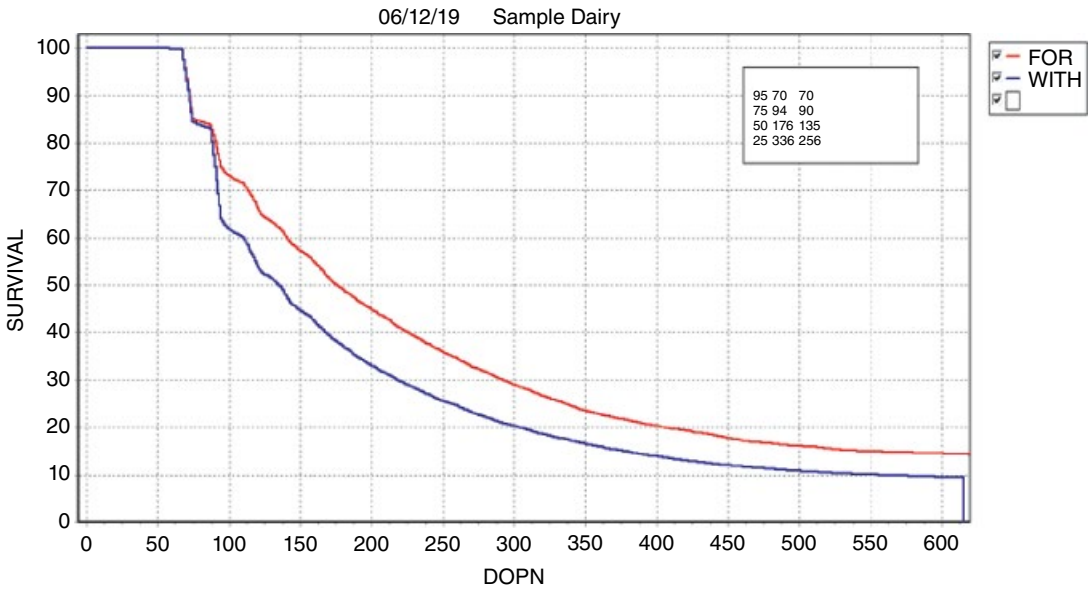

Figure 42.2 Example of a Kaplan–Meier survival curve showing effect of a health condition on days open, where FOR represents the effect a condition (e.g. mastitis) has on days open (DOPN, expressed as days after calving) and WITH represents animals without the condition. The X axis represents risk of survival in the herd. *Source:* Courtesy of Mark Kirkpatrick.

The condition's impact on reproductive efficiency can be further evaluated by determining the proportion of cows remaining in the herd that are pregnant by 120 days in milk. With accurate and consistent record-keeping, additional reproductive insights can be had using tools such as the Kaplan–Meier survival curve analysis in DairyComp 305 (Valley Ag Software) which help to illustrate the effect a condition has on metrics such as days open and survival in the herd [39] (Figure 42.2).

Summary

Dairy herd health and reproductive efficiency are interrelated factors that have a substantial effect on herd productivity and profitability. Dairy producers along with their herd health veterinarian and other advisors should work together to design a reproductive herd health program that recognizes and meets producer goals. The program should identify an economical VWP, then incorporate a protocol that maximizes the number of cows presented for insemination, followed by accurate estrus detection. Metabolic diseases, infectious disease, mastitis, lameness, and heat-related stress should be minimized for optimum fertility. Producers should develop accurate and consistent record-keeping systems to monitor animal health and the consequences on reproduction. Setting achievable goals, implementing programs, identifying bottlenecks to success, and monitoring effectiveness are the hallmarks of a modern production medicine system on a dairy farm.

Herd Diagnostic Testing Strategies

Robert L. Larson

Clinical Sciences, College of Veterinary Medicine, Kansas State University, Manhattan, KS, USA

Introduction

Veterinary practitioners help food animal clients meet a number of specific herd reproduction goals. These include having a high percentage of females exposed to bulls becoming pregnant (i.e. enhancing fertility or minimizing infertility); minimizing the effects of infectious, metabolic, and other disease processes that can cause pregnancy loss or other disease loss; and enhancing the genetic value of the herd through selection and multiplication of economically superior parent animals. To aid their evaluation of an operation's reproductive efficiency, practitioners have a number of tests available to them for use in screening, monitoring, and diagnosing problems in populations and individuals. Any test or procedure that reduces the uncertainty about a disease or production characteristic of an individual animal or herd can be broadly characterized as a diagnostic test [1, 2]. Commonly utilized diagnostic procedures include use of laboratory tests for infectious disease agents, such as serology, immunohistochemistry, polymerase chain reaction (PCR), virus isolation, and bacterial culture. These tests can be used to screen for asymptomatic infectious diseases in apparently healthy animals, surveillance for persistently infected animals for culling from the herd, exclusion from herd entry, or segregation from susceptible herd mates, and to investigate disease outbreaks when clinical symptoms are not specific for a particular infectious agent. In addition, veterinarians use other types of diagnostic procedures to examine individual livestock and entire herds to find and change avoidable risks, for breeding soundness examination of bulls and heifers, for body condition scoring, to diagnose pregnancy via uterine palpation, ultrasonic examination, or blood metabolites, and for feed and ration evaluation (nutritional and toxicological).

Determining Diagnostic Test Usefulness

A valid question confronting veterinary practitioners is whether to use available diagnostic tests for a specific condition [3, 4]. The input that one needs in order to arrive at a logical conclusion includes: ease of test use and interpretation, prevalence or probability data about the condition or disease, diagnostic sensitivity and specificity data, disease or condition epidemiology, and economic costs of the condition and its treatment or prevention [4, 5]. Literature review and mathematic aids such as computer spreadsheets are the tools used to calculate the post-test predictive values of diagnostic tests, economic value of testing, sensitivity of the decision to the individual inputs, and the importance of individual inputs to the decision. These calculations can then be used to evaluate alternative diagnostic testing strategies and to identify the control points that will be monitored for change that can trigger a reevaluation of the decision.

Sensitivity and Specificity of Diagnostic Tests

When considering the use of diagnostic tests to guide clinical decisions, it is very important to understand that the term sensitivity is used to describe test performance in two different contexts, analytical and diagnostic; and a clinician must think about diagnostic test sensitivity in the correct context or risk being misled by the test results [6]. In exactly the same way, when integrating information provided by a description of test specificity, it is critical to know if the information is describing analytic specificity or diagnostic specificity.

Analytic sensitivity is a laboratory characteristic of the test in that it signifies the smallest amount of substance or

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

slightest magnitude of detectable characteristic (visual, olfactory, auditory, etc.) that can accurately be measured from the tested specimen. A test with high analytic sensitivity is able to detect very low concentrations of substance, while a test with low analytic sensitivity would not detect a substance unless the substance was fairly abundant. In contrast, diagnostic sensitivity is a test property that is determined by comparing the test to a "gold standard" test, which is considered to be the true diagnosis as determined using information such as postmortem findings or pathognomonic clinical characteristics or laboratory results. Diagnostic sensitivity is determined in populations of animals and is the percentage of animals that have a particular status (infected, diseased, pregnant, infertile, etc.) that are identified by the diagnostic test as being gold-standard positive for the status.

Analytic specificity denotes the ability of a diagnostic test in a laboratory setting to explicitly classify one particular organism, substance, or status rather than other organisms, substances, or statuses [6]. A test with high analytic specificity would have low cross-reactivity with non-target substances, while a test with low analytic specificity may return a positive result from a specimen that does not have the characteristic or substance targeted by the test because some other characteristic or substance interacts with the test method to return a positive result. In contrast, diagnostic specificity is determined in animal populations and is the percentage of animals that do not have a given condition that are identified by the test as negative for the condition.

Analytic sensitivity is measured as a concentration, such as nanograms per milliliter of serum, parts per million, or particles per microliter, while diagnostic sensitivity is reported as a percentage with the number of true-positive animals in the numerator and the number of animals that truly have the condition in the denominator (includes both the number of animals that have a false-negative classification and the number of animals that have a true-positive classification). Analytic specificity might be reported as the percentage of specimens from animals that do not have the target condition that test negative, while diagnostic specificity is reported as a percentage with the number of true-negative animals in the numerator and the number of animals that are truly free of the condition in the denominator (includes both the number of animals that have a false-positive classification and the number of animals that have a true-negative classification).

Diagnostic testing used in human medicine in the USA is under regulatory oversight whether the test is done in a diagnostic laboratory or a doctor's office, but veterinary medicine is not similarly scrutinized [7]. The initiation of regulatory oversight in human medicine was in response to the recognized importance of rigorous quality assurance and quality control in order to be reasonable assured of providing medical interventions based on accurate diagnostic assessments. Without enforced regulatory assessment of diagnostic tests, veterinarians must recognize the need for quality assurance and quality control and accept the responsibility for frequent and rigorous assessment of the diagnostic sensitivity and specificity of all the diagnostic tests utilized by the practice – not just laboratory tests, but also breeding soundness examination of bulls, reproductive tract scoring of heifers, pregnancy diagnosis, body condition scores, respiratory tract auscultation, and many other commonly implemented clinical procedures.

Diagnostic tests try to separate two populations. One is abnormal, is diseased, or has an undesired condition and the other population is normal or has a desired condition. In most conditions of interest to veterinarians, the affected and unaffected populations overlap based on available diagnostic tests; therefore both laboratory and clinical examination tests must use an arbitrary cutoff to separate test-positive and test-negative populations [2]. Where one places cutoffs for diagnostic tests is very important when deciding into which of two distributions of outcomes a particular animal or herd falls. Because diagnostic measurements of affected and unaffected populations overlap to some extent, diagnostic sensitivity and diagnostic specificity are inversely related, and placing the cutoff is always a trade-off between the impacts of false-negative and false-positive results (Figure 43.1). For test cutoffs not set by the practitioner (i.e. set by a test manufacturer or at a diagnostic laboratory), it is important for the practitioner to be informed of the test's diagnostic sensitivity and specificity, preferably determined in a population that is similar to the population to which the test will be applied.

Where one places a diagnostic cutoff is always a trade-off between false-negative and false-positive results because of the overlap between normal and abnormal populations [8]. Using an example of tachypnea as evidence of respiratory disease in calves requires that the veterinarian define tachypnea with a cutoff number of breaths per minute. Using a cutoff of 25 will likely be more sensitive for detecting calves with pneumonia, but is likely to result in the false-positive classification of many non-pneumonic calves. Placing the cutoff at 40 will increase diagnostic specificity and will reduce the number of non-pneumonic calves classified as tachypneic, but may also fail to identify some truly pneumonic calves (increased false-negative classifications).

Prevalence

Prevalence is the proportion of animals that meet a particular case definition at a given time to the size of the population at that time. The prevalence is the probability of the condition being present in a randomly selected individual from that population. Unfortunately, there is often

(a) In this figure, the cutoff is placed to maximize sensitivity so that there are few false-negative results, but false-positive results occur

(b) In this figure, the cutoff is placed to maximize specificity so that there are few false-positive results, but false-negative results occur

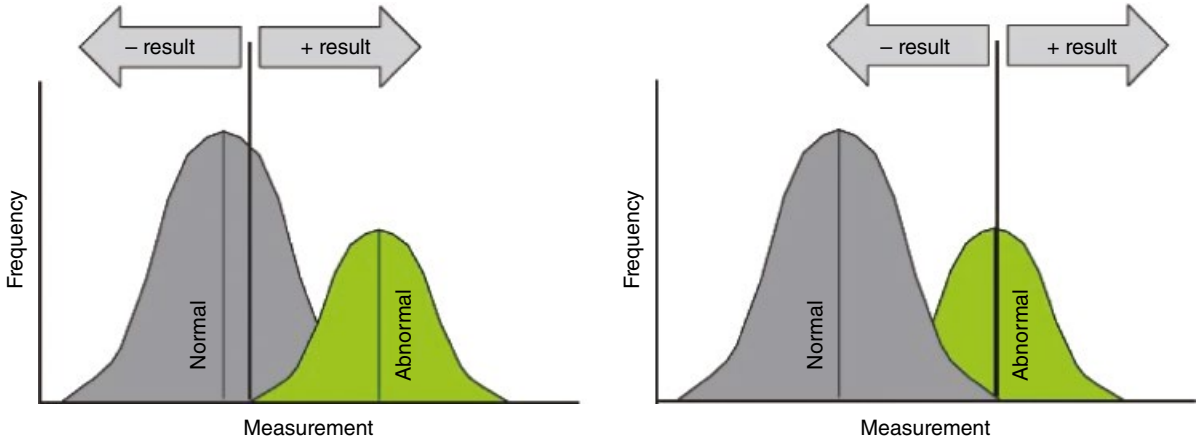

Figure 43.1 When diagnostic measurements of affected and unaffected populations overlap to some extent, diagnostic sensitivity and diagnostic specificity are inversely related, and placing the cutoff is always a trade-off between the impacts of false-negative and false-positive results.

either limited published prevalence information or the published prevalence estimates are so broad as to be of limited usefulness for most of the infectious diseases and reproductive conditions of interest to veterinary medicine. Each practitioner's judgment, based on history and clinical examination of both individuals and the population, aided by what prevalence information is available, is often all that is available to establish the probability for both infectious diseases and reproductive conditions.

Knowing or estimating prevalence is important when interpreting diagnostic tests because for tests with imperfect diagnostic specificity, an increasing proportion of the animals that test positive will be false positives as prevalence or disease probability decreases. For biosecurity reasons, veterinarians often test cattle from very low prevalence populations, so that even a highly accurate test will render inaccurate positive test results when applied to low-risk populations as indicated by the test's low positive predictive value (PPV) in these types of populations.

Similarly, when a test has imperfect diagnostic sensitivity, an increasing proportion of the test-negative animals will be false negatives as prevalence or disease probability increases. Therefore even a highly accurate test can result in inaccurate negative test results (low negative predictive value, NPV) when applied to a population with high prevalence or probability for the condition.

Post-Test Predictive Value

The post-test predictive values of a test are determined not in the laboratory but in the field with the populations where the test is applied; they tell a veterinarian if a valid test is useful in specific populations [2]. The PPV is the proportion of animals with a positive test result that are actually positive for the disease or condition in question and in most situations is influenced more heavily by the test's diagnostic specificity than diagnostic sensitivity. The NPV is the proportion of animals with a negative test result that are truly negative and in most situations is influenced more heavily by the test's diagnostic sensitivity than diagnostic specificity. Both the PPVs and NPVs of a test are affected by the prevalence of the condition in a population (or probability of the condition in individual animals). As the prevalence of the condition is raised, more animals with the condition are present in the population and one has greater confidence that a positive test result is correct. With increasing prevalence, when diagnostic sensitivity and diagnostic specificity are held constant, the PPV of the test is increased and the NPV is decreased, while the reverse is true as the prevalence of the condition is decreasing (Figure 43.2).

The probability that an animal that tests positive is truly positive (PPV) is computed as:

$$\text{Positive predictive value} = (\text{Se} \times \text{P}) / \left\{(\text{Se} \times \text{P}) + \left[(1-\text{P}) \times (1-\text{Sp})\right]\right\}$$

The probability that an animal that tests negative is truly negative (negative predictive value or predictive value of a negative test) is computed as:

$$\text{Negative predictive value} = (1-\text{P}) / \left\{(1-\text{P}) + \left[(1-\text{Se}) / (\text{Sp})\right]\right\}$$

where Se is the test's diagnostic sensitivity, P is prevalence, and Sp is the test's diagnostic specificity.

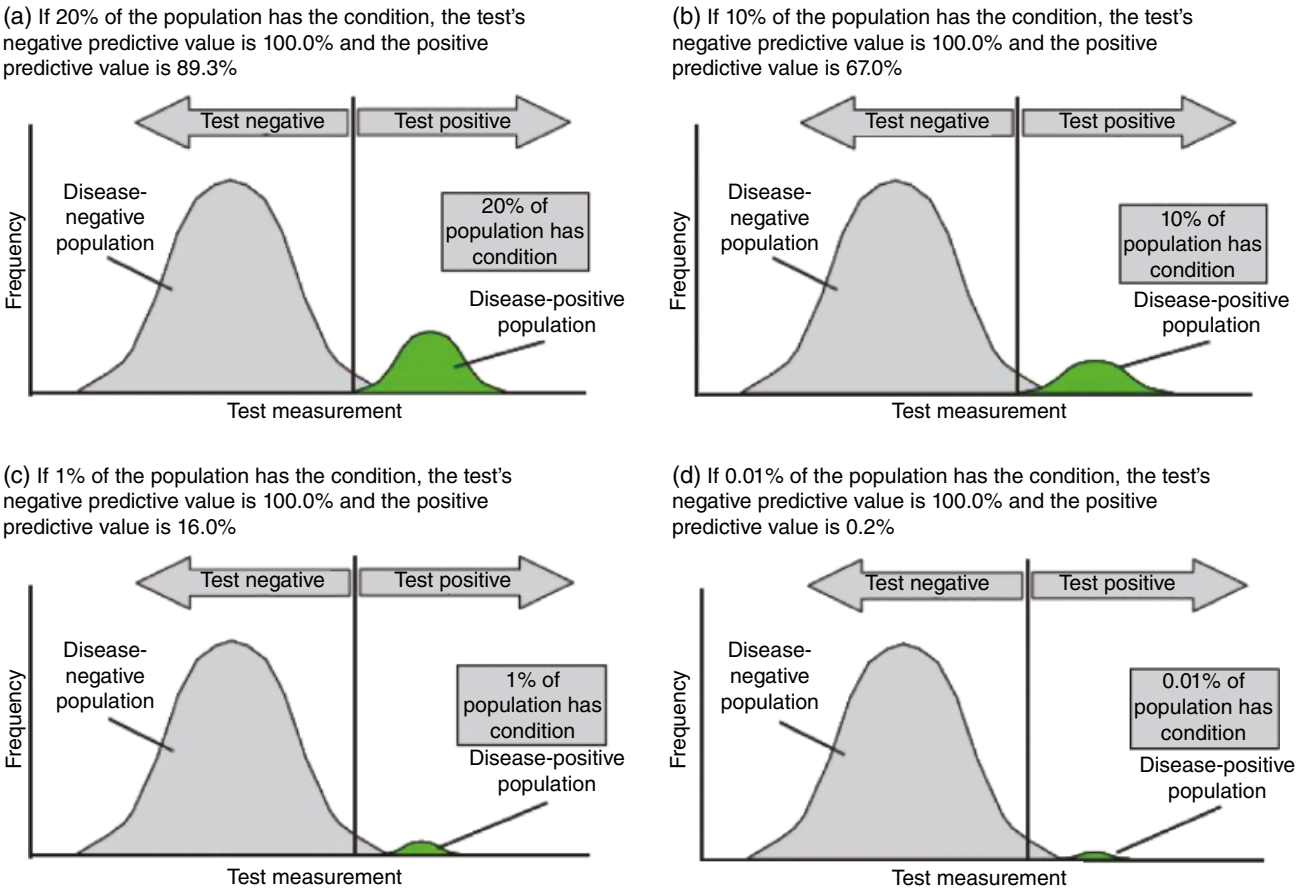

Figure 43.2 If the test has imperfect test diagnostic specificity (i.e. <100%), as the prevalence of the condition decreases, the PPV of a positive test decreases. In these examples, the diagnostic sensitivity and the diagnostic specificity are consistently 99.99 and 95%, respectively, and the prevalence of the condition changes.

An example of how the probability of a condition in certain classes of cattle or in herds with particular previous diagnoses or other history characteristics affects test interpretation is the different certainty a veterinarian will place on a positive test result for bovine viral diarrhea persistent infection (BVD-PI) status depending on the animal signalment and herd history. Using a BVD-PI test that has a diagnostic sensitivity of 99.7% and a diagnostic specificity of 99.3% in different situations will result in different PPVs and hence the certainty of the diagnosis, which will influence the follow-up steps by the veterinarian. If the BVD-PI test is applied to a calf that died following a short disease course of pneumonia and diarrhea in a herd with confirmed cases of BVD in the past two months, the veterinarian may estimate that the probability of the calf being BVD-PI is about 70% before he or she requests the diagnostic test. With a 70% probability of BVD-PI status and diagnostic sensitivity of 99.7% and diagnostic specificity of 99.3%, the PPV is 99.7% and the veterinarian will likely believe a positive test result. In contrast, the veterinarian for a seedstock client who routinely tests all calves on the ranch for BVD-PI status as part of a rigorous biosecurity protocol and as a marketing tool to promote their high-health calves may estimate the probability of finding a truly BVD-PI animal to be very low (<0.1% probability). Using the same tests (99.7% diagnostic sensitivity and 99.3% diagnostic specificity) on this low-risk herd results in a PPV of 12.5% and the veterinarian will likely be very skeptical that the calf is truly BVD-PI.

Diagnostic Testing Strategy

After a single test, it is very unlikely to have both a near-perfect PPV result and a near-perfect predictive value of a negative test result; therefore veterinarians must recognize that they are likely to be placed in the situation where one can only believe one test result direction, either positive or negative. The veterinarian must then decide what to do with the animals that return a test result that is not trusted: either retest the animal or knowingly accept the possibility of a false-positive (situation with low PPV) or a false-negative

(situation with low NPV) without further diagnostic effort. That is, you accept that you may cull or treat some false-positive animals if the cost of further diagnostics is greater than the cost of false-positive intervention; or you accept that you may keep in the herd or fail to treat some false-negative animals if the cost of further diagnostics is greater than the cost of false-negative intervention.

There are two general categories for testing strategies that utilize more than one diagnostic test to determine test-positive or test-negative status. The first of these is described as "testing in series" and is usually used to retest animals with positive test results when the PPV is low after the initial test. The reasons a test would have a low PPV are either low diagnostic specificity of the test or low prevalence in the population. Interpretation of two tests in series requires positive test results in both tests in order to meet the case definition for a positive conclusion. The net results of "testing in series" are a loss of diagnostic sensitivity compared with a single test but a gain in diagnostic specificity. Therefore the PPV is improved and NPV is reduced when interpreting tests in series versus using a single test.

There are several reasons to test in series. In some instances, the second test is more expensive, time-consuming, or difficult than the initial test; therefore we only want to use that test in higher prevalence populations. In other situations, the effect of false positives after a single test is more detrimental than the benefit of finding all instances of disease. If a calf tests positive for BVD-PI status from a herd with low probability of BVD, the PPV will be low and the value of the calf should cause the veterinarian to run a second test interpreted in series and the calf would only be classified as truly BVD-PI if it has a positive result to both the initial test and the follow-up test.

The other category of multiple testing strategies is to test "in parallel" and is usually used to retest animals with negative test results when the predictive value of a negative test is low after the initial test. The reasons that a test would have a low NPV are either that the test has low diagnostic sensitivity or the population has a very high prevalence for the condition.

The current tests for *Tritrichomonas foetus* have very good diagnostic specificity but far less than 100% diagnostic sensitivity, with estimates of 53–77% under field conditions [9–11]. If a veterinarian is testing bulls in a situation where the possibility of trichomoniasis is at least 50%, the NPV is only about 77%, meaning that many test-negative

(a) In this diagram, the test has very good sensitivity and negative predictive value, but the specificity is less than 100% and the positive predictive value is poor. Therefore, the test-positive animals should be re-tested and interpreted "in series".

Positive test results are not trusted:
- Retest positive animals
- Interpret tests in series
- Second test must be positive for the animal to be considered test-positive

(b) In this diagram, the test has very good specificity and positive predictive value, but the sensitivity is less than 100% and the negative predictive value is poor. Therefore, the test-negative animals should be re-tested with a second test interpreted "in parallel".

Negative test results are not trusted:
- Retest negative animals
- Interpret tests in parallel
- Second test must be negative for the animal to be considered test-negative

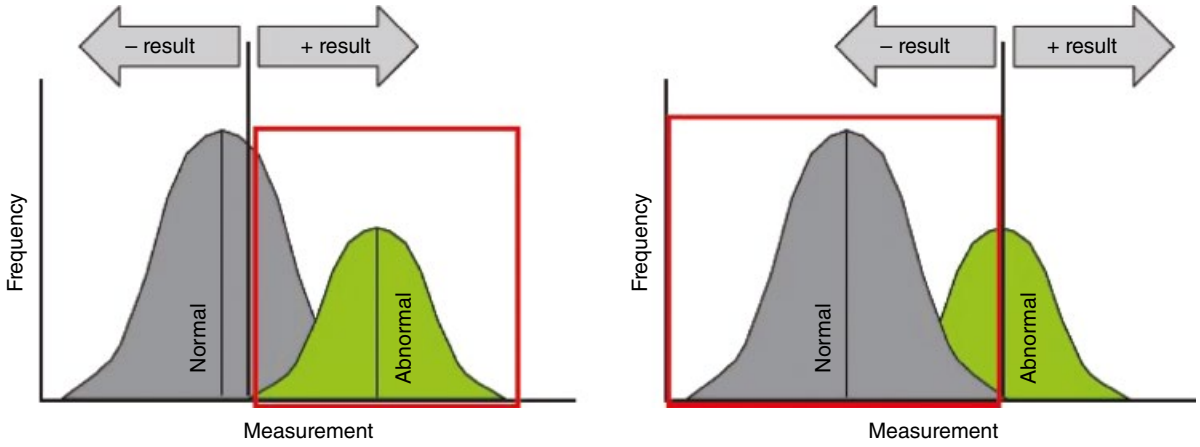

Figure 43.3 After an initial diagnostic test, one test result direction (test-positive or test-negative) should be very good (near-perfect predictive value), but the other test result direction is likely to result in a much lower post-test predictive value. For conditions affecting bovine reproduction, additional diagnostic tests are interpreted "in series" for situations where the veterinarian does not trust initial positive test results and test-positive animals are retested. Additional tests are interpreted "in parallel" for situations where the veterinarian does not trust initial negative test results and test-negative animals are retested.

bulls are truly infected. When testing a herd with known *Tritrichomonas*-positive bulls, the veterinarian will likely estimate the probability of infection in other bulls in the herd to be very high, which decreases one's confidence in negative test results even further. When testing in a herd situation with a disease probability of 75%, the NPV of a single test would be around 50%.

When testing in parallel, two or more tests are applied to the entire population, or to the initial test-negative population. Parallel interpretation of multiple diagnostic tests is used when the veterinarian is concerned about making false-negative mistakes, so that a positive result in any of the tests results in a positive conclusion. The net result of testing in parallel is a gain in diagnostic sensitivity and a net loss in diagnostic specificity. Therefore the PPV is reduced but NPV is improved. Testing and interpreting in parallel is commonly done if tests are fairly easy and inexpensive, or if it is more important to identify all animals with the condition than to avoid false positives (Figure 43.3).

Summary

Interpretation of diagnostic tests is an important component of clinical veterinary practice. Veterinarians use a variety of testing methods including physical examination, laboratory testing, diagnostic imaging, and performance record evaluation. The diagnostic endpoint may be a physical diagnosis of pregnancy, attainment of puberty, or adequate quality and quantity of sperm; or a medical diagnosis of reproductive tract pathology, presence of an infectious pathogen, or abnormal hormonal status. Proper interpretation of test results requires an understanding of how diagnostic sensitivity and diagnostic specificity as measures of test accuracy and prevalence of the condition affect the interpretation of an individual result. For many diagnostic questions, the proper use of more than one test interpreted either in series or in parallel allows veterinarians to optimize diagnostic accuracy and the economic return for the testing strategy.

Breeding Season Evaluation of Beef Herds

Terry J. Engelken

Department of Veterinary Diagnostics and Production Animal Medicine, Lloyd Veterinary Medicine Center, College of Veterinary Medicine, Ames, IA, USA

Introduction

Cow-calf operations that optimize their cost of production and production efficiency should remain competitive through the next cattle cycle [1–3]. There are multiple factors that affect production efficiency of the cow-calf enterprise, but the reproductive performance of the breeding herd plays a key role in sustained profitability. Measures such as pregnancy rate, calving percentage, calving distribution, and percentage calf crop all affect pounds weaned per exposed female. Reproductive and calf performance measures are highly correlated as the level of reproduction of the breeding herd has a direct impact on the number of calves weaned, their age at weaning, and their weaning weight. It is critical that disease and management factors having a negative impact on reproductive efficiency are identified and corrected to ensure optimum productivity of the operation.

Over the years, the process of evaluating reproductive performance in beef herds by veterinarians has been well described [2–4]. Whether referred to as a breeding season evaluation, reproductive profiling, or "pregnancy analytics," this process requires that the producer provide or the practitioner construct adequate herd records to facilitate production evaluation and problem identification. By comparing the current level of production to historical trends on the ranch or known benchmarks of similar operations, needed changes in herd management can be identified and cost-effective solutions implemented. Once this process is in place, annual evaluations become easier to perform and historical trends are identified to document progress and prevent future losses.

Data Collection

The usefulness of available herd information is totally dependent on its accuracy and its relationship to meaningful reproductive performance measures [2, 4]. Data not meeting these criteria are not useful and only make the analysis more difficult for the practitioner to perform. Surveys indicate that as herd size becomes larger, producers are more apt to utilize individual identification in cows, keep production records, and capture that data electronically [5]. However, many smaller operations are capturing data using well-organized hand-written templates. If records are incomplete or inaccurate, it may be more productive for the practitioner to help design a system to fit the needs of the operation. Regardless of the system used to capture data, it is only useful if records can be analyzed and used to make management decisions.

The concept of "event management" has been described as a means of collecting production data, programming herd health services, and providing opportunities for client education [6]. There are major events that occur on an annual basis in the management scheme of any cow/calf operation. These events are repetitive and cyclical, and will follow each other in succession. Examples of major events include calving, branding, and grass turnout, the breeding season, summer calf management, fall weaning, and pregnancy examination. From the standpoint of the client and practitioner, these events represent extensive investments in labor, commodities, and services that are needed to manage the herd at these particular points in time. It is also an opportunity to establish a system to capture important production parameters and inventory numbers to be used for

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

evaluation of herd performance. These numbers may be collected as animals come through the chute, written on clinic invoices, or recorded by the producer and provided to the practitioner for evaluation. This is where the breeding season analysis starts – capturing inventory and production numbers at particular points in time that are driven by herd management procedures.

The production numbers required to begin any analysis have been discussed in depth in other publications [2, 3, 7]. It is important to begin with "the end in mind" before data are collected to ensure that important parameters are tracked so the analysis can be completed. Many of the indices used to evaluate performance are ratios, so these numbers need to be identified and prioritized in any data collection system. As groups of breeding females are processed, their identification number, age, breed, body condition score, pasture location, and estimated days pregnant should be recorded. Additional numbers such as frame score and body weight can be utilized provided they are captured at the speed of processing and will be used to evaluate reproductive performance. Reproductive performance of individual breeding groups within the operation should be evaluated and compared as well. This allows the practitioner to better understand where reproductive shortfalls are occurring based on factors such as breeding group, cow age, or a particular pasture.

The bull battery represents the other half of the reproductive equation. Bull ID number, pasture assignment, length of the breeding season, and prebreeding soundness examination results should be available to the practitioner in the event of decreased reproductive performance [2, 4, 8]. Bull selection is critical if producers are to match the genetic base of the cow herd with the forage base on the ranch. Ensuring bulls are selected for needed calving ease, growth, and carcass characteristics will optimize calf survival and value. Bulls must also be evaluated for structural correctness and need to monitored to ensure that they are servicing females during the breeding season. The ability of the bull battery to get females pregnant early in a limited breeding should never be overlooked as a means of increasing herd reproductive performance.

Weaned calves are the primary income source for cow-calf operations, while weaning percentage, feed costs, and depreciation costs are important indicators of profitability [1, 2, 4]. Larger operations that market heavier calves tend to be more profitable as well. The length of the calving season and calving distribution will have a huge impact on weaning weights due to their effect on calf age at weaning [2, 4, 9]. Calves tend to gain at a consistent rate during the suckling period, so it is not surprising that calves born earlier in the calving season will be older and heavier at weaning. The weaning weight difference between early- and late-born calves from the same herd has been shown to favor the older calves by as much as 80–120 lb [2, 9]. It has also been shown that early calving heifers had significantly improved productive longevity compared to their later calving herdmates [10]. Producers commonly record the individual birth dates of calves, so this may serve as a starting point for program analysis. It is critical that the practitioner help clients understand this relationship between reproductive performance, calf weaning weight, and female longevity when evaluating production shortfalls.

The nutritional management of the cow-calf operation is critical to reproductive success of the breeding herd [2–4]. In addition, the cash cost associated with feeding the cow herd represents the largest annual expenditure for most operations. The nutritional management of the herd can be monitored using body condition scoring at critical times that match the female's production calendar [11, 12]. Body condition should be evaluated at pregnancy examination, 60 days prior to calving, at prebreeding, and before the start of any supplementation program. It should also be monitored through the grazing season to ensure breeding females are maintaining condition. Nutritional monitoring not only gives a current estimate of how the herd is being managed but also provides a baseline to identify potential nutritional shortcomings and needed feeding changes before the next production event. Body condition scores should be stratified across different management groups (age, breed, pasture location) in order to evaluate the impact of nutrition on reproduction across the entire herd. Females in poor body condition can be sorted and segregated into a single group and fed to gain needed weight. Nutritional management and monitoring are critical to maintain adequate reproductive performance and calf health, and identify the best way to allocate expensive feed resources.

Analysis of Herd Records

When evaluating the success of the breeding program, a traditional measure that is commonly used is pregnancy percentage. This measure is calculated by taking the number of animals pregnant in the individual group or herd and dividing it by the number of exposed females. While this measure is easy to calculate and has some value, it gives no additional insight into important factors such as the length of the breeding season, bull to female ratios, grazing conditions, or cow characteristics within the group. A more complete analysis of herd performance would enable the veterinarian to evaluate when individual cows became pregnant and the percentage by each estrous cycle. This type of analysis could also begin with calving dates stratified by 21-day intervals through the length of the calving season. A complete evaluation of herd reproductive and calf performance will also take into consideration

the replacement heifer program, the herd's nutritional status, and bull characteristics [2–4, 7, 8]. This type of analysis will lead to a better understanding of production shortfalls and the needed intervention strategies to correct them. It also leads to clear lines of communication to ensure that needed changes are carried out.

If accurate production records already exist, variations in female reproductive performance can be assessed by cow age, breed, frame score, and body condition score [2–4]. However, in the author's experience it is common to work with producers that realize there is a production shortfall (reproductive or calf performance) but have little in the way of useful documentation to aid the practitioner in their analysis. In these cases, it is incumbent that the veterinarian work with the producer to design a system that captures the needed information and is simple to use. Well-organized hand-written records will nearly always suffice to begin data collection.

Data collection must fit the normal working pattern on the ranch, whether those events are associated with breeding female management or calf working [6]. Two common events often provide the first opportunity to begin data collection – the beginning of the calving season or herd pregnancy examination [2, 4]. If the producer can capture birth dates, inferences can be made as to length of the previous breeding season, the pattern of conception, and expected weaning performance. The producer should also record the number of females and their calves turned out to grass for the breeding season that follows. If data are first collected at pregnancy examination, the veterinarian can evaluate the overall success of the breeding season and the pattern of conception, and utilize body condition scoring to establish a baseline for the nutritional management of the herd. The number of calves weaned and their weights (either individual or group) would be captured at this time as well. This type of record system is event and animal inventory driven and can be used as a starting point to begin benchmarking herd performance.

A set of easily defined production benchmarks is given in Table 44.1. In order to calculate these measures the producer is required to collect only nine inventory or production numbers throughout the course of the year [13]. All of these numbers are associated with major management events that take place in most cow-calf operations and oftentimes the practitioner is present to deliver a component of the health program. These measures are meant to act as a starting point for the producer and veterinarian to begin the process of herd evaluation. While these benchmarks are certainly not all inclusive, they do represent economically important reproductive and calf performance measures that can affect profitability of the ranch.

Pregnancy percentage is one of the most commonly used benchmarks to evaluate reproductive performance (Table 44.1) [3]. This measure is easily calculated but when used alone is of limited value. Pregnancy percentage does not provide any additional information in terms of when conception occurred (fetal age), the length of the breeding season, or the distribution of the pregnancies. It is also important that this measure is based on the total number of females that were exposed for breeding during the previous breeding season. Failure to account for female inventory changes during breeding or being unable to palpate all exposed females may affect the overall accuracy of this benchmark. It is much more useful when combined with calving or pregnancy distributions to better evaluate reproductive performance.

Table 44.1 Production evaluators of reproductive and calf performance.

1) Pregnancy percentage = (number of pregnant cows/exposed females) × 100
2) Calving percentage = (number of females with full-term calf/number expected to calve) × 100
3) Calf death loss percentage
   - Calving season death loss = (number of dead calves during calving season/number of females with full-term calf) × 100
   - Suckling calf death loss = (number of calves weaned/number turned out to grass) × 100
4) Weaning percentage (calf crop percentage) = (number of calves weaned/exposed females) × 100
5) Pounds weaned per exposed female = (total pounds of weaned calves/exposed females)

Source: [13].

Calving percentage is important in evaluation of the overall herd health and nutrition program. This measure is directly related to the level of fetal wastage occurring after females are determined to be pregnant. The inverse of this measure would be the late-term abortion rate. When attempting to determine the level of late-term abortions, it is important to identify cows that were called pregnant but failed to calve. With this benchmark, all full-term calves are included in the numerator even if they are stillborn. The number expected to calve is based on the pregnant female inventory present on the ranch at the beginning of the calving season. Depending upon the culling criteria of the ranch, both pregnant and open cows may be culled prior to the start of calving. Therefore exposed females are not used to calculate this benchmark.

The calf death loss benchmark is divided into two different periods (Table 44.1). This is because it is important to determine if mortality is occurring during the calving season or suckling period. Since the cause of mortality varies depending upon the age and production stage of the calf, understanding when death loss occurs is critical to the establishment and refinement of the herd health program. For death loss during calving, only full-term fetuses are counted in order to differentiate this measure from

late-term abortions. Mortality during the suckling period can be captured with two inventory measures that require counting the calves turned out to grass after calving and those calves present at weaning.

The last two benchmarks in Table 44.1 provide an evaluation of weaning performance and are highly correlated with ranch profitability [1, 2, 4]. Weaning percentage or percentage calf crop compares the number of calves weaned to the number of females exposed to produce those calves. Pounds weaned per exposed female requires that either group or individual weaning weights be recorded, totaled, and then divided by the number of exposed females. Both of these measures are affected by reproductive performance, calf mortality, bull selection, calf growth rate, animal health, and the nutritional management of the cow herd. These measures give an overall assessment of how successful the operation is in maximizing saleable pounds and income. While acceptable levels of production will vary by location and operation type, reasonable benchmarks for US mid-western herds are given in Table 44.2 [7, 13].

Once pregnancy data and calving records are collected, it is possible to construct distributions or histograms [2–4]. These figures exhibit the number of pregnancies or calvings that occur in each 21-day period of their respective seasons. Fetal aging at the time of pregnancy examination is required in order to construct the distribution. Pregnancy distributions should be built for the entire herd and then broken down into specific management groups based on breed, age, body condition score, or pasture location, as deemed necessary by the practitioner [2]. Reasonable targets for mature cows (4–8 years old) using a limited breeding season (45–75 days) include having at least 60% of the females conceive in the first 21-day period and less than 10% open (Figure 44.1) [2, 3, 7]. These targets may vary with different female groups or environmental conditions. Ideally, calving distributions would have more females in the first 21-day period since open cows would not be counted.

A prolonged breeding season often accompanies poor reproductive performance in herds without a routine herd health program (Figure 44.2) [2]. This type of "back loaded" distribution has nearly half of the females delaying conception until after 63 days of the breeding season or remaining open. This distribution may be caused by poor nutritional management, especially when found in young cows. Other factors contributing to this profile could be reproductive pathogens that are causing fetal wastage early in gestation [14]. When evaluating these herds, the practitioner should emphasize those factors that influence conception in the first 21-day period. Body condition scoring prior to breeding and at pregnancy examination will help to rule out nutritional mismanagement. If reproductive disease is suspected, combining pregnancy or calving distributions with information gleaned from the calculated calving percentage and calf mortality will aid the practitioner in determining when losses are occurring. This will give insight to the possible pathogens involved and guide the diagnostic protocol [14].

Table 44.2 Suggested production benchmarks for mid-western herds.

Pregnancy percentage	≥90
Calving percentage	≥97
Late-term gestational loss (%)	≤3
Total calf death loss (%)	≤5
Weaning percentage	≥85
Pounds produced per exposed female	≥500

Source: [13].

The prolonged breeding season depicted in Figure 44.2 will also negatively affect calf weaning performance. The end result of delayed conception and prolonged calving will be calves that weigh less at weaning due to their younger age. These calves will be very uneven in size and body weight, which will decrease their total value [2, 4]. Developing replacement heifers will also be difficult due to the wide range of weaned heifer ages and weights. By helping producers understand the relationship between reproductive performance and calf weaning weight, the practitioner is in a position to recommend cost-effective management changes that will impact ranch profitability.

The pregnancy distribution depicted in Figure 44.3 is not uncommon following bull failure in smaller operations that use single-sire mating groups [2]. The breeding season began well, but female conception ended abruptly. This is commonly the result of a bull injury or the dominant bull becomes subfertile and prevents other bulls from breeding cows. This injury may be a lameness issue but it is often associated with a penile hematoma or preputial laceration. Unfortunately, in many cases, the breeding season is lost by the time the injury is discovered and the bull replaced. Extreme environmental temperatures that cause the bull battery to decrease breeding activity and seek shade may also give this type of distribution. This effect may be amplified in those operations that utilize fungus-infected fescue pastures as the dominant forage. The combination of extreme environmental temperature and heat retention due to fescue grazing will decrease semen quality and libido of the entire bull battery. This will also be a concern when young, overconditioned bulls that have been developed in dry lots on high concentrate rations are turned out for pasture breeding.

Regardless of the form or relative complexity, the purpose of a breeding season evaluation is to define production problems and put in place management solutions. Accurate historical production records must be provided by the

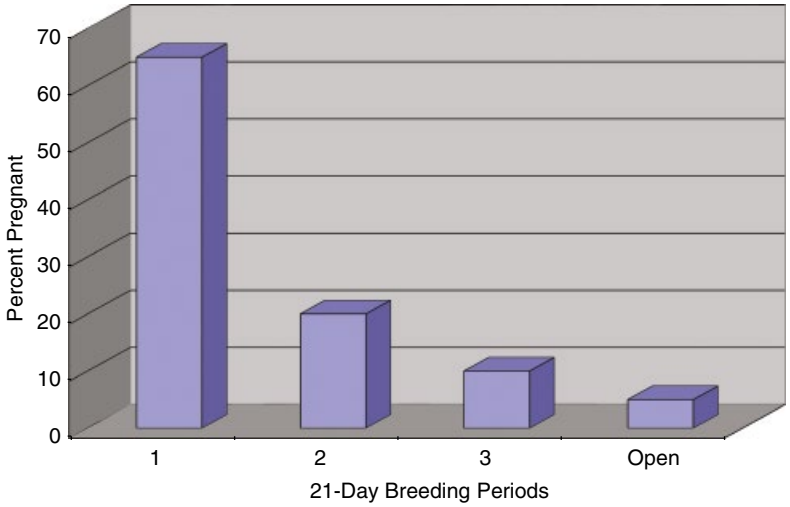

Figure 44.1 Pregnancy distribution showing percentage pregnant by 21-day periods.

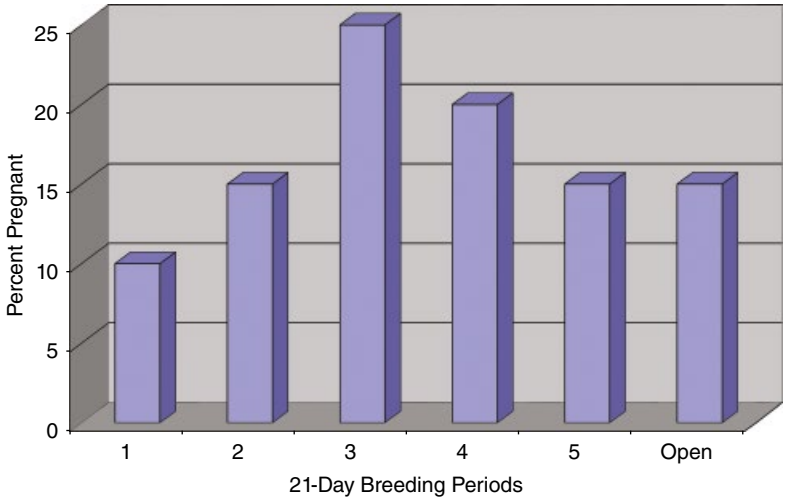

Figure 44.2 Pregnancy distribution depicting a prolonged breeding season, poor conception rate per 21-day period, and a large number of open cows.

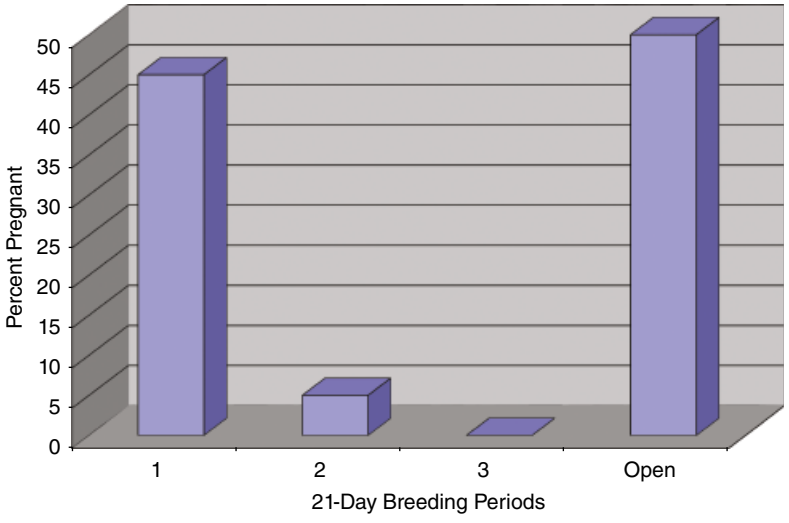

Figure 44.3 Pregnancy distribution in a spring-calving herd following multiple bull failure.

producer or designed by the practitioner to ensure the collection of clinically relevant data. Definition of the problems will include not only the magnitude of the production loss but also which management group on the ranch is affected. The etiology of the production shortfall, whether management or disease related, must be determined. Then management strategies are devised and put in place to ensure a return to optimum productivity of the breeding herd and their offspring. Monitoring of herd production is continued on an annual basis to make sure that the herd is meeting the critical benchmarks as defined by the producer and practitioner. This type of program ensures proactive monitoring of herd performance and increased profitability of the cow-calf enterprise.

Summary

Reproductive efficiency of the breeding herd is an important component that drives ranch profitability. Optimal reproductive performance is not strictly a function of the absolute number of cows that become pregnant, but also includes the timing and distribution of those pregnancies. Because weaned calves marketed represent the primary source of income for these operations, it is critical that the relationship between herd reproduction, weaning percentage, and weaning weight be emphasized to the producer. The success or failure of the breeding season and calf crop can be affected by a wide array of management and disease factors. The practitioner is often asked to provide input on problem identification, trend recognition, and cost-effective solutions. This process is made much easier if the producer can provide accurate records that are current and track clinically relevant outcomes. Once management strategies are put in place to correct a production shortfall, these records become a vehicle that allows for the annual evaluation of changes in herd productivity. This type of program will become very important to these operations, giving veterinarians a unique opportunity to provide this type of service to these clients.

Dairy Herd Record Analysis

Robert Lynch

College of Agriculture and Life Sciences, Cornell University, Ithaca, NY, USA

Introduction

Reproductive efficiency is a key driver to dairy performance and profitability. Dairy managers should keep sufficient records to provide an understanding of various components of the reproductive program. This chapter will discuss the justification for records analysis, general principles for conducting an analysis, and explore various components of both the adult and heifer reproductive programs. Before analyzing a dairy's records, there should be a clear understanding of which questions the user wants answered. Specific reasons to analyze dairy reproduction records include the following: to monitor herd performance, troubleshoot performance issues, and collect research data (this last item will not be discussed in this chapter).

Records monitoring should be part of the herd veterinarian's oversight responsibility. Monitoring involves a check on both how well farm personnel are following protocols and how well the program is performing. Records can also be monitored periodically to check on a dairy's progress toward predetermined goals. *Monitoring example: Metritis incidence will be monitored monthly and an investigation to identify risk factors contributing to an increase will be started if it rises above 15%*. Goals should be specific, relevant, realistic, and should result in improved farm profitability or help to meet other business objectives. Goal setting should not be confused with benchmarking. *Goal setting example: Inseminate 60% of first service breeding eligible cows by observed estrus prior to the start of the timed artificial insemination (TAI) protocol without lowering fertility by [date].* Benchmarking involves the comparison of performance metrics to other farms or industry averages. Provided the benchmarks are relevant to the dairy, a comparison to other farms might help inform the management team when setting their goals. Use caution when doing this as some benchmarks may not be appropriate for the dairy. The farm may already be performing above its peers or industry average in an area, but additional profit could be gained by further improvement. Alternatively, the dairy might be performing far below a benchmark and improvement in this area will take a long time. Setting a lower, more realistic goal with a timeline for achievement would be more useful. The range seen in the reproductive metric averages shown in Table 45.1 highlights the importance of establishing farm-specific goals. Finally, a benchmark simply might not apply to the dairy or might be calculated differently among the comparators.

Troubleshooting involves a thorough investigation of a specific problem or performance concern and often is aided by analyzing dairy records. The prompt to investigate a problem can originate from herd monitoring or elsewhere. Knowledge of the dairy's production history, demographics, protocols, day-to-day operations, and long-term goals can help guide the analysis. *Troubleshooting example: Concern over a recent decline in conception rates lead to a review of farm records which showed the decline was coming from first service TAI breedings. TAI protocols were reviewed with the repro crew and uncovered a change in when cows received their hormone treatments which did not align with the farm's protocol*. Advisors without this knowledge should review these topics with farm management. An understanding of production history and herd inventory management can be gained from the records. A proper analysis should first confirm the issue exists, quantify its impact on overall herd performance, and then attempt to more narrowly define the problem.

Before any analysis can begin, a review of data quality is essential. This should be completed by discussing both the data entry practices of the farm staff and whether entered data are complete. Any analysis should be postponed until missing and incorrect data can be addressed. The scope of

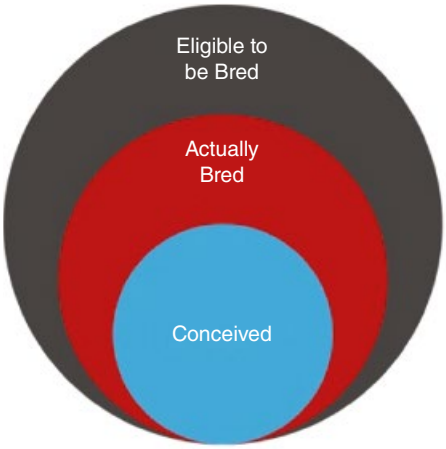
the analysis will be determined by understanding what questions need to be answered and the quantity of the data available. There is a temptation to drill far down into a dataset in an attempt to find answers. Keep in mind the group sizes being evaluated when the data are segmented. As sample sizes get smaller, the more likely random chance can be causing the differences seen in the data. Expanding the time frame of the analysis can help maintain adequate numbers, but will add momentum (historical data influencing an outcome) to a calculation which may delay identifying a problem or miss it all together. Advisors will sometimes need to rely on data without strong statistical power, particularly when working with smaller dairies. In those situations, monitoring farm data for trends can still help inform management as long as there is an understanding that changes could be part of normal variation. Consider using other mathematical tools like medians, statistical process control, and lower confidence intervals when data are limited.



There are several farm management software programs in use on commercial dairies are suitable for data analysis. Examples of herd data tables and graphs found throughout this chapter are intended to allow the reader to become familiar with various outputs from DairyComp and PCDart [2, 3]. The values displayed are not intended to indicate recommended performance metrics. Dairy Herd Improvement Association (DHIA) standard reports can also be useful for evaluating reproductive performance on dairies, particularly the Herd Summary Report (DHI-202) and Reproductive Management Report (DHI-350) [4]. Performance metric calculations can vary from one DHIA center to another, and the advisor should review how metrics of interest are calculated by contacting the dairy's testing service.

Dairy Reproductive Matrices

The basic metrics for evaluating reproductive success on dairies are pregnancy rate (PR), conception risk (CR), also referred to as pregnancies per artificial insemination (P/AI), and heat detection rate (HDR) (Figure 45.1). PR, HDR, and CR averages and standard deviations for dairy herds included in the DairyMetrics DHIA database are shown in Table 45.1. *Example: A group of 100 cows are eligible to be bred over a 21-day period. Fifty of those cows were seen in heat and inseminated. Upon examination, 25 cows were found to be pregnant. The HDR would be 50% (50/100), the CR would be 50% (25/50), and the PR would be 25% (25/100).*

Example pregnancy, heat detection, and conception rate tables from DairyComp and PCDart are shown in Figures 45.2–45.4. These values can also be found on the DHIA Herd Summary report (DHI-202).

Although it is helpful to know how these metrics trend for a dairy, they lack enough specificity to be useful from a management standpoint. Breaking the reproductive program down into a few components will help the advisor

$$PR = \frac{\text{\# pregnancies generated over a 21-day period}}{\text{\# animals eligible for breeding over the same 21-day period}}$$

$$HDR = \frac{\text{\# animals inseminated over a 21-day period}}{\text{\# animals eligible for breeding over the same 21-day period}}$$

$$CR = \frac{\text{\# pregnancies generated form a group of inseminated animals}}{\text{\# animals inseminated}}$$

understand what is contributing to, or detracting from, the dairy's reproductive efficiency. These components are voluntary waiting period (VWP), first service estrus detection (FSED), first service timed artificial insemination (FSTAI), second and subsequent service estrus detection (SSED), second and subsequent service timed artificial insemination (SSTIA), and do not breed (DNB) policy (Figure 45.5).

A review of the farm's records should inform the advisor of both how well employees are adhering to the protocols related to each of these components (*compliance*) and how each component is working (*efficacy*). It may be beneficial to break down a dairy's reproductive program into more components, but this should be limited to where management corrections would be possible. Use caution when filtering data as bias may lead to erroneous results. Setting different goals for first lactation cows and all other cows might be appropriate. Some dairies have different VWP and/or reproductive programs for first lactation cows and all others. Also, first lactation cows tend be more fertile in general compared to older cows. A separate analysis for these groups can be informative as long as group sizes are large enough for meaningful calculations.

Not all components mentioned above will apply to every dairy. For example, a herd with a 100% FSTAI program will not have FSED to evaluate, unless employees did not follow the farm protocol and actually did breed cows observed in estrus prior to their scheduled TAI. A dairy breeding entirely on observed estrus will not have FSTAI or SSTAI fertility to evaluate. The data in Table 45.1 show the average PR, conception rate for first and second + services, and average HDR from DRMS DairyMetrics.

Voluntary Waiting Period (VWP)

There are often two different VWPs on the dairy. The stated VWP (sVWP) is what management has determined to be the minimum days in milk (DIM) a cow must be before she is breeding eligible. The actual VWP (aVWP) is when cows are bred for the first time. This can be visualized by plotting the herd's first breeding events by date and DIM (Figure 45.6). The *a*VWP can be determined by estimating the DIM when approximately 5% of the cows have been inseminated for the first time [5]. If these two periods are different, first service breeding protocols need to be

reviewed with the farm employees. Knowing the dairy's *a*VWP will also allow for more accurate heat detection and PR calculations.

First Service Estrus Detection (FSED) Breeding

For a dairy utilizing estrus detection to inseminate cows when they become breeding eligible, it is helpful to know both the proportion of eligible heats that are detected and which of those inseminations resulted in a pregnancy. Herds managing this program well will breed 50–80% of cows prior to FSTAI with conception rates ranging from 30 to 45% (Table 45.2). First service breeding success can be evaluated in the records like the example herd shown in Figure 45.7.

First Service Timed Artificial Insemination (FSTAI)

Regardless of the TAI protocol used by the dairy, checking that the protocol steps are occurring on the correct days can reveal deviations (Figure 45.8). Fertility to FSTAI pro-

tocols can range from 24 to 60% P/AI (Table 45.3). Consider the differences in trial designs when comparing their results to a commercial dairy's data. Were the protocols started at the same DIM or days after the last breeding? Were the number of hormone treatments and timing between treatments the same? Were cows bred if seen in heat and excluded from the TAI protocols or not? Were pregnancy examinations done around the same number of days after breeding?

Herds doing well breeding cows on first service based on observed estrus tend to have slightly lower P/AI for the cows making it to TAI when compared to herds managing first service with 100% TAI. This is partly due to a lower proportion of fertile cows inseminated by TAI and the availability of TAI protocols that maximize fertility when estrus detection is not a priority.

Second and Subsequent Service Estrus Detection (SSED) Breeding

Dairy herds willing to invest time and resources to breeding cows seen in heat after first insemination can breed between 65 and 75% of eligible cows and achieve P/AI in the range of 30–41% (Table 45.2). The wide range in heat detection efficiency displayed reflects the many variables that can influence estrus behavior including the interval between the previous breeding and the initiation of the next TAI protocol.

A check on the distribution of days between breedings should show a concentration of breeding activity around the typical estrus cycle length (Figure 45.9).

Second and Subsequent TAI (SSTAI)

The farm's management preference will dictate which, if any, TAI protocols are used for cows found to be open after their previous breeding. The example herd shown in Figure 45.9 enrolls cows for resynch to occur at either 42 or 49 DSLB. Research trials have demonstrated that resynchronization protocols can achieve from 22 to 43% P/AI (Table 45.4) and can be evaluated in the herd records (Figure 45.10). The proportion of cows bred to a resynch protocol will range from a low 20% all the way up to 100% for farms not utilizing estrus detection at all.

Do Not Breed (DNB) and Culling

There comes a time when a milking cow is no longer profitable to keep in the herd. Every dairy should set and review herd removal policies to maximize profitability. Herd records can be monitored for compliance to the DNB and culling policies.

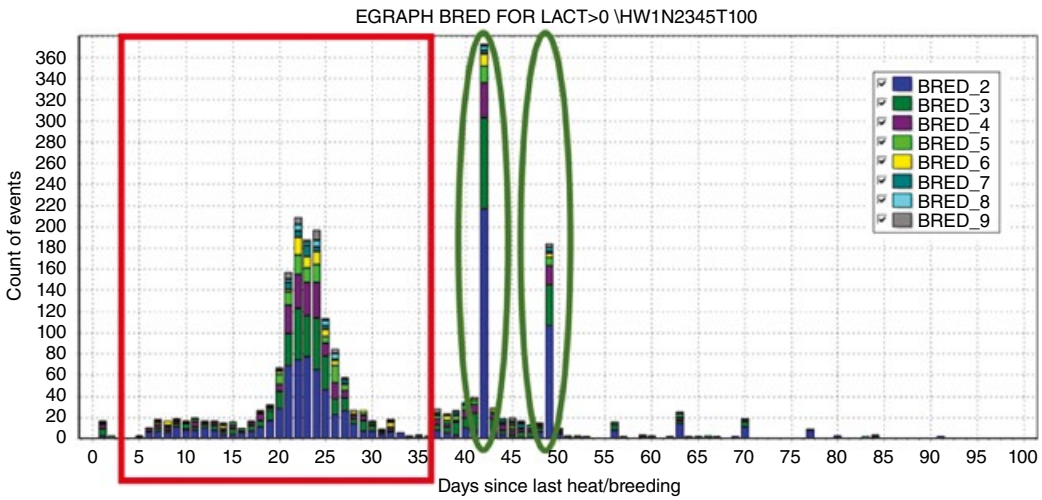

Figure 45.9 Days since last breeding (DSLB) histogram. Area in red shows the proportion of breeding events that occurred prior to a resynch protocol, which for this herd is approximately 60%. This chart also shows the farm's resynch breedings (green ovals) occurring at 42 and 49 days since last heat (DSLH) (DairyComp, EGRAPH, Example Herd Data).

Other Reproductive Analyses

Breeding Interval

A breeding interval analysis groups conception results by a series of ranges in days between the previous breeding (Figure 45.11). The majority of breedings should occur in the 18- to 24-day range, a typical estrus cycle length. Dairies can generally keep the percentage of breedings occurring in the 4- to 17-day range to less than 10% (Table 45.5). The fertility to these breedings tends to be low and a higher percentage of breedings in this category may be an indication of inaccurate heat detection. Dairies with greater than 15% of breedings occurring greater than 48 days after the previous breeding should improve heat detection efforts and/or identify open cows and re-enroll them in a breeding protocol sooner (Table 45.5).

Technician Effect

The technician responsible for breeding cows should be identified in the records (Figure 45.12). Use caution when comparing the fertility of breedings between technicians. Breeders are often inseminating different groups of cows. *For the example shown in Figure 45.12: Technician 01 only breeds cows seen in heat by weekend staff, Technician 07 does all the synchronized AIs, and Technician 10 only breeds cows still open after three breedings, i.e. "problem cows." These technicians are breeding different cows from a fertility and heat detection accuracy standpoint*. In addition, some technicians may have bred very few cows during the analysis period.

Table 45.5 Summary of breeding interval herd data from 37 dairy herds with a median herd size of 1000 milking cows.

Measurement	Median value
Pregnancy rate (standard 50-day VWP)	24%
Breedings 4–17 days	9%
Breedings >48 days	10%

Weekly/Monthly/Seasonal Analysis

Depending on herd size, tracking CR by week, month, or season can identify significant deviations in overall fertility (Figure 45.13). Identifying a real change in overall CR is not specific, but things like semen storage or handling problems will affect all breedings. Heat stress effects on herd fertility can be seen as well.

Advanced Breeding Technologies

Some dairies utilize embryo transfer (ET), *in vitro* fertilization (IVF), and ovum pick-up (OPU) protocols. It is helpful to understand how well these strategies are working and their impact on overall herd reproductive efficiency. Farms using these technologies sparingly will not likely see a significant change in their overall reproductive efficiency. Farms breeding a large number of their animals as part of an ET program could see a decline in reproductive efficiency. For example, delaying the breeding of a group of heifers to ensure an adequate number of good embryo recipients will be available for an upcoming flush will, by definition, lengthen the age at first breeding and lower the HDR among those heifers.

Transition Cow Health

Fresh cow health conditions, particularly metritis and ketosis, can lead to poor reproductive performance. The dairy should record disease events consistently based on case definitions in order to make analysis of these data possible.

Dairy records can be used to calculate monthly disease incidence (Figure 45.14). The population at risk would be the cows that calved in the month of interest. The most recent month to be included should be one in which all the cows have completed the risk period. The example shown in Figure 45.15 shows the monthly metritis incidence over the previous year. The date range was selected to include only cows 15 DIM or more, since puerperal metritis typically occurs in the first 14 DIM and cows less than 15 DIM have not completed the risk window and could still have a metritis event. The exception to this is for animals removed from the herd prior to completing the risk period due to the disease of concern. When evaluating disease incidence, the user should select a time period that includes as many cows as possible to increase accuracy, but not over such a prolonged period of time that the calculation is no longer meaningful. If it will take several months to compile enough health event observations to allow for 95% confidence in the result, identification of a problem could be delayed, leading to additional expense to the dairy.

$$\text{Disease incidence} = \frac{\text{Number diseased in the at-risk population}}{\text{Number of the at-risk population}}$$

Figure 45.14 Calculating disease incidence.

Milk Quality/Mastitis

The dairy industry has understood for many years that cows with high somatic cell counts or clinical mastitis early in lactation are at risk of poor reproductive performance. The records review should include an analysis of the milk quality related data. Evaluating new subclinical infection risk, chronic subclinical infection, and clinical mastitis rates on a routine basis can not only help the dairy identify opportunities to improve its milk quality, but also result in reproductive improvements.

Dead on Arrival (DOA)/Calving Difficulty

Monitoring for calvings labeled "dead on arrival" (DOA) and calving difficulty can identify calving pen issues to be addressed by the veterinarian (Figure 45.16). Not only can dystocia lead

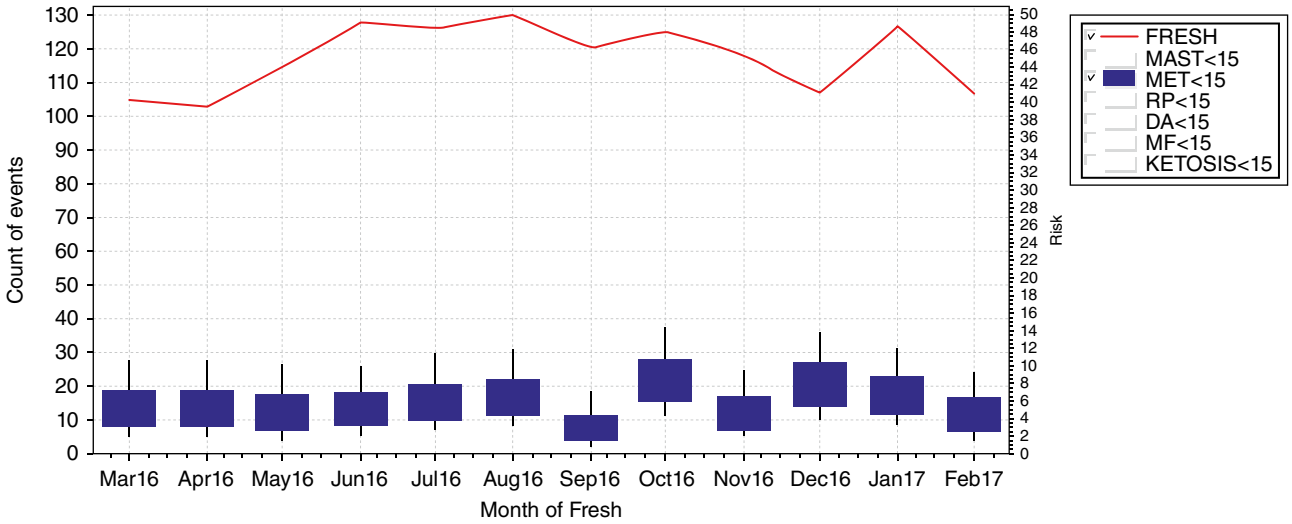

Figure 45.15 Monthly incidence of fresh cow disorders – limited to metritis events occurring prior to 15 DIM. to future breeding problems, but also it may result in fresh cow disease, poor milk production, and premature removal from the herd. Encouraging the dairy to record this information in a consistent manner will allow for routine analysis.

Lameness

Lameness can be a costly health problem for some dairies and can detract from a herd's reproductive efficiency (see Chapter 42). Dairies should keep adequate records to inform management on the incidence and causes of lameness. Records should separate new lame events from routine trims, rechecks, and chronic lameness. The herd advisor should monitor the records for lameness treatment rate (number of limb cases per hundred cows) trends, predominant lesions, DIM patterns, and lactation differences [41]. Understand that lameness is often underreported and should be cross-referenced with periodic locomotion scoring [42].

Abortion

Estimating abortion rates and setting goals for a dairy is difficult to do. The dairy industry has calculated abortion rates in several different ways. A true abortion incidence is calculated by dividing the total number of observed pregnancy losses by the total number of pregnancies created over a defined period of time (Figure 45.17). To be accurate, the time period analyzed should be chosen to ensure

$$\text{Abortion incidence} = \frac{\text{Number of abortions occurring during the defined risk window}}{\text{Number of pregnant cows past the defined risk window} + \text{Number of abortions occurring during the defined risk window}}$$

Figure 45.17 Abortion incidence calculation.

$$\text{Abortion prevalence rate} = \frac{\text{Number of pregnancies lost over a period of time}}{\text{Number of pregnancies generated over the same period of time}}$$

Figure 45.18 Crude abortion rate calculation.

all cows included will have completed the risk window. Abortion risk exists throughout gestation, making this value inherently lagged as most of the pregnancies will have been lost several months prior to the calculation. This risk window can be narrowed if the majority of pregnancies lost on the dairy occur early in gestation, which is often the case. For dairies that generate pregnancies at a relatively steady rate, calculating a crude abortion rate can inform the dairy when making decisions to investigate a potential emerging abortion problem (Figure 45.18).

Setting an abortion rate threshold is also challenging since the timing of pregnancy diagnosis and pregnancy reconfirmation will dramatically change the observed incidence of pregnancy loss. The earlier in gestation pregnancy is diagnosed, the higher the "normal" pregnancy loss percentage will be. Also, the longer the interval between initial pregnancy diagnosis and pregnancy reconfirmation, the higher the "normal" pregnancy loss percentage. Research has demonstrated an overall pregnancy loss of 25% from initial diagnosis at 28 days up to expected calving (Table 45.6) [46]. Average late embryonic (days 28–60 gestation) mortality is 12.8%, ranging from 3.2 to 42.7% [47, 48].

Table 45.6 Reported late embryonic loss.

Pregnancy diagnosis (days after insemination)	Pregnancy reconfirmation (days after insemination)	Loss (%) [reference]
30	260	3.6% [43]
28–30	40–54	16% [44]
30	80	4.2% [45]
28	98	20.2% [46]
28	84	7.2% [47]

Flawed Reproductive Metrics

Some traditional reproductive metrics should be avoided since they will not provide meaningful information to the dairy. Calving interval (CI) is defined as the time between the current calving date and the previous calving date. Average CI is inherently lagged information and does not include cows that have not calved at least twice; therefore currently open cows are excluded. Days open (DOPN) is defined as the number of days between a cow's calving date and conception date. Average DOPN excludes cows that have not yet been confirmed pregnant and therefore will not provide useful information to the dairy. Services per conception (SPC) is defined as the number of breedings a cow had before conceiving. The average SPC excludes all cows not confirmed pregnant and therefore it is not an accurate reproductive metric.

Replacement Heifer Reproduction

Understanding how well the dairy is managing the reproduction of its replacement heifers is as important as knowing its management of the reproduction of its adult herd. Heifer reproduction analysis can be broken into a few pieces: age at first breeding and calving, voluntary wait (or weight) period, HDR, PR, and CR. The dairy's records should allow for an evaluation of the heifer program's reproductive efficiency and check on compliance to the protocols being used.

Distribution of Age at First Calving

The average age at first calving is often cited as a good number for a dairy to know about its herd. This value is not sensitive enough to be a useful metric for management. Understanding the distribution in age at first calving will help identify the proportion of heifers that did not conceive in a timely manner (Figure 45.19). The economic consequences of a delay in age at first calving for replacement animals can be estimated from these data. Further analysis is needed to understand what is contributing to the delay.

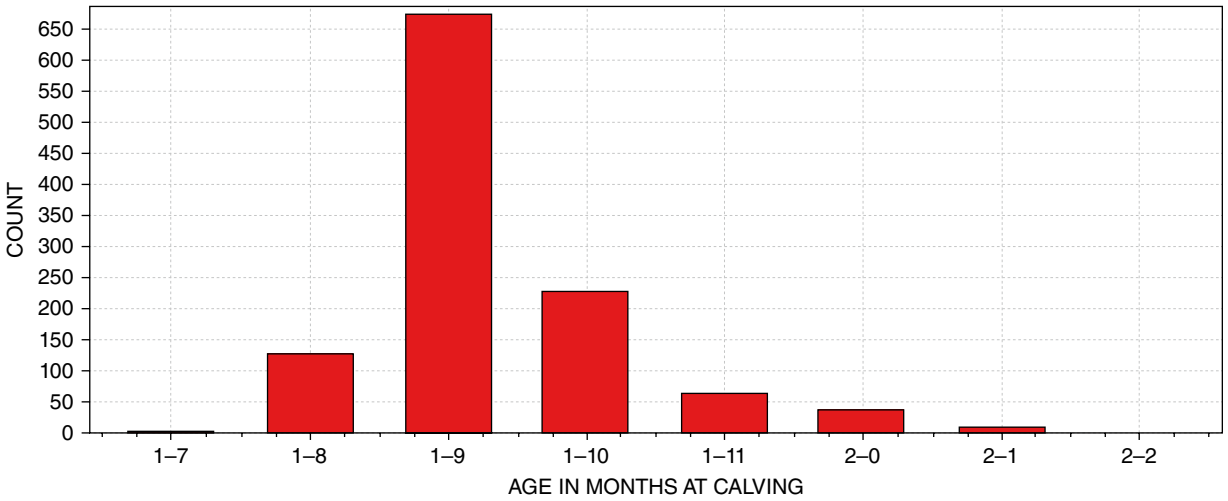

Figure 45.19 Distribution of age at first calving shown in years–months (DairyComp, GRAPH AGEFR FOR LACT = 1, Example Herd Data).

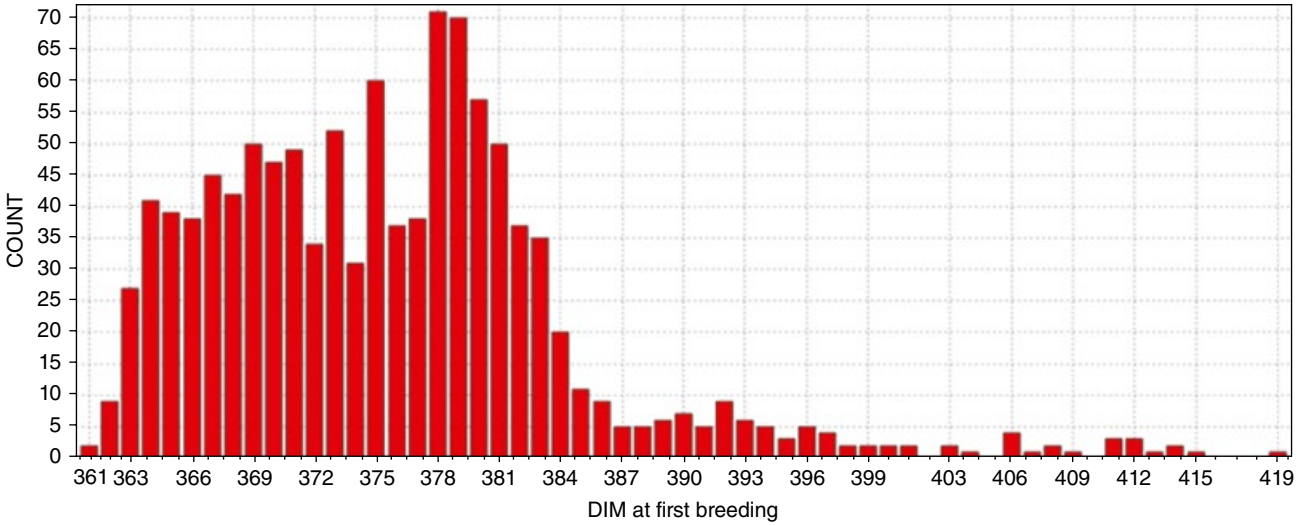

Figure 45.20 Distribution in age at first breeding shown in days of age (DairyComp, GRAPH BRED1 FOR LACT = 0, DIM is actually days of age for this graph, Example Herd Data).

Distribution of Age at First Breeding

The distribution of actual first breeding of heifers will identify the proportion of animals missing the farm's target (Figure 45.20). The delay in breeding may have been intentional or a breakdown in the breeding protocol.

Voluntary Wait Period (VWP)

Heifers should be bred when they reach sexual maturity, which is determined by body weight. When heifers reach 55–60% of their mature body weight, and they will be managed to maintain their target growth rate up to first calving, it is appropriate and financially advisable to begin breeding.

Heat Detection Rate (HDR)

Estrus detection is used by 75% of US dairies using artificial insemination to breed their heifers [49]. Heifers tend to show behavioral estrus very well, so heat detection efficiency goals will be higher in this group compared to adult herds. Well-managed dairies and heifer growers can achieve an HDR of 70–75% and have 90% of their heifers inseminated for the first time by 45 days after entering the breeding pen. Evaluating the farm's HDR based on a 365-day VWP, an age when most appropriately managed dairy heifers could be bred, can uncover intentional or unintentional delays in breeding, leading to unnecessary heifer raising costs. The example herd shown in Figure 45.21 shows the age in days when heifers were bred for the first time.

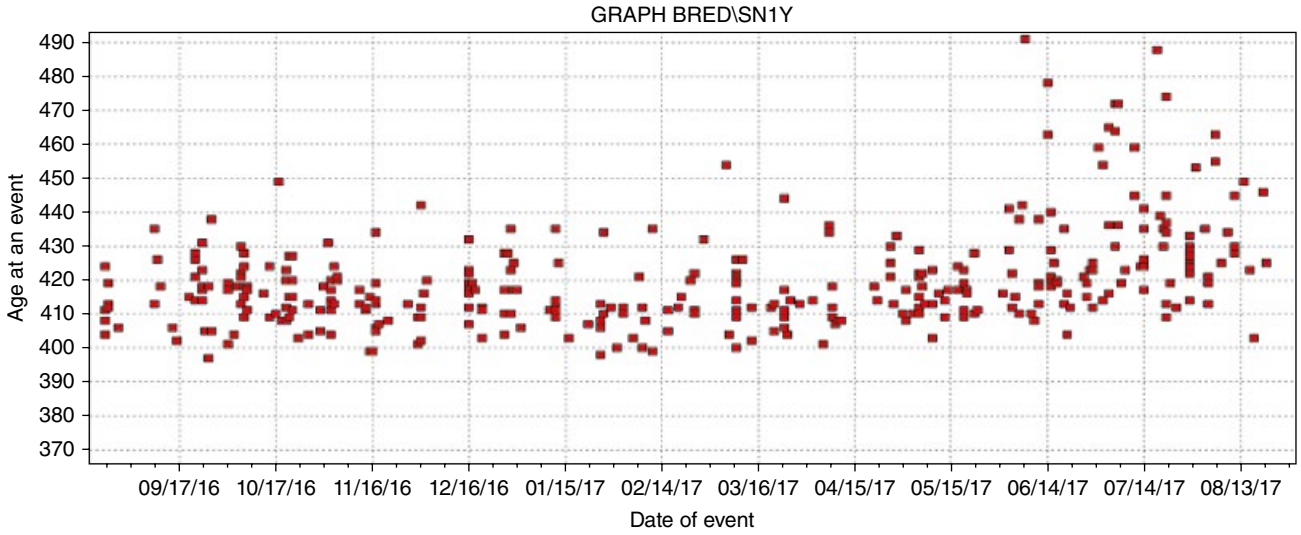

Figure 45.21 Age at first breeding scatterplot. This farm followed a 400-day VWP. Notice the breeding activity shown on the right side of the graph appearing more delayed (DairyComp, EGRAPH, Example Herd Data).

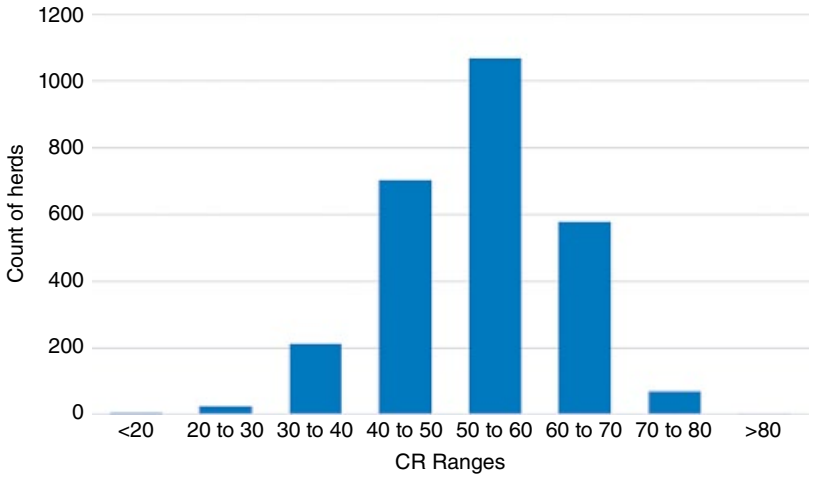

Figure 45.22 Distribution of herd mean CR for heifers bred with conventional semen using least squares mean from a linear model. *Source:* Based on [50].

Pregnancy Risk (PR)

Based on when heifers actually enter the breeding period, PR is the best measure of how effective the heifer breeding program is. The calculation is made the same as in the adult herd. Farms can consistently achieve heifer PRs of 40–50%.

Conception Risk (CR)

Dairy heifers tend to have better fertility than adult cows, so CR goals should be 60–65% when conventional semen is used (Figure 45.22). Research has demonstrated some TAI strategies for replacement heifers can be more profitable for dairies with below-average heat detection efficiency [51]. If heat detection is not feasible in the heifer herd, fixed-time artificial insemination (FTAI) protocols can achieve 50–65% P/AI [52].

Sexed Semen

Sexed semen has been available for many years and its use has been largely dedicated to replacement heifers to both accelerate the herd's genetic progress and minimize the expense by using it in the highest fertility animals on the dairy. Sexed semen technology has progressed since it was first made available commercially and fertility to these breedings is approaching that of conventional semen. Tracking fertility of sexed and conventional semen AI can be informative to management (Figure 45.23).

Semen Type	%	# Bred	# Preg	# Open	Conc %	SPC	Others
Non-Sexed	64	462	291	171	63	1.6	46
Sexed	36	265	133	132	50	2.0	15
TOTAL	100	727	424	303	58	1.7	61

Figure 45.23 Conception risk comparison – heifer breedings to non-sexed and sexed semen (PCDart Conception Tracker, Example Herd Data).

Average Daily Gain (ADG)

Many dairies and custom heifer raisers are routinely weighing their replacement heifers to monitor for optimal growth. These data should be periodically analyzed to identify problems with average daily gain (ADG). Correcting barriers to growth early will minimize issues associated with getting heifers to breeding size at the farm's target age. Remember, management needs to have an accurate average mature cow body weight, which will vary from farm to farm.

Summary of Findings

At the conclusion of a records analysis, it is important to summarize and report significant findings to farm management. This should include corrective measure recommendations to address any problem areas identified. When possible, the financial implications of the problem and costs associated with proposed corrections should be included. Partial budgets similar to the example shown in Figure 45.24 can be particularly useful in this effort.

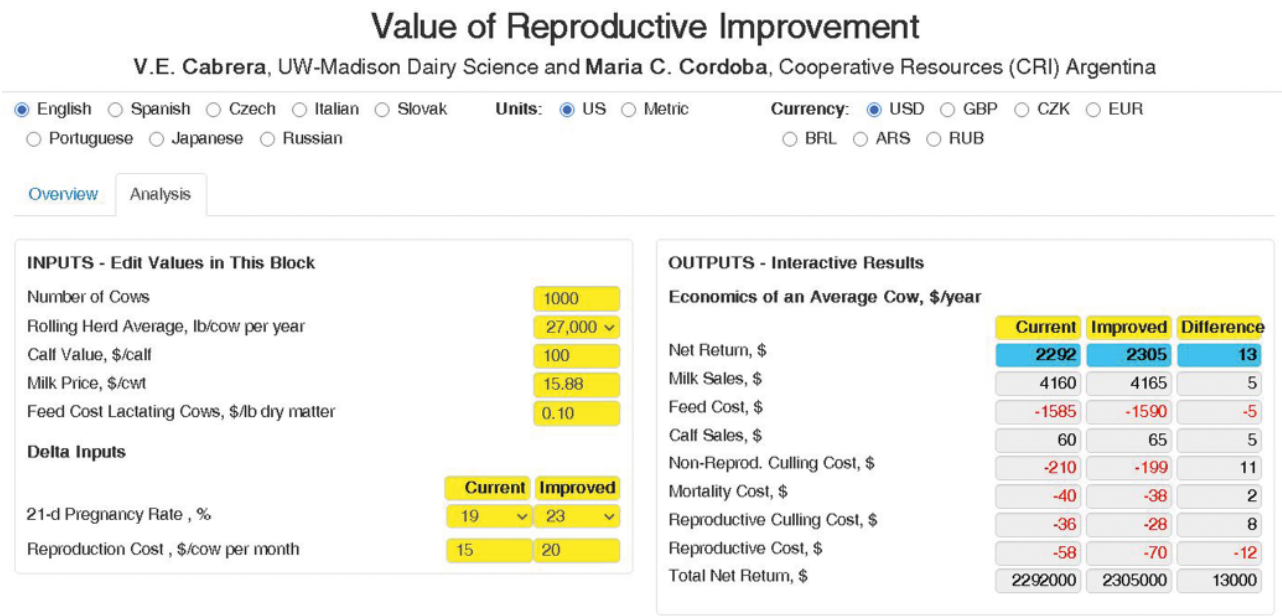

Figure 45.25 Value of reproductive improvement tool. *Source:* From [54].

The economics associated with improvements in reproductive efficiency are difficult to do without complex calculations. To assist with this, several resources are available including the Wisconsin-Cornell Dairy Repro (a reproductive programs economics analysis tool) and the Dairy Reproductive Economic Analysis Tool (Figure 45.25) [54]. With the correct inputs, these modeling tools can perform economic analyses comparing reproductive programs or estimate overall improvements.

If the analysis is part of routine monitoring, the reporting can simply be included as part of the herd health visit. An analysis conducted as part of a troubleshooting effort should be more detailed and documented. The written report can be included in the dairy's management records and shared with the farm's advisors when appropriate. A written report can be particularly useful when follow-up is needed to check on progress toward correcting problem areas, or as part of the historical record informing future investigations.

Summary

An accurate analysis of a dairy's reproductive records can be very beneficial to farm management. Problems within the breeding programs can be identified and corrected early. Goals can be tracked, motivating improvement. An advisor who can provide insight from the farm's records will be valued and play a critical role in the dairy's management team.

Marketing the Bovine Reproductive Practice: Devising a Plan or Tolerating a System

John L. Myers

Pecan Drive Veterinary Services, Vinita, OK, USA

Introduction

Nothing is more common than hearing a veterinarian complain about how little income results from the practice of veterinary medicine. While such a complaint is not limited to the veterinary profession, somewhere in each of these discussions a remedy appears as if it were as simple as turning on a light or repairing a dystocia: marketing is the remedy. When it surfaces as a cure to veterinary poverty there are as many interpretations of what marketing is or does as there are individuals engaged in the discussion.

The goal in these marketing discussions is always profit, when in fact the term "marketing" implies aspects of a business many of which do not necessarily have a direct effect on profitability. A definition of marketing as adopted in 2007 by the American Marketing Association is as follows: Marketing is the activity, set of institutions, and processes for creating, communicating, delivering, and exchanging offerings that have value for customers, clients, partners, and society at large [1]. Perhaps another definition would be that marketing involves obtaining the client, satisfying the client, and retaining the client.

Principles in Marketing

Pursuit of literature about marketing frequently exposes one to the four Ps of marketing:

1) Product
2) Price
3) Promotion
4) Place.

In the context of a bovine reproductive practice, the product to be marketed would be either a service offered or some specific item such as a drug, a feed ingredient, or an instrument. The price is a fee that represents a reasonable profit and would be competitive with other businesses offering the same or similar services or items. Promotion would be those efforts taken to let prospective clients know that the practice is actively pursuing delivering what is for sale. Finally, place would be how the service or item is distributed so that clients can easily obtain the service or item at a time and location convenient to the client.

For this discussion, the assumption will be that the bovine reproductive practice would be offering a service rather than an item, and as such three more Ps come into play:

1) People
2) Physical evidence
3) Process.

There is an intangibility of service. A bull having undergone a bull breeding soundness examination (BBSE) looks much the same after the examination as he did before. A person buying a pickup, however, has a tangible object that was not there before its purchase. Clients therefore make judgments about the service by looking for clues about quality of the service as it is accomplished. This is done by assessing the skill, appearance, and efficiency of all of the people involved in the examination – from the office employees, to the assistants and the veterinarian. The physical evidence of the examination would be the professional quality of any documents such as a certificate, billing charges, and information materials or handouts that are presented after the service is accomplished. The process involves the entirety of the examination from reception of the client, the handling of the bull, the efficiency, availability, and convenience of instruments or supplies, and the adequate presentation of the results resulting from the examination.

A Marketing System or a Marketing Plan

Regardless of the efforts, conscious or not, of any active business, a marketing system exists. Services are delivered, processes and people are in place, and promotion, pricing, and distribution of those services occur whether this system is efficient, reasonable, profitable, or successful. If one attempts to modify the system, efforts toward improvement in one aspect of the business may be detrimental to other aspects [2]. The veterinarian may be quite successful, for instance, in satisfying a client by doing excellent work in a limited number of services, but the efforts do not result in obtaining more clients. If that veterinarian embarks on a strategy of promotion that restricts the dedication to performing the service, there will be no resulting improvement in the marketing system. Likewise, if the veterinarian channels efforts into obtaining and satisfying the client but because of other competitor's superior promotion efforts the veterinarian is unable to retain existing clients, then no progress is made.

A marketing plan should therefore try to address all aspects of the system instead of merely propping up deficiencies that already exist. The resulting balance should result in a more successful, profitable, and enjoyable practice.

Three Pillars of the Marketing Plan

Before one embarks on a plan, three prerequisites must be firmly in place with commitment dedicated to each.

1) *Competence*. It is one thing to desire to operate a practice dedicated to bovine reproduction and quite another to have available the expertise needed to make it successful. Competence cannot be acquired and then left unattended. Dedication to constant study, attendance at quality seminars and conventions, interaction with knowledgeable colleagues, and familiarity and openness to new ideas and techniques are essential for a successful practice and career. This dedication and effort is expensive in both a monetary and temporal significance.
2) *Dedication of resources*. While no program will succeed if adequate funding or resources are not dedicated to it, the amount of resources requires careful consideration. The veterinarian's time is an available resource, although calculating the value of that time is difficult but necessary. Regardless, if a well-balanced and carefully considered plan is in place, the appropriate numbers should be budgeted and documented and, like all budgets, adhered to or altered as necessary.
3) *Comfort with, or at least toleration of, the plan*. Many times marketing plans and schemes will fail because there is not complete acceptance of the proposition. The competence to perform may be in place and adequate financing is available, but there is revolt at the features of the marketing plan simply because they do not lie within the comfort zone of the personality of the veterinarian. Advertising may seem too gauche, speaking to producer groups may be terrifying, and promoting oneself may strike one as arrogance. Toleration of discomfort in the pursuit of a beneficial outcome is the price one pays for personal growth. Abandoning a program because the personal discomfort overmatches any possible benefit dooms the best plans and propositions.

Devising the Marketing Plan

For purposes of discussion, the assumption will be made that a budgetary consideration of 1% of anticipated annual revenues will be dedicated to the marketing plan. This would not be enough in an entity that depends heavily on product sales (such as automobiles or hamburgers), but the 1% figure does fit well within budgets of large companies that provide services and products such as a rural electric cooperative or a pipeline engineering concern. Therefore, if the annual revenue of the practice was $500 000 per year, then $5000 would be budgeted toward the marketing plan. In this budget it is necessary to place a value on the time the veterinarian or other individual spends on the project.

Obtaining the Client

The best, but perhaps not the easiest to attain, promotion one can do is to benefit from positive word of mouth. When first embarking on a practice or when trying to urge the practice on to greater levels of revenue, the word of mouth technique may not be sufficient to satisfy the aggressive practitioner. While there may be overlap between the following categories, four divisions will be addressed.

1) *Expanding the service repertoire*. There may be requests from current or possible clients that desire a specific service, such as fetal sexing by ultrasound or embryo transfer, which is not currently available at the practice. An investment in instruments and techniques to satisfy the requests not only makes possible client satisfaction but also brings in more clients looking for the same service.
2) *Promotion of existing services*. Many times clients are unaware that certain services already exist in the practice. Brochures should be prominently displayed explaining the services, details of the services readable on invoices or receipts, and the physical evidence of these services displayed in a place of congregation

such as the reception room or laboratory. Examples of physical evidence might be ultrasound images or BBSE certificates.

3) *Development of associations that lead to programs given by the veterinarian*. Extension agencies, drug and pharmaceutical companies, breed associations, and livestock organizations are always in need of presentations. Volunteering for these types of programs offers an ideal opportunity to display one's expertise. Further, writing articles in trade magazines is an excellent method of displaying one's proficiency and knowledge.
4) *Advertisements*. Although once controversial, other medical professions have wholeheartedly embraced advertising on billboards, magazines, clothing, and other items that are given away. This is an expensive proposition and care should be taken to ensure maximum exposure to potential clients while still operating within budget and ethical restraints. A bovine reproductive practice may need to expand beyond normal practice boundaries and so advertisements in regional livestock publications or breed association magazines that the veterinarian could still service may be appropriate.

Satisfying the Client

Client satisfaction relies on much more than veterinary competence. A wise marketing plan makes use of multiple possibilities to satisfy the client and encourage the client to return for further services.

Process

One must beautify the process. The appearance of the practice, including the appearance and demeanor of the people employed, will give the client an important clue to the satisfaction possible in the service about to be received. An investment in training of the staff to this end is important, but many times it is the veterinarian who falls short in appearance and demeanor. A holistic approach embraced by all will keep everyone, including the veterinarian, working toward an efficient and professional process in providing service that is done in an attractive and pleasant environment.

Physical Evidence

As stated before, providing a service frequently leaves nothing to behold after completion of the project. It is imperative, therefore, that eye-catching, professional, easily readable, and memorable physical evidence be provided for the satisfaction of the client. In the case of a BBSE, the Society for Theriogenology (SFT) has for several years provided to its members a triplicate paper record that adheres to the standards for the BBSE as established by the SFT. Because the form was illicitly, and in violation of the copyright, copied by non-members and even non-veterinarians not following SFT guidelines, the SFT has recently produced a computer-generated online BSE form that not only embraces the best standards on BSEs, but also provides a professional-looking document that compiles statistics on all bulls entered into the program in a national and international database.

The possibilities of in-house produced documents should be carefully considered in the bovine reproductive practice. At the end of a pregnancy examination experience, even if individual records are not kept on individual animals, a recap of the satisfaction, or lack thereof, of the pregnancy status of the herd as discussed between the veterinarian and the manager should be documented on a form expressly for that purpose and a copy kept as clinic records and one left at the ranch. Placing the forms in folders, or mailing a copy back to the ranch or to the owner, ensures that the recommendations and evaluations are studied by all concerned and keeps that veterinary clinic's name in front of the client. Professional-looking forms and handouts should be developed for all procedures offered by the practice that would benefit from such a distribution.

Place

An important aspect of client satisfaction would be how the service offered would be placed, or distributed, for the convenience of the client. Consideration of this distribution of services encompasses facilities, scheduling, and availability of the veterinarian. There are successful bovine practices that are strictly based on offering the service at a haul-in facility, others that are strictly on-farm practices, and others that fall somewhere in between. Many times it may be more convenient for the client to have the veterinarian at the farm to perform services, but on a limited number of animals a much better job of control and execution of the service can be done at a quality facility managed by the veterinarian. Construction of such a facility is expensive and cannot be justified unless the veterinarian is available at the appropriate times and not elsewhere trying to perform veterinary procedures on animals inadequately captured or unsatisfactorily restrained. If change is made between one type of philosophy and another, client education becomes paramount.

Scheduling is frequently a primary source of dissatisfaction for clients. Unfortunately, conflicts will always exist whereby the client either has to wait longer than would be convenient for placement on the schedule or is postponed longer than anticipated to receive the service scheduled in the first place. Hopefully, the bovine reproductive practice will develop into a practice more amenable to scheduling and less dependent on servicing emergencies, but a great deal of patience and client education must take place for

the satisfaction of the client and the veterinarian. Experience and a knowledgeable person at the clinic (it may be the veterinarian) should smooth out some of the rough edges that always occur when several clients need services rendered at much the same time.

Finally, distribution of services works much better when the veterinarian concentrates on fewer services and elevates the quality of the services provided. A bovine reproductive practice implies specialization, and clients tolerate delays or scheduling conflict better when the veterinarian is working hard on the business and species on which the client makes his or her living.

Price

No more difficult decision is made in the practice than how to set pricing, and price is the most sensitive issue the practice will face. With adequate and fair pricing, the practice thrives, but without it the practice stumbles or sits idle. While the client is usually more satisfied with a lower price, that client may respond negatively to the corners that were cut to deliver the service with a corresponding decrease in results.

There will be advocates for either higher or lower pricing based on the benefits either side has to gain, but to the individual practice owner the ideal price means work is cheerfully accepted but at any lower level would be refused. Achieving that is difficult. This problem therefore needs serious and thoughtful consideration but it is nonetheless possible to solve. Flexibility is sometimes beneficial in price-setting, but there are perils.

The practitioner should consider the type of client the practice intends to attract but should also realize that attracting as many clients as possible would be desirable even if the veterinarian decides later that neither the veterinarian nor the client are destined for a beneficial relationship. Some, perhaps the best, clients respond well to education. For these clients, time spent in thoughtful conversation about the benefits the bovine reproductive practice can provide at a specific price is the most productive part of the relationship. The veterinarian should encourage, plan, and efficiently execute these sessions. Other clients will not respond to education and merely want a brief explanation of what is to be done and the associated price; these clients have already decided what the benefits will be and are not anxious to hear the veterinarian's viewpoint.

Thus, there are three types of clients: those that respond to education, those that will respond to education in the future, and those that will never respond to education. One cannot predict which group will be most profitable, but one can predict which group will be most enjoyable and rewarding.

While pricing is a difficult issue, the practitioner should recognize the prospect that many clients do respond to flexibility and creativity rather than responding only to competitive pricing. Flexibility and creativity can be perilous, however, so once again the practitioner should carefully weigh a new or different price structure regardless of how elegant it may seem.

Hourly versus price per task In a dairy practice or perhaps certain beef practices it may be essential to offer services by the hour. For many this is advantageous to both the veterinarian and the client. In other practices, however, there is seasonality due to set breeding seasons that results in fluctuation between being very busy and being relatively idle. In such cases bidding services by the hour necessitates a rate that must cover those times when the clinic is idle and may result in a rate that is unattractive to the client. The hourly rate of, say, a dairy practice considers the same prospect, but the dairy practitioner may have a more level production, thereby having less idle time for which an accounting must take place. An answer might be to encourage elective work during the non-busy time, even at an hourly rate.

Guarantees Many veterinarians can successfully work by a promise of outcomes. There are ethical issues at play here, but taking on a project and being rewarded by a positive outcome (higher conception rates, higher weaning weights, etc.) can be profitable if the veterinarian is confident that the strategies and procedures implemented should produce the expected positive results, especially to a reluctant prospective client. This should be a short-term proposition as the culture the veterinarian wants to cultivate is for clients to use the practice's services because they are already confident that outcomes will be beneficial.

Consulting It is hard to envision a bovine reproductive practice that does not provide consulting in some fashion, but it is equally as difficult to envision that practice dependent strictly on consulting. It would seem that by definition of the bovine reproductive practice there would be some skill (in addition to consulting) that would be brought into play, for example surgery, palpation, embryo transfer, or BBSE. While performing these procedures there is usually time to consult in the hope of developing protocols that would improve the outcome of the procedure, or at least defining what has produced a positive outcome. Consulting at this time hopefully will be covered by the charge of the procedure, but should result in positive results in the future as well as goodwill in the present. Care must be taken, however, in consulting at no charge when no other procedure or prospect of a procedure is anticipated. Telephone consultations may fit in this category.

Dispensing Traditionally, many veterinary clinics have made a sizeable portion of their profit from dispensing of drugs, biologicals, and other products. The profit made in

these activities covered other areas of the practice that were not priced at an adequate rate (such as consulting). While a dispensing practice is entirely possible, and many times quite profitable, competition from larger corporations has complicated the issue. Some clients prefer to obtain pharmaceuticals from the veterinarian, thinking this will ensure that procedures related to product administration will be done correctly. The trend seems to be the contrary to that and toward requesting prescriptions for those items necessary and purchasing them online or from other large outlets. If one is to compete in the dispensing business, care should be taken not to let it interfere with other non-dispensing procedures and one must develop skills in inventory control, purchasing, and promotion that may not already be possessed within the practice.

Retention of the Client

Attention to client retention is more than admitting existing customers are more valuable and profitable than prospective ones, it is the realization that high-quality service and exceeding expectations should be emphasized more than obtaining profits. Those clients who are loyal and engaged are the best promoters of the bovine reproductive practice.

The bovine reproductive practice would in theory thrive on repeat business from existing customers, and therefore procedures should be instigated that would keep the practitioner and the clinic in the mind of the client without seeming excessive. Follow-up phone calls from the veterinarian or staff on outcomes from previous work is warranted. Hopefully, however, a line of communication is established during the client–veterinarian relationship that lends itself to a steady stream of information between the two parties.

Newsletters

Newsletters or other means of updating clients on available procedures, current or changing issues that apply to the client's production, and diseases or syndromes recently diagnosed are well received but difficult to produce on a consistent basis. Companies that produce newsletters can be tailored to the practice, but many times do not evoke a personal touch that resonates with the client. If there is a desire to do this and there is a corresponding willingness and capital to get it done, a newsletter can prove beneficial to client retention.

Email or Social Media

Information and personal contact can be easily distributed by email or one of the social media avenues (Facebook, LinkedIn), although not all clients readily embrace such communication. As the sophistication of these outlets improves, using such devices will be a convenient and obvious method of client correspondence and feedback.

Personal Contact

Many veterinary clinics of different or general specialties already have reminder systems in place for vaccinations or other procedures. In theory, the bovine reproductive practice would not have the volume of clients that need reminding of, for instance, rabies vaccinations that exist in a small animal practice. This leaves in place the opportunity for a personal phone call on a calculated basis for business to be lined up. Herd palpations, BBSEs, and other procedures that have been done in the past and should be accomplished in the future are excellent, although there may be preferences on the client's part of how any particular information would most effectively be received. The important part is to have a system in place that accomplishes this as a matter of procedure rather than when the spirit moves. Every service provided is an opportunity to make contact in the future.

Evaluation of the Marketing Plan

Regular evaluation of the marketing plan should be part of the overall design. One should attempt to measure both objectively and subjectively what effect the plan has on the practice. While revenue or repeat business is easily determined, other determinations such as client satisfaction and staff morale are equally important but more difficult to assess. Building a consensus about what the marketing plan should do and how to measure the success of the plan may be the most important elements in the marketing concept.

Summary

Every veterinary practice has a marketing system in place. The methods for attracting, satisfying, and retaining clients or customers are present from the moment the business begins, but whether that system is effective enough for a prosperous venture depends on several factors. Conditions that are favorable for success in the present may not be present in the future.

The veterinarian launching a bovine reproductive practice is in a more favorable situation than many counterparts in other specialties of veterinary practice. Assuming the veterinarian is competent and accessible to clients desiring bovine reproductive services, and further possesses no problems with health, personality, or other distractions, no other individual has the attributes needed to deliver those services than a well-trained veterinarian. The veterinarian is the only individual who can legally provide the pharmaceuticals, techniques, and procedures needed to accomplish some of the reproductive services. No other profession can issue the health inspection papers that are important in the transport of animals, semen, and embryos.

No one else has the training to grasp and treat the correlation between sickness, health, and reproductive performance. Finally, there is a reported shortage of individuals capable of supplying all these services.

There is, however, a marked incursion into bovine reproduction made by those outside the veterinary profession. As this results sometimes in fair or unfair competition between those with a veterinary degree and those without, many veterinarians have voiced objections. These veterinarian voice complaints about legislation unfavorable to the profession, the lack of enforcement of existing laws to protect veterinarians, criticisms of the public for failing to recognize the supremacy of veterinarians, and, finally, protests about the profession itself for not providing its members with the skills necessary to make an adequate living.

Concurrently the veterinary profession, especially the bovine practitioner, is populated with talented and creative individuals capable of providing efficient and quality medical and reproductive services under less than ideal conditions. Collectively and individually there is no reason the bovine veterinary reproductive specialist should be impeded from establishing a specialty practice of sufficient profitability if the veterinarian applies as much thought, creativity, courage, and cunning into marketing as has already been made in other parts of the business.

The success rate of businesses is fairly consistent across all types of industry and failures are not always related to poor marketing. The most common complaints about the failure to succeed in bovine veterinary practice, however, can be offset by a well-conceived marketing plan, even though its execution will require courage, creativity, and the ever-present hard work.

In his book *Lessons From a Desperado Poet*, author and large-animal veterinarian Baxter Black demonstrates methods of marketing that have successfully ushered him into the difficult world of entertainment, publishing, and performance [3]. His talents are obvious, but remarkable in this book is the relentless pursuit of creative strategies and hard work that preceded his success. While many of his methods would not be appropriate in a marketing plan for a bovine reproductive practice, his example as one who pursues all avenues in his quest for markets should be an inspiration to all veterinarians.

The profession needs to claim what is rightfully and legally mandated from the federal and state level surrounding pharmaceuticals and their use, the provision of specific practice acts, and the validity of the veterinary client–patient relationship. Notifying authorities of non-veterinarians or veterinarians not in compliance is the responsibility of each ethical veterinarian regardless of the personal discomfort involved.

It should also be noted that there are valuable contributions to be made by those outside the veterinary profession and an amicable relationship with these individuals can enhance the bovine reproductive practice.

In any business, the rewards of entering that enterprise must be commensurate with the effort needed to succeed. While there is an inclination to find challenge and enjoyment from a bovine reproductive practice, if the rewards (monetary, prestige, professional satisfaction) do not justify the sacrifices (number of hours worked, working conditions, vocational hazards) such a practice will fail. In short, in order for the bovine reproductive practice to succeed on a national scale, we must attract quality veterinarians, pay them well, provide adequate equipment and safety, and spread the work among others, enabling the veterinarian to have a life outside of the practice.

It is, therefore, imperative to have the professional skills needed for bovine reproduction and the marketing abilities to entice quality veterinarians into the field. If the marketing effort fails, and with it the ability to reward veterinarians adequately, the outlook for the bovine reproductive practice fails as well.

Helping clients provide the nation and the world with high-quality, safe, and reasonably priced food is a noble occupation. Resources and support are readily available. Rewards are within the grasp of those willing to use their talents – marketing and otherwise – and their dedication to success.

Management of Vaginal, Cervico-Vaginal, and Uterine Prolapse

Augustine T. Peter[1] *and E. Heath King*[2]

Introduction

Eversion of the vagina or both uterine horns from the vulva is commonly referred to as vaginal or uterine prolapse (from *prolabi*, to fall out), respectively. It is not unusual to encounter these cases in cattle, particularly in the developing world. Vaginal and cervical eversions usually occur before calving and uterine eversions after calving. There is no relationship between occurrence of these conditions. An excellent review [1] has been provided describing the management of these conditions from the perspective of replacing, repairing, and, if need be, amputating the uterus. Noteworthy is a detailed description on manual eversion of the uterus to correct a uterine tear, a technique that involves the use of different pharmaceuticals [2, 3]. This chapter will address this condition from three perspectives: it will describe these maladies and provide remedies with representative images, both real and created; it will provide a summary of information reported in the global literature, including practical solutions provided by practitioners; and it will address these clinical situations from productive and fertility perspectives and, most importantly, from an animal welfare perspective.

Vaginal and Cervical Eversions

Eversion of the vagina is a relatively common occurrence, particularly in cattle, compared to other species [4]. There appears to be a genetic component to its occurrence in beef cows compared to dairy cows. Among beef breeds, Hereford [5], heavier breeds such as Charolais and Limousin [6], and Shorthorns are more affected than others. It has been known that *Bos indicus* breeds are predisposed to this condition, along with cervical eversion.

Many factors have been suggested to contribute to this condition [7–10], including increased intra-abdominal pressure in late pregnancy, extreme cold weather, excess perivaginal fat, prior injury to perivaginal tissues, intake of large volumes of poorly digestible roughage, poor vaginal conformation, persistence of medial walls of the Müllerian ducts [11], and changes in hormonal secretions, particularly increased estrogen as observed in late pregnancy and in estrus. It has been suggested that higher concentrations of estrogens found during pregnancy can contribute to excessive relaxation and edema of pelvic ligaments that support the vagina. Besides the above, incompetence of the constrictor vestibule and constrictor vulvae muscles may have a role in etiology [7]. This condition is observed in embryo donor cows that are exposed to hormonal stimulation of ovaries. Imbalance in calcium and phosphorus, and hypocalcemia have been considered to be contributing factors by some researchers [12]. It should be pointed out that association with hypocalcemia was suggested merely based on response to calcium therapy rather than on clinical signs of hypocalcemia. However, as eloquently suggested [12], it can be tentatively postulated that subclinical hypocalcemia could be derogatory to the internal environment of the physiologically stressed female because of pregnancy and parturition.

The majority of vaginal and cervical eversions occur in the last few weeks of pregnancy; however, the condition may occur several months before calving. In some cows, it may occur during estrus. Vaginal eversions are classified into four grades according to severity of eversion, extent of injury, and exposure of the cervix in such eversions.

- Grade 1 eversion: a small intermittent protrusion of vaginal mucosa through the vulval lips is noticed (Figure 47.1) when the animal lies down. Often this tissue becomes dehydrated and traumatized and leads to a grade 2 eversion.

Figure 47.1 Grade 1 eversion: vaginal eversion occurs intermittently, particularly when the animal lies down.

A grade 1 eversion is readily repaired by applying any of the retention sutures described later.

- Grade 2 eversion: vaginal mucosa protrudes through the vulval lips continuously (Figure 47.2), with the possibility of the urinary bladder getting trapped in the everted organ. If left untreated, a grade 2 quickly progresses to a grade 3 eversion.
- Grade 3 eversion: the entire vaginal mucosa and cervix protrude continuously through the vulval lips (Figure 47.3), with a trapped urinary bladder and an exposed cervical mucous plug. The cervical seal may liquefy, allowing bacterial contamination of the uterus, leading to placentitis and fetal death. Often these fetuses become emphysematous and cervical dilation is insufficient for a vaginal delivery. This condition is often referred to as a cervical eversion but more correctly should be referred to as a cervico-vaginal eversion. This distinguishes it from eversion of the cervix alone, as sometimes is observed in *B. indicus* breeds. In the latter case, only the cervix everts as a pedunculated mass through the vulva.
- Grade 4 eversion: an eversion of such a duration that the entire vaginal mucosa appears necrotic and fibrosed (Figure 47.4). Infection is so extensive that the urinary bladder may become involved in it and peritonitis is a possible result.

The objective of treatment in pregnant animals is to replace and retain the vagina and cervix within the pelvic canal and to deliver and wean a live offspring. Many management and treatment options are described for vaginal and cervical eversions [1, 4, 7, 9–11, 13–34]. These can be placed in two general categories: those aimed at permanent reduction, and others that afford a temporary solution. It should be mentioned that one approach may not fit for all grades. Severity of eversion, time to expected delivery, the veterinarian's preference, and the owner's ability or willingness to manage the patient after treatment will dictate the treatment option. The elected initial treatment option needs to be changed after assessing patient response. This is particularly relevant if tenesmus becomes an issue. If the patient is close to parturition, induction is recommended to prevent recurrence prior to parturition.

Short-Term Treatment Options

Caslick's Suture

This technique (Figures 47.5 and 47.6) should be reserved only for a grade 1 vaginal eversion with no irritation that occurs close to parturition and when tenesmus is not expected to be a concern. Unfortunately, a simple Caslick's suture in many cases is insufficient. As intra-abdominal pressure increases, tenesmus begins and the suture is ripped out or the vagina begins to evert below the sutures. Furthermore, vulval softening and stretching that occur closer to parturition contribute to this phenomenon. Caslick's suture may suffice in patients that are not pregnant and have a grade 1 eversion during estrus. This is often the case with embryo donor animals whose ovaries are frequently superstimulated with hormones for the sole purpose of increasing the number of ovulations.

Buhner Stitch

This is an effective treatment for more advanced grades and those that are chronic in nature [17, 18]. To have a successful outcome, the stab incision has to be placed deeply such that the retention line is as cranial to the vulval lips as possible (Figure 47.7). A disadvantage is that it is unforgiving,

Figure 47.5 Caslick's suture being applied to a non-pregnant cow with grade 1 vaginal eversion. *Source:* Reprinted from *Clinical Theriogenology* with editor's permission.

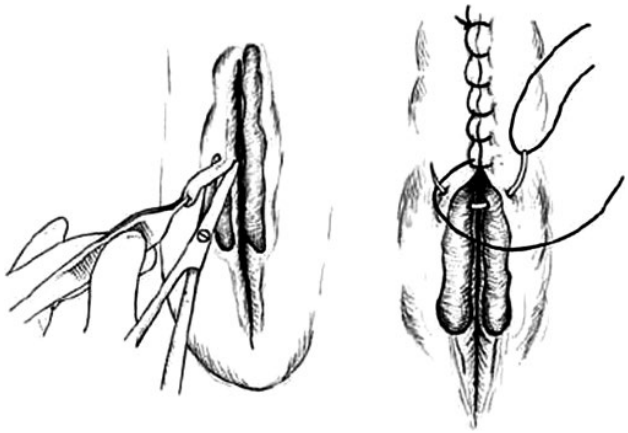

Figure 47.6 Caslick's suture procedure. *Source:* Illustration by Dr. T. Barkley.

and if assistance is not available when the patient begins to calve, severe trauma to the vulva may occur or the calf becomes undeliverable and dies in utero or the patient may die as a result of uterine rupture and fatal hemorrhage. Following epidural anesthesia, the vulva is thoroughly washed with detergent and a 1-cm stab incision is made on the midline below the vulva and as far forward as practical. A second incision is made midway between the anus and dorsal commissure of the vulva (Figure 47.7). A Buhner needle is then passed deeply from the ventral incision up one side of the vulva and out through the dorsal incision. Buhner tape (non-wicking type) is passed through the eye of the needle and the needle is retracted through the ventral incision along with the tape.

The procedure is repeated on the opposite vulval lip and the two ends are tied leaving approximatel a two-finger opening in the ventral vulva for urination. Preference is to tie a bow knot and then tie the two loops of the bow in a

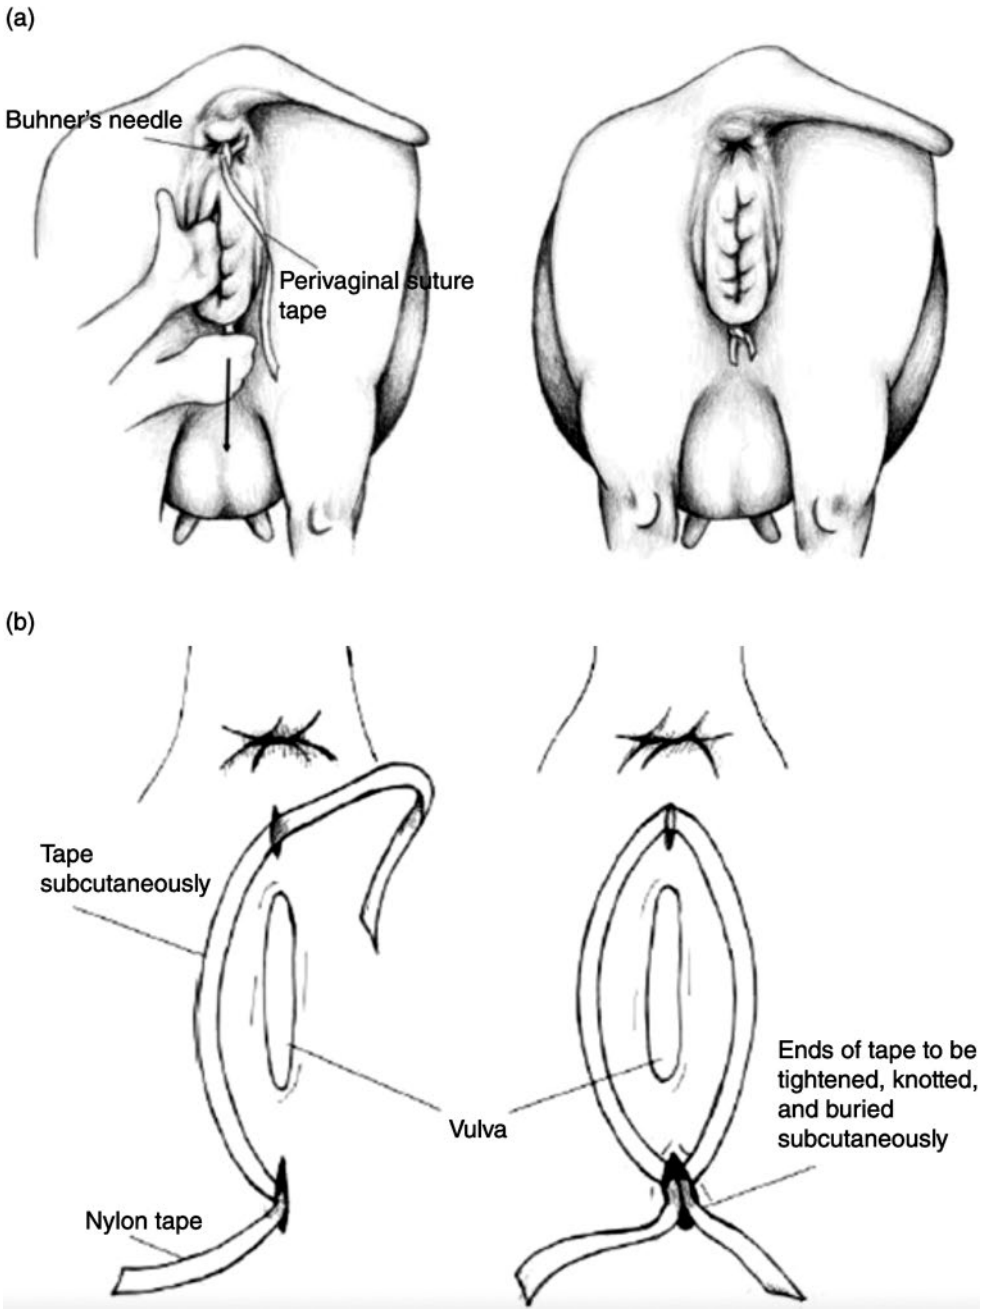

Figure 47.7 Buhner stich procedure. Note locations of dorsal and ventral retention lines. *Source:* Illustration by Dr. T. Barkley.

single square knot. This allows the knot to be loosened but to retain the suture so that if the patient should try to evert again, it can be replaced and the knot retightened. This can also be done in the evenings if observation of the patient for parturition is not possible overnight.

If the procedure is performed properly, the tape should not be visible at the dorsal incision and this helps to prevent feces tracking down the needle paths. It should be stressed to caretakers that their presence at the onset of calving is crucial for a successful outcome. If observation is a problem, medium-sized catgut can be doubled and used as a suture material; this helps in patients that are within 10 days of calving as the gut will break during parturition.

Bootlace Technique

This is not a highly preferred technique as the vulval lips are inverted and suture placement is tedious. However, it is stronger than a Caslick's suture. Following an epidural anesthetic procedure and disinfecting the vulva and

surrounding area, four to five small eyelets are made with umbilical tape or hog nose rings [11] on either side of the vulva in a dorsal to ventral line at the hair to hairless junction on the vulval lips. After placing eyelets, umbilical or Buhner tape is used to "lace up" the vulva much like a boot (Figure 47.8). As the pattern is tightened, the vulval lips invert. Again, bootlace sutures must be loosened prior to calving to avoid serious trauma to the vagina.

Horizontal Mattress (Halstead) Technique

In this technique a needle is passed through the vulval lip on the right, beginning deep at the junction of the labia with skin of the rump. The needle is continued across the vulval opening and through the left vulval lip at the same depth as the right. The needle is then passed back from left to right at the same plane as the first passage but beginning approximately 2–3 cm ventral to the first passage. This procedure can be done using a Buhner or large cutting needle. Place as many sutures as needed to close the vulva down to approximately two fingers wide to allow for urination.

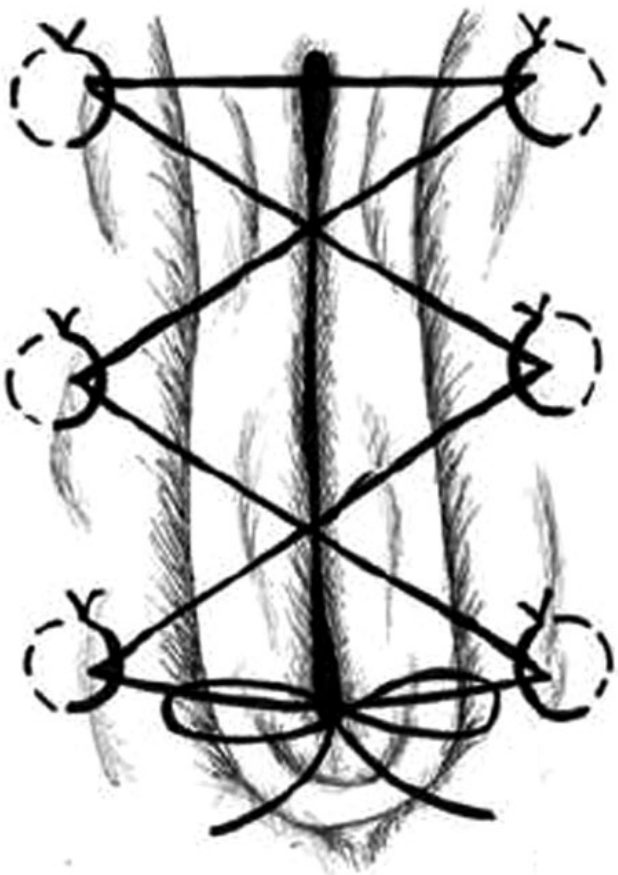

Figure 47.8 Bootlace technique. *Source:* Illustration by Dr. T. Barkley.

A disadvantage of the technique is that even if sutures are not pulled really tight, vulval edema frequently develops and can be quite severe. This can be lessened if suture tension is dispersed by "stents." Polyvinyl chloride tubing (1.3 cm diameter) can be cut to the length of the vulva and holes drilled 2–3 cm apart; similarly, wooden dowels [24] or latex tubing can be utilized. A stent is placed either side of the vulva and a horizontal mattress suture is passed through the holes and tied (Figure 47.9). This approach has good deep retention and pressure is more evenly dispersed.

Deep Vertical Mattress Technique

This is similar to the horizontal mattress pattern described above. The difference is that a vertical mattress suture pattern is used and stents are recommended to disperse tension on the vulval lips (Figure 47.10). This replacement method can also have serious consequences if assistance is not available at the onset of parturition.

Permanent or Semipermanent Treatment Options

Minchev Vaginopexy

Two Minchev techniques are described that differ only in location of needle insertion. In the original Minchev technique the needle is passed through the lesser sciatic foramen. This is an excellent prepartum method that aims to retain the vagina in the correct pelvic location by adhesion formation between the submucosa of the vagina and surrounding fascia. Anesthetic is given epidurally and the gluteal area is shaved and disinfected. In the original Minchev technique, a large S-shaped needle is threaded with 0.95-cm umbilical tape and a gauze bandage or large plastic or metal plate is attached at the tape's end; the needle is then taken in vaginally and the lesser sciatic foramen is located on the dorsolateral wall of the vagina. The needle is pushed through the dorsal area of the foramen in order to avoid the pudendal nerve. It is then pushed through the skin in the gluteal area and a suture pulled up snug (do not tie too tightly) and another button, plate, or gauze is tied into the suture. This is repeated on the other side.

Modified Minchev Vaginopexy

This modified technique is similar to the original one except that the stay sutures are placed anterior to the lesser sciatic foramen 5 cm lateral to the midline and just posterior to the shaft of ilium, providing more cranial fixation of the vaginal

wall (Figure 47.11). Care must be taken to avoid the sciatic nerve, pudendal artery, and rectum when placing the needle. These structures can be identified cranial and slightly dorsal to the lesser sciatic foramen. The needle is passed through the sacrosciatic ligament approximately 4–5 cm lateral to the sacrum and just posterior to the shaft of ilium.

An adaptation of this technique has been described [33] that utilizes a Gerlach needle for suture placement (Figure 47.12). The cow is prepared as above, and a Gerlach needle is introduced into the vagina with the point (tip) guarded by the thumb and forefinger. The needle is then introduced into the vaginal wall near the cervix at the 10 or 2 o'clock positions, and if necessary the vaginal wall can be retracted caudally to allow for passage through the sacrosciatic ligament to the exterior. The Gerlach needle is then

Figure 47.12 Gerlach needle (left) and Buhner needle (right). *Source:* Reprinted from *Clinical Theriogenology* with editor's permission.

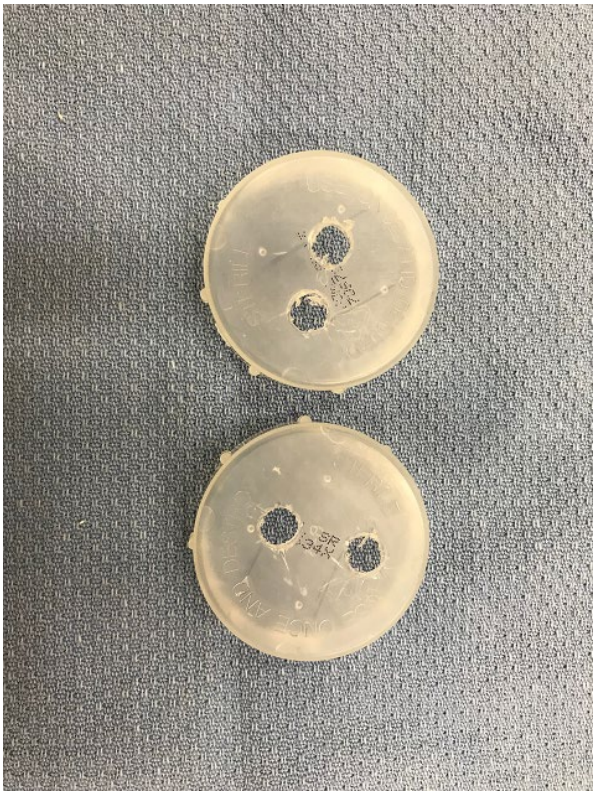

Figure 47.13 "Syringe case tops" prepared for use. *Source:* Reprinted from *Clinical Theriogenology* with editor's permission.

threaded with #8 polyamide thread suture or umbilical tape and withdrawn from the vulva. A suture is cut from the needle and the two ends are threaded through the two holes previously prepared in a plastic disc that can be fashioned from 60-cc syringe case tops, sample cup lids, or the bottom of a 500-ml fluid bottle (Figure 47.13). The two tails of the suture exiting the gluteal region are then drawn taut and tied over a gauze externally (Figure 47.14) [33].

The advantages of the modified Minchev technique include the fact that cows rarely show tenesmus when the vagina is replaced and the cow can calve unassisted. However, it is recommended that sutures are removed in two to four weeks. A commercial prolapse repair kit is available (Figure 47.15; Pro-Button Prolapse, Jorgensen Laboratories, Loveland, CO). The assembled kit is soaked in disinfectant. A stainless-steel pin with a 15-cm plastic trocar is passed through the 7.5-cm plastic button and is carried vaginally. A trocar is pushed dorsal or anterior to the lesser sciatic foramen, pointing dorsolaterally to avoid the rectum, and then through the sacrosciatic ligament and biceps femoris to the skin outside. The stainless-steel pin is removed and a 6-cm plastic button is placed on the protruding trocar. Pushing down on the 6-cm button enables the 7.5-cm button to be held firmly between the vaginal wall and sacrosciatic

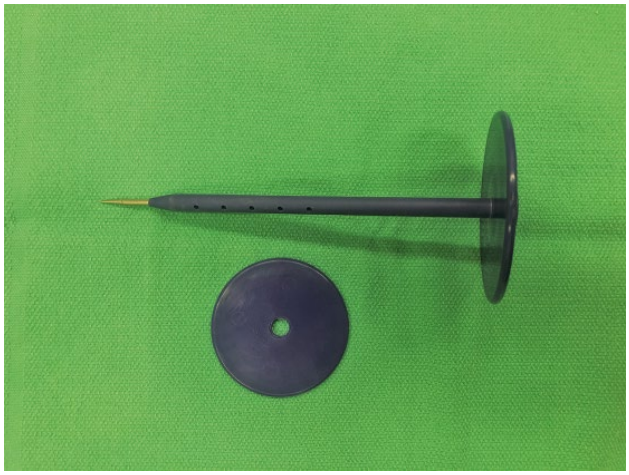

Figure 47.15 Example of trocar and plastic buttons used for modified Minchev technique.

ligament. A cotter pin is inserted through the hole in the protruding trocar. A plastic trocar is cut about 2.5 cm above the cotter pin. In severe cases, it may be necessary to place buttons on both sides of the anterior vagina. However, it should be recognized that recurrence of eversion is possible since only the dorsum of the vagina is held. Further, when internal placement is too far caudal, a partial eversion may occur, eliciting straining that results in total eversion.

Winkler Technique Cervicopexy

This technique [34] is an effective method of vaginal retention because it fixes the cervix in place, making it difficult for the vagina to prolapse. The basic procedure is aimed at suturing the cervix to the prepubic tendon. There are numerous descriptions of placing the suture in the cervix and how to suture through tendon. Approaches to suture placement are either through a left paralumbar approach [26] or through the vagina. The former approach is more time-consuming but safer, while the vaginal approach is quicker but can result in a broken needle. The vaginal approach could be done in two ways: either by including the lower half of the cervix or by just including the external os of the cervix on one side (Figure 47.16). Before placing the suture vaginally, anesthetic is given epidurally and a mild antiseptic douching of the vagina is performed. The prepubic tendon is then palpated at its attachment to the pelvic brim. As the fingers are moved laterally about 5 cm on both sides of the midline, a small triangular-shaped area free of tendon is felt. This is formed by a short band of tendon extending posterolateral to the iliopectineal eminence of the pelvis. A large curved cutting needle is bent into either a U shape (Figure 47.17, left) or other shape (Figure 47.17, right) and about 150 cm of nonabsorbable suture material is attached. The needle is then carried into the vagina and passed from the inner lumen of the external cervical ring out peripherally. The needle is grasped again and passed down in a medial to lateral direction through the prepubic tendon and carefully curved around to come up through the triangular area. The needle is grasped again, passed through the external cervical ring from periphery to center, and brought on out of the vagina. Some clinicians prefer to pass the needle through the vaginal wall initially, then pass the needle through the prepubic tendon medial to the lateral direction, and pull the needle back through toward the intravaginal part of the

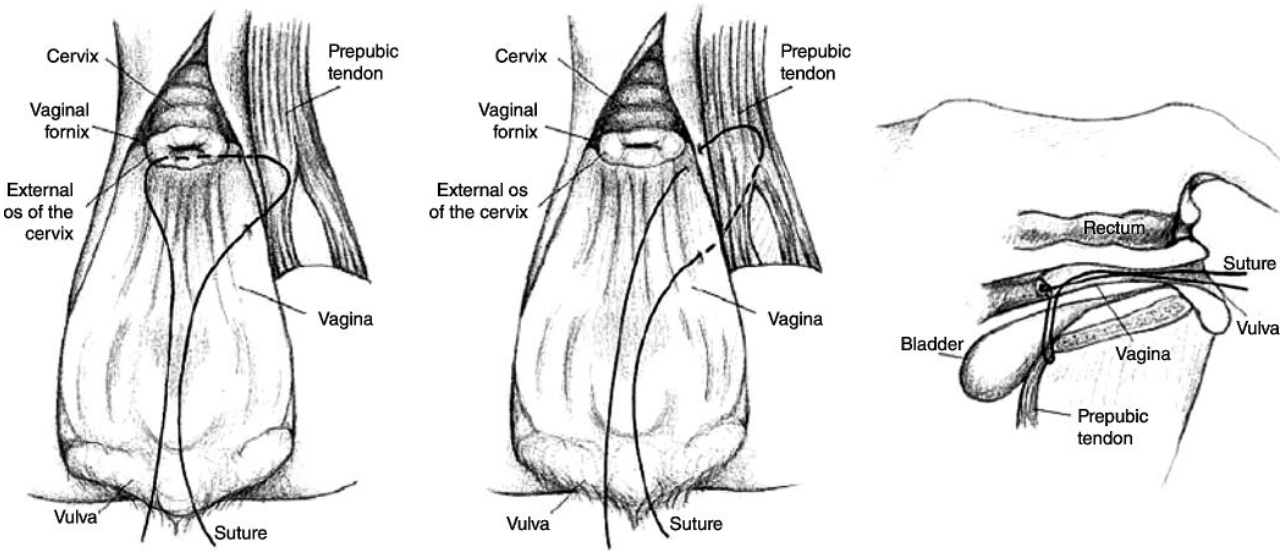

Figure 47.16 Schematic representation of Winkler technique for cervicopexy. *Source:* From Dean A. Hendrickson, A. N. Baird, Turner and McIlwraith's Techniques in Large Animal Surgery, © 2013, John Wiley & Sons.

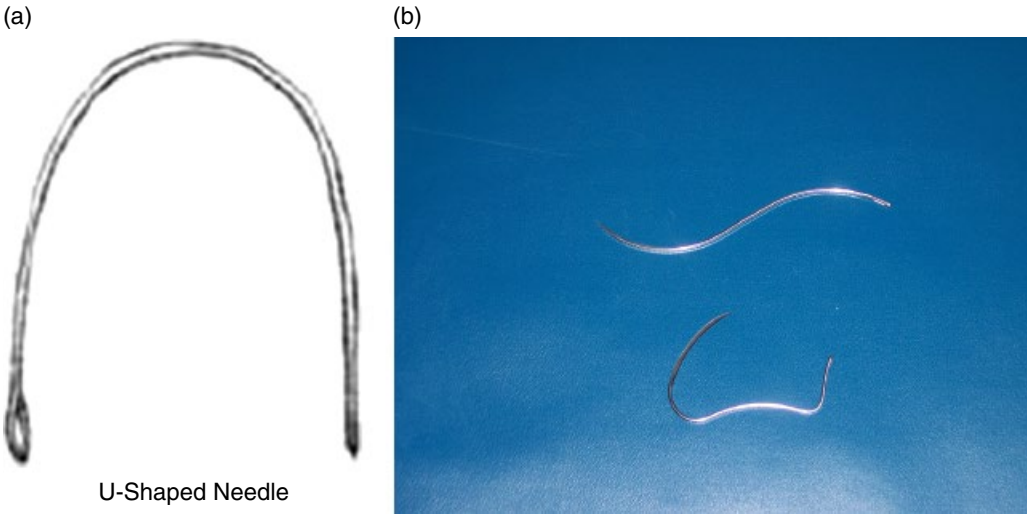

Figure 47.17 (a and b) Special needle used for Winkler technique for cervicopexy. *Source:* Illustration (a) by Dr. T. Barkley.

cervix; the needle is then directed across the lower half of the cervix and brought outside to tie a knot. This latter procedure may prevent breaking of the needle. A catheter is then passed through the urethra so that as the suture is tied the urethra is not trapped in the suture.

To tie a suture, knots are started on the outside of the vulva and slid forward. Suture is tied tight enough to prevent posterior movement of the cervix. To assist in placing cervical sutures, Knowles cervical forceps can be used to fix the cervix cranially, making passing of the needle through the cervix easier, or in some cows the cervix can be retracted sufficiently to be presented at the vulva again, making placing of the cervical sutures easier.

Other descriptions of this procedure do not advocate passing the needle through the cervical opening but rather through the side of the cervix without penetrating the lumen. This approach is greatly aided by fixation of the cervix with forceps [3, 26]. Advantages of this approach are that the cow can calve on its own, post-repair tenesmus is rare, and the cow can still be examined per vaginum. Occasionally the suture in the cervix can break, resulting in recurrence of eversion. This procedure is recommended for chronic cases which the owner wishes to keep, especially embryo donor cows, in which the problem is likely hormonally induced rather then there being any genetic predisposition. However, if the condition is likely to occur again or if it is probably hereditary in nature, the affected animal should be culled.

Uterine Eversion

Uterine eversion occurs mostly within 24 hours after fetal delivery, with the majority of cases occurring shortly after parturition. While relatively uncommon (<1% of parturitions) [35], it is nevertheless a true emergency situation encountered in practice. In many instances the everted organ is readily contaminated (Figure 47.18), traumatized physically or by extreme weather (heat/cold), becomes edematous, may hemorrhage, and may evert severely enough to rupture the uterine vessels, leading to rapid shock and death.

Owners should be instructed not to transport the animal and to place the everted organ inside a plastic bag to reduce contamination. Fortunately, many of these cows are unable to stand up and run due to hypocalcemia, partial paralysis, or exhaustion. However, on occasions, the cow is capable of standing up and may become fractious as she attempts to outrun the uterus or knocks the uterus between her hocks (Figure 47.19). Since these cases often result in rupture of uterine vessels and rapid death due to internal hemorrhage, one should approach them very cautiously.

Many factors [8, 36] are believed to contribute to uterine eversion, including reduced uterine contractility due to decreased uterine activity following primary or secondary uterine inertia. Hypocalcemia and reduced prostaglandin and oxytocin receptors and myometrial defects due to overstretching contribute to primary uterine inertia. Among others, mere physical exhaustion and dystocia are responsible for secondary uterine inertia. Apart from uterine inertia, situations in which there is continuing tenesmus as noted in dystocia, manual extraction of the calf, retained fetal membranes, delayed cervical involution, and laceration of the reproductive tract can lead to eversions. Prolonged recumbency that follows paralysis or hypocalcemia can lead to increases in intra-abdominal pressure, a potential factor for eversion. Hypocalcemia is also believed to make the uterus atonic, delaying the involution of the cervix, a predisposing factor for uterine eversion [37]. However, it has been suggested that hypocalcemia can be the result of uterine eversion rather

Figure 47.18 Everted uterus with evidence of contamination. *Source:* Reprinted from *Clinical Theriogenology* with editor's permission.

Figure 47.19 Uterus is further traumatized by knocking between the hocks. *Source:* Reprinted from *Clinical Theriogenology* with editor's permission.

than a cause of it [38]. The roles of parity [39] and hypocalcemia still remain an enigma in uterine eversions etiology [40, 41]. Overconditioned animals may be more prone to increased intra-abdominal pressure due to increased fat reserves in the abdomen. Other non-animal factors can contribute to this condition. For example, outbreaks can occasionally occur due to extreme weather conditions and pasture composition. Further, it has been suggested that alterations in availability of dietary calcium, phosphorus, and magnesium may have a role in creating uterine inertia and predisposing animals to this condition. Uterine eversion outbreak noticed in animals kept on a cool-season grass pasture supports this hypothesis. It has also been suggested that high estrogen concentrations in pasture may play a role. The foregoing description undoubtedly attests to the multifactorial etiology of this condition.

Many methods of reduction and practical tips have been described [1, 36, 37, 42–60]. Replacing the uterus can be done in either a standing or a recumbent position, depending on circumstances and the clinician's preference. The animal may have to be cast, rolled, and pushed to lie on its abdomen to facilitate pulling the hind legs straight behind to facilitate reduction [36]. Obviously, if the cow is in pasture with partial paralysis, the recumbent position is dictated. Replacing the uterus in the recumbent position is greatly facilitated by positioning the cow in the sternal position with both hind legs extended out behind (Figure 47.20)

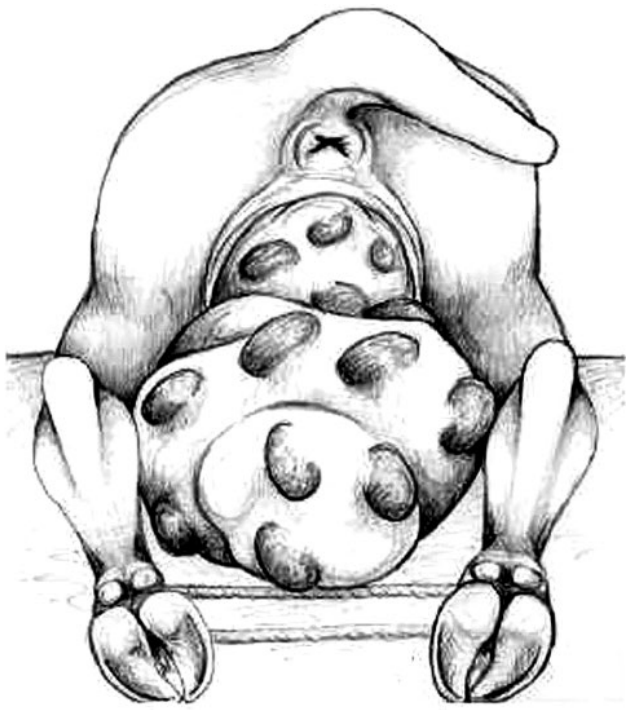

Figure 47.20 "Okie position:" note extension and elevation of hind legs. *Source:* Illustration by Dr. T. Barkley.

with the head facing downhill ("Okie position"). This position tilts the pelvis forward and allows the clinician to get behind the cow and cradle the uterus in their lap as it is placed back into the cow. Others prefer the standing position (Figure 47.21) if the cow can be adequately restrained and help is available to place a towel or bed sheet (or something similar) under the uterus and lift it up as the clinician replaces the uterus (Figure 47.22) back into the cow.

Replacement Guidelines

- Give epidural anesthesia.
- Remove as much fetal membranes as possible.
- Clean the endometrium.
- Placing the uterus in a plastic bag with cold water will assist in cleaning the uterus and reducing edema.
- A generous amount of obstetrical lube should be applied to assist in reduction.
- A pressure bandage can be applied for 10–15 minutes beginning distally and working toward the cow. Sugar may be applied sparingly. Use of hypertonic substances like granular sugar will further reduce edema but can cause more endometrial damage by drying and abrading the tissue. A 50% dextrose solution can be used to provide osmotic activity without mechanical irritation.
- Identify the non-gravid horn (strong intercornual ligament prevents its eversion) by observing for the presence of an oval or slit-like opening bordered by a ring of small cotyledons and reduce it first.
- Begin applying steady pressure at the cervix/uterine body area using both hands with a clenched fist to reduce the everted uterus into the vagina. Some clinicians prefer to wear oven mittens during reduction to avoid inadvertently puncturing the uterus with their fingers. Once the uterine body is reduced into the vagina, the uterine horns are gradually massaged into the birth canal or vagina.
- Fully invert the uterine horns. If the operator's arms are not long enough, the rounded bottom of a 1-l soda bottle, wiffle ball bat, or probang can be used to completely invert the uterus.
- Give non-steroidal anti-inflammatory drugs and parenteral antibiotics.
- Oxytocin should not be given until the uterus has been reduced or replaced.
- Use of a retention suture is discussed below.

A probang (Figure 47.23) is commonly used to make sure that the tip of the uterine horn is fully inverted. The rounded edges of a probang prevent possible tears that may occur to the friable uterine wall during the procedure. A child's wiffle bat can be used as an inexpensive alternative to the probang (Figure 47.24).

Failure to fully straighten the uterine horns can result in re-eversion or ischemic necrosis of a portion of the uterine horn. Placement of a suture in the vulva after uterine replacement is controversial. If the uterus responds to oxytocin and the cow is able to stand, then re-eversion is highly unlikely and a vulval stitch is not needed. On the other hand, if the cow is unable to rise and tenesmus recommences, a

vulval stitch may be indicated for 24–48 hours. After reduction, 20–30 IU oxytocin should be injected and repeated two more times in 30-minute intervals and calcium therapy instituted if necessary. Antibiotic therapy is probably warranted in the case of a severely injured and contaminated uterus but may not be necessary in the case of a relatively fresh and cleanly reduced eversion.

Uterine Amputation

There are two approaches to uterine amputation: open and closed [1, 2, 61, 62]. The open approach involves incising the uterine body and location and ligation of the major uterine vessels in the stretched broad ligament prior to amputation of the uterus. An advantage of this approach is that any viscera contained within the prolapse can be returned to the abdomen before the uterus is removed. With this surgical approach, the wall of the uterine body is opened from the cranial cervix to bifurcation of the uterine horns to expose contents within the everted uterus and major vessels in the broad ligament (mesometrium). Vessels are identified by "fanning out" mesometrium and double ligated, preferably when they are not under tension. Vessels are severed between the ligatures and the mesometrium incised and allowed to retract into the abdominal cavity. A series of adjacent slightly overlapping mattress sutures are then placed across the uterine body just proximal to the cervix. The uterus is then amputated 2–3 cm below this line of sutures. The stump may then be sutured with a simple continuous pattern. Postoperative treatment should include administration of tetanus toxoid, non-steroidal anti-inflammatory drugs, and appropriate antibiotics.

Figure 47.24 A child's wiffle bat can be used in place of the probang.

In the closed approach (Figure 47.25) the entire organ is ligated and left to slough in 10–14 days. This is a salvage operation applied in cases of severe ischemic necrosis and/or lacerations. With this approach, viscera could be unintentionally trapped in the everted uterus with fatal consequences. Ligatures for this latter approach can be made of surgical tubing or bungee cord, or the bloodless castrating unit used for castrating large bulls works well.

Discussion

Vaginal and Cervical Eversions

Prepartum vaginal and cervical eversions can be perplexing and disturbing problems both to the producer and the veterinarian. Expense and effort can be costly at times. These everted structures should be promptly replaced within the

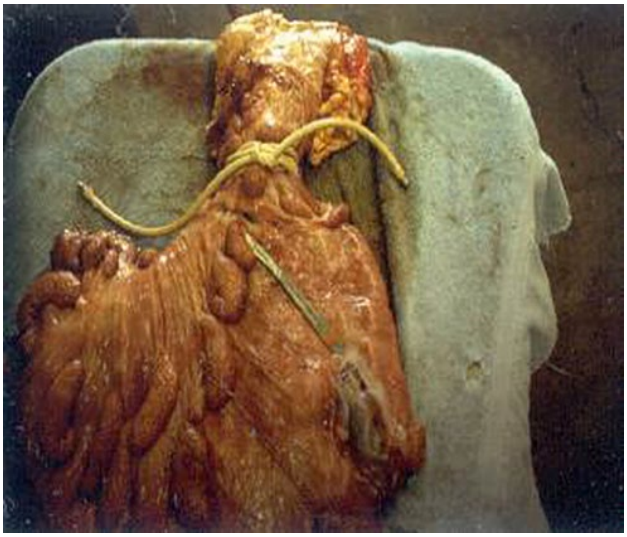

Figure 47.25 A closed approach of uterine amputation. Note location of ligation. *Source:* Reprinted from *Clinical Theriogenology* with editor's permission.

vaginal vault and secured such that contamination, laceration, sepsis, fibrosis, or necrosis do not occur. This approach will prevent compromise of cervical and vaginal relaxation at parturition and most importantly will enhance animal well-being by preventing unnecessary injury at parturition [63]. Some attempts made by producers to correct the situation can have many unintended consequences and can inflict unnecessary pain and injury to the animal. In this regard, client education is paramount. Although there may be temporary relief, the animal may evert again at the next parturition if the primary cause for an eversion is not corrected [11]. It is very important to realize that satisfactory reduction and retention alone are not sufficient since recurrence rate is high if the primary or inciting cause is not removed. This not only forces subsequent repair but more importantly, in some instances, can result in mutilation of vulval and perivulval tissue and become an important animal-welfare issue. Many techniques have been developed and stood the test of time. Each one is unique and the technique chosen depends on the condition and expertise of the clinician. What was said a few decades ago still stands true: better techniques for handling chronic vaginal eversions are needed [28]. New knowledge in this area by developing alternative techniques and improving current techniques will keep our discipline vibrant.

Not many studies have characterized the future fertility of affected animals. However, we ought to consider the possibility of future occurrence in light of animal well-being rather than fertility. In this regard, it is pertinent to consider some of the treatments administered. These are aimed at preventing recurrence by narrowing the birth canal [6, 21] by creating adhesions between the retroperitoneal surfaces of vaginal and adjacent or subjacent structures. These methods can prevent recurrence but may result in injury to the animal at parturition. Further, should these animals conceive, subsequent pregnancies are frequently complicated by recurrence. Hence, consideration should be given to culling affected animals after their calves are weaned [9]. Animal health advisors have an important role to play to help producers make a decision to eliminate these animals from the breeding herd. Considering the injury the animal may endure at the present and subsequent reductions, it behooves us to strongly suggest removing such animals from the herd [62].

Uterine Eversion

Appearance of a heavy mass of tissue outside the body of an animal can be intimidating and at times the process of reduction can be overwhelming. Truly the prospect of performing a successful reduction and the thought of recurrence can place one in mental anguish. We always look for ease of operation and reduced physical effort on our part to reduce eversion. In an attempt to facilitate the process of reduction, mechanical aids have been used successfully [49, 51, 57, 58]. However, raising the rear end of a live cow may appear inhumane [46]. Next, application of agents such as sugar [46, 59] or salt [53] on everted tissue to reduce edema before reduction is not supported uniformly. Although the authors prefer a careful application as supported by others in practice [46], it remains controversial [8] since it may amplify endometrial trauma. This technique may have certain academic skepticism despite its benefits.

The chance of immediate recurrence can be eliminated if reposition is done completely, without allowing invagination of the uterine horns to occur at the ovarian pole. Overall, the mortality rate ranges from 18 to 20% [8, 37]. Prognosis for survival and future reproductive performance depend on several factors, but time from occurrence to treatment is critical for a positive outcome. Despite extensive trauma that may occur before replacement, those that are replaced correctly and survive have an acceptable prognosis for future fertility [37, 64]. Occasional bladder eversion and intestinal entrapment that occurs with an everted uterus may result in a poor prognosis. Timely intervention by a professional can minimize animal discomfort and economic loss to the producer. Treatment given by an uninitiated non-professional has to be discouraged since severe damage can be inflicted to the animal [45]. A unique retention technique developed to prevent recurrence [60] should be considered to obviate situations such as necrosis, gangrene, and severe trauma, necessitating amputation.

The chance of recurrence at the next parturition has been discussed [2, 65] and heritability or additive susceptibility

with subsequent pregnancies for this condition is not apparent [1]. Since no known heritable component is recorded, there is no increased probability of occurrence at subsequent parturition. Therefore one should not be too hasty in recommending salvage of affected cows. Chance of recurrence is minimal and this has to be discussed with the producer. It should be remembered that in the developing world, cattle are an economic asset and cost of therapy must be balanced against the value of the animal. In addition to the value of the animal, its fertility will dictate whether the animal has to be culled or not. A major factor that can influence this decision is the degree of trauma caused to the uterus and the time it has taken to repair [36]. Future fertility of cows is reduced and there is a slight increase in risk at subsequent calving, but increased risk is not sufficient to justify culling [2].

As the profession moves more and more into animal health and production than restorative therapy, it is incumbent on us to prevent the occurrence of these conditions by careful selection of breeding stock, observing quality animal husbandry methods, providing adequate care to periparturient animals, and finally eliminating potential recurring cases. All the above will enhance animal well-being and place the profession as animal-welfare contributors.

Induction of Parturition and Abortion

Jennifer H. Koziol

Department of Clinical Sciences, College of Veterinary Medicine, Purdue University, West Lafayette, IN, USA

Introduction

Insight into the control of pregnancy and parturition began with the early work of Liggins [1, 2] and continues today with a great deal of research revolving around induction of parturition or abortion in cattle. This research has culminated in protocols for the induction of parturition and abortion that are successful and widely accepted in the veterinary and cattle industries today. However, these protocols are not perfect as the issue of retained fetal membranes following the induction of parturition is still a risk that one must consider. Another hurdle to the use of induction of parturition is the need for known breeding dates to ensure cows that are induced will give birth to a viable neonate. Current methods of estimating fetal maturity in the absence of known breeding dates are minimal and an area for further research.

Physiologic and Endocrine Profiles of Pregnancy

Progesterone is essential for the establishment and maintenance of pregnancy in all mammalian species that have been studied [3]. In cattle, the corpus luteum (CL) is the primary source of progesterone throughout gestation and luteal regression is necessary for parturition to occur [4]. Progesterone is also produced by the binucleate cells in the cotyledon of bovine placental tissue [5, 6]. This placental source of progesterone begins around 120 days of gestation. Between 120 and 150 days and approximately 240 days of gestation the placental source of progesterone alone is sufficient to maintain pregnancy. Placental progesterone gradually declines during the last four to six weeks of pregnancy and the maintenance of pregnancy once again becomes dependent on the CL [7, 8]. Thus if luteolysis occurred between the fifth and eighth month of gestation, pregnancy would be maintained for a time simply from placental progesterone, but parturition would likely occur several weeks before the normal due date once placental progesterone began to decline and the CL was expected to maintain pregnancy.

While the bovine placenta has the ability to produce progesterone, it does not contain the enzymatic activity for 17α-hyroxylase; therefore there is negligible placental estrogen production. However, as the fetal hypothalamus, pituitary, and adrenal glands mature, increasing amounts of cortisol are produced by the fetus. Rising fetal cortisol in the last four to six weeks of gestation gradually reduce uteroplacental synthesis of progesterone [9]. This decline in progesterone secretion is due to cortisol induction of enzymes that convert placental progesterone to estrogen. Cortisol induces 17α-hyroxylase and 17,20-desmolase activities in the placenta, catalyzing the formation of androgens from progesterone [10]. Androgens are then rapidly converted to estrogens by the placental P450 aromatase system (Figure 48.1).

During pregnancy, high concentrations of progesterone maintain uterine quiescence mainly by hyperpolarizing the myometrial cells. At the end of gestation, falling progesterone and increasing estrogen produces depolarization of the myometrial cells and stimulates the formation of myometrial cell gap junctions enhancing the sensitivity of the myometrium to stimulatory agonists [11]. Declining progesterone and rising estrogen results in increased expression of oxytocin receptors in the myometrium [12]. Increased estrogen concentrations also stimulate the production and release of prostaglandins [13]. Researchers have suggested that in sheep, fetal cortisol from the adrenals stimulates prostaglandin E2 (PGE2) synthesis in the cotyledons [14]. The increase in PGE2 results in increased upregulation of estrogen synthesis in the cotyledons which leads to the release of PGF2α

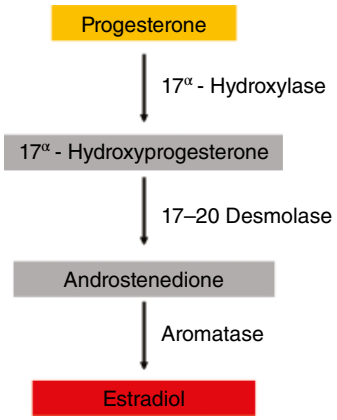

Figure 48.1 Progesterone is synthesized to estradiol following the upregulation of enzymes secondary to the rise in fetal cortisol.

from the endometrium, resulting in myometrium contractions. However, in cattle fetal cortisol directly induces PGF2α and PGE2 secretion in cotyledons [15–17]. Prostaglandins are also involved in the mechanisms of cervical ripening, which is essential for successful parturition.

Fetal endocrine control of parturition was demonstrated by Liggins in his studies on parturition in sheep. He showed that electrocoagulation of the fetal pituitary prevented normal term parturition and went on to demonstrate that the hypothalamus–pituitary–adrenal (HPA) axis was responsible for initiating parturition as infusion of glucocorticoid or adrenocorticotropin (ACTH) initiated premature parturition [18].

The trigger for the spontaneous onset of labor is the greatly increased cortisol production by the adrenal gland of the maturing fetus. The increase in activity of the fetal HPA axis at the end of gestation is likely caused by programmed maturation in the fetal hypothalamus, or elsewhere in the fetal nervous system, rather than a response of the fetal pituitary to a chronic stress such as might be caused by a developing inadequacy of space and nourishment within the uterus. Some other external influence on the maturing hypothalamus, such as a progressive increase in the secretion of the placenta, is another possibility [19].

Throughout the last two to three weeks of development in utero the fetal adrenal increases in size relative to body weight and the cellular sensitivity to ACTH increases [3]. The increase in sensitivity to ACTH is partially the result of increased adrenal cortical mass and partially the result of increased cellular responsiveness to ACTH. The increase in size and sensitivity of the adrenal gland combined with increasing circulation of ACTH account for the increased cortisol secretion that triggers parturition. Recent evidence suggests that at least some of the activity of the fetal HPA axis is due to positive feedback from placental estrogen. Increasing estrogen in fetal plasma greatly increases ACTH concentrations in fetal plasma [20].

Since fetal cortisol levels gradually rise in the last month of gestation, particularly in the last week [9], placental maturation may require exposure to elevated cortisol levels for a period of time prior to calving. This hypothesis is supported by a reduction in the incidence of retained placenta when long-acting corticosteroids are used to induce parturition [21, 22].

Induction of Parturition

Precautions

At present, one of the main obstacles to widespread use of induction of parturition is the need for accurate knowledge of breeding dates to prevent the birth of non-viable calves and an increased incidence of retained fetal membranes. Calves born up to two weeks preterm have good vitality and can attain good maternal immunity derived from colostrum [23, 24]. The incidence of retained fetal membranes is related to the degree of prematurity of the placenta at the time of induced parturition. Complete maturation of the bovine placenta occurs approximately three to five days prior to parturition [25, 26]. Rises in glucocorticoids and estrogen levels are crucial to the placental maturation process, with the increase in both hormones resulting from increasing fetal cortisol release during the last part of pregnancy [27–29]. Consequently, cows induced one to two weeks prematurely usually retain the placenta in over 75% of cases, whereas cows induced within a few days of term, or at term, have a 10–50% placental retention rate. In most reports, cows with induced parturition and retained fetal membranes did not have reduced pregnancy rates [30, 31]; however, first-service pregnancy rates were significantly lower in cows that had retained placentas than cows that did not retain their placentas [27, 32].

The effect of induction of parturition on milk yield in the following lactation and on the concentration and yield of colostral immunoglobulins most likely depends on how early parturition is induced. In general, when parturition is induced within two weeks of normal term, the onset of milk production would be a few days slower than in natural calvings, but overall production levels for the entire lactation period are within expected limits [9, 22]. When parturition was induced up to 22 days before the normally expected calving date there was a significant decrease in the yield (4–9%), but not the concentration, of colostral immunoglobulin G (IgG) [33]. When birth occurred 10–15 days or more before due date, calves had lower levels of colostral immunoglobulin [21, 33]. This may be due to

an impaired ability to absorb immunoglobulin [34, 35] and reduced intake due to calf weakness [21].

When short-acting corticosteroids are used to induce calving close to term, the immunoglobulin concentration of colostrum is not different from that in naturally calving cows; however, the total immunoglobulin content may be lower due to a reduced volume of colostral secretions [33, 34]. The ability of these calves to absorb immunoglobulin is not reduced, as serum γ-globulin concentrations after suckling are similar to those of naturally born calves [35, 36].

Indications

Induction of parturition has become increasingly more requested by beef cattle owners over the years. Especially, among those with cattle of significant economic value – whether that be the dam, fetus, or both, as seen in the seedstock and show cattle industries. Induction of parturition affords multiple advantages to the cattle owner, including concentration of labor, increased calvings during daylight hours due to the timing of injection protocols, and decreased chance of fetal oversize due to prolonged gestation length. These herds often have excellent breeding records, which include known breeding dates, artificial insemination dates, or embryo transfer dates, which are paramount in reducing known risks of inducing parturition which include non-viable, premature fetuses and retained fetal membranes.

Cows may be induced at 285 days of gestation to prevent prolonged gestational periods. This can be advantageous as the fetus can gain 0.45–0.68 kg/day in the final weeks in utero in normal gestations [37, 38]. When gestations are one to two weeks overdue, as is more commonly the case in some of the large European breeds of cattle, fetal weight gains could be as high as 1 kg/day [39, 40]. In such cases, calf birthweight might easily become too large to allow normal parturition. This is also the case with feti derived from *in vitro;* maturation (IVM)/*in vitro;* fertilization (IVF), which have been known to result in large offspring syndrome [41].

It has been reported that when a short-acting glucocorticoid was used to terminate prolonged gestation in continental breed heifers, there was dystocia due to poor birth canal relaxation and ineffective labor [36]. However, too early intervention in the calving process might have been partially to blame for this finding. In most cases, the stages of labor and pelvic relaxation are normal. Although no data are available, clinical experience from common usage of the procedure indicates that calf viability and colostral transfer are good. An additional benefit of induction of parturition in these cases might be to allow the female an extra 10–14 days to resume cycling for rebreeding in the subsequent breeding season. However, despite gestations having progressed for a normal duration, retained fetal membranes are a risk with induction of parturition. Thus the subsequent problem of metritis or endometritis may cancel any benefits of extra time gained through induction of parturition for the cow to resume cycling since endometritis may delay the first postpartum estrus.

The use of induction protocols in the commercial beef industry is often limited by the lack of known breeding dates and the inability to accurately determine fetal age in late gestation. Induction of parturition in commercial cows is often limited to the treatment of uterine hydrops, cardiac failure, or other health-related matters in which salvage of the fetus, or the life of the cow, is considered.

In dairy herds, parturition may be induced one to two weeks early to prevent excessive udder edema and distension, which may predispose the cow to mastitis and difficulty in milking. Induction of parturition with long-acting corticosteroids was once heavily utilized by dairy producers in New Zealand and Australia as an important management tool for initiation and synchronization of lactation with the grazing season [42, 43]. This management tool allows for a compact calving and consequently lactation season that allows for maximal utilization of the forage growing season. An additional benefit is that cows have the maximum number of days to become rebred in the abbreviated breeding season that follows. Inevitable though some cows will fail to become pregnant or will become pregnant too late to calve on time the following year. These cows would ordinarily be culled due to their inability to calve at the appropriate time to maximize days in lactation. Induced calving applied in association with an extended mating period reduces herd wastage. Cows that were not pregnant at the end of a defined mating season can be mated and identified by bulls fitted with a chin-ball marking harness. In the following calving season these cows can be induced to calve one to three months prematurely.

While the induction of parturition using long-acting corticosteroids has advantages from a seasonal dairy management standpoint, there are a number of downfalls including decreased calf viability, increased retained fetal membranes, photosensitization, infections, and cow mortality [44–46]. There are also mixed results regarding induction on lactational performance, with some studies reporting no effect and others suggesting a 4–9% reduction in milk yields [21, 47, 48]. Reproductive performance of induced cows does not appear to be substantially compromised in the subsequent breeding season despite increased rates of retained fetal membranes in multiple studies [21, 48, 49]. Due to animal welfare concerns the practice of induction of parturition in Australia and New Zealand has come under scrutiny. As a consequence, its use in herds has been dramatically reduced, especially in New Zealand dairy herds.

Methods of Induction of Parturition

Various types and combinations of hormone treatments have been studied for efficacy and safety of induction of parturition, including corticosteroids or prostaglandins in combination with various estrogen preparations [30, 31, 50–55] and oxytocin [56] without appreciably reducing the incidence of placental retention. Dimenhydrinate [57] and relaxin [58] in combination with dexamethasone have been reported to reduce placental retention; however, the number of cows treated with dimenhydrinate was small and relaxin is not commercially available. RU-486 or mifepristone, a potent antiprogesterone, used alone or in combination with relaxin and administered to beef cows on day 277 or 278 of gestation, resulted in basal levels of progesterone (P4) by 48 hours after injection and calving at 53–55 hours after treatment. There were no complications at calving and no retained fetal membranes; however, there were only two animals per treatment group and inductions were done very close to normal term, so a great deal more study is needed before this method can be recommended [59].

Short-Acting Corticosteroids

The most commonly used corticosteroids for inducing parturition are dexamethasone (20–30 mg) and flumethasone (8–10 mg) given as a single intramuscular injection. Parturition is induced with 80–90% efficacy when the injection is given within two weeks of normal term. The interval from injection to parturition is 24–72 hours, with an average of 48 hours. In cows that have not calved by 72 hours after treatment the induction is considered to have failed. Retreatment in such cases is often successful in inducing parturition. Relaxation of the pelvic ligaments, cervical dilation, and filling of the udder occur rapidly, and labor and parturition are normal. Calving difficulty scores that have been recorded for induced parturition have generally not been different from those of natural calvings; however, frequently a higher incidence of minor assistance is given. This is probably because personnel are readily available during induction trials and assistance is more likely to be given even when not absolutely necessary [60, 61].

Calves born less than two weeks prematurely are vigorous and calf mortality is not increased. The actual secretion of milk at the onset may not be plentiful in induced cows; however, colostral immunoglobulin levels and total milk production for the lactation period are very close to normal. Induced calves attain similar blood levels of immunoglobulins as calves born naturally. Retained fetal membranes were common with short-acting corticosteroids alone, with cows closer to their expected due (<1 week) dates having fewer reported cases of retained placentas compared to those that were further from due dates.

Long-Acting Corticosteroids

Long-acting corticosteroids alone allow for induction of parturition prior to expected due dates and in cases where calf viability is not of primary importance, as in the case of some seasonal dairy operations. Dexamethasone trimethylacetate (25 mg) or triamcinolone acetonide (TRI) (4–8 mg) may be used and appear to provide similar outcomes [22, 50, 62]. An intramuscular injection is given once 2–12 weeks prior to the due date for calving, and parturition occurs over a wide range of 4–26 days. Usually the further a cow is from her due date, the longer it takes for a response [43]. Despite prolonged elevated systemic corticosteroid levels, cow health is generally good; however, preexisting diseases, particularly subclinical infections, may be exacerbated by the treatment and there is a potential increase in cow mortality [63].

The udders of treated cows are consistently engorged with milk about one week after injection, although it may be another week or more before they actually calve. It has been suggested that these cows should be milked before calving if the udder is obviously full to prevent regression of secretory tissue. Total milk production per lactation can be expected to be reduced by 4–9% [21, 48, 49].

The incidence of retained placentas with the use of long-acting corticosteroids is quite low (9–22%) compared with short-acting corticosteroids. This is likely due to upregulation of placentome genes involved in PGE2 synthesis and the conversion of pregnenolone to androstenedione which facilitates functional maturation of the placenta [17]. However, there is a high incidence of calf mortality (7–45%), which appears to be due to calf prematurity, premature placental separation, and an increased frequency of uterine inertia.

The variability in response to treatment with a long-acting corticosteroid can be reduced by treating with a short-acting corticosteroid or prostaglandin about a week after the long-acting corticosteroid treatment [22]. Most cows will calve two to three days after the second injection. The interval from injection to calving tends to be shorter and more predictable after prostaglandin than after a short-acting corticosteroid, and fewer repeat injections are required with prostaglandins. However, calf mortality does not decrease with this method.

Prostaglandins

Induction of parturition with prostaglandins intramuscularly gives very similar results to induction with short-acting corticosteroids, with a range of 24–72 (mean 44.9) hours from treatment to calving. As with short-acting corticosteroid-induced parturitions, there is a high incidence of retained placentas and a 10–20% rate of induction failure when treatments are given within two weeks before normal term [64, 65]. The later the stage of gestation at

which prostaglandins are administered, the greater the efficacy with which a single injection induces calving.

Some investigators have reported that cows with prostaglandin-induced parturition, particularly those induced more than two weeks prematurely, suffer a higher incidence of dystocia due to uterine inertia or malpresentation of the fetus than naturally calving cows [66]. However, others indicated no difference in the frequency of dystocia in cows induced to calve one to two weeks prematurely with either corticosteroids or prostaglandins. Moreover, the induced parturitions had no greater frequency of dystocia than spontaneous parturitions. In one experiment it was observed that cows induced with cloprostenol had a longer interval from appearance of the placental membranes (onset of stage 2 of parturition) until delivery of the fetus than cows treated with dexamethasone or a combination of dexamethasone and cloprostenol. Cows receiving only cloprostenol had higher concentrations of progesterone at parturition, which may have suppressed uterine contractions compared with cows receiving dexamethasone. This may indicate that those receiving only cloprostenol may have had a placental source of progesterone that was eliminated in cows receiving dexamethasone [64].

Corticosteroids and Prostaglandins in Combination

Hormones used to induce parturition initiate endocrine events similar to those normally triggered by rising fetal cortisol levels. Corticosteroid injections appear to efficiently remove the placental source of progesterone by induction of enzymes that convert placental progesterone to estrogen. Failure of corticoids to induce parturition may be due to failure to remove the ovarian source of progesterone. On the other hand, prostaglandin injections are efficient removers of the ovarian source of progesterone, but may fail to induce parturition due to remaining placental progesterone. However, a combination of the two hormones acts in concert to remove both sources of progesterone, resulting in fewer induction failures and less variability in the time from treatment to parturition.

Experiments have been conducted to compare parturition induced by a combination of dexamethasone and cloprostenol, dexamethasone alone, and cloprostenol alone, with saline-treated controls [64]. Cows receiving a combination of prostaglandin and dexamethasone calved earlier (range 25–42 hours from treatment to calving), and the interval from injection to calving was less variable than with dexamethasone alone (29–65 hours) or cloprostenol alone (37–57 hours). In addition, with the combination treatment there were no induction failures, whereas dexamethasone and cloprostenol treatments resulted in induction failure in 10.5–16.6% [64]. The calving process for the combination treatment was considered to be normal. The rate of placental retention is significantly higher with all methods of induction of parturition than in control cows, but this was expected since with induction of parturition calving occurred before the due date and thus placental maturation would not have been completed.

Long-Acting Corticosteroids in Combination with Dexamethasone and Cloprostenol for Daylight Calving and a Low Incidence of Retained Placentas

At present, the main impediments to the use of induction of parturition are the need for known breeding dates, minimal control of the time of calving, and an elevated incidence of retained fetal membranes. It has been determined that calves that are born within the last two weeks of gestation are usually very vital and adjust well to extrauterine life [64].

Long-acting corticosteroids for induction of parturition resulted in the lowest incidence of retained fetal membranes compared with other induction methods. It would appear that the long-acting corticosteroids more closely mimicked the natural endocrine events of gradually rising fetal cortisol resulting in placental maturation. Cows receiving a combination of dexamethasone and cloprostenol had a less variable interval from injection to calving and there were no induction failures. Thus an induction regimen using a long-acting corticosteroid pretreatment followed by a combined dexamethasone and cloprostenol treatment was developed in hopes of establishing a protocol that results in reliable induction of parturition for calving during daylight hours combined with a low incidence of retained placentas.

Several experiments were carried out to determine the optimum dosages of two different long-acting corticosteroids and the optimum time interval from pretreatment with the long-acting corticosteroid and induction with combined dexamethasone–cloprostenol treatment [27, 32]. Experiments utilized Hereford and Hereford–Angus cows with known breeding dates. This important work is summarized here. In the first experiment [27], on day 270 of gestation 121 cows were placed in five groups. Groups I, II, and III received 25 mg of Opticortenol (dexamethasone trimethylacetate, a long-acting corticosteroid). Cows that had not calved by day 277 received 25 mg dexamethasone (DEX, Group II) or a combination of DEX and 500 μg cloprostenol (CLO) (DEX + CLO, Group III). Cows in Group IV received only DEX + CLO on day 277. Cows in Group 5 were untreated controls.

Pretreatment with Opticortenol followed by induction of parturition with DEX + CLO on day 277 resulted in calving during a very short time interval (28 ± 0.8 hours after induction) and the incidence of retained placentas was no different from that of the control group (13 vs 6%). The length of labor, birthweights, and calving difficulty scores were no different between groups. There was no difference in the

number of premature calves between groups and the only calf that died was in the control group.

In a second experiment [27], cows were assigned, in a 2 × 2 factorial design, to one of four treatment groups and a control group. On day 270 of gestation cows in treatment groups received either a high dose (1 mg/25 kg) or a low dose (1 mg/50 kg) of Opticortenol. The cows were further subdivided to be induced with DEX + CLO on day 274 or day 276. Induction treatments were performed at 9 a.m. in order to achieve daylight calvings. All cows in the treated groups calved between 7 a.m. and 11 p.m. about 30 hours after the induction treatment; however, the group receiving a high dose of Opticortenol and the induction treatment on day 276 had a lower incidence of retained placentas (29%) than other treatment groups. The incidence of retained placentas was 5% in the control group.

The length of stage 2 of labor, birthweights, calving difficulty, and calf viability were not different between groups and no premature calves were born in this experiment. Calf IgG concentrations at 48 hours of age were not different, whether the calves were born to induced cows or to untreated control cows, and there was no increase in neonatal illness in calves born to induced cows. In the breeding seasons following these experiments, the first-service conception rates and pregnancy rates did not differ between groups. However, first-service conception rate and overall pregnancy rate were lower in cows that retained their placentas than in cows that did not.

Two further experiments [32] were designed to determine whether pretreatment with a different long-acting corticosteroid, TRI, before induction of parturition with combined dexamethasone and cloprostenol (DEX + CLO) could be used to reduce the incidence of retained placenta and to produce a predictable calving time. The experiments were also designed to determine the optimum dosage of TRI and the optimum interval from pretreatment with TRI to induction treatment with DEX + CLO. It was determined that when cows are treated with TRI on day 270 of gestation, the optimum dosage of TRI was 1 mg/60 kg and the optimum interval from TRI to DEX + CLO was day 277. Cows receiving this combination of treatments had no retained placentas compared with 5% retained placentas in the control group. All induced cows calved between 24 and 48 hours after DEX + CLO, and 94% began to calve between 7 a.m. and 7 p.m., whereas only 58% of control cows began to calve during the same period of time. The length of stage 2 of labor, birthweights, calving difficulty, and calf viability did not differ among groups.

The results of these studies support the hypothesis that exposure to elevated blood corticosteroid levels prior to induction with DEX + CLO will result in a low incidence of retained placenta compared to induction with DEX + CLO alone. The use of long-acting corticosteroids to induce placental maturation followed by DEX + CLO to ensure parturition at a predictable time was quite successful in meeting the goals of calving in daylight, with a low incidence of retained placenta.

Induction of Abortion

Induction of abortion in cattle is a common procedure and is done for a variety of reasons. Heifer calves may become pregnant at a very early age, predisposing them to dystocia as well as retarded growth during pregnancy and during the subsequent lactation. Pregnancy in feedlot heifers usually results in reduced economic efficiency and calving management problems that feedlots are ill-suited to handle. Pathological conditions of pregnancy, including hydramnios, hydroallantois, fetal maceration, and fetal mummifications, must be terminated in order to save the life or breeding value of the affected animals.

Endocrinological Aspects

Pregnancy maintenance depends on continuous adequate concentrations of circulating blood progesterone whether pregnancy is normal or abnormal. All treatment methods intended to terminate pregnancy, except surgical removal of the fetus, must directly or indirectly eliminate the sources of progesterone. The CL is the main source of progesterone in cattle throughout pregnancy; however, the placenta and to a minor extent the adrenal glands contribute to circulating levels of progesterone. A functional CL is essential for the maintenance of pregnancy during the first 120–150 days of gestation and during the final month of gestation. From approximately 120–150 days and approximately 240 days of gestation placental progesterone alone is sufficient to maintain pregnancy; therefore lysis of the CL during this period will not terminate pregnancy.

Treatment of the pregnant bovine with prostaglandin results in luteolysis in both normal and abnormal gestations at any stage. In some cases, luteolysis appears to be incomplete and sufficient progesterone remains to maintain the pregnancy. In such cases, the female may undergo partial cervical dilation and may experience some abdominal straining, but then returns to the normal course of gestation and maintains the pregnancy to term. Ovulation and formation of a new CL may occur in these cases [65].

Glucocorticoids such as dexamethasone may reduce placental secretion of progesterone as early as the fifth month of gestation. However, glucocorticoid treatment alone will not induce abortion until the final months of gestation when these steroids are able to induce premature parturition.

In order for glucocorticoids to play a role in initiation of parturition, the fetoplacental unit must be functional. Thus in cases of fetal mummification or maceration, glucocorticoids will fail to induce abortion.

Methods of Inducing Abortion

Some of the older methods for the induction of abortions include per rectum enucleation of the CL, rupture of the fetal heart or fetal membranes and fetal decapitation, or the use of estrogenic hormones such as diethylstilbestrol or esters of estradiol. All of these methods have some significant disadvantages compared with prostaglandins [54, 67–70]. The luteolytic effect of prostaglandins will induce abortion during the first four to five months of gestation, which are dependent on the CL. During months five to eight of gestation, either PGF2α or glucocorticoid treatment alone will fail to induce parturition, although combined treatment with PGF2α or dexamethasone is highly reliable for inducing abortion during this period [71].

Situations Requiring Induced Abortion

Mismating

Veterinarians are sometimes asked to terminate pregnancy in a mismated female. The treatment of choice in these cases is to cause luteolysis. A luteolytic dose of prostaglandin may be administered as early as seven days after mismating since the bovine CL becomes responsive to prostaglandins by five to seven days after ovulation. Estrus will occur approximately three days after the prostaglandin injection and females can be rebred on that estrus if desired. First-service pregnancy rates will be normal on the estrus concurring with abortion for pregnancies advanced as far as 60 days at the time of prostaglandin-induced abortion.

Feedlot Heifers

Pregnant feedlot heifers are undesirable for a multitude of reasons, including problems associated with calving (an increased rate of dystocia, retained fetal membranes, and mortality), decreased average daily gain, inferior feed/gain ratio, and lower slaughter values [72–76]. Data from the National Animal Health Monitoring System (NAHMS) study suggest pregnancy rates in feedlot heifers are approximately 7–8%, but higher numbers may exist within some groups of cattle [77]. The main course of treatment is to utilize an abortifacient to terminate pregnancies early in the feeding period to minimize economic losses associated with heifers calving in a feedlot situation.

Heifers that calve or are aborted in the feedlot generally show poor performance in comparison with non-pregnant heifers. Problems associated with pregnant feedlot heifers include a lower feed efficiency and growth rate, lower dressing percentage and quality grades at slaughter, and management problems such as dystocia and retained fetal membranes should calving occur in the feedlot. It has been estimated that feedlot pregnancy results in losses of $44–115 USD per head [72]. The stage of gestation of the feedlot heifer will affect the degree of economic loss. In the early stages of pregnancy the anabolic effect of the luteal progesterone may actually be beneficial. Daily gains were higher in heifers pregnant up to 120 days and dressing percentage and quality grades at slaughter of heifers pregnant up to 120 days were equal to those of open heifers. Therefore heifers in early pregnancy and undergoing a relatively short feeding period could be expected to perform similarly to open heifers; however, this is seldom the case, with most pregnant heifers requiring four to six months on feed before slaughter.

All females that have recently entered a feedlot should be examined by transrectal palpation or ultrasound for pregnancy. Abortion can be induced at the time of examination. Animals induced to abort should be in good health and well adjusted to the feedlot, since induction of abortion may cause immunosuppression, especially if the protocol requires the use of dexamethasone, thereby increasing the disease risk of that animal. It is usually recommended that heifers be allowed a 21-day adjustment period to the feedlot before inducing abortion.

Growth-promoting agents containing progestins may interfere with induction of abortion and should be withheld until after abortion occurs. Heifers that are up to 150 days pregnant can be aborted with approximately 90% efficacy with a single luteolytic dose of prostaglandin [76, 78]. Those that are greater than 150 days pregnant must be treated with a combination of a luteolytic dose of prostaglandin and 25 mg of dexamethasone. Abortion will occur in 95% of these cases within 3–9 days.

Behavioral estrus occurs in 75–80% of aborting females, but since physical signs of abortion may go unnoticed and some fail to abort, all abortions should be recorded and the remainder of treated animals must be reexamined about 10–14 days after the abortion treatment. Lack of luteolysis is the most likely cause of abortion failure, and retreatment will usually induce abortion. Fetal mummification occurs in 2–4% of aborted females and this incidence is likely at least twice as high as that recorded in normal populations of cattle. Cattle that are more than four months pregnant at the time of abortion will retain the placenta in more than 80% of cases [13]. The placenta is usually passed in about one week and treatment is rarely necessary. Postpartum endometritis and purulent discharges occur in many heifers, but in most cases resolve spontaneously.

Ovariectomy as a means of inducing abortion and control of estrus in feedlot heifers has been suggested. In one experiment, ovariectomy was compared with manual or

chemical abortion and incorporation of melengestrol acetate (MGA) in the diet [79]. Ovariectomy reduced average daily gain and feed efficiency in the first 24 days. Prostaglandin-treated heifers reached slaughter condition earlier than ovariectomized or MGA-treated heifers. Only with the use of PGF2α were all pregnancies successfully terminated.

Hydropic Conditions of the Uterus

Hydropic conditions are seen sporadically in both beef and dairy cattle. Hydrops allantois is more commonly documented and can be a life-threatening disease for the affected animal due to the large volume of fluid that accumulates in the allantoic space. Salvage slaughter may be recommended, as prognosis for future fertility is poor to guarded. However, when treatment is selected, fluid drainage by abdominal catheterization paired with concurrent oral or intravenous fluid therapy should be considered as a first step in treatment. Large volumes of fluids will be required for several days to maintain hydration. Treatment to induce abortion with a luteolytic dose of prostaglandin in combination with 25 mg of dexamethasone usually will result in partial cervical dilation and accompanying loss of fetal fluid by 30 hours after treatment. Parturition is usually abnormal, with incomplete cervical dilation, primary uterine inertia, and lack of a strong abdominal press. However, since the fetus is usually small, with most cases developing at seven to nine months of gestation, fetal removal by repositioning and traction is usually successful. Postpartum metritis is a common sequela and frequently causes death. The prognosis for cesarean section is equally unfavorable because the uterus is atonic and friable and the fetal membranes are nearly always retained [80].

Fetal Mummification and Maceration

Fetal mummification or maceration occurs when a fetus dies without concomitant luteolysis and adequate cervical dilation to allow expulsion. A functional CL is often present and therefore the first step in treatment is the administration of a luteolytic dose of prostaglandin. Expulsion of the fetus usually begins within two to four days after treatment. A second treatment is usually not necessary. Estrogens have also been used; 50–80 mg of diethylstilbestrol or 5–10 mg of estradiol intramuscularly will usually result in fetal expulsion in 24–72 hours. (Editor's note: the use of estrogens in food animals is currently prohibited in the USA.) A second treatment may be necessary, and in rare cases three or four treatments at 48-hour intervals are required [80]. Whether prostaglandins or estrogens are used, expulsion of the fetus may not be complete because of poor cervical dilation and dryness of the cervix and birth canal. Lubrication and manual assistance are often necessary to achieve fetal delivery and postpartum medical care may be necessary.

Summary When deciding if and when to induce parturition, known breeding dates are a must if calf viability is of concern, and the risk of post-induction side effects including retained placentas and subsequent metritis should be discussed with the client. Long-acting corticosteroids followed by DEX + CLO have shown the most promise in controlling calving times and reducing the incidence of retained placentas but require more time and cattle to be handled multiple times. If inducing abortion, appropriate fetal aging is imperative to allow for the correct use of pharmaceutical agents, and pregnancies of 120 days of gestation or longer will require dexamethasone plus prostaglandin.

Introduction

Dystocia is a term derived from Greek, meaning difficult birth, where the dam needs assistance in giving birth. It is well known that parturition is one of the most dangerous activities of any mammalian species and can result in the death of the dam, the fetus, or both. Thus, increased mortality and morbidity rates are to be expected in addition to labor and treatment costs. Even with management that one would determine to result in a successful outcome – an alive, healthy dam and calf – dystocia results have negative economic consequences. Following dystocia, a cow typically has a delayed return to estrus, which in turn impacts rebreeding in both beef [1] and dairy cows [2]. Also, calf performance has been shown to be negatively affected, with this being manifested by lower weaning weights.

The common etiologies for dystocia are fetopelvic disproportion, fetal malpresentation, a fetal abnormality, uterine inertia, and uterine torsion. Fetopelvic disproportion, which is simply described as excessive fetal size relative to the pelvic size of the dam, in addition to being the most common cause of dystocia [3], is realistically the only risk factor for dystocia that is amenable to preventive management and thus will be the focus of this chapter. Malpresentation as an etiology is typically overrepresented in the minds of cattlemen, as most forelimb and head malpresentations are in fact the result of fetopelvic disproportion.

Researchers have used kilograms of traction pressure or a more common five-point subjective scoring system to assign dystocia. The traction pressure can be measured with a traction pressure gauge attached to the calf puller [4]. The subjective calving difficulty scoring system (1–5) is determined as follows: 1 is designated for no assistance, 2 for easy pull, 3 for mechanical pull, 4 for hard mechanical pull, and 5 for cesarean section [4, 5].

Cursory thought on fetopelvic disproportion leads one to a couple of immediate areas to address: the increased incidence of dystocia in the heifer versus the multiparous female, and the impact of calf birth weight. Thus, heifer selection and development combined with management to avoid incompatible calf birth weights guide the approaches we will outline to decrease the incidence of dystocia.

Overall, studies show that it is paramount that producers have correct breeding management combined with genetic selection programs to decrease dystocia in cows [6]. Additionally, a timely diagnosis of dystocia and then assistance and correction will help reduce calf mortality [6].

Fetopelvic Disproportion

Fetopelvic disproportion results from the relative incompatibility of fetal birth weight and maternal pelvic size. Genetics, more specifically breed (strain within breed, and of sire and dam), influence calf birth weight, as do other factors such as gestation length, nutrition, season, and climate. Maternal pelvic size is influenced by parity, weight, frame (or skeletal size), and age.

Although birth weight and maternal pelvic size appear unrelated, there are factors that are associated genetically, such as frame size. This must be taken into consideration when management decisions are made to influence one without impacting the other. For example, when heifers in a commercial setting are selected solely based on pelvic area (pelvic height × pelvic width) there is a tendency to select older, larger heifers, which in turn typically have larger calves. Thus, an improvement in pelvic size is often

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

offset by having heavier calves. One must take all factors into consideration and use management tools in such a manner as to exploit each factor without detriment.

Risk Factors for Dystocia

The incidence of dystocia in heifers has been calculated to be anywhere from three to ten times that of multiparous cows, whether in beef [7] or dairy [8] cattle. This is consistent regardless of where in the world cattle are being raised [8]. Increased risk with heifer calving occurs when no interventional management is implemented.

In an observational study performed by Holm et al. [9], data were collected on a large group of heifers over two years. In addition to measuring body weight, pelvic area, and body condition score at the time of a prebreeding examination, the heifer's birth weight and the occurrence of dystocia at her birth was recorded. The heifer's body weight correlated to pelvic area, and for every increase of 1 cm^2 in pelvic area there was a 2% decreased risk for dystocia. Now one should note that this decrease in risk or odds of dystocia is not the same as a decrease in incidence. For example, if there is a 5% risk of dystocia, the odds would be 1 : 20 and a decrease in the odds of 2% would change that to 1 : 20.04. In this study, there was no association between dystocia and either the heifer's birth weight or dystocia occurring at her birth [9].

The birth weight of a calf is of course a central factor when addressing the issue of fetopelvic disproportion as a primary causative factor in dystocia. Additionally, calf birth weight represents an independent risk as the incidence of dystocia increases with every kilogram increase in calf birth weight in both beef [7] and dairy [10] cattle and this is independent of parity (Table 49.1). A recent study showed an increased incidence of dystocia in primiparous cows when compared to multiparous: 10.7 and 3.75%, respectively [6].

Table 49.1 Breed of sire means (in pounds) for 2011-born animals under conditions similar to US MARC.

Breed	Birth weight	Weaning weight	Yearling weight
Angus	87.3	577	1045.3
Hereford	91.7	571.5	1009.7
Red Angus	88.1	561.5	1013
Shorthorn	93.7	556.5	1022.9
South Devon	91.4	566	1030
Beefmaster	92.1	575.6	1002.9
Brahman	98.3	587.7	989.3
Brangus	90.8	568.2	1008.4
Santa Gertrudis	92.6	570.5	1013.9
Braunvieh	89.9	549.4	981.8
Charolais	94.7	592.4	1047.7
Chiangus	90.9	546.2	987
Chiangus	90.9	546.2	987
Gelbvieh	89.6	575.4	1027.1
Limousin	90.8	574.7	1007.7
Maine-Anjou	91.8	554.1	1000.8
Salers	89	566.4	1019.5
Simmental	91.5	586.1	1038.8
Tarentaise	89.1	576.2	1008.2

Note: Because of the prevalent use of the English system of weights and measures in the calculation of EPDs, pounds were used in this table.

Heifer Management to Decrease Dystocia

Heifer calving has long been accepted as an inherent risk factor for dystocia. Efforts to address or ameliorate the incidence of dystocia in heifers focus on heifer selection and heifer development or conversely sire factors that would influence calf birth weight. For example, a study showed heifers had a higher dystocia rate when compared to cows [11]; more specifically, it has been shown that first parities are associated with 4.7 times higher odds for dystocia than later parities in dairy cows [10]. Another study compared beef heifers at two and three years old, with lower dystocia rates evident in the older heifers because of their larger precalving pelvic dimensions, with a consequent smaller disproportion between dam and calf sizes [4]. Also, primiparous cows were seen to be 2.5 times more likely to have dystocia when compared to multiparous cows [12].

Maturity index in heifers is calculated taking into consideration factors such as heifer age, birthweight, prebreeding weight, dam age, dam weight, and nutrition and it significantly predicted dystocia [13]. Thus, a higher maturity index was associated with decreased dystocia rate and also increased chance of a first and second pregnancy [13].

A usual practice is to breed heifers when they reach a target weight of 60% of their adult weight to minimize dystocia risks [5]. However, when heifers were bred at 53% of their mature birth weight there was no difference in dystocia rate when compared to heifers bred with 58% of their birth weight, which would reduce the costs of developing heifers [5].

Pelvic Measurement

Fetomaternal disproportion, with disproportional calf birthweight to dam size and conformation, will often result in dystocia. As pelvic conformation, narrowness of the pelvic

inlet, sacrum length, and skeletal maturity are primary maternal factors associated with dystocia, the assessment of pelvic measurement in heifers can be beneficial [14].

Measurement of the pelvic area is routinely done in beef heifers, using a caliper-type pelvimeter (Rice pelvimeter, Lane Manufacturing, Denver, CO; or a Krautmann-Litton Bovine Pelvic Meter, Jorgensen Laboratories, Loveland, CO), with pelvic height being the measurement between the cranial end of the pelvic symphysis and the dorsal wall of the pelvis, and pelvic width the measurement of widest distance between the medial aspect of the ileum. Thus, the pelvic area is calculated as the product of pelvic height × pelvic width [4, 9, 11]. Using the calf body weight at birth and pelvic area measurement, it was calculated that for a 1-kg increase in calf body weight there was a 37% increase in the odds of dystocia [4]. For every 1 cm^2 in pelvic area there was a 2% decrease in the odds of dystocia (after adjusting for calf body weight, year of birth, and dam parity) [4, 9]. Interestingly, neither the heifer's weight during her first calving nor the heifer's birth weight was associated with dystocia [4]. Additionally, it has been estimated that the odds of dystocia decrease by 11% per square decimeter (dm^2) increase in pelvic area of the dam [10].

In beef heifers, pelvic area affected dystocia; if heifers had smaller pelvic area measurements at 12 and 22 months (animals calved within 25 months) it resulted in more heifers needing cesarean sections [9]. Also, related to skeletal maturity of the dam, it has been shown that older heifers have a decreased risk of having dystocia even with primiparous cows having calves with lower birth weight and shorter gestational length when compared to multiparous cows [10].

When pelvic area results were used to estimate the culling of heifers, the remaining females had higher body weight and higher calving rate, with the calves showing a tendency to have higher birth weight [9]. Thus, this might be a good indication to measure pelvic area in heifers and use those results to decide if the animals should be rejected for breeding or bred with an easy-calving bull (one that sires calves with low birth weight) [14].

Furthermore, even though pelvic measurement in heifers has been shown to be a valuable tool in animal selection to decrease dystocia, it is rarely used in dairy cattle [15].

However, there are controversial results regarding the use of pelvimetry in beef heifers as it has been reported that pelvimetry was a bad test to predict dystocia, with a large overlap of pelvic area in heifers that had or did not have dystocia (heifers with both small and large pelvic area had dystocia) [11]. This negative outcome of pelvic measurements to predict dystocia might be due to imprecision of measurements with low agreement between and within veterinarians using the Rice and Krautmann-Litton pelvimeters [11].

Management that Addresses Calf Birth Weight

Sire Effects

Sire Breed

The sire breed is an important factor as it genetically and epigenetically contributes to fetal growth and calf birth weight. It is important to point out that maternal effects are less heritable than paternal effects [16]. A study using 4579 first-parity females (Angus, Hereford, or MARC II – one-fourth Angus, one-fourth Hereford, one-fourth Pinzgauer, and one-fourth Red Poll) mated to seven breeds of sires from the US Meat Animal Research Center (MARC) Germplasm Evaluation Program showed that Hereford, Angus, Gelbvieh, and Brangus sires resulted in calves least likely to result in dystocias [16]. Contrarily, Chiangus, Charolais, and Limousin sires were the most likely to sire calves that would need assistance at birth [16].

Expected progeny differences (EPDs) is a useful tool to identify sires that are likely to sire calves with low or high risk of dystocia. For instance, birth weight EPDs (BW EPDs) could predict the birth weight of the sire's calves in comparison to other sires. Moreover, calving ease EPDs (CE EPDs) and/or calving ease direct EPDs (CED EPDs) could predict the relative calving ease of a sire's calves in comparison to other sires. Therefore, in cases of heifers that are expected to be at high risk of dystocia, it is recommended to select sires with low BW EPDs or high CED EPDs to reduce the risk of dystocia [14].

Calf Birth Weight, Size, and Conformation

Calf birth weight is the key intermediate fetal factor affecting risk of dystocia, as heavier calves are often associated with larger body dimensions. It was estimated that an increase of 1 kg in birth weight corresponded to a 13% increase in the odds of dystocia in dairy cows [10]. Moreover, a study with beef heifers showed that calf birth weight was the most significant risk factor for dystocia occurrence and severity [4], with body weight explaining approximately 41% of the genetic differences in dystocia [16]. Again, breeding yearling heifers with sires with low BW EPDs should decrease the risk of dystocia.

Gestation length also influences calf weight, which is influenced by genetic effects [17]. It has been shown that cows that have a shorter gestation produce calves with lower birth weight. Therefore, to reduce incidence of dystocia, short gestation length can be genetically selected. Gestation length was positively correlated to both calf birth weight and dystocia in calves from 14 *Bos taurus* bulls of different breeds mated to Hereford and Angus cows [17].

Double-muscling, also known as muscular hypertrophy, is a genetic condition associated with muscular hypertrophy due to mutation of myostatin (MSTN, also known as growth differentiation factor 8, GDF8). Doubled-muscled calves are heavier and larger and consequently associated with a higher risk of dystocia. The highest frequency of doubled-muscled calves has been reported in Belgian Blue breeds [16]. Delivery by cesarean surgery is the best choice for such cases.

Fetal anomalies and monsters, such as conjoined twins, fetal duplication, schistosomes, and anasarca calves, are also a predisposing factor for dystocia.

Dam Effects

Dam Breed

The dam breed effects for calving difficulties were reduced for Simmental and Charolais and increased for Red Angus and Chiangus cows [16]. Additionally, it is important to point out that maternal effects are less heritable than paternal effects [16].

Moreover, it has been reported that dairy cows have a higher prevalence of dystocia when compared to beef cows, possible because beef calves have undergone a stricter selection for calving ease [6].

Nutrition and Body Condition Score

Body size and parity are the key intermediate maternal factors affecting the risk of dystocia. Females that have not received an adequate diet and have a low body score might have a predisposition for dystocia [21]. Inversely, if the cow has been overfed there usually is an increased calf birth weight and fat deposition in the pelvic area, consequently leading to dystocia [21].

Primiparous, two-year-old Angus heifers received different diets during the first trimester of pregnancy, with animals receiving a high- or low-gain diet so they had a different rate of liveweight gain. Although the treatments were successful, resulting in heifers with different weights between treatments, there were no differences between the treatments in the number of heifers that had calving difficulties that resulted in assisted parturitions, and calf birth weights were not different between the groups. Contradictorily, when different diets were implemented before insemination and during the first 90 days of gestation, birth weight of calves and postpartum weight of heifers were different; however, the small numbers were not sufficient to show whether the reduction of calf birth weight of 3–4 kg (8–15%) would be responsible for a reduction in dystocia [22].

Thus, it might be beneficial to restrict concentrate/energy intake and avoid heavy or poor feeding during the last three weeks of pregnancy to avoid fat deposition.

Effect of Calf Gender

Male fetuses are often associated with a longer gestational period and consequently heavier body weight than females. Therefore, male calves are often associated with increased risk of dystocia during parturition in comparison to female calves. It was estimated that male calves are associated with a 25% increase in the odds of dystocia in dairy cows compared to female calves [10, 15]. Another report shows that male calves were 9.3 times more likely to require assistance during parturition compared to female calves. Consequently, the use of sexed semen for female calves might be beneficial in reducing dystocia, especially in smaller yearling heifers [22].

Furthermore, various studies have shown that there was a significant greater calving difficulty with male calves [12, 14, 19, 20, 22].

Effect of Season

There have been reports showing the effect of season on birth weights and consequently dystocia in cows; however, there have been different results between studies. When calving during winter was compared to summer in Holstein cows, there was 15% higher odds for dystocia to occur during winter calving, possibly due to the fact that during cold winters there will be an increased uterine blood flow to the uterus, with a subsequent higher calf birth weight, and also because dams would consume more hay during cold temperatures, which would provide more nutrients to the fetus [4, 10, 15].

Also, related to effect of season, beef heifers that were bred at 15 months (using calving ease bulls) and calved as two-year-olds had increased blood flow, evaluated with Doppler ultrasound, at 210 days of gestation when they calved during the spring compared to fall and heifers with higher calf weight [23].

Fetal Malpresentation and Twining

The normal presentation, position, and posture consist of a calf in cranial longitudinal position, dorso-sacral, with extended limbs and neck. When calves are not in this manner, such as with a posterior presentation, there is an increased incidence for dystocia [21]. The incidence of malpresentations is 2.7–4.1% [24, 25]. This aspect is very important, as fetal malposition was reported to be the leading fetal cause of dystocia in a study conducted in Italy [6]. Therefore, it is recommended to observe heifers hourly

when calving starts and to be ready to assist if calving is prolonged or if the calf is not in normal presentation.

Twin calves usually weigh less than singletons [12]. However, twin calves are usually associated with higher malpresentations than single calves (17.4 vs 2.7%) [25]. Dairy cows carrying twins should be frequently observed during the prepartum period and assisted during calving [25].

Heterosis

Heterosis is the result of mating two diverse breeds of animals so that there is an interaction between genes that increase the performance of the resulting calf compared to the purebred calf [18]. This breeding practice should also result in more vitality in crossbred calves, which might result in lower dystocia incidence [19]. Also, breeding a dam and bull of different breeds might reduce calving difficulty [19]; however, results from controlled crossbreeding studies have varied [12, 19, 20].

When groups of crossbred cows, using pure Holstein dams and crossbred dams of Holstein with Normande, Montbeliarde, and Scandinavian Red, were bred to Brown Swiss, Montbeliarde, and Scandinavian Red bulls the cows with crossbred calves had less calving difficulty when compared to those with purebred calves [19].

Conversely, a study that collected data during approximately four years with the objective of evaluating the percentage of pregnancy parameters when Holstein and Jersey animals were crossbred, with special consideration to avoid inbreeding in the purebred crossings, showed that direct heterosis was not significant for incidence of dystocia; however, there were direct genetic effects with purebred Holstein calves having more chances of requiring assistance at birth. Even with no statistical difference with crossbreeding, this study concluded that it is beneficial to use a Jersey sire on a Holstein dam to minimize dystocia [12]. Another study evaluated nine different breeds that were bred to generate three composite populations for effects of heterosis and found that although it was significant for calf birth weight, it was not significant for calving difficulty [20].

Overall, these studies suggest that there will be lower dystocia incidence if producers use bulls and cows of different breeds to produce crossbred calves.

Genetic Effects

With the use of high-throughput screening, such as next-generation sequencing (NGS), additional genetic information can be established for cattle regarding calving traits, including calving ease which is directly related to incidence of dystocia. One approach that has been used is to analyze the quantitative trait locus (QTL), which corresponds to a region of DNA associated with a specific phenotypic trait, to identify genes that have an importance for calving traits. Additionally, single-nucleotide polymorphisms (SNPs) consist of a variation at a single position in a DNA sequence of an individual, located in specific genes, and are identified to be associated with calving traits.

A study using Illumina paired-end sequencing examined QTLs and defined a region that was related to calving ease targeting the BTA18: 57 321 450–57 625 355 region of the *B. taurus* genome that had been previously identified as having a strong effect for calving traits. This work was able to identify candidate genes located in the BTA18 gene cluster that were associated with calving ease, such as sialic acid-binding immunoglobulin (Ig)-like lectin 12 (SIGLEC12), CD33 antigen-like (CD33), and carcinoembryonic antigen-related cell adhesion molecule 18 (CEACAM18) [26].

Assisted Reproductive Technology (ART)

The use of assisted reproductive technology (ART) in cattle has increased since the 2010s. However, one of the disadvantages of this technology is that some embryos derived from ART have abnormal development or developmental anomalies such as large offspring syndrome (LOS). The term LOS is used to describe calves born as a result of somatic cell nuclear transfer (SCNT) or *in vitro* embryo production (IVP). LOS is characterized by the birth of calves with heavier birth weight than normal. A study showed that 26% (of 27 calves) were above the 97th percentile of body weight, showing the overgrown feature often associated with LOS after ART [27]. Thus, with these larger calves there is an increased risk of dystocia, necessitating assistance during calving.

Summary

In a well-managed herd which has proper management at artificial insemination/natural service, before calving and at calving, considering factors such as when to breed heifers, proper sire selection, proper nutrition, and having trained personel to assist calving, the percentage of births that need assistance is expected to be low. As dystocia can result in costs of assistance and veterinary service or death of the calf and dam, it is very undesirable for it to occur in a cattle breeding operation (Figures 49.1 and 49.2).

Therefore studies using large numbers of animals, modern statistical models (such as QTL), and high-throughput sequencing are essential to better define risk factors that can lead to calving difficulty, so that veterinarians and producers can better manage beef and dairy cows and reduce dystocia rates in herds.

Dystocia and Accidents of Gestation

Herris Maxwell

Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

To produce saleable products, replenish herd populations, and align the genetic base with production goals, sustainable cattle production relies on successful reproduction. The establishment and maintenance of pregnancy requires the integration of a complex series of events with many opportunities for disruption that may compromise gestational outcome, including failure of fertilization, embryonic death, abortion, pregnancy-associated disease of the dam, birth of animals with congenital anomalies, and perinatal death losses. Intricately choreographed events leading to successful gestation are sometimes imperfect and accidents of gestation adversely impact reproductive success.

Embryonic Death

Following appropriately timed insemination with high quality semen, fertilization (i.e. union of male and female gametes to form a zygote) rates are high in otherwise healthy and anatomically normal cattle [1]. Failure of the development of the embryo to the fetal stage (42 days in cattle) is termed embryonic death, which is often arbitrarily subdivided into early embryonic death and embryonic death later in development, without a universally accepted definition of the stage of development separating the two. The corpus luteum undergoes luteolysis following embryonic death and, though frequently unobserved, the products of conception are expelled from the uterus via the cervix (Figure 50.1) [2]. Although abortion and perinatal death are easily recognized as sources of reproductive failure, embryonic death is the larger component of overall pregnancy wastage.

Strategies to minimize embryonic loss have proven elusive but are emerging with investigations of the causes of failure of pregnancy to develop. Several review articles [3–5] outline specific conditions associated with embryonic death and pregnancy wastage, including uterine environmental deficiencies, heat stress, teratogenic toxins, nutritional deficiencies, viral infections, and chromosomal abnormalities. Characterization of the bovine genome has facilitated discovery of genetic combinations which are embryo lethal in the homozygous state [6–9] and discovery of other embryo lethal mutations is expected to follow.

Development of commercially available genomic testing provides a viable method to identify carrier animals for recognized conditions. Breed associations working with progressive producers are actively implementing strategies to minimize reproductive loss as these tools become available.

Fetal Death

Abortion

In cattle, a conceptus greater than 42 days gestational age is defined as a fetus, and pregnancy loss after onset of the fetal period and prior to the possibility of extra-uterine survival is appropriately referred to as abortion. Of lesser overall magnitude than embryonic death, abortion results in loss of an annual production cycle for the cow and frequently results in culling.

Abortion may be the result of bacterial, viral, or fungal infections, toxins, genetic defects, nutritional imbalance or deficiency, endocrinopathies, stressful events, or inappropriate pharmacologic intervention. Obtaining an accurate diagnosis is necessary to formulate and implement effective preventive measures and requires the investment of time and resources. Unfortunately, even with extensive

diagnostic investigation, the etiology of abortion may not be apparent and the proportion of case submissions successfully diagnosed at accredited diagnostic facilities seldom exceeds 50%. Laboratory diagnostic success improves with an accurate herd history and timely evaluation of appropriately collected samples, including the fetus and placenta, and maternal serum, and with multiple case submissions when more than one pregnancy loss occurs.

Fetal Mummification

Following death in utero, the bovine fetus is usually expelled from the uterus and passes through the cervix and vaginal vault. Retention for up to a day or longer resulting in autolysis prior to expulsion is not uncommon. Occasionally expulsion efforts fail and the dead fetus is retained within the uterus. If luteolysis does not occur and the retained fetus is not contaminated by bacteria, the cervix remains closed and the conceptus can undergo an aseptic process of partial desiccation and absorption of much of the fetal and placental fluids, leading to fetal mummification [10]. Mummification following fetal demise occurs in only a small percentage of bovine abortions. Most cases of fetal death resulting in a mummified fetus occur between the third and sixth month of gestation, with occasional reports in more advanced pregnancies. Cows carrying mummified fetuses exhibit no obvious external signs other than anestrus associated with the retention of the corpus luteum and vaginal discharge is not seen until the cervix opens following luteolysis.

Diagnosis is usually made at the time of routine examination for pregnancy or during examinations prompted by failure to calve at the expected time. Transrectal palpation of the uterine contents is generally sufficient for diagnosis, with the finding of a relatively thick-walled uterus tightly surrounding the fetal remnants. Palpable placentomes are absent and the contours of the fetus are smooth, rather than irregular and sharp as occurs in cases of fetal maceration. Transrectal ultrasound examination of the uterine contents is a useful diagnostic aid.

Retention of the mummified fetus may resolve following spontaneous lysis of the persistent corpus luteum and the expulsion of the mummified remnants into the vaginal cavity. The passage of the mummy may be the first indication of pregnancy loss [11]. Often the cow will be observed straining when the fetus enters the vaginal vault and complete resolution may require manually assisted vaginal retrieval of the fetal remnant.

Induction of luteolysis with prostaglandin F2α is the most common therapeutic intervention following diagnosis of fetal mummification. The cow or heifer should be monitored daily for complete expulsion of the fetal remnants and assistance provided if necessary [10]. Multiple treatments may be required in some cases. Successful rebreeding following either spontaneous or induced expulsion of a mummified bovine fetus is common.

In some cases, luteolytic therapy fails to result in expulsion of the mummified fetal remains. Surgical removal via hysterotomy may be required for refractory cases and for larger fetuses. Surgical retrieval may improve the preservation of fertility compared to assisted transcervical extraction [12]. Surgical approaches that provide access to the uterus through flank laparotomy, ventral midline incision, or colpotomy are described in Chapter 55 of this text. The choice of surgical approach is guided by the surgeon's experience and the size of the mummified fetus (Figure 50.2).

Fetal Maceration

In the absence of a functional corpus luteum, aborted fetuses are usually expelled following fetal death but may be retained when cervical dilation is insufficient to allow eviction of the fetus. A retained aborted fetus will initially undergo autolysis. Degeneration is accelerated as fetal tissues are contaminated with either abortifacient bacteria or saprophytic bacteria which gain access to the uterus through the open cervix. At normal body temperature, bacterial contaminants invade fetal tissues and multiply rapidly. If not expelled in a timely manner, fetal soft tissues will progressively undergo a process of degeneration and liquefaction known as fetal maceration, leaving shreds of fetid fetal tissue, skeletal remnants, and inflammatory exudates within the lumen of the inflamed uterus.

The physical condition of cows with a macerated fetus in utero can range from severe systemic illness associated with overwhelming metritis and toxemia, to cases in which

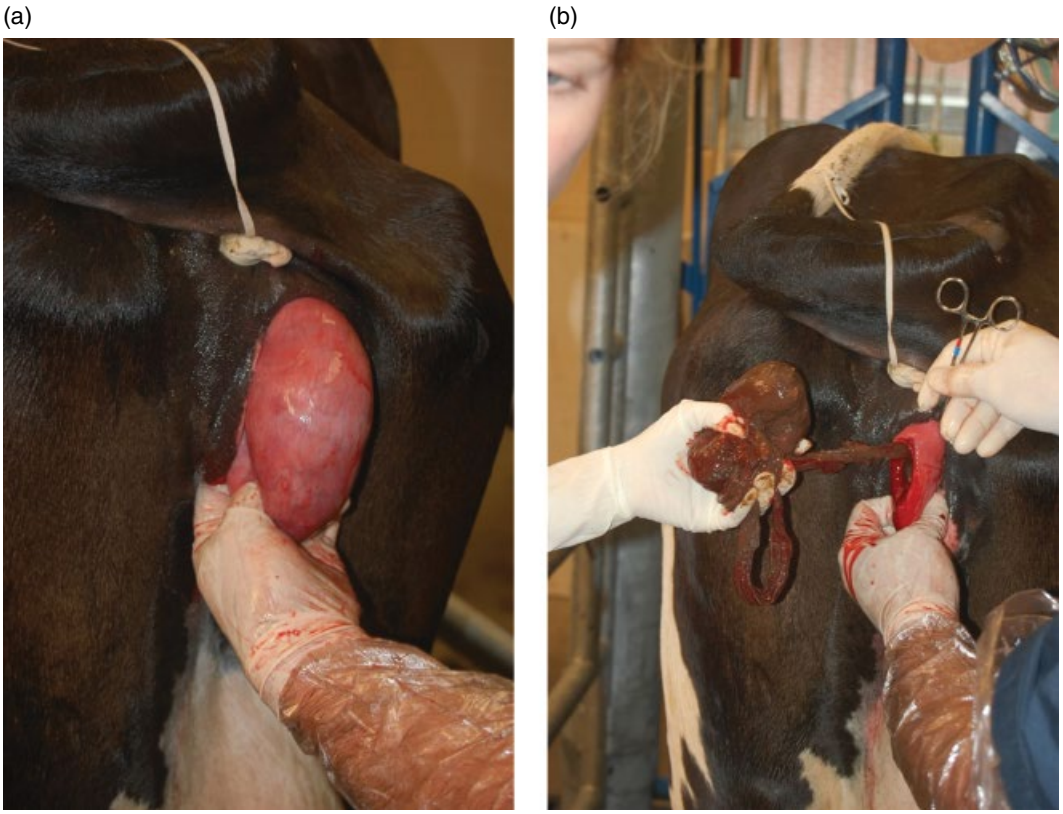

Figure 50.2 (a) Uterine horn containing a fetal mummy exteriorized through the vulvar lips utilizing a colpotomy incision. (b) Extraction of a fetal mummy from the uterine horn exteriorized through the vulvar lips utilizing a colpotomy incision.

intermittent straining and the presence of a fetid vaginal discharge in the dam are the only readily apparent signs. In some cases, all signs of systemic disease in the dam may have resolved by the time of examination, but the cervix will remain at least partially open and a fetid uterine discharge from the vagina is present. Diagnosis is based on physical findings utilizing transrectal or transvaginal palpation of the uterine contents. In contrast to the rather smooth contours of a mummified fetus, maceration-associated degeneration results in skeletal collapse and formation of sharp bony fragments, with a palpable crepitation of the disjointed skeletal remnants described as feeling similar to a bag of gravel. If no systemic disease is present, salvage by slaughter is recommended. Humane euthanasia should be considered for many other cases.

Manual dilation of the cervix and piece by piece removal of degenerating fetal remnants is possible but is difficult and time consuming. Bony fragments are embedded in the wall of the tightly contracted and markedly inflamed uterus (Figure 50.3). Options for surgical retrieval are hampered by the lack of an approach that provides sufficient access to exteriorize the tightly contracted uterus, and the presence of septic uterine contents. Following successful manual removal of fetal remnants and appropriate supportive care, some cows improve and gain weight but rarely achieve a subsequent pregnancy.

Developmental Defects and Congenital Anomalies Resulting in Fetal Death or Production of a Non-Viable Neonate

Successful pregnancy results from a complex series of developmental events which culminate in birth of a normal neonate. Deviations from normal development can result in pregnancy wastage in the embryonic or fetal stages or in stillbirth, birth of non-viable neonates, or birth of defective but viable offspring. Defects present at the time of birth are classified as congenital, with their origins predating parturition, and result from disruptions in normal developmental sequences. Viable neonates with congenital defects are adapted survivors from single or multiple disruptive events which occurred during fetal or embryonic development. Similar disruptions can result in fetal death (abortion) in those fetuses that cannot compensate for loss of function (Figure 50.4).

Figure 50.3 Skeletal remnants from macerated twin fetuses extracted per vagina. Removal of a macerated fetus through the partially open cervix is difficult and smaller bones are tightly embedded in the endometrium.

Figure 50.4 Duplication of the fetal head and neck. Fetuses with duplications of the head or limbs (dicephalus or polymelia) do not conform to the limits imposed by the birth canal and result in dystocia. *Source:* Image courtesy of Dr. Ethan Andress and Dr. Jenna Innes, West River Veterinary Clinic, Hettinger, ND.

Historically, the origins of most developmental disruptions were undefined and the resulting offspring were described as the result of accidents of gestation. Severely malformed cases were referred to as fetal monsters. More recently, genetic, toxic, and infectious agents have been causally associated with several specific syndromes and over time definitive causes of many other recognized congenital anomalies will be discovered, providing opportunity for effective avoidance strategies. Development of commercially available genetic testing services allows breed associations to address the incidence of specific recognized hereditary mutations by either prohibiting inclusion of carrier animals in the respective herd book or identification of carriers to minimize occurrence of affected individuals through informed breeding management decisions.

Non-genetic etiologies for congenital anomalies include toxins and viral agents. Teratogenic toxins found in plants or introduced into the environment in the form of synthetic chemicals are implicated as agents inducing congenital anomalies. Nearly identical anomalies may occur following infection of the pregnant cow with any of several viral pathogens coincident with fetal development in the late embryonic and early fetal periods. Avoiding exposure to potentially teratogenic plants, toxins, and viruses during critical periods of fetal development and enforcement of biosecurity and vaccination protocols are necessary components of overall reproductive management. Often the cause of fetal malformation is not known. *Schistosomus reflexus* (Figure 50.5) and *Perosomus elumbis* are two well-recognized instances of fatal fetal deformity for which a definitive cause has not yet been discovered.

Severely deformed calves will not readily conform to the physical limitations imposed by the birth canal at parturition and result in memorable dystocias necessitating fetotomy or cesarean section.

Vaginal Prolapse

Eversion of the vaginal floor or wall and/or of the cervix through the vulvar lips resulting in vaginal or cervicovaginal prolapse occurs most commonly during mid to late

Figure 50.5 *Schistosomus reflexus* fetal monster. Arthrogrypotic limbs and abnormalities of the axial skeleton make vaginal delivery of severely malformed fetuses difficult. Delivery by cesarean section or fetotomy is usually required.

Figure 50.6 Vaginal prolapse with eversion of vaginal wall and external cervical os.

Figure 50.7 Reduction of prolapsed vaginal tissue following cleansing and debridement.

gestation. Increased abdominal pressure from the presence of the large gravid uterus, a physiological increase in circulating estrogen concentrations during advanced pregnancy, and anomalies of the vaginal wall and cervix leading to tenesmus are contributing factors to subsequent eversion of the vaginal mucosa. Vaginal and cervical trauma associated with previous parturition or dystocia and excessive abdominal fill associated with diets composed of low quality forage may also play a role. In some breeds (Hereford and Shorthorn) primary vaginal prolapse exhibits familial patterns, suggesting a heritable phenotypic component. *Bos indicus* cattle and their crosses often have a posterior widening of the caudal cervical rings with a large external cervical os that allows eversion of more cranial cervical rings following successive parturitions and contributes to the occurrence of cervicovaginal prolapse in those breeds. Pregnancy-associated vaginal prolapse is likely to recur in subsequent pregnancies and subsequent breeding of affected animals is not recommended. Similar vaginal prolapses are sometimes seen in genetically valuable animals subjected to repeated superovulation for collection of embryos and are not thought to be heritable.

Diagnosis of primary vaginal or cervicovaginal prolapse is based on the typical appearance (Figure 50.6). Initially the vaginal mucosa may only be seen when the cow is in sternal recumbency, but a progressive cycle of irritation, tenesmus, and accumulation of tissue edema eventually results in more permanent protrusion of the vaginal floor and sometimes the external cervical os. Treatment consists of appropriate debridement of damaged tissues and reduction of the everted vaginal tissues into the pelvis, reestablishing anatomy of the vagina (Figure 50.7).

Desiccation and trauma to the exteriorized vaginal mucosa accumulate over time and complicate reduction of the prolapsed tissues in long-standing cases. A variety of retention techniques described to maintain the tissues in normal alignment following reduction are discussed Chapter 47. The practitioner's choice of technique must always include an assessment of the proximity to calving and the impediments to successful parturition inherent in many of the retention strategies.

Uterine Torsion

Uterine torsion is an infrequent accident of gestation and results in dystocia requiring specific obstetrical interventions or cesarean section. Both the degree of uterine torsion

and the duration of the torsion affect progression of labor, clinical outcome, and case management [13]. Uterine torsion can occur in any breed, with large, deep-bodied cattle and dairy breeds having increased risk. Brown Swiss cattle are overrepresented and *B. indicus* breeds may have a lower incidence of occurrence, perhaps due to lower birth weights and anatomical differences in the attachments of the broad ligaments to the uterus. Predisposing factors include a previous pregnancy and the presence of a large fetus [14]. Twin pregnancies are less likely to be affected [15].

Not all factors contributing to torsion of the uterus are understood. The uterine horns are suspended from the body wall by the broad ligaments which attach on the ventral surface and lesser curvature of the uterine horns. As pregnancy progresses, much of the enlarged uterine horn containing the fetus extends cranial to the area of abdominal attachment of the ipsilateral broad ligament and occupies the ventral abdomen, stabilized by the proximity to the body wall, the rumen, and other abdominal viscera. Because cattle typically rise from recumbency by first elevating the rear quarters, and assume recumbency by first lowering the fore quarters and cranial portion of the body, the pregnant uterus will be suspended by the broad ligament multiple times daily as the cow lies down to rest and arises from sternal recumbency, providing an opportunity for rotation of the gravid uterine horn following a slip or fall, or as the result of unfortunately timed fetal movements [14]. Other contributing factors may include a lack of rumen fill and poor abdominal muscle tone.

Most diagnosed cases of uterine torsion in cattle are late gestational events and are frequently first recognized at the time of obstetrical examination following failure of parturition to progress normally. Torsions of 45–90° are sometimes discovered in otherwise healthy cattle examined transrectally for pregnancy diagnosis or other reasons and often resolve without intervention.

Torsion of the uterus up to 180° does not result in vascular compromise and clinical signs do not become evident until the onset of labor and failure to progress toward delivery. As the degree of torsion exceeds 180°, uterine blood flow is increasingly compromised and subsequent venous congestion is followed by uterine and placental edema which may lead to death of the fetus. Ischemic necrosis of the uterine wall may follow and predispose to uterine rupture and death of the dam.

Successful manipulation to correct torsion of the uterus requires assessment of the direction of the torsion. When diagnosed at term during an obstetrical examination, a spiral fold in the floor and wall of the vagina is often palpable and allows the obstetrician to recognize both the presence and direction of the torsion. When the vaginal examination does not clearly define the direction of the torsion, as can occur in preterm torsion or in a torsion that has no vaginal involvement, transrectal palpation of the broad ligaments of the uterus allows determination of the direction and degree of twisting and facilitates case management. The normal relationships of the broad ligaments and uterus and the altered relationships in clockwise and counterclockwise torsion of the uterus are illustrated in Figure 50.8.

Dystocia due to uterine torsion when the cervix is dilated and the degree of torsion does not prevent manual access to the fetus per vagina can often be addressed by direct manipulation of the fetus and uterus to reestablish the normal anatomic relationships. If the operator's hand can be placed on the head or shoulder of the calf, the torsion can often be relieved by repeatedly rocking the fetus dorsally in ever-increasing arcs opposite the direction of the torsion until the center of gravity of the pregnant horn passes the critical point of balance and the uterus settles into its normal location. This technique requires considerable physical strength and is most successful when the operator is of sufficient stature to gain the necessary mechanical advantage during the manipulation.

If direct manual manipulation and rocking of the fetus is not feasible, use of a detorsion rod in conjunction with obstetrical chains is equally beneficial in cases with vaginal access to the fetus. Figure 50.9 illustrates a uterine detorsion rod and obstetric chains placed on a fetus in a manner that will allow the obstetrician to correct the torsion by twisting the detorsion rod, applying sufficient pressure to

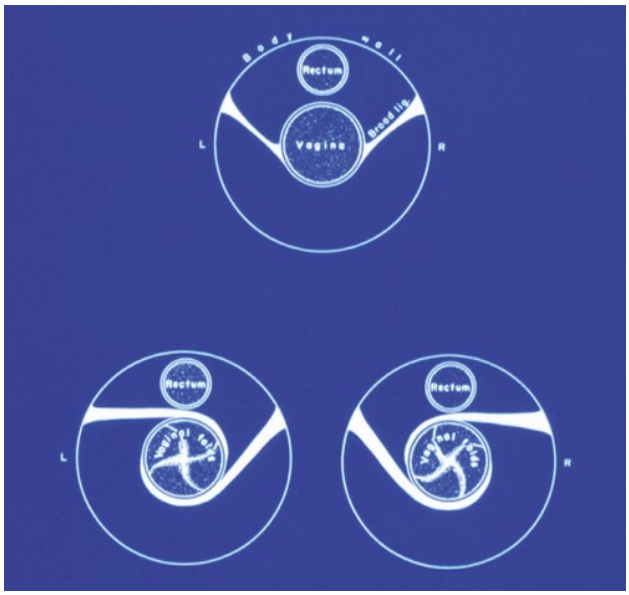

Figure 50.8 Relative positions of the broad ligaments of the uterus. Top image illustrates the normal relationship. Image lower left illustrates findings in a clockwise uterine torsion. Image lower right illustrates findings in a counterclockwise uterine torsion. *Source:* Image from [11], © 1971, Stephen J. Roberts.

Figure 50.9 Positioning of obstetrical chains and a detorsion rod for treatment of uterine torsion. The chains are placed as proximally as possible and threaded through the rings on each end of the instrument and secured to allow rotation of the fetus as the rod is twisted in the direction opposite the torsion. Careful monitoring to the limbs and chains during the rotation is necessary to prevent damage to the uterine mucosa.

rotate the fetus and uterus dorsally beyond the previously described point of balance. In skilled hands, utilization of a detorsion rod is often successful and requires less strength than the direct manual manipulation described previously. Proper placement of the chains can be difficult due to limited access related to the narrowing of the lumen of the vaginal vault and uterine body associated with the torsion.

Rolling a cow to correct uterine torsion is a commonly used technique and preferred over direct manipulation by many veterinarians. Following diagnosis and determination of the direction of torsion, the cow is cast into lateral recumbency on the side ipsilateral to the direction of the torsion. A long plank is placed over the caudal abdomen and a person of substantial size stands on the plank to immobilize the uterus as the cow is rotated through dorsal recumbency and into lateral recumbency on the opposite side. If the initial attempt is unsuccessful, the procedure may be repeated several times (Figure 50.10). The requirement for assistance limits the opportunity for application of this technique.

Following detorsion of the uterus, vaginal delivery of the fetus is possible if the cervix is sufficiently dilated to allow passage of the fetus. Cesarean section or fetotomy may be necessary should the cervix not dilate fully.

A standing flank laparotomy may be required to surgically alleviate the torsion when other methods fail. Vaginal delivery may be possible following surgical detorsion but hysterotomy is often required [14].

Hydropic Conditions

The accumulation of excessive uterine fluid in the pregnant uterus occurs sporadically in cattle as a manifestation of fetal fluid overproduction, failure of the placenta to appropriately remove fetal fluid, or a combination of those factors. Cases of pregnancy-associated uterine hydrops are divided into hydrops allantois when excessive accumulation of fluid occurs in the allantoic space, and the less common hydrops amnion in which an accumulation of excessive amnionic fluid occurs secondary to fetal defects. Hydropic conditions constitute an important component of the abnormal offspring syndrome sometimes associated with *in-vitro* fertilization (IVF) and somatic cell nuclear transfer (SCNT)-derived bovine pregnancies [16].

Hydrops allantois is the more common cause of uterine hydrops, accounting for greater than 90% of the cases of uterine dropsy. The pathophysiology leading to hydrops allantois has most often been attributed to defective placental function or placental insufficiency, and the placentae of affected fetuses frequently have a reduced number of placentomes with concurrent adventitious placentation. A cluster of hydrops allantois cases lacking placental abnormalities has been reported in closely related Japanese Black Cattle homozygous for a missense mutation in genetic coding for solute carrier family 12, member 1 (SLC12A1) protein. Fetal polyuria and excessive accumulation of allantoic fluid occurred due to the inability of the fetal kidney to reabsorb sodium. Genetic testing was developed and aggressively applied to identify carrier animals and reduce the occurrence of this simple autosomal recessive heritable condition in the breed [17].

Cases of hydrops allantois are uncommon events in most cattle populations, reportedly occurring in only one of 7500 pregnancies resulting from natural mating or artificial insemination. In one report, the incidence in pregnancies resulting from IVF or SCNT was significantly higher than in the wider cattle population, seen in as many as one in 200 such pregnancies as a component of abnormal offspring syndrome [18] related to altered gene expression and associated defective placental function from embryos matured and cultured in artificial media [16, 19].

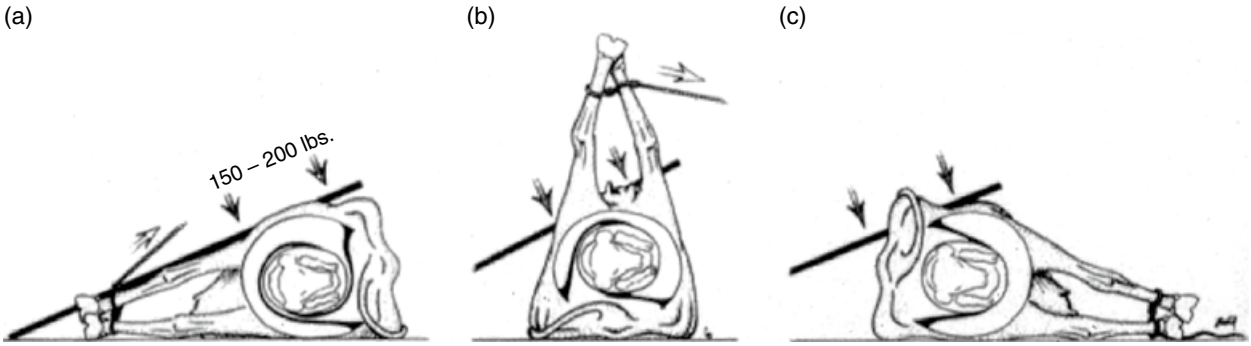

Figure 50.10 Schematic representation of the "plank in the flank" technique for correction of uterine torsion.

Hydrops allantois develops progressively after mid gestation, with the herdsman often reporting abdominal enlargement occurring over a few days, although the excessive accumulation of allantoic fluid likely began weeks prior to this being appreciated. Bilateral symmetrical abdominal distension is the most obvious finding, and external abdominal ballottement will elicit a fluid wave that crosses the abdomen (Figure 50.11). Cows are often thin by the time of diagnosis. The distended uterine wall can be palpated transrectally, but placentomes are difficult to discern and the fetus is usually not palpable. The fetus will seldom be viable following delivery and medical termination of the pregnancy or cesarean section is usually required to save the dam (Figure 50.12). Vaginal delivery will invariably require obstetrical assistance due to the lack of effective uterine contractions. Even with intensive medical management, the prognosis for life of the dam is guarded due to hypovolemic shock following fluid loss at the time of delivery and high risk of metritis post-partum. The prognosis for future fertility is poor. Humane euthanasia or salvage for slaughter is often indicated due to poor treatment outcomes.

Figure 50.11 Holstein cow with hydrops allantois. Note the bilateral abdominal distension and lack of mammary development. Ballottement of the abdomen induced an easily observable fluid wave.

Hydrops amnion is a rare gestational accident in cattle. The regulation of amnionic fluid volume is incompletely understood, but excessive accumulation can be seen in conjunction with craniofacial anomalies or neuromuscular disruptions which impair the ability of the fetus to swallow otherwise normal amnionic fluid. Excess amnionic fluid begins to accumulate slowly from mid-gestation to term [20], and the volume of amnionic fluid associated with amnionic hydrops can increase from the expected 2–3l [21] to 20l or more [22]. Abdominal enlargement resulting from excess accumulation of amnionic fluid may not be apparent until the last month to six weeks of gestation in affected pregnancies, and the excessive fluid volume may not be noticed until the time of parturition.

Cases of hydrops amnion have been related to congenital anomalies in which craniofacial defects in the fetus prevent the fetus from swallowing amnionic fluid [23, 24]. Heritable genetic defects, developmental disruption secondary to ingestion of teratogenic toxins, or viral infection during critical stages of fetal development can all initiate craniofacial fetal defects which may be accompanied by hydrops amnion. Pregnancy resulting from the breeding of American bison bulls to domestic cows frequently results in hydrops amnion [25].

Figure 50.12 Cow pictured in Figure 50.11 following a standing cesarean section.

Prepubic Tendon Rupture

The prepubic tendon is composed of the tendinous attachments of the rectus abdominis muscle, the internal and external abdominal oblique muscles, the pectineus muscle, and the gracilis muscles to the anterior border of the pubis [26]. This complex tendon provides a strong anchor point for the abdominal wall musculature to support the abdominal viscera. When rupture of the prepubic tendon or the closely related muscles of the ventral abdominal wall occurs, the loss of this anchor point is followed by progressive distension of the caudal ventral abdominal wall which may be accompanied by significant edema extending cranially to the umbilicus or beyond. The affected patient is painful and often becomes anorectic. Rupture of the prepubic tendon and associated caudal ventral abdominal musculature is seen almost exclusively in late gestation and may be associated with normal pregnancy, twin (or triplet, quadruplet, etc.) pregnancy, hydrops allantois [27], or prolonged gestation resulting in fetal giantism [11].

Prepubic tendon rupture carries a poor prognosis for the calf and for the life and future reproductive potential of the dam. Induction of parturition with assisted vaginal delivery or surgical delivery of the fetus(es) may preserve the life of the cow and sometimes result in delivery of a live calf provided the pregnancy is sufficiently advanced [11]. The inability of the dam to mount the abdominal press necessary for normal parturition mandates provision of obstetrical intervention at delivery.

Prolonged Gestation

Prolonged gestation occurs when spontaneous initiation of parturition does not occur at the expected time and duration of gestation far exceeds the upper limits of the normal range. Cases of pathologically prolonged gestation occurring as the result of defective development of the fetal hypothalamic–pituitary–adrenal axis associated with genetic mutations, teratogenic toxins, or infectious agents have been described.

Inherited autosomal recessive conditions in which dams pregnant with a fetus homozygous for a genetic mutation fail to go into labor have been described in both Holstein and Guernsey cattle [23]. As in the case with other autosomal recessive syndromes, the heterozygous parents (dam and sire) are unaffected and have a normal phenotype. The genetic anomaly producing excessive gestation length in Holsteins results in affected calves that are large at birth with fetal hirsutism, overgrown hooves, and small, nonfunctional adrenal glands [28]. A different heritable prolonged gestation syndrome described in Guernsey cattle resulting in agenesis of the fetal pituitary gland is characterized by small calves with severe craniofacial deformities [29]. Pregnancy duration in excess of 500 days has been reported.

Not all heritable causes of prolonged gestation are the result of these two well-described syndromes, and nonheritable developmental disrupters including toxins and viral infections which disrupt formation or function of the hypothalamic–pituitary–adrenal axis may interfere with the initiation of the normal parturition cascade.

Dystocia

Dystocia occurs when parturition is prolonged or difficult and results in increases in calf loss near the time of delivery and in increased incidence of morbidity and mortality of affected calves during the perinatal period. Dystocia may also be associated with decreased subsequent fertility in the dam due to delayed resumption of estrous cycles postpartum and decreased conception rates following insemination. Early recognition of the difficulty associated with the calving process and appropriate intervention can minimize but not eliminate herd-level economic impact.

Fetopelvic disproportion, in which the fetus is oversized relative to the maternal pelvis, is the most common cause of dystocia. Other common causes are related to inappropriate presentation, position, or posture of the fetus during delivery, simultaneous presentation of multiple offspring, metabolic disease (e.g. hypocalcemia) in the dam, and fetal anomalies. Dystocia is more common in primipara, with calving assistance required in up to 51.2% of first-calf heifers in one report from three Colorado dairy herds [30]. Heifer development programs designed to achieve adequate growth prior to breeding and during gestation in conjunction with sire selection for low to moderate birth weights are necessary components of dystocia reduction at first parturition.

Figure 50.13 Complete uterine prolapse following unassisted delivery. Hemorrhage from the uterine artery led to death in this case.

Uterine Prolapse

Uterine prolapse (Figure 50.13) sometimes occurs following parturition and constitutes a true emergency due to the prospect of life-threatening sequelae including hemorrhage and shock [31]. With early detection and prompt replacement, the prognosis for life of the patient is often good. Reports on the potential for rebreeding vary from moderate to good, and affected cows are not felt to be at increased risk for uterine prolapse at a subsequent calving [32–34]. Uterine lacerations, entrapment of the urinary bladder or intestine, severe desiccation of the exposed uterine tissues, and excessive blood loss leading to hypovolemic shock complicate case management and prognosis for return to function [34]. Amputation of the prolapsed uterus may be required for cases that are non-reducible or in which extensive uterine damage has occurred. More detailed descriptions of case management and reduction technique are found in Chapter 47 of this text and in several review articles [31–33].

Diagnosis is based on the appearance of the mucosal surface and the presence of caruncles on the everted uterus following parturition. The gravid horn may be prolapsed alone or portions of both uterine horns may be expelled. Predisposing factors include dystocia, with or without obstetrical assistance, hypocalcemia, and lateral or sternal recumbency with the forequarters elevated. Uterine prolapse represents a true veterinary emergency, and extreme care must be exercised while handling the patient to prevent damage to the exposed uterus and to minimize the possibility of rupture of the uterine arteries and subsequent hemorrhagic shock and exsanguination.

In most cases, the uterus can be cleansed and returned to the abdominal cavity after administration of epidural anesthesia to minimize straining as the prolapsed horns are reduced. The uterus should be examined carefully and lacerations repaired prior to reduction. On occasion, the bladder or other abdominal viscera may be contained within the prolapsed organ, complicating reduction. Following replacement of the uterus, care should be taken to fully extend the tips of the uterine horns to minimize recurrence. If concurrent hypocalcemia is present, administration of calcium borogluconate may be delayed until after reduction to minimize abdominal straining as the uterus is guided through the pelvis. Retention sutures, such as a Buhner stitch, should not be necessary if the tips of the uterine horns are appropriately positioned post reduction, but likely do little harm and may provide an additional level of security in cases in which pelvic trauma increases the likelihood of a continued abdominal press. Postoperative antibiotics and judicious use of ecbolic agents are indicated to promote uterine involution.

Obstetrics: Mutation, Forced Extraction, and Fetotomy

Kevin Walters

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

The provision of obstetric services continues to be an important aspect of the large animal practice. Previous chapters have covered prevention (Chapter 49) and described and defined dystocia (Chapter 50). Chapter 52 covers the surgical management of dystocia (cesarean section). The purpose of this chapter is to describe the non-surgical obstetric management of dystocia as well as the decision parameters utilized to abandon one technique and proceed to another. This begins with a basic list of equipment and restraint options, and then progresses through the management of progressively more difficult obstetric cases.

Obstetric Terminology

Terminology that describes both normal and abnormal dystocia as well as techniques employed is valuable for effective case management discussion among both veterinarians and veterinary students. The following are accepted definitions of presentation, position, and posture which serve to describe fetal orientation with respect to the dam.

- *Presentation:* describes fetal orientation by the relationship of the spinal axis of the fetus to that of the dam: thus either longitudinal or transverse (sideways), and if longitudinal either cranial or caudal (cranial–longitudinal is normal), and if transverse either dorsal or ventral. A transverse presentation is very rare in cattle.
- *Position:* further describes fetal orientation based on the relationship of the dorsum of the fetus to the quadrants of the maternal pelvis, these being sacrum (dorsosacral is normal), right and left ilium, and pubis [1]. Note that while the dorsosacral position is considered to be the normal position for a fetus, slight rotation to a position midway between dorsosacral and right or left dorso-ilial will often facilitate delivery. In fact this is what typically occurs naturally as a cow shifts position from lateral to sternal recumbency during normal parturition.
- *Posture:* describes the relationship of extremities with respect to the body of the fetus. For example, for a forelimb this could be fetlock, carpal, or shoulder flexion.

Definitions for various obstetric techniques are as follow.

- *Mutation:* defined as those procedures by which a fetus is returned to its normal orientation with respect to presentation, position, and posture. Procedures utilized include repulsion (retropulsion), rotation, version, and extension of extremities [1, 2].
- *Forced extraction:* the manual or mechanically assisted removal of the calf through traction.
- *Fetotomy:* the reduction and removal of the fetus by division and removal of extremities and sections. In a percutaneous fetotomy, the dissection is made through the skin and this is the classic fetotomy procedure as described by Bierschwal and DeBois [3]. In a subcutaneous fetotomy, a "freeing" incision is made through the skin to allow a limb's bulk to be removed. This is typically a partial fetotomy in which only one or two extremities are removed.
- *Cesarean section*: the surgical removal of a fetus via laparohysterotomy.
- *Repulsion (retropulsion):* the pushing of the fetus back out of the pelvis to facilitate other corrective steps.
- *Rotation*: the turning of the fetus on its long axis.
- *Version*: the rotation of the fetus on its transverse axis.
- *Extension of extremities*: the correction of flexural abnormalities of the extremities.

Basic Equipment

This is an area in which the opinions of obstetricians might vary. There are instruments that one individual might consider unnecessary that another would not approach an obstetric case without. Therefore the approach taken will be to first list obstetric tools that most would deem absolutely necessary and then add others and their potential uses [4].

Basic obstetric kit needs include at least two obstetric chains, two handles, a fetal extractor, a Krey hook, and basic surgery pack. Obstetric chains can be obtained in lengths of 53, 76, 114, and 152 cm. Chains are preferred over straps made for obstetrics for at least two reasons. The chains are more easily cleaned and despite the appearance are less likely to cause damage to the fetus or dam. With respect to handle selection, the old Muir obstetric handles are time tested but with the caveat that the heavier models are best. The type or model of fetal extractor is usually based on operator preference and its use is not controversial from my perspective. The Krey hook, which is routinely used in fetotomies, is listed among the basics as it is often useful in the vaginal delivery of a fetal abnormality or dead calf in which only a partial fetotomy is performed. A basic surgery pack is needed for such procedures as an episiotomy, a single appendage removal (partial fetotomy), or cesarean section (Figure 51.1). Additional obstetric tools that are useful include the calf-saver snare, which is easier to place around the head than using chains, a de-torsion bar, and a double blunt eye hook (Figure 51.2). Although limbs as well as the head and neck can be removed without a fetotome, to perform the classic fetotomy the following tools are necessary: a fetotome (model selected based on operator preference), saw wire, a wire guide, an "embryotomy" knife, and if not already in the obstetric kit a Krey hook (Figure 51.3).

Figure 51.1 Basic obstetric equipment: (A) 152-cm obstetric chain; (B) 76-cm obstetric chain; (C) Krey hook with attached chain; (D) T-bar obstetric chain handle; (E) Moore's obstetric handle; (F) components of disassembled fetal extractor.

Case Management

Restraint

The restraint approach utilized must be safe for obstetrician and patient. Both facilities available and patient temperament dictate the approach taken. Haul-in facilities are almost always superior to those found on farms and indeed if a significant percentage of a practice is devoted to bovine obstetric work, suitable facilities are a good investment.

Although on-farm dystocia cases are often recumbent, most obstetric procedures and specifically mutation are easier on the well-restrained standing cow. Often a cow that has previously refused to stand will do so after the administration of an epidural, presumably due to the abatement from the pain associated with labor [1].

A cattle chute is adequate for examination, preparation, and the administration of an epidural, but you must have the ability to open a side or otherwise get the cow out in case she goes down during the obstetric procedure. In virtually all cases, with the exception of a purpose-designed dystocia chute or stanchion, you will be better off with the cow haltered and tied in the corner of a stall/pen/lot.

History

As the large-animal practitioner must often utilize to some extent a form of triage in determining which client's request or patient must be attended to first, the obstetric case begins with the perfunctory question of duration of labor. This may be of marginal value without an understanding on the part of the client of the stages of labor. For example, the time period that an owner relates is almost always from the time they first noticed the cow, without any respect to the stage of parturition. The stages of labor are as follows.

- Stage 1: early labor, with a typical duration of 4–12 hours. Its conclusion is marked by rupture of the allantois.
- Stage 2: delivery of the calf. This is also referred to as "true labor" and typically lasts 30 minutes to 4 hours, but the calf can often live 8–10 hours [4].
- Stage 3: passage of the fetal membranes.

Thus the appropriate question to ask the owner/attendant is whether or not fetal membranes or an extremity is visible, followed by queries to ascertain whether allantoic rupture has occurred ("Have the waters broken?"). Simply determining this provides the answer with respect to continued observation or immediate attention. Additionally, the knowledgeable stockman might be able to describe the presentation based on observation or their preliminary examination. Just as the knowledge that labor has progressed to stage 2 dictates prompt attention, so does a posterior presentation.

Other questions relate to parity, past calving history, and sire. The young veterinarian must realize that extensive questioning is often off-putting to the cattleman and one may be wise to simply expedite matters and obtain necessary information during the course of the management. The relative value of the cow versus the calf may also be important and will often be a factor in the management approach.

Examination

The examination begins as the cow is approached and as the animal is restrained. The temperament and physical condition are assessed. Prior to the obstetric examination, the tail should be tied to her neck (or held by an assistant) and the perineum cleaned with soap and water. The obstetric examination can be performed before or after the administration of an epidural, but at any rate should be done quickly and with the purpose of guiding the direction of obstetric management. Thus fetal viability, presentation, position, and posture, and degree of fetus–dam disproportion are evaluated.

Fetal viability and even how long a calf may have been dead are important determinants with respect to management. If the presentation and position are normal but an extremity is malpostured, the fetus can be repulsed and the posture corrected, followed by traction for example. A very large and viable calf in a heifer or relatively small cow directs one to cesarean section, as in turn a large dead fetus may dictate a fetotomy.

The presentation is easily assessed if the obstetrician can identify the head or conversely the tail/tailhead. When a determination must be made based on palpation of a limb, one should simply remember that the first two joints of the forelimb, the metacarpal joint (fetlock) and the carpus (knee) will both flex in the same direction, while the fetlock and hock flex in opposite directions.

The examination must therefore be performed in an efficient thoughtful manner with the goal of directing the first or next obstetric procedure and avoidance of the creation of a potential complication. It is intertwined with management, and reassessment of the case may result following an unexpected finding or the inability to complete a prescribed plan of action.

Obstetric Procedures and Decision-Making

As the reader would hopefully surmise from the section on examination, obstetric management is fluid, but should follow a reasonable course that results in a successful outcome, which in turn is dependent on the initial findings.

A common dystocia presentation is a fetus in anterior presentation with normal posture (for this and other dystocia images see Chapter 50). If traction results in a severe and immediate crossing of the forelimbs as the shoulders engage the maternal pelvis, the calf is likely too large to be delivered vaginally. Thus the next step would be to move to a cesarean section or fetotomy. In the case that the fetus is of a size in relation to the dam that vaginal delivery should be possible, examination to determine the cause of dystocia should follow. Was there adequate cervical dilation? Is the

heifer or cow exhausted or suffering uterine atony? Are there concurrent issues such as hypocalcemia? Is there inadequate dilation of the vulva? Depending on the answer, your next step could be to simply apply traction, but these issues should all be considered.

An anterior presentation in which the fetus is rotated in position based on head or limb orientation, findings from your vaginal examination, or findings of a rectal examination should lead to a diagnosis or suspicion of torsion. Diagnosis and obstetric management of uterine torsion is discussed in Chapter 50 and surgical management is discussed in Chapter 52.

For an anterior presentation with lateral deviation of the head, the fetus can be repulsed. This is obviously easier when the patient is standing and following epidural analgesia. The head can then be pulled into position (into the pelvis) by grasping the orbits. If the operator lacks the hand strength to do this, the double blunt eye hook can be employed. In the case in which they cannot be reached, first pull at the neck and this will pull the head closer. These attempts may be alternated with repulsion. Alternatively, or in cases when the head cannot be pulled into position, the calf-saver snare or an obstetric chain may be used. Correct application of the calf-saver snare and obstetric chains is important to avoid injury to the calf. They should be placed behind the ears and through the mouth. When utilizing a chain the loop should be placed in a manner so that it will not tighten when traction is employed. Also, traction can be utilized to move the head into position, but should not be used to effect delivery.

For an anterior presentation with one or more forelimbs back, the fetus is again repulsed and the limb(s) brought into position. Depending on the severity of the malpostured limb, correction may be stepwise, first reaching for and pulling on the upper aspect of the limb below the shoulder, then the carpus, and finally the fetlock. Affixing an obstetric chain around the fetlock and providing traction alternating with repulsion of the fetus is often necessary. Oftentimes only an elbow back is hindering delivery and is corrected by selective traction.

During the application of traction, once the thorax has cleared the pelvis, stop briefly and attend to the calf. Move any fetal membranes from over the calf's nose and mouth. Stimulate the calf if necessary by slapping the head or pulling on the tongue. Then before resuming traction, rotate the calf about 30–45°. This will likely prevent a "hip-lock" as can occur when the hips of the calf engage the maternal pelvis. In the situation when a hip-lock occurs the following tips are useful. If the cow is standing, orient the direction of traction almost straight down. If the cow is recumbent (lateral) at this time, first try the same change in orientation of traction. If a fetal extractor is employed, simply take the far end and direct it toward and between the cow's hind legs. Alternatively, or if the aforementioned technique does not work, rock the cow on her back, grabbing a hind foot, and roll her over (from right lateral recumbency to left or vice versa). Regardless, continued traction on a calf when there is a hip-lock without changing the direction of traction usually results in injury to calf and/or dam.

A posterior presentation in which the hindlimbs are flexed and back is the classical "breech." Correction requires repulsion of the fetus and, in a stepwise fashion, first flexing and retracting the hock, followed by the fetlock, and finally bringing each hind foot into position for delivery. This is extremely difficult in the recumbent animal, so all attempts to restrain the patient standing should be made and obviously, as whenever repulsion is necessary, epidural analgesia is employed. Care during repulsion is also crucial as uterine tearing can occur (etiology and repair is discussed in Chapter 55). If the cow or heifer has been in laborious efforts for an extended time, the reservoirs of fetal fluids for lubricating the genital tract will likely be exhausted and the uterus can be contracted to the point where performance of mutation(s) can be severely compromised. Pumping lubricant or water or a mixture of both through a nasogastric tube into the uterus can provide lubrication and separation of the uterus from the fetus, aiding mutation efforts. An additional tip to achieve uterine relaxation is to administer 10 ml of 1 : 1000 epinephrine intravenously to the cow/heifer [5, 6]. Be cautious utilizing this therapy, for there can be extreme consequences resulting in death due to side effects of epinephrine. This therapy should be considered on a case-by-case basis from the judgment of the clinician. This therapy will provide a tocolytic effect on the uterus that will allow mutational efforts of the fetus. Isoxsuprine and clenbuterol are also tocolytic agents that have been utilized in the bovine, but these two pharmaceuticals cannot be used in food-producing animals in the USA; therefore they are only mentioned here for reference. Once the malposture of both pelvic limbs is corrected, traction can be administered; however, with this, or in a normal posterior presentation, care must be taken to keep the calf's tail down during traction and delivery. Two possible deleterious sequelae can follow an upwardly fixed tail. First, due to the tension, the sharp ventral coccygeal processes can abrade or lacerate the dam's dorsal vagina. Second, and more commonly, the calf's tail will break, resulting in a neurologic deficit. With this injury the calf may still be able to walk, but lacks proprioception and additionally usually lacks bladder tone.

The goal for the management of dystocia is always to avoid injury first to the dam and then the calf. Prolonged obstetric efforts rarely end well so, regardless of the mutation techniques employed, a time limit of 10–15 minutes without

progress should lead to reevaluation of technique, and specifically in the case of a viable fetus to a cesarean section.

Forced Extraction

The term "forced extraction" refers to both manual and mechanically assisted extraction of the fetus. Since it is rare that problems (specifically injury) occur as a result of manual traction, the focus of this section is on traction in excess of that provided manually, thus referring specifically to the use of a fetal extractor. Because a fetal extractor can provide a level of traction that can be deleterious to either or both the dam and fetus, its use has been controversial. From a practical aspect its use is safe when used judicially.

Injuries that can result from forced extraction are significant and their consideration is important. Obturator or calving paralysis, which is more likely due to injury to or around the sciatic nerve rather than the obturator nerve, can occur as a result of prolonged dystocia, but is most commonly a result of excessive traction, as is tearing of the uterus, cervix, or vagina. Metacarpal and metatarsal fractures can result from incorrect placement of obstetric chains, but likewise are more likely with excessive traction.

This said, prevention of injury can virtually always be assured with adequate lubrication and careful application of traction. Methylcellulose-based lubricants can be pumped into the uterus and around the fetus, and then added during extraction. A note with respect to the selection of commercially available obstetric lubricants: the product J-Lube™ when exposed to the abdomen of cattle has resulted in death [7]. Thus if your obstetric management plan may potentially lead to a cesarean section and as abdominal contamination during this surgery is often unavoidable, its use is contraindicated. Traction should be applied slowly, carefully, and only in conjunction with the dam's contractions, and should be stopped when no progress results.

As stated previously, the model of fetal extractor utilized is based on operator preference. Remembering the old adage that no more traction should be applied than that of two strong men, the "power" requirement of a fetal extractor need not be excessive. Thus many of the time-tested older models are very adequate. A model developed several years ago features the ability to provide alternate traction to each of the two forelimbs. While it seems intuitive that this provides an advantage, in a well-constructed experimental model Becker et al. [8] concluded that simultaneous traction was optimal.

In summary, providing adequate lubrication, correctly applied obstetric chains, rotation of the fetus 30–45° during extraction, and applying traction with the dam's contraction efforts are all key to safe and judicious mechanical extraction.

Fetotomy

Fetotomy by definition is the dissection of the fetus into two or more parts while still within the uterus or vagina. Subcutaneous fetotomy was developed in the eighteenth century in which instruments were used to dismember a fetus while leaving the fetal skin intact to protect the uterus and provide points of traction [9]. This technique has been utilized far less since the development of the percutaneous fetotomy technique. The percutaneous fetotomy utilizes a braided wire as a saw to cut through skin, muscles, bone, and connective tissue to dissect or dismember the fetus into small portions for assisted vaginal delivery [3].

The standard Utrecht technique for a cranial or anterior presentation fetotomy is removal of the head, one forelimb, the other forelimb, and the trunk (potentially two cuts), and bisection of the fetal pelvis. This summarizes the complete fetotomy used to dismember an oversized fetus that has resulted in fetopelvic disproportion. This procedure will encompass five to six cuts to complete. A complete fetotomy is not always necessary for delivery of the fetus. Frequently a partial fetotomy, which may include one to two cuts, will provide the relief necessary to deliver the fetus. The standard cuts have been modified to incorporate more anatomical parts but which are still manageable portions easily removed from the genital tract [10].

Preparation for this procedure will depend on the environment in which the cow is confined and restrained, whether in a hospital, corral, or pasture setting. Deposition of obstetric lubricant or water mixed with lubricant can be infused into the uterus by the obstetrician based on their appraisal of its need to provide lubricating protection to the genital tract at any point during these obstetric procedures.

Anterior Presentation

If manipulative efforts to relieve the dystocia have not been successful and fetotomy is pursued, results of the manipulative process will determine the initial cut of the fetotomy. Malposture and malposition will have an impact on the initial cut as well. The fetotome should be threaded with a section of saw wire that is at least five times the length of the fetotome. This length of wire should be sufficient to allow a loop at the head of the fetotome that is large enough to be manipulated over the fetal head, as well as extension beyond the ends of both barrels of the fetotome at the handle to allow fixation of handles to the wire for sawing. This allows tension to be applied on the wire handles in an alternating manner to perform the cut. Tension applied to the wire handles will allow placement of the wire to be confirmed. The obstetrician should evaluate the wire saw as it exits the barrels of the fetotome to ensure that the wire is

not crossed just prior to entering each barrel. If so, this would lead to premature failure or breakage of the wire. The crossing of the saw wire can be alleviated by rotating the fetotome on its long axis. The appropriate direction is determined by the obstetrician after this evaluation. Initiation of the cutting action of the wire saw is conducted by exerting tension on the wire handles in an alternating manner. The amount of tension is increased. Initially the assistant makes short smooth strokes with the wire handles until the saw wire is fully engaged in the fetal tissue. The assistant can now extend the length of stroke and increase the amount of tension applied to the handles to perform the cut. The assistant or wire saw operator can determine when the cut is complete due to a dramatic decrease in resistance of the wire saw in tissue.

If the initial cut is intended to remove the fetal head, the threaded fetotome should be introduced into the genital tract. The loop of wire should be manipulated by hand to encompass the head. The head of the fetotome should be advanced into the tract so that it lies caudal to the ears. Tension may be placed on the wire after fetotome placement and the obstetrician can feel for placement of the wire around the neck. The standard Utrecht procedure describes placement of the fetotome head caudal to ramus of the mandible and potentially ventral as well. I prefer to advance the fetotome head to a location on the dorsum of the fetus at approximately the withers or craniomedial to both scapulae (Figures 51.4 and 51.5).

Apply tension to the wire saw handles and perform the cut through the fetal neck. The obstetrician can place a hand over the head of the fetotome during this cut to provide protection to the uterus dorsal to the instrument head. The obstetrician can provide traction to the fetal head for removal. It may be necessary to apply the fetal head snare or an obstetric chain if manual traction is unsuccessful at removal of the fetal part. This cut eliminates the neck as a potential impingement if traction is applied to the fetus at this point for delivery. This cut may also provide more medial excursion of the shoulders as they engage the maternal pelvis if traction is attempted at this time [11].

If removal of the fetal head does not provide satisfactory conditions for fetal extraction, the obstetrician can then proceed to removal of one of the thoracic limbs of the fetus. This can be accomplished by utilizing the previously threaded fetotome. A wire loop can be manipulated around the limb chosen for removal as the instrument is introduced into the genital tract. The instrument should be advanced along the lateral aspect of the limb to a point that the head of the instrument is dorsocaudal to the caudal extent of the scapula [1]. An obstetric chain may have been previously placed on the limb. Be careful not to entangle the chain in the saw wire. If a chain was not already in

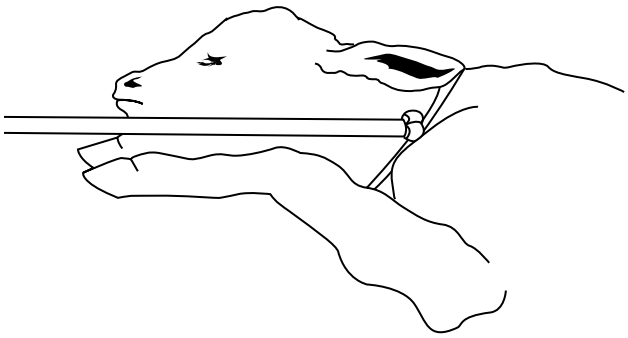

Figure 51.4 The author's recommended placement of a fetatome head for removal of fetal head and neck.

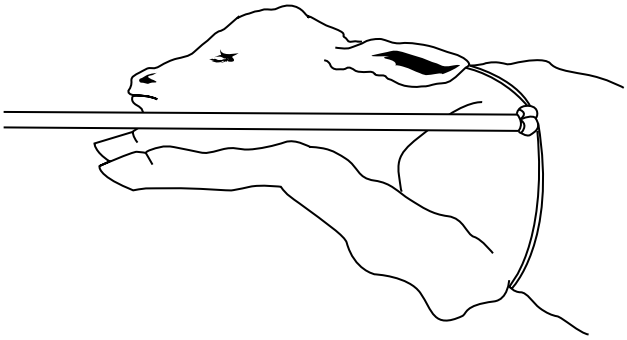

Figure 51.5 An alternate "cut" that incorporates the head and one shoulder, allowing removal of both with a single section.

place, one needs to be placed in order to provide traction during the cut. After instrument placement, tension on the wire will allow the obstetrician to determine if wire placement is correct. The wire should follow a path from the axillary region dorsally and ventrally to the upper limb and enter the instrument head dorsocaudal to the scapula. The obstetric chain can now have tension applied to it and the chain introduced into the locking plate at the handle of the fetotome. This will maintain the leg in full extension during the sawing action. The obstetrician may place a hand over the head of the fetotome during this cut to provide protection of the uterus. Once the cut is complete, the obstetrician can disengage the chain from the fetotome and apply traction to the fetal limb for removal. The instrument can be removed at this time as well. Palpation of the caudal region of the cut should be performed to ensure no bone fragments were left as a result of the cut that could potentially traumatize the genital tract. If fragments of the scapula are discovered, they can be removed by blunt dissection with the hand to prevent trauma to the genital tract if traction is attempted at this time [3].

Removal of the second thoracic limb is conducted in the same manner as the first. The same precautions should be taken to ensure that trauma to the genital tract from sharp bony fragments are minimized. Additional lubrication may

need to be deposited at this time due to multiple introductions and removals of equipment from the genital tract [12].

If an attempt is made at this time to extract the remaining portion of the fetus, evisceration of the thoracic cavity through the thoracic inlet can be conducted by hand. If the fetus is emphysematous, manual penetration through the diaphragm and evisceration of as much of the abdominal contents as possible manually through the thoracic inlet will accomplish a reduction in size of the remaining fetal portion. The Krey hook could be applied to the cranial end of the vertebral column as an appropriate place for tension application. To continue with the fetotomy, the head of the fetotome with loop of wire can be introduced into the genital tract, and the loop manipulated around the cranial end of the thoracic cavity. The loop is manipulated caudally on the trunk of the body to a point caudal to the last rib and cranial to the wings of the ilium in the lumbar region. The fetotome should be advanced into the genital tract so that the head rests in a dorsolateral position to the trunk of the fetus. It is sometimes difficult to manipulate the wire along the trunk of the fetus. The saw wire can be attached to a wire introducer or passer that is introduced into the genital tract. It is passed over the dorsal part of the trunk and then is retrieved by reaching under the ventral aspect of the fetal trunk. The wire introducer/passer is withdrawn from the genital tract. The saw wire is detached from the introducer/passer and threaded into the fetotome using a wire threader. The fetotome head should be positioned in the location previously described for this cut. The obstetrician should apply the Krey hook to the cranial end of the vertebral column. With the fetotome head in place, the obstetric chain attached to the Krey hook can have tension applied and engaged into the locking plate on the fetotome. The cut can be performed. If the thorax is of too large a diameter to pass through the genital tract, it can be reduced in size further by introducing the wire director/passer attached to the wire saw through the thoracic inlet and exiting the caudal opening created by the cut through the abdomen. The wire director/passer is retrieved from the caudal aspect of the trunk and withdrawn from the genital tract in order to thread the wire into the fetotome. The wire should be placed close to the attachment of the ribs to the thoracic vertebra. Performing the cut at this site will allow collapse of the thoracic cavity, which reduces its size for removal from the genital tract. Remain cognizant of sharp bony edges that can potentially traumatize the genital tract during manipulation. The assistant can provide traction to the chain while the obstetrician navigates the fetal thorax through the genital tract (Figure 51.6).

Positioning of the fetal pelvis for bisection can be accomplished by attaching the Krey hook to the lumbar vertebral column and applying traction to maintain the fetal portion

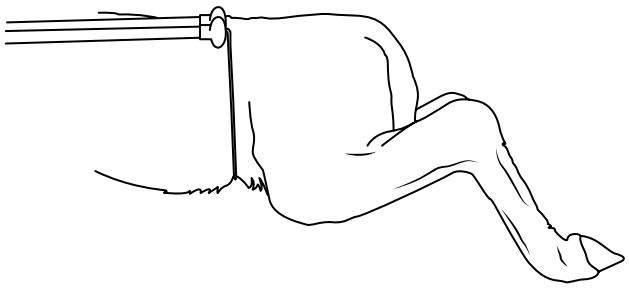

Figure 51.6 Wire placement for mid-abdomen cut.

in the opening of the maternal pelvic inlet. Saw wire from a half-threaded fetotome with wire introducer/passer attached can be introduced into the genital tract and passed over the dorsal aspect of the fetal pelvis to about the level of the inguinal region. The obstetrician can then retrieve the introducer by passing their hand between the cranial margin of the maternal pubis and fetal pelvis in order to grasp the introducer between the fetal limbs and withdraw it from the genital tract. The wire introducer can be removed and the wire saw can be threaded into the fetotome. The fetatome can then be introduced into the genital tract while tension is maintained on the wire saw to keep it in place. The head of the fetotome should be positioned so that it rests against the previously cut lumbar region of the fetus. It should be ipsilateral to the tail groove chosen for wire placement. It should also be slightly lateral to the vertebral column, so that this cut will bisect the fetal pelvis, but not in symmetrical pieces (Figure 51.7). With the fetatome in position, the chain attached to the Krey hook should have tension applied to it and then be engaged into the locking plate on the handle of the fetotome. The obstetrician can evaluate the placement of the wire saw; it should traverse a path from one barrel of the fetotome dorsally along the fetus, pass through the groove between the fetal tailhead and ischial tuberosity, and continue running ventrally through the inguinal region and along the ventrum of the fetus to enter into the opposite barrel of the fetotome [13]. If all is in order, the cut can be performed. The fetotome can be withdrawn from the genital tract when the cut is complete. The portion of the fetal pelvis that is grasped by the Krey hook can be guided out from the genital tract. The remaining final portion of the fetal pelvis can then be removed.

Posterior Presentation

If the calf was determined to be in posterior presentation during the genital examination, the following describes the procedures necessary to conduct a fetotomy in this presentation. Preparation of instrumentation and self will be the same as that for an anterior presentation. A fetotome threaded with the appropriate length wire saw and attached

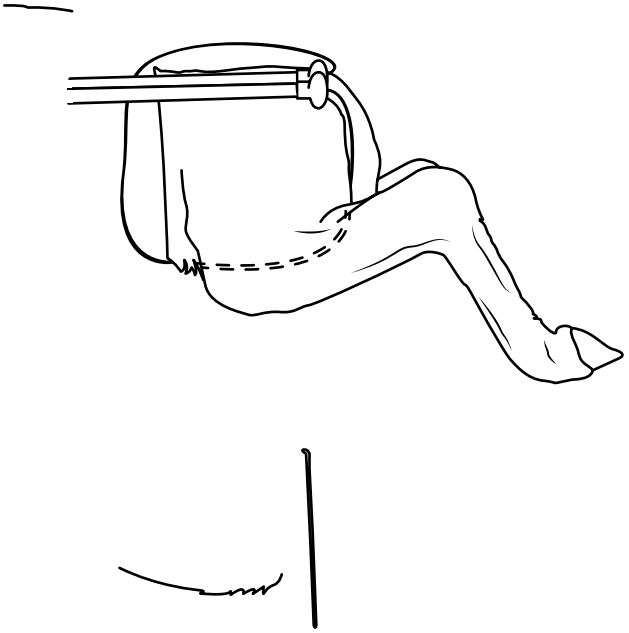

Figure 51.7 Wire placement for bisection of fetal pelvis.

wire saw handles should be available to initiate this procedure. The prepared fetotome can be introduced into the genital tract of the cow by the obstetrician. A loop of the wire saw protruding from the head of the fetotome can be manipulated over the claw of the selected pelvic limb to encircle it. The fetotome will be advanced similarly as for thoracic limb removal. It should be advanced along the lateral aspect of the limb so that the head of the fetotome comes to be positioned on the dorsal aspect of the pelvis in the area of the greater trochanter [1]. If a chain has not already been placed on the selected fetal limb, it should be placed at this time to provide traction during wire sawing. The chain should have tension applied to it and then be engaged into the locking plate on the fetotome handle. The cut can be performed to dissect the selected limb. When the cut is complete, the chain can be disengaged from the locking plate. The fetotome should be withdrawn, and the fetal pelvic limb can be removed from the genital tract.

A chain can be applied to the remaining pelvic limb, and traction applied to the chain to determine if the fetus can be delivered or additional dissection is necessary [3]. If the remaining fetal portion cannot be delivered, the obstetrician must determine whether the opposite pelvic limb requires amputation or dissection through the lumbar vertebra to allow for delivery of the remaining pelvic limb and pelvis. If the opposite pelvic limb requires amputation, it can be removed using the same technique as the first.

If the obstetrician chooses to dissect the fetus at the lumbar vertebra, there are two methods of wire placement. The obstetrician can choose to introduce a fully threaded fetotome into the genital tract and manipulate the wire loop around the claw to encircle it. The wire loop is manipulated proximally around the limb as the fetotome is advanced into the genital tract. The wire loop is manipulated cranially to a point that is just caudal to the last rib. The fetotome is advanced so that the head lies dorsolateral to the cranial lumbar vertebra. The second method uses a half-threaded fetotome. The wire saw exiting the barrel from the fetotome should have the wire introducer/passer attached. This instrument is introduced into the genital tract and advanced cranially to the region of the fetal lumbar area. The wire introducer is advanced ventrally on one side of the fetus and deposited. The obstetrician can retrieve the wire introducer by withdrawing the hand to the dorsal aspect of the fetus and then advancing it ventrally on the opposite side of the fetus to the area where the wire introducer was deposited. When the introducer is identified by the obstetrician's hand, it can be grasped and withdrawn from the genital tract so that the wire may be threaded into the fetotome. An obstetric chain should be applied to the pelvic limb if one has not already been placed. Once the fetotome is advanced into the proper position and wire placement is verified, traction must be applied to the obstetric chain, and it should be engaged into the locking plate of the fetotome handle with the limb in full extension. The cut can be performed at this time, and when the cut is complete the obstetric chain should be disengaged from the fetotome. The fetotome can be removed from the genital tract as well as the pelvis and attached limb.

Manual evisceration can be performed after the fetal pelvis has been removed which will reduce bulk in the abdomen of the fetus. A Krey hook and attached obstetric chain can be introduced into the genital tract and applied to the vertebral column so that controlled traction may be applied to retain the fetus in the maternal pelvic inlet while the fetotome is positioned for the next cut. To perform the next cut, a fully threaded fetotome can be introduced into the genital tract, and a loose wire saw loop should have the obstetric chain passed through it. The fetotome should be advanced cranially to the region of the caudal aspect of the scapulae, and the wire loop should be manipulated cranially to encircle the thorax so that it lies just caudal to the scapulae. Traction can be applied to the chain and it can then be engaged into the locking plate of the fetotome. Once fetotome and wire position are verified, the cut can be performed. The chain can be disengaged from the locking plate to allow removal of the fetotome. If this portion of the thorax is too large in diameter to be removed, it can be cut longitudinally along the rib attachment to the vertebral column as described for the anterior presentation.

After removal of the thorax, the remaining fetal forepart must be dissected. The Krey hook should be introduced to

the genital tract and applied to the fetus just lateral to the vertebral column. With moderate traction applied to the fetus, the obstetrician can proceed with the division of the fetal forepart of choice. This can be accomplished by either removing both forelimbs or diagonal longitudinal division of the forepart. I choose to perform diagonal longitudinal division of the forepart. To accomplish this, a half-threaded fetotome with wire introducer attached is utilized. The wire introducer is taken into the genital tract and is manipulated dorsally to the fetus and then ventrally between the neck and one forelimb to be deposited.

The obstetrician should withdraw the hand partially. To retrieve the wire introducer the hand should then be advanced ventral to the fetus to the area of deposition of the wire introducer. Once identified and grasped, the introducer should be withdrawn diagonally so that the wire comes to pass medially to the opposite elbow. The fetotome is threaded and advanced into the genital tract. The fetotome head should be positioned just lateral to the vertebral column on the opposite side from wire passage between the neck and forelimb. The Krey hook should be in position contralateral to the fetotome head and should not interfere with the wire saw. This cut will divide the forepart diagonally into unequal portions [3]. The fetotome can be removed after the cut is complete. Traction can be applied to the obstetric chain attached to the Krey hook to remove the fetal forepart it is grasping. The remaining fetal forepart should now be removed from the genital tract.

Subcutaneous Fetotomy

Subcutaneous fetotomy can be performed without special instrumentation. However, chisels have been fabricated and utilized in this procedure. Various scenarios may occur to which this procedure can be employed. Several modifications of this procedure have been described in the literature [14]. This procedure is utilized to remove a thoracic limb from a fetus, but it may also be employed for removal of a pelvic limb. The concept will be the same, but the exact method will vary tremendously due to major differences in anatomical structures between thoracic and pelvic limbs. The procedure will be briefly described as if removing a thoracic limb.

To perform this procedure, it is beneficial to have the fetal head cranial to the cervix to allow more access to the pelvic canal to perform the procedure. This can be accomplished by removal of the head or repulsing the fetus into the uterine body. Now that a thoracic limb has been chosen for the subcutaneous fetotomy, manipulate the limb into extension. A circumferential incision is made through the skin at the level of or proximal to the metacarpus (Figure 51.8).

Figure 51.8 Circumferential incision.

Proximal to the fetlock is the more suitable location because it potentially may be exterior to the vulva.

Second, an incision is made from the level of the scapulohumeral joint of the chosen limb descending down the cranial aspect of the limb to the recently made circumferential incision (Figure 51.9). The choice of incisional instrument is the preference of the veterinarian. Finger or palm fetotomy knives, scalpel blades, pocket knives [14], and utility knives are all cutting instruments that will accomplish the task. The utility knife does provide a mechanism for safety to the patient and operator due to function of the device by being able to project and retract the blade from the handle. The linear incision is more easily accomplished with tractional force applied to the limb. Alternatively, if one cannot easily begin the incision at the scapula, an incision can be made originating from the edge of the circumferential incision previously made (Figure 51.10). In either situation, the two corners of the incision formed by the linear and circumferential junction can be dissected and reflected caudally of the limb. Small incisions can be made in the area of these corners that can be utilized as finger holds while performing fetotomy, and later an OB chain can be placed in the hole to be utilized as a traction point.

Blunt dissection of the skin away from the limb should be performed to the level of the scapulohumeral joint. If one has a fetotomy chisel, it can now be employed to separate the skin from the limb (Figure 51.11). Digital dissection has been utilized to perform this procedure routinely

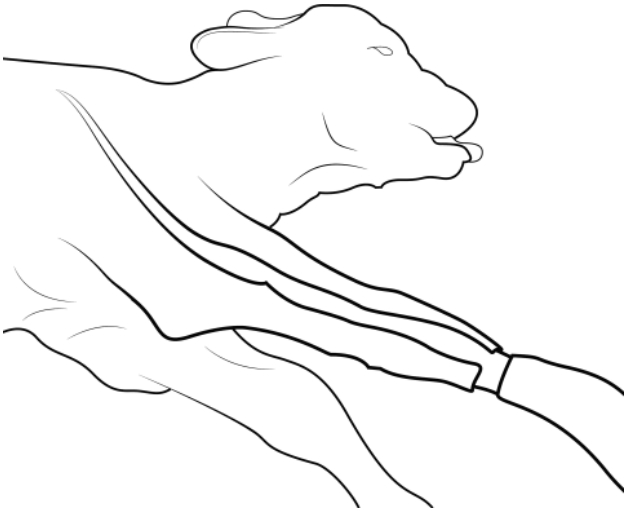

Figure 51.9 Incision started at the scapula of the fetus and extended toward the circumferential incision.

or a detorsion bar can be employed for skin separation in this procedure. Also, depending on the state of fetal decomposition, dissection of the skin from the musculature may not be necessary. When the skin dissection is completed to the level of the scapulohumeral joint, an OB chain can be applied to the distal limb and tractional forces applied to detach the thoracic limb from the fetus. Additional dissection will likely need to be employed if only manual force can be applied to the limb for detachment. Once the limb is detached from the fetus, it can be removed from the genital tract of the dam. Then proceed with further extraction efforts for removal of the entire fetus. The skin of the removed limb can be incorporated into points of attachment of OB instruments for removal of the remainder of the fetus from the dam.

Figure 51.10 Alternative incision originating from the edge of the circumferential incision.

Figure 51.11 Skin dissection with use of an obstetrical chisel.

Fetal Malpostures and Monstrosities

The obstetrician can be presented with a variety of fetal malpostures that result in dystocia. In each case, the obstetrician should use clinical judgment to determine if fetal manipulation and mutation are potentially hazardous to the genital tract of the dam. If this is determined to be true, then the obstetrician can approach the dystocia by performing custom fetotomy cuts to relieve the malpostures and allow for fetal delivery. The approaches to the cuts will be determined by the variety of malpostures.

Fetal monsters are another cause of dystocia where fetotomy should be given primary consideration. Because of variation in size, disfigurement, and flexibility of these fetal monsters, the obstetrician will have to determine the plan and approach for removal of such anomalies. The same principle of fetal size reduction should be applied to alleviate dystocia from such causes [3].

Obstetrics: Cesarean Section

Cathleen Mochal-King

Department of Clinical Sciences, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

A cesarean section (C-section) is a surgical procedure that is utilized to relieve or in some cases prevent dystocia [1–3]. Causes of dystocia are categorized as maternal or fetal and are covered in Chapter 50. Indications for C-section include dystocia cases in which the calves are alive and valuable that cannot be delivered vaginally, and/or dystocia cases in which the calf is dead but delivery by another means jeopardizes the life or future fertility of the cow.

A C-section is rarely completed under strict asepsis, but this is not due to the fact that it is so often performed in field settings. This is even the case when a C-section is performed in a hospital setting in a surgery room. A C-section is classified as a clean contaminated procedure. This classification describes a surgery in which a non-sterile body cavity is entered under a controlled condition without unusual contamination; in this case, the uterus is the non-sterile cavity [4]. Furthermore, Mijten et al. demonstrated that uterine cultures collected during C-sections often resulted in positive bacterial cultures, but 83% of these samples were heavily contaminated, leading to the conclusion that endogenous bacterial contamination of the surgical site from the hysterotomy is likely inevitable [4]. The fact that bacterial contamination is probable does not excuse inattention to surgical preparation or to cleanliness. It is important to minimize exogenous bacterial contamination through efficient and quick performance of the procedure. Additionally, Mijten et al. recommended the administration of antimicrobials preoperatively to diminish postoperative complications as a result of endogenous contamination [4].

Success of a C-section is defined as a live cow with a live calf and the ability to rebreed the cow. These outcomes are dependent on a number of variables in addition to the surgeon's skill. Many of these variables are beyond the surgeon's control. A realistic approach to this surgery is to evaluate the case, the surgical theater, the cow's size, her condition and attitude, the owner's expectations, and the prognosis. Then tailor your plan to the circumstances and conditions presented. For example, there are several surgical approaches that have been described. It is typical for a surgeon to identify more with one approach than another due to preference and comfort level. However, there are specific case presentations for which a particular approach offers definite advantages. Newman discusses the importance of case selection when determining the surgical approach. To aid a surgeon's treatment plan, Newman categorizes the C-section procedure as elective, emergency non-emphysematous, and/or emergency emphysematous [5]. This categorization of the procedure is relative to the condition of the calf and its effects on prognosis and case management.

The elective category allows the surgeon to choose to some extent the time and the place that the surgery will be performed as well as the ability to make other preparations. Thus, this category carries the best prognosis for success, the exception being when the timing of the procedure might be elective but is performed due to an infirmity of the dam (fractured limb, etc.). The emergency obstetrical case in which a decision to proceed to a C-section is made early in the course of the dystocia without excessive manipulation and particularly while the calf is still alive likewise carries a very good prognosis. For both these case categories only basic postoperative management is required. The situation in which the decision to proceed to a C-section to deliver an emphysematous calf should carry with it the expectation or at least readiness for complications, significant postoperative care, and a guarded prognosis. Sometimes the decision to proceed to a C-section occurs after extensive obstetrical manipulation or even partial fetotomy efforts. This, in the opinion of the author, carries a less favorable prognosis than the emphysematous category.

Elective C-Section

Indications for an elective C-section are a valuable fetus, complicating factors such as a dam with a prepartum vaginal prolapse, a small or malformed pelvis, a recent life-threatening condition, and/or a prolonged gestation [1–3]. In any case, a history that includes breeding date or embryo transfer date should help assess the expected calving date. Calves born less than two weeks prematurely should not be unduly at risk for complications or fatalities (Chapter 48).

A C-section can be scheduled without respect to the initiation of parturition. Research performed comparing the timing of an elective C-section with respect to the stage of parturition revealed that the presence of full cervical dilatation before performing the C-section better allowed postnatal respiratory and metabolic adaptation in full-term calves [6]. When comparing an elective C-section to a vaginal delivery it is believed that aspects of vaginal delivery aid calves in transitioning from the womb. Specifically, in a study in which the hematological profiles of calves delivered by an elective C-section were compared to those of unassisted vaginal deliveries, C-section calves were uniformly more hypoxic and had a greater likelihood of experiencing respiratory distress [7]. Due to the experimental design, all of the deliveries (both vaginal and C-section) were uncomplicated. The hypoxia in the C-section calves was not due to or associated with respiratory or metabolic acidosis. Probo et al. hypothesized that during unassisted vaginal delivery calves benefitted from both the compression of the fetal thorax that occurs during transit through the pelvis and the temporary suspension by the hindlimbs improving postdelivery oxygenation [7]. Both of these events occur during spontaneous vaginal delivery.

To ameliorate these disadvantages, one option is to administer dexamethasone (20 mg) with or without a prostaglandin to induce parturition (Chapter 48). This of course makes the C-section less "elective." Certain techniques can be performed on the neonate post delivery to improve respiratory function. These are likely beneficial following the delivery of any calf. Carefully lifting the newborn by its rear legs as illustrated in Figure 52.1a for a few seconds should correspond with the stage of normal vaginal delivery in which the calf is momentarily suspended (Figure 52.1b). This must be performed without swinging or shaking the calf, which although a common practice can be injurious to the calf. Also note that lifting a newborn in this fashion could potentially result in excessive pressure to the diaphragm. Thus, closely follow the admonition that this be done quickly – specifically, less than 90 seconds. Following suspension, place the newborn in lateral recumbency. Grasp the thoracic limb, elevating and lowering the limb. This limb motion lifts the calf's chest off the ground, facilitating thoracic excursions. Repeat this motion three or four times. Additionally, or alternatively, respiratory efforts can be stimulated by "tickling" the nasal openings of the newborn with a straw or twig, or even an enteral feeding tube, inducing a sneeze, further aiding airway clearance (Figure 52.2).

Emergency C-Section

As stated, for prognostic reasons the decision to perform a C-section must occur in a timely manner. Several clinical signs or circumstances can direct a quick decision to proceed to surgery. The first clinical assessment indicating a

Figure 52.2 "Tickling" the nasal openings of the newborn with an enteral feeding tube.

cesarean is the obviously small heifer with a small or an abnormally shaped pelvis [1–3]. Next, as obstetrical manipulations are made and extraction of the calf is being attempted, pressure on the proximal aspect of the fetal forelimbs by the pelvis resulting in crossing of the forelimbs is an indication of fetal–maternal pelvic size incompatibility. Additionally, failure to progress in delivery of the calf is an indication for surgery. Clinicians should have a preset metric (time frame) for progress during obstetrical procedures. For example, if obstetrical manipulation is being made without progress for a period of 10 minutes, then one must proceed to surgery. Note – this is not to say the calf must be delivered in that or another designated time frame, but that "progress" must be made.

In the case in which the fetus is dead and especially if it is emphysematous, the prognosis is less favorable. Case management and treatment plans must be discussed with the owner in regards to outcome prior to proceeding. Although a fetotomy is an option when the calf is dead, certain clinical presentations favor a C-section. C-section is the treatment of choice for the emphysematous breech, the unreducible uterine torsion, an undilated cervix, preexisting vaginal or cervical trauma from lay delivery attempts, and uncooperative patient temperament [1–3, 5]. These cases, as stated previously, dictate aggressive postoperative care and an increased risk of complications

Overview of Surgical Approaches

Surgeon preference, patient temperament, environment, and case presentation dictate the surgical approach selected. C-sections may be performed under standing sedation or cast in recumbency. The surgical approach determines the type of restraint employed and the method of anesthesia use, whether regional or general. Surgical approaches that have been utilized for C-section are the flank (left or right), the ventral midline, and the paramedian. There are no advantages of a paramedian over a ventral midline [8], so that approach will not be covered.

Standing Left Flank

The standing left flank approach is the most common surgical technique for C-section in cattle. The left flank approach is superior in that the rumen prevents prolapse of intestinal loops from the incision. This standing procedure is not recommended in animals that are likely to become recumbent during the surgery due to exhaustion, hypocalcemia, obturator nerve paralysis, and/or highly fractious nature [2].

Standing Right Flank

The standing right flank approach has limited indications. It can be utilized when there is ruminal distention or adhesions on the left side from a previous left flank surgery [9]. It has also been advocated as the best approach for a C-section performed due to hydrops allantois or hydrops amnii. In these cases, an attempt is made to remove the fetus and close the uterus without the massive fluid loss that will result in hypovolemic shock [8]. The right flank incision may also be utilized in the management of an uncorrected uterine torsion. The surgical technique for a right flank cesarean is similar to a left flank approach with the exception that on entering the abdomen extra care must be taken to avoid lacerating the small intestine, as the rumen is not available to serve as a shield [1–3]. It is recommended that the surgical incision does not extend to far ventrally, to prevent the small intestine from escaping the incision.

Ventral Midline Approach

The ventral midline is preferred by some clinicians as the primary approach utilized for C-sections. This approach has several advantages and there are some specific indications even for those that favor a standing flank method. The ventral midline approach is the preferred surgical technique for removal of an emphysematous fetus [1–3]. This technique allows for greater access to the uterus and minimizes abdominal contamination during delivery. The ventral midline also offers the benefits of closure of the linea alba, allowing for greater suture holding strength and less incisional hemorrhage when compared to the paramedian approach. The greatest disadvantage of the ventral midline technique is that it requires the cow to be cast in dorsal recumbency.

Cesarean for the Treatment of Uterine Torsion

A C-section must be performed to deliver the calf in cases when a uterine torsion cannot be corrected by other methods. Surgically assisted correction of the torsion via a flank laparotomy followed by vaginal delivery of the calf is preferred over a hysterotomy [8–10]. However, Frazer demonstrated that a third of all uterine torsion presenting to veterinary school referral hospitals resulted in C-sections [11]. Although either a standing flank laparotomy or a ventral midline approach can be utilized, the standing left flank approach will be described.

The incision for the flank laparotomy should be made about 25% longer than ordinarily done for a routine section. Once in the abdomen, an attempt is made to correct the torsion. A second operator utilizing a detorsion bar transvaginally may be utilized to assist this effort, but typically intra-abdominal manipulation is all that is necessary. Following reduction of the torsion, delivery of the calf is dependent on several factors. Fetal viability, uterine health, and cervical dilation dictate the manner of the delivery. If cervical dilation is sufficient, a vaginal delivery may be made at this time and the flank laparotomy closed. If dilation is not adequate or the calf viability is questionable, proceed with a hysterotomy.

In the situation in which the torsion cannot be corrected or the uterus ruptures during manipulation, realize that access to the hysterotomy and/or the uterine tear will become difficult as the uterus returns to its normal position. At this time, the author recommends a second approach from the right flank to assist in the closure of the hysterotomy and/or management of the tear. In both of these scenarios described, either the torsion that could not be corrected or the uterine rupture, the fetus is likely dead and the uterus has already undergone extensive damage. Thus, case management reflects heroic measures which carry a guarded prognosis. However, considering the value of some animals and the expectations of the modern owner, practicality is often dismissed.

Restraint and Anesthesia

Flank laparotomies can be performed with the patient standing or in right lateral recumbency. Restraint when performed standing can range from haltered and tethered to the almost complete immobility provided by a cattle "squeeze" chute. In fact, some cattle chutes with adjustable side panels can be set so narrow at the floor level as to prevent a cow from lying down.

An anesthetic technique described by Abrahamsen that provides analgesia and enhances patient cooperation while maintaining recumbency is the "Ketamine® stun" which is the administration of ketamine in combination with butorphanol and xylazine [11]. Specifically, it can be administered intramuscularly (IM) at a dose rate of butorphanol 0.01 mg/kg, xylazine 0.02 mg/kg, and ketamine 0.04 mg/kg. This will provide duration of effect for 45 minutes. Abrahamsen also reported a simplified protocol utilized originally by Dr. David Anderson while at Kansas State and simply referred to as the "5–10–20 technique." This refers to an approximate dose calculated for a 500-kg cow but reported to be safely utilized on cattle ranging from 340 to 660 kg. The combination dose is 5 mg butorphanol, 10 mg xylazine, and 20 mg ketamine administered IM to the patient [12]. The timing to onset of the clinical effect for this combination when administered prior to clipping and prepping the surgical site is typically perfect. Regional anesthesia options are the proximal paravertebral block or the inverted L block, both described in Chapter 17.

Surgical Procedure: Standing Flank Approach

The surgical site should be clipped and thoroughly scrubbed with chlorhexidine. The author recommends using cloth or paper drapes to cover the chute to reduce contamination of the exposed uterus (Figure 52.3). A vertical skin incision is made in the middle of the paralumbar fossa, beginning 10 cm ventral to the transverse vertebral processes and extending distally for a distance of 25 cm [1–3]. The incision is extended to a length sufficient to allow extraction of the calf. Alternatively, an oblique celiotomy incision can be made [13]. This skin incision is begun 8–10 cm cranial and 8–10 cm ventral to the cranial aspect of the tuber coxae and extended cranioventrally at a 45° angle, ending 3 cm caudal to the last rib. The oblique approach allows for better access to the gravid uterus.

Figure 52.3 Surgical pack.

Incision of the skin and the subcutaneous tissue exposes the fibers of the external abdominal oblique muscle. This muscle is incised vertically the entire length of the skin incision. Next the internal abdominal oblique muscle is incised in a similar fashion. Upon completion of this incision the aponeurosis of the transverse abdominal muscle is revealed. Care must be taken in this step to prevent inadvertent entrances into the rumen. To avoid perforating the rumen, tent the transverse abdominal muscle with tissue forceps to make a small incision through the muscle and the peritoneum with a scalpel blade or Metzenbaum scissors. Once a small opening is made, elongate the incision using the tissue forceps as a tissue guard. Incise the remaining transverse abdominal muscle and the peritoneum with the blade or the Metzenbaum scissors. When the peritoneum is incised and the abdominal cavity opened the sound of air entering the potential space is heard. The rumen is identified and pushed cranially to allow access to the uterus (Figure 52.4). In the case of a fetus in a normal anterior position, a hindlimb within the gravid horn will be both the most recognizable and most accessible part of the calf. The distal hindlimb is used as a handle to exteriorize the uterus through the abdominal incision (Figure 52.5).

Figure 52.4 The rumen is identified and pushed cranially to allow access to the uterus.

When the part of the uterus that encases the distal limb is exteriorized the hock is then identified and "hooked" outside the incision. The uterus is incised along the greater curvature, and care must be taken to incise only the gravid horn and avoid the uterine body. The incision begins over the hock and extends to the claw. Care must be taken to avoid incising the placentomes and the fetus itself. Be forewarned that incisions that are too short will result in tearing of the uterine wall as the calf is delivered. These tears are always ragged and somewhat perpendicular to the incision line, complicating subsequent closure. After the incision is made, obstetrical chains can be attached to facilitate delivery. Following delivery of the calf the uterus is then examined: for the presence of another fetus, uterine trauma, and tears of the uterine wall.

Uterine Closure

The placenta is not removed unless it is easily detached. Care must be taken not to include the placenta in the uterine closure. Often it is helpful to trim away some of the

Figure 52.5 In the case of a fetus in a normal anterior position, a hind limb within the gravid horn will be both the most recognizable and most accessible part of the calf. It can then be grasped and used as a handle to exteriorize the uterus through the abdominal incision.

membranes from the incision prior to closure to prevent incorporating it into the suture line. The uterus is then closed with an inverting continuous suture pattern. The Cushing pattern, a modified Cushing pattern, or the Utrecht uterine suture is recommended (Figures 52.6–52.10). The advantages of the Utrecht pattern are reduced postoperative adhesions because the suture and knots are buried [3]. A tapered needle and chromic or plain catgut suture (no. 2 or 3) is recommended as at least one study comparing plain catgut to polyglactin 910 revealed no significant advantage to the use of the synthetic product [14]. A single-layer closure, utilizing the Utrecht pattern, is adequate unless there is concern with regard to the competency of the first suture line or the condition of the uterus. In cases in which the uterus contains severely contaminated fluid, a two-layer closure is indicated. A simple continuous suture pattern followed by a Cushing pattern improves the competency of the closure in a contaminated environment. Regardless of the suture pattern chosen for closure, it is important not to delay suturing as the uterus begins to involute quickly [3].

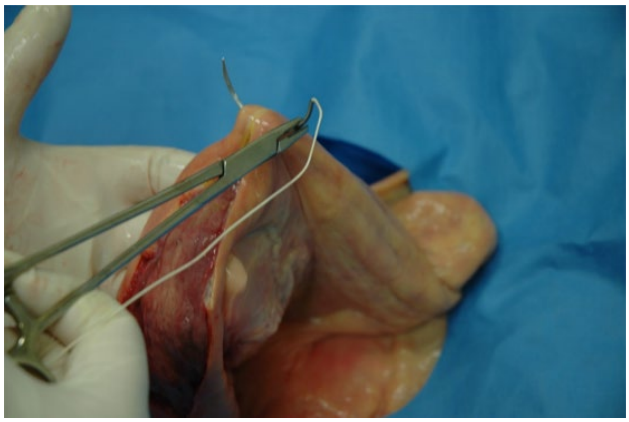

Figure 52.6 Initiating the Utrecht suture pattern, begin the suture line proximal to the uterine incision; do not enter the lumen of the uterus.

Once closure of the uterus is complete, removal of blood clots and contamination from the serosal surface is imperative in reducing postoperative adhesions (Figure 52.11). Following closure of the uterus the administration of 10–20 units of oxytocin into the uterine wall and 30–40 units intravenous (IV) will hasten uterine involution and aid in passage of the placenta (Figure 52.12).

Then, depending on the level of abdominal contamination, it may be advisable to lavage the abdomen with large volumes of saline to remove clotted blood and debris. If there is gross, severe contamination, large volumes can be used and egress of lavage fluids can be facilitated by placement of a rumen trocar through the ventral abdomen, as described in Chapter 55. In addition, carboxymethylcellulose, heparin, potassium penicillin, flunixin meglumine, glycerol, and tetracycline have all been advocated as components of a postsurgical abdominal lavage [5, 15–17].

When the exteriorized portion of the uterus has been maintained outside the abdomen for delivery and uterine closure, it can be assumed that there is no abdominal contamination. Contamination must be assumed in cases such as an unresolved uterine torsion, a fetus in the "breech" posterior presentation, or large fetal size preventing the complete exteriorization of the uterus [1]. This raises a couple of issues. First, a cautionary note with respect to the use of a popular obstetrical lubricant, J-Lube™, which has been shown to be fatal to cattle, horses, and mice following intra-abdominal exposure [16]. Thus, because abdominal contamination by the uterine contents is always a possibility, it is recommended to avoid the use of J-Lube in obstetrical cases that

(a) (b)

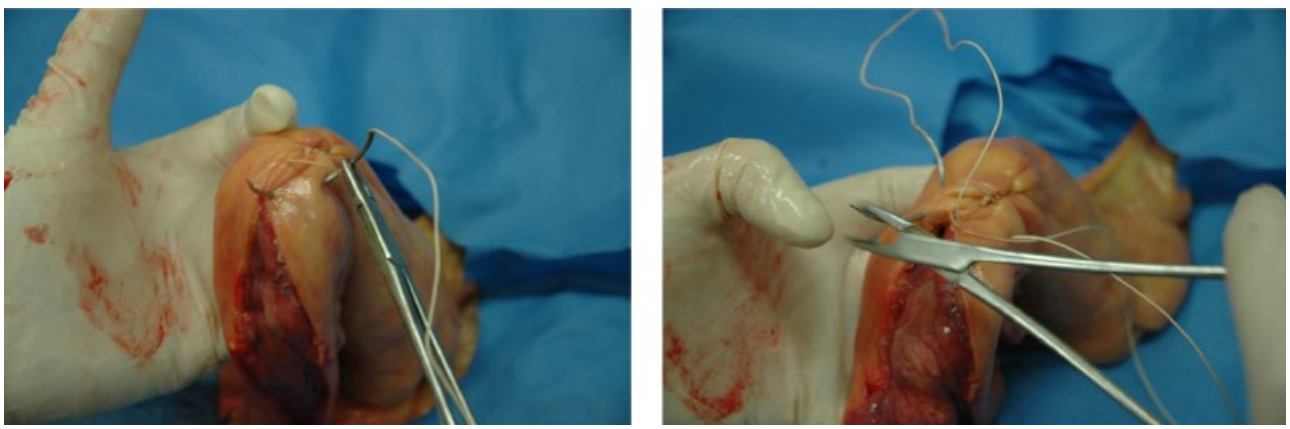

Figure 52.7 (a) and (b) Once the knot is secure, back place each bite at a 45° angle oblique to the incision proximal to the exit of the previous bite.

Figure 52.8 Tighten the incision by pushing the uterus away from the suture line. This gives the closure a bunched or pursed appearance.

Figure 52.9 Completion of the Utrecht suture line to bury the knot.

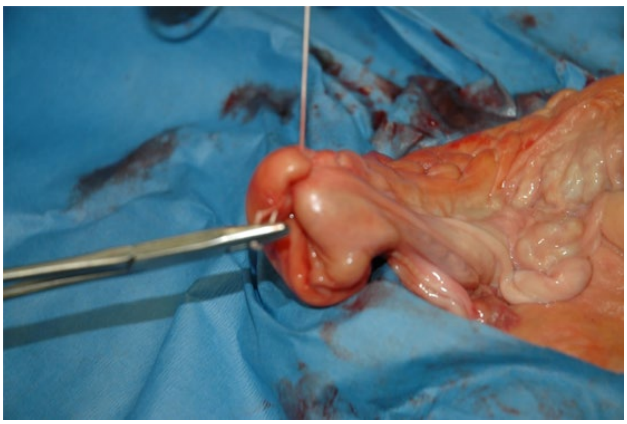

Figure 52.10 Note that as the Utrecht knot is tightened, the remaining suture is covered.

ultimately result in a C-section. Conversely, sodium carboxymethylcellulose, which is a very good obstetrical lubricant, not only is safe but also has been used in abdominal lavage fluids to minimize adhesions [16].

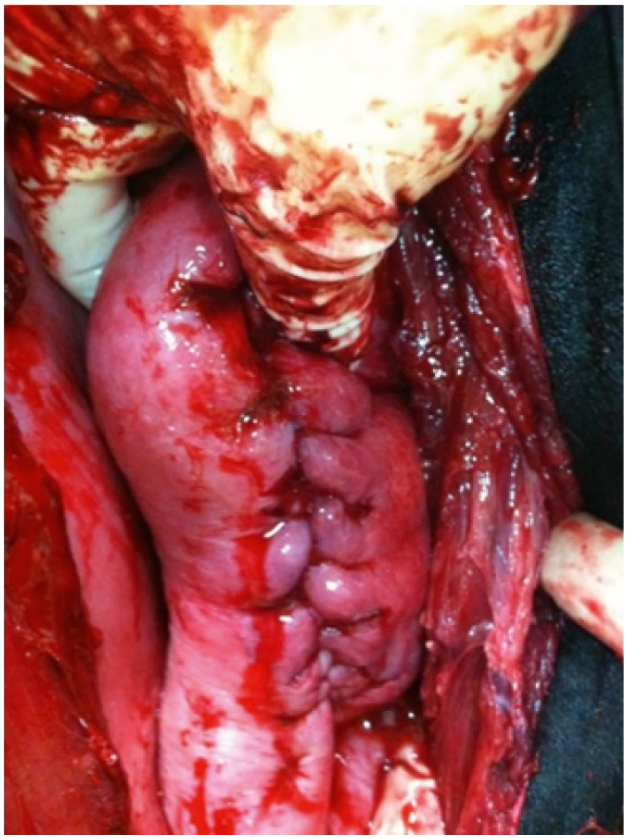

Figure 52.11 This image demonstrates the accumulation of blood clots along the incision that incite the formation of adhesions, reducing fertility. Notice how the uterus is withdrawn into the incision. A surgeon must work quickly due to the rapid involution of the uterus.

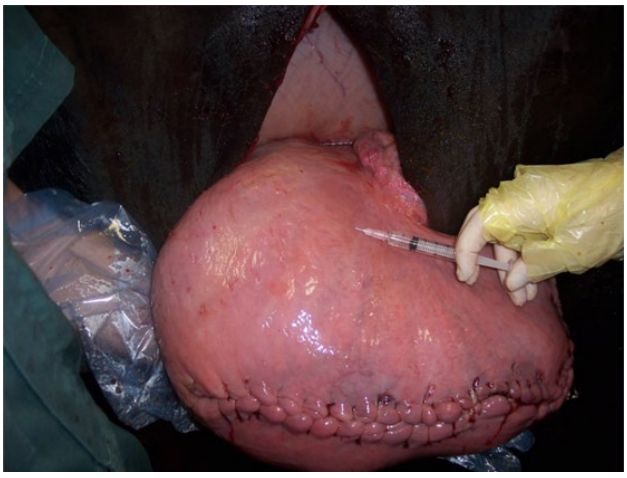

Figure 52.12 Injection of oxytocin into the uterine wall prior to abdominal closure.

Body Wall Closure

Abdominal wall closure is achieved in three layers. The peritoneum and the transverse abdominal muscle are closed together with simple continuous suture pattern using no 2. or

3 chromic catgut or synthetic no. 3 polyglactin 910. The internal and external abdominal oblique muscles as well as the subcutaneous fascia are closed with a simple continuous suture pattern using no. 3 polyglactin 910. The author recommends closure beginning distally and working proximally to help contain viscera within the abdominal cavity. Skin closure can be performed with 0.6-mm nylon (Braunamid™) utilizing a pattern of the surgeon's choice [1–3].

Surgical Procedure: Ventral Midline Approach

The cow is cast in dorsal recumbency with both the head and the forelimbs tied in extension (Figure 52.13). The abdomen is clipped and aseptically prepped. Regional anesthesia is performed with a line block utilizing 2% lidocaine, being sure to inject within the subcutaneous and intramuscular spaces (Figure 52.14). A midline incision is initiated immediately cranial to the udder extending cranially 5–7 cm beyond the umbilicus [2]. Once the skin and subcutaneous tissues are incised, a small stab incision is made through the linea alba. This stab incision is large enough to pass a finger or forceps to elevate the body wall to allow extension of the incision along the linea while minimizing risk of abdominal visceral penetration. Once the abdomen is entered, downward pressure on the body wall will help to push the gravid horn of the uterus toward the incision. To minimize gross contamination to the abdomen, a sterilely packaged plastic Mayo stand cover works well to isolate the uterus. Make a small incision into the Mayo cover, pulling the gravid horn through the Mayo stand cover. Tear the opening so that the cover is tightly adhered to the uterus but allows enough room for manipulation. Place the Mayo cover so that the abdominal incision and viscera are covered and only the gravid horn is exposed (Figure 52.15). Manipulation of the uterus, delivery of the calf, and closure of the uterus are as previously described.

Figure 52.13 Cow cast in dorsal recumbency with both head and forelimbs tied in extension.

Figure 52.14 Regional anesthesia supplied by a line block utilizing 2% lidocaine injection within the subcutaneous and intramuscular spaces.

Closure of the linea alba and peritoneum is obtained by using either a simple continuous or near-far-far-near pattern with no. 3 polyglactin 910. To facilitate closure, placement of towel clamps along the incision or several interrupted cruciate sutures will help alleviate tension as the incision is closed. The subcutaneous tissues are apposed with absorbable suture in a simple continuous suture pattern. The skin should be closed with 0.6-mm nylon (Braunamid) in a simple interrupted cruciate pattern; continuous patterns are difficult to remove from a ventral midline incision.

Postoperative Management and Complications

Complications following C-section include endotoxemia, peritonitis, metritis, adhesions, and reduced fertility [1–3, 5]. Mostly these complications are the result of bacterial contamination. As previously stated, all cesareans should be considered clean-contaminated surgeries even in the best of circumstances. Therefore broad-spectrum antibiotics and non-steroidal anti-inflammatories should be administered prior to surgery. Systemic antibiotics should be maintained for three to five days following surgery depending on the degree of surgical contamination. Severely endotoxic animals by definition should be treated with antimicrobials several days beyond the resolution of

Figure 52.15 (a) and (b) The gravid horn has been placed like a "sack" inside a sterile disposable Mayo stand cover, then the remaining Mayo cover is packed within the incision, protecting the abdominal viscera.

the endotoxemia. Endotoxic animals will require additional cardiovascular support of IV fluid therapy.

Clinical signs of peritonitis, pyrexia, inappetence, and ileus usually become apparent by three days following surgery. In the absence of these clinical signs, antibiotics may be discontinued.

Intra-abdominal adhesions can reduce future fertility. The chapter has previously stated that utilizing the Utrecht suture pattern and removing blood clots from the uterine serosa will remarkably reduce postoperative adhesions. The author recommends using 11 of carboxymethylcellulose prior to body wall closure to further decrease the risk of postoperative adhesions.

Postoperative fertility is reduced by approximately 15% of that of cows that did not have a C-section, with postoperative fertility rates expected to be between 60 and 80% [1, 2].

Retained Fetal Membranes

Augustine T. Peter

Veterinary Clinical Sciences, College of Veterinary Medicine, Purdue University, West Lafayette, IN, USA

Introduction

Placenta is the transporting epithelium between fetal and maternal circulations; it is created and owned by the fetus, protected by the dam, escapes antigenic rejection, loses its purpose immediately after rupture of the umbilical cord, and is expelled after fetal delivery. Bovine placenta fascinated early farmers, excited many scholars to create more than 3000 documents since 1919, including the author [1], and continues to provide remuneration for veterinarians all over the globe because of its retention. Failure of placental expulsion constitutes retained placenta. Much has been documented regarding retained placenta in theriogenology textbooks [2–6] based on these authors' own vast clinical experience and information gleaned from scientific publications. Excellent review articles by leading veterinary clinical investigators have more vividly encapsulated the various aspects of this clinical condition [7–25]. What is known about its clinical signs and negative influence on postpartum reproductive performance has not changed in the last century. However, over the years, many hypotheses with regard to its occurrence (particularly at the tissue and cellular levels), risk factors, preventive measures, and treatment plans have been proposed. Headings for this topic include definitions, developmental morphology of placenta to better understand the process of detachment and etiology, pathogenesis, treatment, and prevention. It will become very apparent on reading this chapter that there are many instructive similarities among these topics.

Definitions

The fetal part of the placenta, namely the fetal membrane (allantochorion), normally separates from its maternal moorings during the process of parturition. The process of parturition is marked by vascular, contractile, and mechanical dynamics designed to expel the fetus and its membranes (allantochorion and amnion). Fetal and maternal parts of the placenta have equal regulatory roles in the timely separation of the fetal part of placenta. Hence, use of the term "placenta" in this chapter will point to a collective structure created by dam and fetus. Retention is primarily due to failure of the villi of the fetal cotyledons to detach themselves from the maternal crypts of the caruncle. The process of separation and inversion of the allantochorion (allantoic surface faces outside) is completed on average within eight hours of initiation of parturition, depending on the parity and age of patient. In general, all parts of the allantochorion and amnion need to be expelled within 0.5–12 hours after calving. Thus retention of fetal membranes is referred to as retained placenta or, more correctly, as retained fetal membranes (RFM), with the term "fetal membranes" referring to both the allantochorion and amnion. While the use of "fetal membrane" (singular) for allantochorion is accepted, to avoid confusion the term "allantochorion" will be used in this chapter.

Developmental Morphology

Presently, bovine placenta is described as cotyledonary synepitheliochorial based on the morphology that is established around 40–50 days into pregnancy. Earlier classification as syndesmochorial was based on a misunderstanding of the number and form of the layers intervening between fetal and maternal circulation. This classification needed correction because of new evidence. The earlier assumption that the uterine epithelium is lost in the process of placentation resulting in direct apposition of trophectoderm to the maternal connective tissue is no longer tenable. Now it is known that uterine epithelium persists, although initially modified

to a variable degree into patches of a hybrid fetomaternal syncytium formed by migration and fusion of a particular type of trophectodermal cells with uterine epithelial (UE) cells. These trophoblast binucleate/giant cells (TGC) migrate and modify uterine epithelium by apical fusion to form fetomaternal hybrid syncytial plaques with up to eight nuclei at the junction of fetal and maternal tissue. These syncytial plaques are replaced by regrowth of UE cells by day 40, and subsequently TGC–UE fusion produces only transient trinucleate minisyncytia throughout the remainder of pregnancy.

Research findings have necessitated a change in the morphological terminology of placentation and defined bovine placenta as synepitheliochorial. The prefix "syn" indicates the contribution of TGC to fetomaternal syncytium and contrasts with the simple microvillar interdigitation between trophoblast and uterine epithelium (epitheliochorial) over the rest of the placenta. Cotyledonary refers to the presence of localized areas of trophectodermal proliferation forming "cotyledons" in placenta and each cotyledon is the fetal part of a placentome. Placentome is formed by the tuft of branching chorionic villi from the cotyledon that grow and enmesh with corresponding maternal caruncular crypts, providing a finger-in-glove arrangement. These crypts develop from the preformed flat endometrial caruncles (Figure 53.1), present in the non-pregnant cow, which are aligned along the uterine horns. Normally, placenta consists of 80–90 of these placentomes. The placentomes are linked together by areas of flat apposition between trophoblast and caruncular epithelium (CE). The CE cells are similar to UE cells and are homogeneous in population unlike trophoblast. Placentomes guarantee a firm anchorage by the complementary interdigitation of fetal villous trees with maternal crypts and by the interdigitation of the apical microvilli from uninucleate trophoblast cells (UTC) and CE directly by cell–cell contact or indirectly by cell–matrix contact. Secondly, placentome formation with a synepitheliochorial interhemal barrier provides vast increase in surface area necessary for the continuously increasing substance exchange between dam and fetus. It is important to note that placentomal gross morphology and the pattern of fetomaternal interdigitation (villus/crypt architecture of the mid to late pregnant placenta) differ considerably between bovid species but detailed cellular structure of the maternofetal interface is similar throughout pregnancy. It is pertinent to point out that no maternal tissue is shed in the afterbirth (secundines) of cattle. On the other hand, a few fetal villi may be caught and left in maternal crypts.

Etiology

Placentomal maturation coupled with appropriate structural, endocrinological, and immunological changes result in easy separation and expulsion of the fetal membranes. Furthermore, vascular, contractile, and involution changes that occur in the uterus before and during parturition help in the separation and expulsion of fetal membranes. It should be very well recognized that the process of maturation and timely separation and expulsion of fetal membranes involves well-orchestrated regulation by both maternal and fetal components of the placenta.

Placentome Maturation

It has been established that a physiological parturition occurs on the face of mature placental structures. The fact that induction of parturition is followed by RFM in most cases supports the observation that immaturity of placentome may be one of the contributing factors for RFM since parturition is initiated before term in such cases. Similarly, that RFM has been an issue in most abortion cases lends credence to the notion that a mature placentome is a prerequisite for the separation of allantochorion.

Endocrine Changes

Maturation of placenta is followed by specific endocrine changes. These changes are important to bring about contractile and apoptotic events, and expression of genes for

matrix metalloproteinases and their inhibitors. Although a mature placenta is capable of initiating favorable steroidogenic and arachidonic cascades, altered expression of antioxidative defense mechanisms at this juncture can interfere with steroidogenesis at the cellular metabolic level. Poor expression of the antioxidative defense mechanisms against reactive oxygen species (ROS) can result in an imbalance between production and neutralization of ROS, preventing proper detachment of the allantochorion.

Closer to parturition, increases in peripheral estradiol concentrations and less perceptible changes in progesterone are observed. Progesterone perfuses into placentomes which may contribute to its imbibition within placentome, enabling structural, and functional changes. These changes facilitate contraction of myometrium by estradiol along with other hormones including oxytocin and specific prostaglandins. It is important to note that these structural changes can possibly occur only in a mature placentome that has been exposed to adequate duration and quantity of estradiol.

Regarding prostaglandins, the type, and quantity of prostaglandins produced can influence the contractility of the myometrium. For example, a lower ratio of prostaglandin (PG)E_2 to $PGF_{2\alpha}$ within fetomaternal compartments of placentome and an elevated steroid hormone receptor status possibly reduces the rate of apoptosis occurring in chorionic epithelium before calving. There may be other unknown factors involved in the regulation of apoptosis; nevertheless, it is recognized that dysfunctional expression of apoptotic regulating factors can contribute to failure of separation.

Expression of matrix metalloproteinases and counteracting tissue inhibitors of metalloproteinases in the fetal compartment are essential to balance extracellular matrix formation and degradation, critical in the separation of the allantochorion. Specifically, they are responsible in breaking down collagen within the villi and assisting in the separation of villi from the crypts.

Finally, it should be remembered that despite the complexity of various prostaglandins and their production and our incomplete understanding of their specific roles, the use of prostaglandins to prevent the occurrence of RFM in induced parturition has yielded inconclusive results.

Structural Changes

Although the tight connection within placentome is essential during pregnancy, it has to cease to allow allantochorion separation. Indeed, distinct remodeling and loosening of adherence occurs within placentome during late pregnancy. Transformations that occur in placental epithelium and connective tissue during the last month of pregnancy prepare the placentome for critical loosening of tissues involved in fetomaternal interdigitation. This process has to proceed undisturbed and has to culminate in separation of allantochorion at the right time. Changes include progressive collagenization of maternal and fetal connective tissues, flattening of maternal epithelium lining crypts nearest to the caruncular stalk, and appearance of TGC that become polynuclear shortly before the detachment process. Currently, research is focused on studying the difference in protein profile of retained and non-retained fetal membranes, which may shed further light on etiology [26].

Immunological Changes

Expression of major histocompatibility complex (MHC) class I in bovine trophoblast cells and their tight regulation are biologically relevant. Early in pregnancy, a complete shutdown of major MHC class I expression by trophoblast cells appears to be critical for normal placental development and fetal survival. This immunological camouflage is vital to avoid recognition by the multifactorial array of cellular and hormonal mechanisms that mediate rejection. In a mature placenta, maternal immunological recognition of fetal MHC class I proteins triggers immune and inflammatory responses that contribute to rejection of allantochorion at parturition. It is interesting to note that in these situations there is a clear adaptation of the immune system for a function distinct from protection against pathogens. In summary, MHC compatibility has significant molecular consequences and can result in an increased incidence of RFM.

The inflammatory response is followed by the maternal immune response. Two characteristic actions are evident in the inflammatory process, namely production of neutrophil-activating factors and the chemotactic activity of neutrophils. These are important for successful immune-assisted detachment of the allantochorion. It has been suggested that the function of peripheral leukocytes may be reduced, which may be a cause for, or an effect of, retention leading to other complications such as mastitis in RFM cases.

Vascular Changes

During contractions of the uterus, uterine pressure is constantly changing and this leads to alternating anemic and hyperemic conditions and temporary changes on the surface of fetal chorionic villi. As a result, the attachment of chorionic epithelium in maternal crypts becomes impaired. Further, subsequent rupture of the umbilical cord shuts down blood supply to the fetal villi and helps in the separation process by reducing the size of villi. Anemic changes that occur to the fetal villi after calving because of rupture

of the umbilical cord are essential and these mechanical processes of detachment should not be underestimated. Identical changes occur in caruncles due to uterine contractions. Uterine contractions continue to reduce the amount of blood directed to the uterus. Consequently, caruncles become smaller in size due to reduced blood supply, resulting in the dilation of maternal crypts.

Contractile Changes

Abdominal contractions noticed during expulsion of the fetus result in changes to the shape of the placentome due to abdominal pressure, an essential step in the process of separation. Concurrent and intermittent uterine wall contractions change the shape of the caruncles further from oval to round due to fetal pressure on them, facilitating detachment of cotyledons from the caruncle. The characteristic sharp contractions of the circular myometrial muscle layers that closely follow each other and which are superimposed on contractions of longitudinal myometrial muscle layers noticed in the parturition process help not only in expelling the fetus but also in allantochorion separation. These rhythmic waves of contraction (every three to four minutes) cause cotyledons to open up in a fan-like manner as they pass over them and enable separation of the allantochorion. Hence defective myometrial contraction can lead to retention. Progesterone diffusing from the placenta to the myometrium and estradiol synthesized locally at this time may have a role in the initiation and suppression of these contractions. Presence of uterine contractions even after delivery helps in the process of separation. This is also necessary to prevent hemorrhage and to aid in the expulsion of fetal membranes. These peristaltic and contraction waves, besides reducing the size of the uterus and aiding in forcing fetal membranes into the birth canal, can also markedly reduce the amount of blood circulating in the endometrium. Further, the influence of oxytocin and ongoing uterine involution in these processes cannot be overlooked, as noted where injection of oxytocin and suckling had beneficial effects in shedding of fetal membranes.

Pathogenesis

Considering the essential changes that facilitate the process of separation and expulsion of fetal membranes, it is obvious that retarded or unsuccessful separation and expulsion can be due to interference with these changes. Paying attention to interfering factors and eliminating them, if possible, will reduce the incidence. Some of these factors are discussed in the section "Prevention." In general, the interfering factors can be classified as direct or indirect.

Direct Factors

Direct factors include immature placentomes, non-inflammatory edema of the chorionic villi that results from uterine torsion and cesarean sections, dystocia, necrosis between the crypts and villi following a possible antepartum allergic reaction, premature involution of placentomes, hyperemia of placentomes, inflammation, mechanical prevention of expulsion, and inflammation of fetal membrane.

Although inflammation is attributed as a direct interference, the role of prepartum uterine infection is questioned and it is more likely that uterine infection follows after retention due to either poor uterine involution or the fact that the membrane is retained. However, the incidence of retention in infectious abortion cases suggests that infection may be a factor. The most likely reason for retention in such cases may be immaturity of the placentome rather than infection. It should be remembered that poor calving hygiene can lead to parturient infection and retention, although the mechanism is not clearly understood.

In most induced parturition cases, retention of allantochorion can be attributed to possible immature placentomes. However, retention does not occur in all induced cases and furthermore it is influenced by the type of glucocorticoid administered. Besides immaturity, administration of these agents may result in dysfunctional apoptotic processes or interfere with the immune-assisted separation process discussed earlier or specific actions such as the expression of cyclooxygenase by PGF_{2a}. Furthermore, these treatments can inhibit the normal loss of TGC that occurs closer to parturition and modulate the action of other hormones.

Indirect Factors

Indirect factors include intensive stress, duration of pregnancy, extensive distension, season, sex of the fetus, stillbirth, deficiency of trace minerals and vitamins, and situations where the uterus becomes atonic and unable to contract in cases such as dropsy, twinning, fetal gigantism, subclinical hypocalcemia, and other pathological conditions. Other indirect factors that may have a role can be broadly categorized into hormonal, hereditary, nutritional, and circulatory causes; incidentally, these may also contribute to unexplained cases of atonic uterus. The required changes for separation and expulsion of the allantochorion and the interfering factors are schematically summarized in Figure 53.2.

It is not known whether apoptotic, degenerative, and necrotic changes are noticed in placentomal and interplacentomal regions because of allantochorion retention. As mentioned earlier, apoptosis that started prior to separation will continue during retention. It should be emphasized that

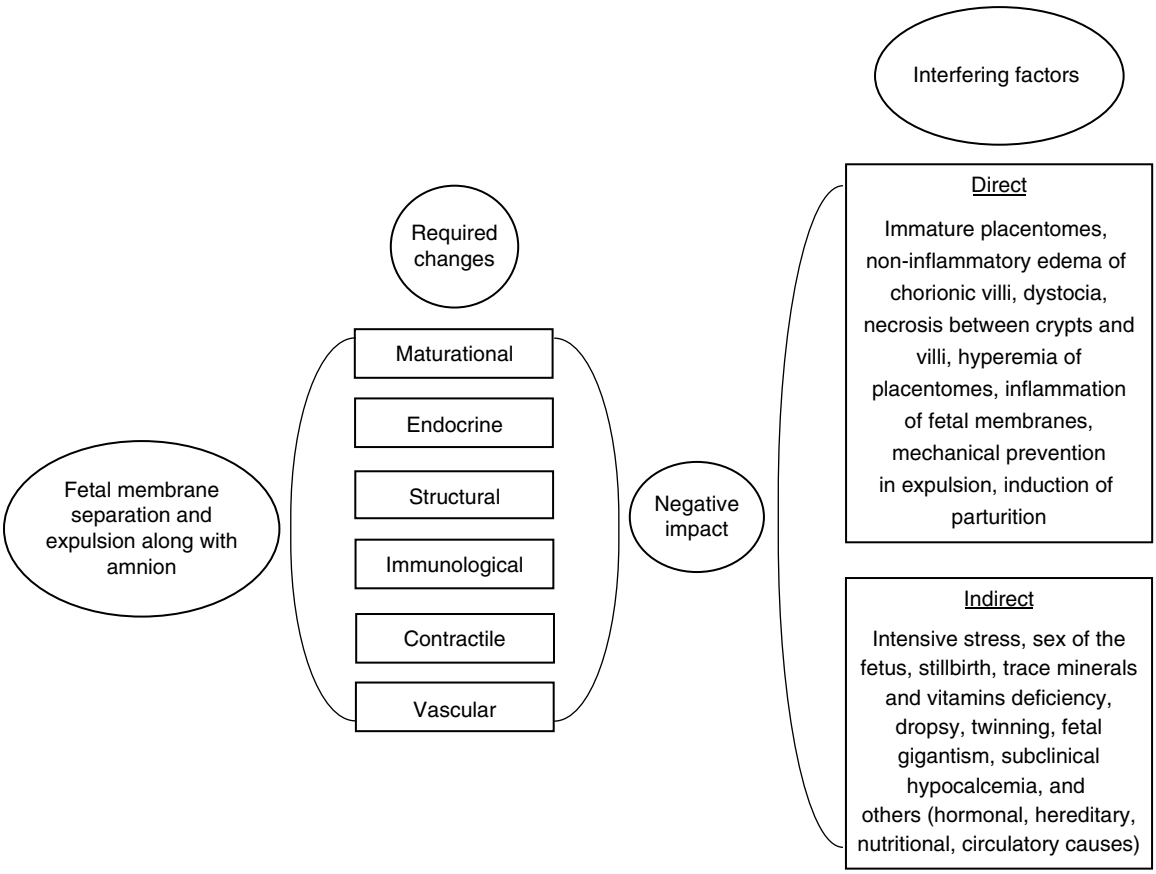

Figure 53.2 A schematic depicting changes required for normal fetal membrane separation and expulsion. Refer to text for details of these changes. Interfering factors that have a negative impact on these processes are listed.

degenerative changes might have been responsible for retention; however, in almost all cases these changes will occur after retention. Similarly, in certain cases small portions of necrotic epithelium present between the chorionic villi and the cryptal wall might contribute to retention, but again the process occurs after retention, depending on the period of retention. In general, the lesion may vary from slight evidence of inflammation to severe necrotic or leathery or hemorrhagic inflammation of allantochorion. Depending on the etiology and its severity, lesions may extend to areas of membrane that occupied the non-gravid uterine horn.

Clinical Signs and Complications

Normally, if fetal membranes are not passed within 36 hours, and in the absence of manual intervention, they tend to persist for 6–10 days as a putrefying tissue and drop away as a putrescent mass in uncomplicated retention. Progress of putrefactive liquefaction of the villi allows separation, and uterine involution aids in completing separation. Some cotyledons toward the cervical end would have separated by the time the calf is born. Involution of the uterus to restore its spiral configuration aids in separation. Mild contractions of the uterus and cervix are accompanied by, and correlated with, transient dilations of the caudal cervix that facilitate evacuation of normal uterine exudate. In protracted cases there is a large amount of uterine exudate with its characteristic foul-smelling odor. Vaginal/uterine examination of a cow in such cases can evoke forceful straining that results in expulsion of fetid uterine exudate along with feces.

In general, depending on the duration of retention, a case can have fresh fetal membranes hanging from the vulvar lips (Figure 53.3) without any obvious smell, or it might be one that has undergone degenerative changes, as reflected by the appearance of fetal membranes and the presence of malodorous stench. There may not be elevation of body temperature with or without marked illness in all cases even if retention has continued beyond 72 hours. Immediate complication may be reduction in milk yield, which may not always be noticeable and the impact may be negligible on the herd basis. Some animals exhibit outward signs of ongoing uterine changes in response to spontaneous uterine infections or uterine infections that followed due to manual removal. Along

Figure 53.3 A fresh case of retained fetal membrane with minimal changes. *Source:* Courtesy of Robert Lofstedt.

with a rise in body temperature, other signs may be obvious such as anorexia, depression, increase in pulse rate, and loss of body weight. These are symptoms of either endometritis or puerperal metritis and the signs may depend on the intensity of the disease process and the number of uterine layers involved in the inflammatory/infectious process. Further, the foregoing clinical signs may be severe if other conditions such as peritonitis, mastitis, necrotic vaginitis, parturient paresis, and acetonemia occur simultaneously with uterine changes.

Apart from immediate complications, long-term complications include delayed uterine involution, minor to major effect on fertility, inherent loss of milk production, or loss due to discarded milk because of antibiotic treatment. The immediate effect on fertility is mainly due to impaired uterine and ovarian activities. There will be an increase in days from calving to first estrus and the occurrence of subsequent estruses. In essence, the resumption of normal cyclic ovarian activities is prevented, possibly due to delay in uterine involution and elimination of bacterial infection. Estrous cycles may be irregular, leading to increases in the number of breedings and finally leading to increases in days open. It is difficult to determine the overall losses; however, considering the ramifications of the condition, it can have a very serious impact depending on its prevalence and incidence.

Treatment

Considering the variety of causes and mechanisms, it is not surprising that treatments have met with limited success. However, more than treatment, a case of RFM, like other clinical conditions of the immediate postpartum period, enables the veterinarian to become an educator more than a curer of all animal ailments. Basic goals of any therapeutic regimen should be return of the cow to reproductive usefulness as soon as possible and the prevention of primary and secondary complications that can lead to economic losses from lowered milk production and delayed conception. The primary complication is a normal uterus becoming a diseased or pathologic uterus and the goal of treatment is to prevent its occurrence.

The aim of treatment is to ensure that RFM are shed within a reasonable time with minimal intervention. It should never be the goal to manually remove by force, except in cases where the allantochorion has completely detached but the membranes are not expelled for any unexplainable reason. In other words, the only time that manual removal should be practiced is when the attending veterinarian fortuitously finds the entire fetal membranes free and expulsion only hindered by a partially closed cervix. In this case the fetal membranes are gently teased through the cervix, with care being taken not to traumatize the cervix or vagina during the procedure. Removal should be completed within a few minutes and carried out gently, paying attention to hygienic measures. Aggressive intrauterine manipulations probably increase endotoxin production and its absorption into the circulation, resulting in elevated body temperature. Intrauterine or systemic antibiotic treatment is not necessary. However, lack of secretion of thick tenacious mucus by the cervix in RFM cases allows infection to gain entrance to the uterus and the process of removal can further favor endometrial infection. Hence some cases may need systemic antibiotic treatment depending on the severity of the problem and condition of the animal.

In general, manual separation of the caruncular and cotyledonary attachment is not a preferred method. Although it appears to have many harmful effects on the animal and on future fertility, it is believed to be practiced for aesthetic reasons. This practice seems to give a "conservative trust to an old routine" and is accepted in many parts of the world and taught in the veterinary curriculum. If it is practiced, the cow's tail should be secured by tying it to the opposite front leg. The vulvar area is then prepared with a suitable antiseptic scrub, and tetracycline boluses or capsules are introduced into the cervix and uterine horns with a clean plastic sleeve after the allantochorion is separated carefully by releasing the attachments between the caruncle and cotyledon. Systemic administration of ceftiofur hydrochloride is benefi-

cial for prevention of metritis. Although some veterinarians prefer a predominantly intrauterine approach for antibiotic therapy to combat uterine infection, a systemic approach has certain advantages. For example, absorption of antibiotics from the uterus is not impaired as in local treatment, antibiotic concentrations attained in the uterine tissue are similar to blood concentrations, and uterine infection is seldom localized since it involves more layers than uterine mucosa.

Dilating the cervix after a couple of days in an attempt to expel fetal membranes is not recommended. This causes more trauma to the cervix and uterus, predisposing to further complications, notwithstanding the pain inflicted to animals. Complications include immediate septicemia, drop in milk and appetite, elevation of temperature, loss of weight, and possible death, or else a prolonged period of convalescence during which time shreds of membrane and exudate are expelled, pyometra or chronic metritis develops, or protracted or even permanent infertility may result from uterine abscess, perimetritis, salpingitis, or severe endometritis. It is a good idea not to examine the cow until 72 hours after parturition unless the cow develops clinical signs of anorexia, an elevated temperature, and other symptoms of septicemia. It should be noted that in some cases it is impossible to insert a hand into the uterus after 48 hours and cervical closure occurs in normal cases earlier than this timeframe. Delaying for 72 hours allows the endometrium to construct a protective barrier by walling the fetal membranes off and thereby lowering the chance of septicemia or toxemia. Autolysis that will eventually occur enables separation and expulsion. In such cases, treat as a large abscess in which the necrotic core has not been separated from the surrounding tissues. At no time should fetal membranes be tied to an object or cut closer to the vulva. Surgical procedures governing the handling of an abscess should also govern the handing of an infected uterus. Conservative treatment is indicated and essential. Removing fetal membranes in an incomplete, rough, and insanitary manner is not advisable. In certain cases, there may be collection of uterine exudate; gentle vaginal/uterine examination allows the fluid to drain out by the position a standing animal would take in response to such an examination.

Uncomplicated cases require no treatment and thereby the impact on future fertility is minimized. A "non-drug approach" to the problem should not be forgotten. However, the malodorous stench generated by retention cannot be ignored and it requires courage to prescribe no treatment, so it would be prudent to adopt a rigid attitude of non-interference. A conservative approach (intrauterine antibiotics, maybe including systemic drugs, and leaving the fetal membranes) is better than manual removal at the behest of the client, since clients would prefer that the unsightly fetid mass hanging from the genital tract is removed earlier.

If fetal membranes are retained for 24–48 hours and the cow is running a fever (rectal temperature >39.5 °C) or anorectic, the animal should receive immediate attention and treatment. In addition to monitoring rectal temperature, close observation of the animal is critical. Nothing replaces close observation that recognizes an animal's changing appearance and behavior. The minimum treatment would be parenteral administration of antibiotics. Systemic treatment alone is effective and intrauterine antibiotic treatment is not recommended in all cases since more harm can be done by the manipulation. For systemic administration, ceftiofur is preferred over oxytetracycline: the latter is approved for beef and non-lactating dairy cattle and has a 22-day preslaughter withdrawal period, while ceftiofur is appealing because of injection-site tolerance, no milk discard, and 3-day preslaughter withdrawal period. Although environmental fragility and residue chemistry of cephalosporin compounds have not been explored completely, these may be a concern with regard to animal and human food safety. If oxytetracycline is used, four days of milk discard is required. Penicillin can also be used provided a similar milk discard time is followed. It should be remembered that there may not be better reproductive performance due to antibiotic treatment, but in general proper antibiotic treatment may reduce the chance of the treated animal being culled from the herd.

In the USA, it is required that all these treatments should be carried out with the knowledge of a practitioner who is aware of the Animal Medicine Drug Use Clarification Act. It is incumbent on the practitioner to ensure that the right dosage, route of administration, and duration of treatment are strictly followed. Clients also need to be clearly instructed about the withdrawal time for milk and preslaughter withdrawal period. Cows that appear depressed and which are dehydrated need further examination and uterine exudate should be drained by flushing. No single course of treatment is safe and effective in every circumstance. Considering the perceived and real effects of the use of antibiotics in animals on human health, intrauterine agents such as chlorhexidine, hydrogen peroxide, and recently ozone have been tried.

Use of ecbolic drugs has been suggested as a way to improve uterine and myometrial contractions to aid in separation and expulsion. Foremost is $PGF_{2\alpha}$, but its use is questioned since the endometrium produces this compound adequately during the immediate peripartum period. The inconclusive nature of the findings supports this notion. Some studies have advocated its use at later times in the postpartum period to improve fertility by regulating the uterine involution process and facilitating early resumption of ovarian activity. However, findings are not uniform, real effectiveness remains undetermined, and most results seem

to deny any positive effect. However, there may be instances where it may have some benefit, particularly in the presence of a corpus luteum that hinders the restoration of uterine health in the face of uterine infection.

Administration of compounds prophylactically or as a treatment option based on their ability either to facilitate separation of the allantochorion or to contract myometrium have been developed over the years and continue to be used. Many other agents continue to be used to reduce the deleterious effects on fertility. The prophylactic use of agents such as antibiotics and estrogens to prevent endometritis and improve fertility is a reasonable goal. Estradiol compounds are used as an adjunct treatment option to aid in restoration of endometrium and prevent metritis. This method has empirical appeal; however, paucity of beneficial information, possible side effects, lack of conclusive scientific evidence, its effect on humans as a food residue, and marginal return considering the time and cost involved limit its universal application. Lack of availability in some parts of the world due to regulatory measures also precludes its use.

Other compounds such as gonadotropin-releasing hormone (GnRH) have been used to improve fertility in the postpartum period with variable results. However, GnRH has benefit when the ovary and uterus are structurally and functionally ready for the initiation of follicular activity and the animal is fit for breeding. In certain herds that practice earlier breeding, GnRH may be beneficial. A small dose and repeated use of oxytocin has more scientific validity for treatment because of its ability to cause tubocervical contraction of the uterus and thereby expel fetal membranes and uterine exudate. Furthermore, for the same reason, its use in cesarean section is warranted to facilitate separation of the allantochorion. The amount used is important since it can enhance milk ejection prematurely. In general, lack of unified opinion has been magnified by endless clinical reports and testimonials concerning the ever-growing list of hormones and antimicrobial solutions. Use of ozone [27–29] may have its benefit, but much research is needed.

Administration of collagenase into the umbilical arteries has been studied extensively and is found to aid in separation of the allantochorion. Although the technique is promising, time, the cumbersome nature of the procedure, and cost limit its use. Further, the effect on future fertility remains undetermined.

It is recommended that all cows affected with RFM be examined 20–30 days after removal of fetal membranes to determine the progress of uterine involution. A good transrectal examination of the reproductive tract not only helps to identify problems, if any, but also stimulates the uterus and enables expulsion of uterine contents. Transrectal uterine massage around this time, starting from the uterine horns to the cervix, for three to five minutes may stimulate uterine mucosa and restore the dynamic function of the myometrium. This procedure is contraindicated in cases of fibrinous, hemorrhagic, acute purulent endometritis and closed cervix cases. Complications of unresolved cases are many and are aggravated by the animal's body condition, age, and management practices. It should be noted that permanent sterility may result due to pyometra and metritis if proper treatment is not instituted. Aged animals may need longer time to recover, so breeding should be delayed. All cows with persistent mucopurulent discharge from the vulva following RFM should be reexamined and treated.

In summary, manual removal of retained membranes is not recommended and each case does not require treatment during or after expulsion of fetal membranes. Systemic antibiotic treatment can be reserved for animals that have fever, while some animals may in addition need fluid therapy. Oxytocin can have beneficial effects if correct dose and regimen are used.

Prevention

Proper treatment of the affected animal will reduce economic losses due to increased calving interval, increased culling rate, discarded milk due to antibiotic treatment, and costs of veterinary treatment and drugs. However, in the modern cattle industry, prevention is more important than treatment in order to augment profitability. It is hard to define the percentage incidence that can be allowed or a percentage that calls for drastic preventive measures. Paying attention to the direct and indirect factors discussed earlier and eliminating these can reduce the incidence, and possibly prevent the occurrence, of RFM. In the interests of animal health and welfare, it is prudent to examine the calving cow and nutrition management, particularly dry-cow nutrition, if the incidence exceeds 10%.

It appears that there is no genetic breed predisposition to this condition; however, repeatability is possible if problems are not addressed. No simple reason can be attributed to the occurrence. Some of the factors involved may be lack of ideal body condition at the time of calving, stress during pregnancy and calving, lack of trace minerals, and lack of a sound vaccination program. Function of the placenta should be maintained during pregnancy and it should preserve its plasticity throughout pregnancy for easy separation. Selenium supplementation may have a beneficial effect in a herd with a regular history of the condition.

One factor that can be addressed is to reduce calving problems. In this regard, selection of bulls based on birthweight expected progeny differences and calf birthweight will reduce calving problems. It should be recognized that these parameters vary in breeds. It should also be remembered that the influence of dam on the calf's body weight is greater than that of the bull. Pelvic measurements and judicial

application to herds can reduce calving problems and will reduce the incidence of dystocia and other complications of parturition including RFM. However, pelvic measurements and their application may have lost their perceived impact due to its feeble effect in reducing the incidence of dystocia.

During the course of pregnancy and parturition, the adverse effects on reproduction should be minimized. In this regard, separation of the periparturient cow and use of straw as bedding appear to be beneficial. One of the preventive measures adopted was to treat every case of retention with antibiotics. This may not be beneficial except in cases that have higher body temperatures, as discussed before. Some of the prepartum peripheral hormonal changes have been suggested to mirror the changes taking place in the placenta that most likely lead to RFM. Despite much research in prepartum endocrine/enzyme parameters to predict the occurrence, there is no current method available to apply in practice. Even if some of the hormonal measurements can help to identify these cases, it is a futile exercise to obtain a sample from each animal and, furthermore, with no clear method available to prevent its occurrence after the prediction, it is not economically justifiable.

Summary

While certain aspects of the condition, such as clinical manifestation and remedial measures, have remained the same over the years, the focus has been on prevention of the condition. This should be the direction in which the dairy industry should move, considering herd health, production, and animal and human welfare issues. It is incumbent on veterinary and allied professionals to improve the health of the cattle population by providing adequate housing and maintaining their body condition during the different aspects of reproduction to prevent this clinical problem.

Dedication

This chapter is dedicated to the memory of the late Professor S.J. Roberts, a founding father of theriogenology, who drew the author to theriogenology by his monumental and exhaustive textbook that he created during the non-computerized age and nurtured this author during his academic career.

Acknowledgments

This chapter would not have been possible without the information gleaned from earlier books and review articles on this and related topics. Only the following are listed in the bibliography and the author acknowledges the scholarship of these researchers.

Postpartum Uterine Infection

Dinesh Dadarwal and Colin Palmer

Department of Large Animal Clinical Sciences, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Introduction

After calving, cows need to resume ovarian cyclicity and complete uterine involution in a timely fashion to improve their chances of becoming pregnant in a reasonable time frame. The focus of this chapter is to discuss risk factors, pathogenesis, diagnosis, treatment, and management of primary uterine diseases: metritis, endometritis, and pyometra in postpartum cows. *Metritis* refers to the inflammation of all three layers of the uterus, while cows affected with *endometritis* have inflammation that is limited to the uterine epithelium. Pyometra is the accumulation of purulent material in the uterine lumen, which persists due to the presence of a corpus luteum. Inflammatory conditions of other parts of the tubular genital tract (cervicitis and vaginitis) will also be addressed in this chapter concerning their diagnosis and potential impact on fertility.

According to a 2016 study, the per-case cost attributable to metritis alone in dairy cows was estimated at USD $127–366 depending on parity. This variation in cost was due, at least in part, to a higher differential milk loss in multiparous versus primiparous cows [1]. In general, the economic impacts of uterine infections during the postpartum period are related to treatment costs, milk production losses (actual decline in milk yield and discarded milk), and impaired fertility (embryonic losses). Cows with uterine infections have increased calving to conception interval (hence increased intercalving period) and are more likely to be culled from the herd, thereby decreasing their lifetime productivity.

Risk Factors

The prevailing opinion is that multiple factors are responsible for predisposing a cow to develop a uterine infection during the postpartum period. Dairy cattle are more frequently diagnosed with uterine infections than beef cattle, despite the duration (35–45 days) of uterine involution being the same within the species. The difference in susceptibility to uterine infection is often attributed to metabolic stress due to higher milk production and more intensive management practices associated with modern dairying in many parts of the world. Dairy cattle are also observed more frequently and are more likely to be included in reproductive herd health programs than beef cattle; therefore affected animals are more likely to be flagged for examination and treatment. Data from an older study showed that age-matched dairy cattle produced more milk and lost body weight by 15 weeks of lactation in comparison with their beef cattle counterparts that were fed a similar ration [2]. Further, these dairy cows had increased levels of metabolic stress markers (non-esterified fatty acids [NEFA] and beta-hydroxybutyric acid [BHB]) but lower levels of insulin and glucose than the beef cows during the intensive sampling period. Within the dairy cow cohort, milk yield of >35 l/day was associated with a risk of developing uterine disease compared to those producing <35 l/day even though these two groups of cows had similar genetics, uterine bacterial load, and housing conditions [3].

Calving-related events such as dystocia, twins, stillbirths, and abortions are highly correlated with an increase in the proportion of cows diagnosed with uterine diseases (Table 54.1). Frequently, cows with calving problems also have retained fetal membranes due to interrupted endocrinological and histological processes associated with placental maturation, separation, and expulsion. Undoubtedly, this is why retained fetal membranes are often cited as an important risk factor for the development of uterine infection. Peripheral immunosuppression, negative energy balance (body condition score loss), and metabolic disorders (hypocalcemia and ketosis) occurring during the transition period (three weeks prior to and three weeks after calving)

Table 54.1 Risk factors associated with the development of uterine diseases in postpartum dairy cows.

Uterine disease	Risk factor (odds ratio) [reference]
Metritis	• Retained fetal membranes (27.7) [4] • Stillbirth (6.3), twin births (6.6) [4] • Dystocia (2.56–4.32) [4, 5] • Hypocalcemia (1.8) [6] • Clinical and subclinical ketosis[a] (1.75–1.91) [7, 8] • Negative energy balance[b] (1.51) [8]
Endometritis	• Retained fetal membranes (3.9–40.3) [9, 10] • Stillbirth (7.5) [10] • Ketosis (2.2–3.8) [10–12] • Hypocalcemia (3.5) [11] • Dystocia (2.2) [5, 9, 10] • Twins (2.2) [13] • Metritis (1.4–2.3) [5, 13]

[a] Subclinical ketosis: increased BHB levels (>1.4 mM).
[b] Negative energy balance: increased prepartum NEFA levels (>0.4 mM) and postpartum NEFA levels (>1.0 mM).

also increase the likelihood of cows developing the uterine disease during the postpartum period (Table 54.1). Other factors such as parity, sex of the calf, season, and milk yield have been associated with a higher incidence of uterine disease in dairy cows [4]; however, these elements are most likely acting through other predisposing factors identified above. For example, primiparous cows are more likely to develop dystocia and thus are more predisposed to having retained fetal membranes and/or metritis.

Pathogenesis

The pathogenesis of uterine inflammatory conditions has been reviewed in detail elsewhere [14, 15]. Cows in the transition period are susceptible to developing infection due to peripheral immunosuppression [16–18]. The degree of immunosuppression during this period is influenced by the occurrence of calving-related stress; the extent of the negative energy balance which occurs post-calving in dairy cattle; changes in the hormonal milieu; and increased oxidative stress [19, 20]. Following calving, all cows experience uterine inflammation associated with the cleanup phase of uterine involution. The ability of the bovine uterus to resolve this inflammation is dependent upon the balance between uterine defense mechanisms and the microbial population.

Uterine involution is a complex process that includes clearance of cellular debris and bacteria, de-epithelialization and subsequent epithelial regeneration of the caruncles, and a tremendous reduction in size from the pregravid state. Following the expulsion of the fetal membranes, less intense uterine contractions continue during the immediate postpartum period under the influence of prostaglandin F2 alpha (PGF) and oxytocin to expel remaining uterine contents through the cervix [21, 22]. Clinically, this material referred to as lochia is observed as odorless, mucoid, and bloody to reddish-brown-colored discharge on the ground where a recently calved cow was laying, or may be seen adhering to the ventral commissure of the vulva and/or around the tail. The amount of lochia expelled is maximal during the first two to three days post-calving owing to the higher frequency of postpartum uterine contractions at this time. Thereafter, both the amount expelled and the appearance change such that astute observers may see a purulent or mucopurulent discharge by two weeks postpartum; however, it should not be visible after the third week postpartum in normal, healthy cows [23].

The initial postpartum uterine inflammatory response is most likely instigated by degenerating placental tissue, followed by bacteria entering through the vagina [15]. Repeated bacterial recontamination of the uterus continues to occur during the first two to three weeks postpartum due to a patent cervix and a natural vacuum created by contraction and relaxation of the uterus [24, 25]. Longitudinal studies using routine bacterial culture and isolation techniques showed that the proportions of cows with mixed populations of bacteria in their uterine cultures declined progressively: 9/10 cows during the first two weeks; 8/10 between the third and fourth week; 5/10 between the fifth to sixth weeks; and 1/10 between the seventh to eighth weeks postpartum [3, 26, 27]. Bacteria commonly isolated from samples taken from the postpartum uterus included *Escherichia coli*, *Trueperella pyogenes*, *Fusobacterium necrophorum*, and *Prevotella* spp. [3, 26, 27]. These species of bacteria have been reported to work in synergy to populate the uterus, evade uterine defense mechanisms, and cause uterine inflammatory disease. All have a negative impact on subsequent fertility. A preponderance of *E. coli* during the first week postpartum is followed by an increased abundance of Gram-positive bacteria, mainly *T. pyogenes*, during the second week [28]. Evidently, bacterial species prefer certain domains within the uterus, with *E. coli* and *T. pyogenes* on the surface of the uterine epithelium, while *F. necrophorum* prefers the uterine submucosa for growth and propagation [29]. A synergistic association between aerobes (*T. pyogenes*) and anaerobes (*F. necrophorum*) along with the acquisition of specific virulence factors

further potentiates their ability to overcome uterine defense mechanisms and populate the uterus [30, 31]. Certain *E. coli* isolates develop genes that allow them to adhere to uterine epithelial cells, while *T. pyogenes* strains possess adhesion properties and also secrete pyolysin that facilitates penetration by damaging the uterine epithelium [32]. Both *E. coli* and *T. pyogenes* possess the ability to reduce the oxidative burst capabilities of neutrophils, thus creating an environment favorable to sustained uterine inflammation [33]. Recent studies using sequencing techniques based on the 16s ribosomal RNA gene have reported that there may be a more diverse microbiome in postpartum cows that are undergoing normal uterine involution compared to those with metritis and endometritis [34]. Furthermore, this apparent divergence of uterine microbiota was evident as early as seven days postpartum when cows that developed endometritis weeks later were compared to those that had an otherwise healthy postpartum period [35].

At the cellular level, the damage-associated molecular patterns (DAMPs) and pathogen-associated molecular patterns (PAMPs) of cellular debris and bacteria, respectively, are recognized by the pathogen recognition receptors (PRRs) present on the uterine epithelial cells (Figure 54.1) [14, 15]. In response, epithelial cells secrete pro-inflammatory cytokines (interleukin [IL]1α, IL8, IL6) and also stimulate resident macrophages (present in the uterine submucosa) to release additional cytokines (tumor necrosis factor alpha [TNFα]). These cytokines attract neutrophils along with some macrophages into the uterine lumen to limit bacterial growth and propagation through phagocytosis. Uterine epithelial cells also participate in inhibiting bacterial colonization of the uterus by secreting antimicrobial peptides and providing a physical barrier to the entry of bacteria into the submucosa. Between 8 and 14 days postpartum, the caruncular epithelium is sloughed off. Although it is an essential part of uterine involution, the denuded surface is susceptible to infection, necessitating the existence of a highly functional cell-mediated immune system to provide protection during this period [36].

Coincident with the waning of uterine inflammation, reepithelization of caruncular regions of the uterus is completed by 30 days postpartum, thus reinstating the epithelial barrier [36]. Some cows would develop a persistent uterine inflammation (primarily endometritis) beyond the fifth week postpartum, which has been associated with poor phagocytic and oxidative burst capabilities of peripheral neutrophils and macrophages [37–39]. Currently, the reasons for such prolonged impairment of leukocyte functionality are unknown but are likely linked to continued metabolic stress in these cows.

Uterine Diseases

Metritis

Inflammation involving all the layers of the uterus, i.e. endometrium, myometrium, and serosa, is known as metritis. Histopathologically, there is edema of the endometrium (mucosa and submucosa) along with leucocytic infiltration and mucosal sloughing. Edema and granular myofibrillar degeneration in the myometrial layer also occurs and fibrin deposition and hemorrhage may be evident on the serosal surface (perimetrium) [40]. By far, metritis is the most clinically evident form of uterine inflammation in cows and is commonly seen within the first two weeks postpartum, with a few cases occurring in the third week after calving. On average, 20% of dairy cows develop metritis; however, the prevalence ranges from 1 to 41% influenced by breed, geographical location, and herd management practices [6, 41, 42]. A severe form of metritis, often referred to as acute puerperal metritis or toxic septic metritis, may occur within the first week after calving. Acutely affected cows have body temperatures >39.5 °C, an enlarged flaccid uterus, and watery red-brown to purulent discharge with a fetid odor (Figure 54.2), and show signs of toxemia (anorexia, sudden and profound drop in milk yield, recumbency, dehydration, and tachycardia) [43, 44]. Animals with subclinical metritis do not show signs of systemic involvement [43, 44]. Following an episode with metritis, cows have a significant drop (15–20%) in their first service conception rate, an increased calving-to-conception interval by almost one estrous cycle length, and a higher risk of being culled from the herd versus their herdmates that have undergone normal uterine involution [45–47].

Commonly isolated bacterial species from cases of metritis include *E. coli* predominantly, followed by *F. necrophorum* and *Prevotella* spp. Strains of *E. coli* expressing FimH adhesion protein appear to have an affinity for attachment and growth on the uterine epithelial surface [30, 31]. Likely, the early growth of these virulent strains of *E. coli* in the uterus (2 days postpartum) facilitates infection with *F. necrophorum* later (8–10 days postpartum) [48]. By the beginning of the second week postpartum, *F. necrophorum* may have already gained access to the uterine submucosa at the deepithelized caruncles and invoked an inflammatory response. In addition to other virulence factors, *F. necrophorum* secretes a leukotoxin that can lyse innate immune cells [49], to potentiate its own growth and that of other invaders such as *T. pyogenes*. This synergistic relationship has been reported as an essential factor in the pathogenesis of several inflammatory conditions involving different tissues and organ systems [50]. Moreover, these synergisms

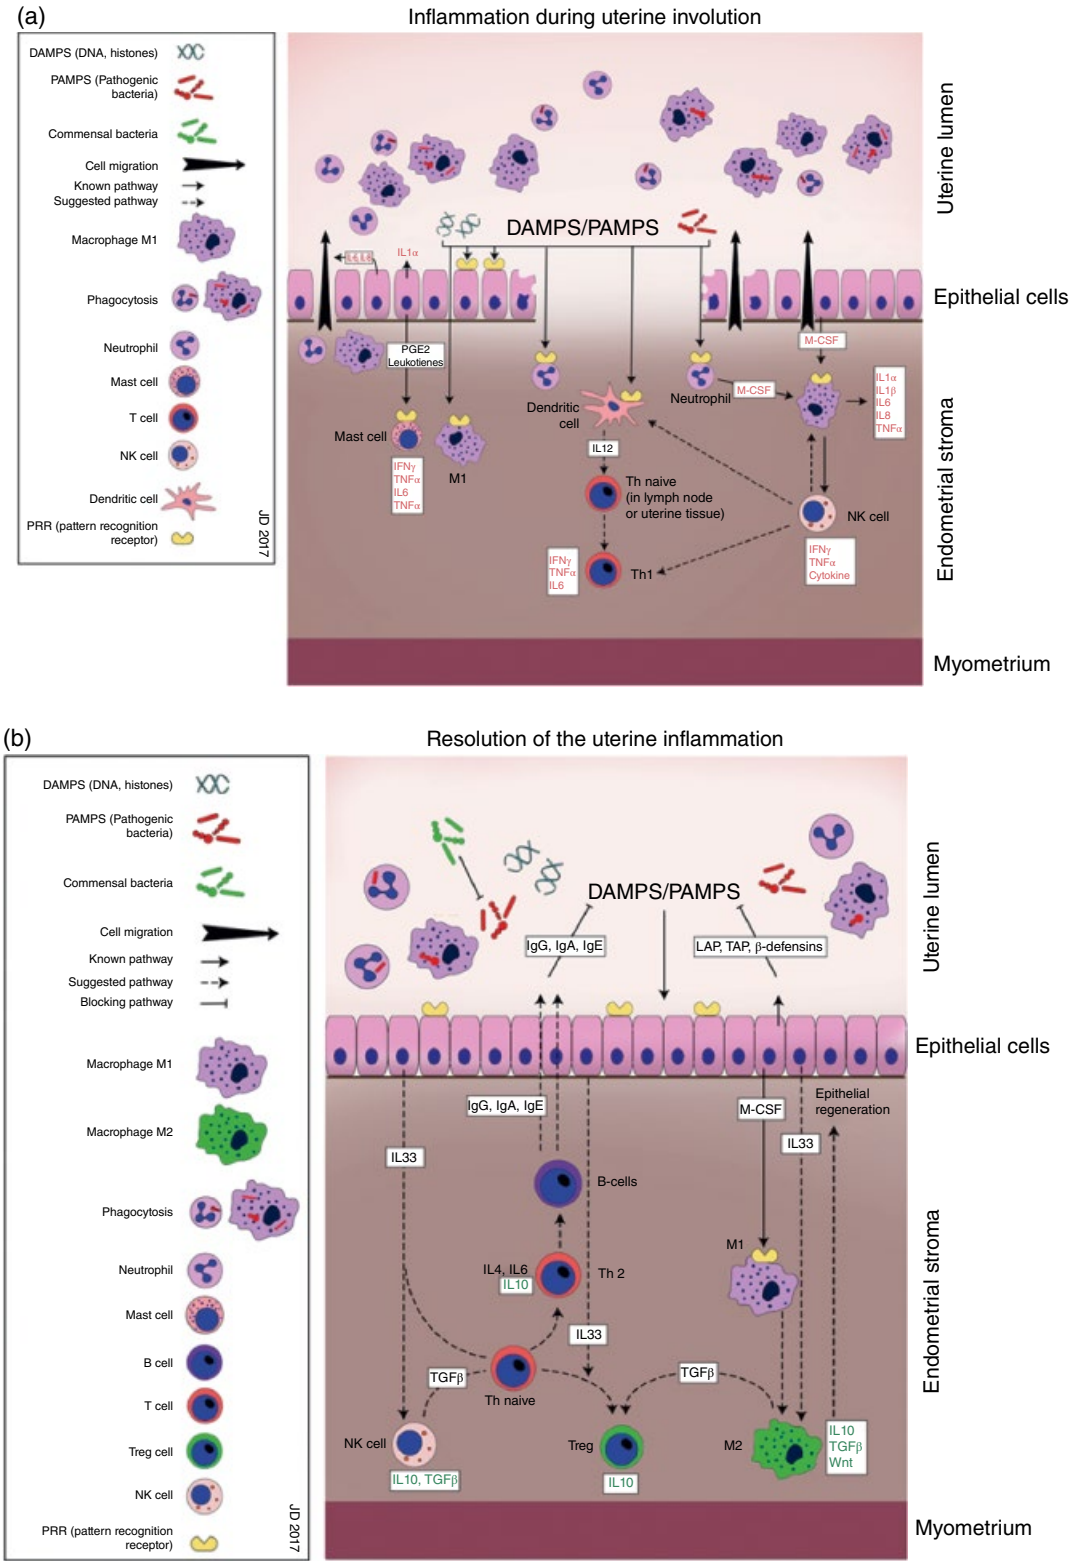

Figure 54.1 Known (solid arrows) and proposed (dotted arrows) mechanisms for the progression (a) and resolution (b) of uterine inflammation in the postpartum cow. Cytokines in red and green text indicate those participating in pro- and anti-inflammatory mechanisms, respectively. (a) Early in the postpartum period, both DAMPS molecules arising from placental separation and tissue degeneration and PAMPS molecules from pathogens and environmental contaminants are recognized by PRRs on uterine epithelial cells. Activation of epithelial PRRs results in pro-inflammatory cytokine and chemokine (IL6 and IL8) release that recruit neutrophils and

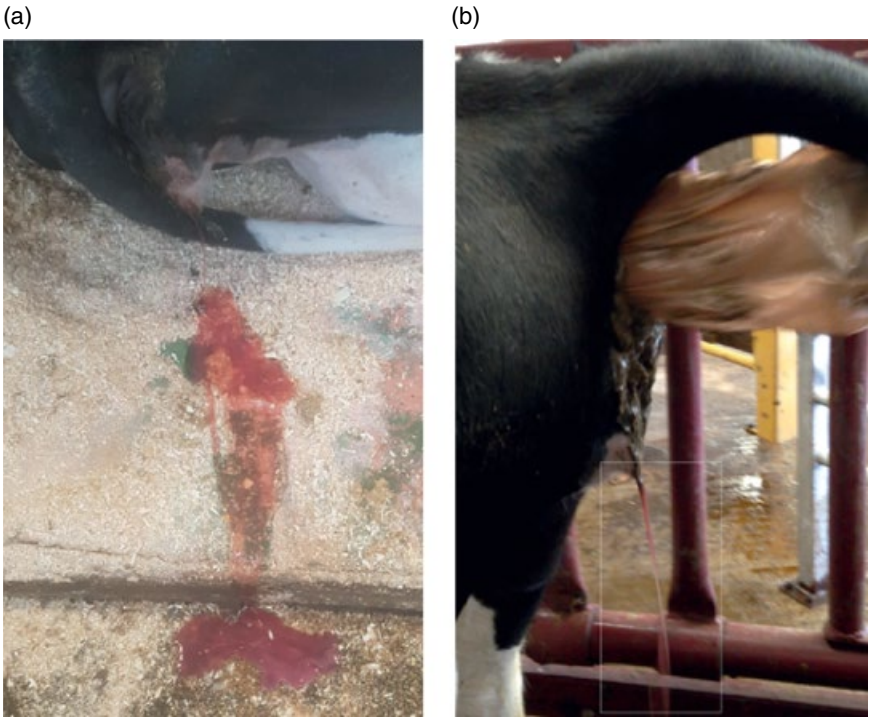

Figure 54.2 (a) and (b) Uterine discharge from cows diagnosed with metritis. *Source:* Courtesy: Gordon Hamm and Dr. Kamal Gabadage, University of Saskatchewan, Saskatoon, Canada.

could be the reason why infection persists in a proportion of cows that are later diagnosed with endometritis.

Diagnosis

Cases of metritis are often presented as cows with a history of calving difficulties and/or retained fetal membranes that have recently become anorectic or dropped their milk production. Often there is an associated elevation in body temperature, now understood to be due to increased levels of endogenous pyrogenic cytokines such as IL1, IL6, and TNFα and/or due to the downstream effects of pathogen binding to their toll-like receptors on the thermoregulatory center in the hypothalamus [51]. A higher than normal body temperature may also be observed during the hot and humid months in many otherwise normal fresh cows [52]. Therefore a thorough physical examination to determine systemic involvement and rectal palpation to assess the uterine status are always warranted. On transrectal palpation, the uteri of cows with metritis are felt as distended and flaccid and observed to lack characteristic longitudinal ridges or "rugae" on the dorsal uterine surface – the sign of a healthy, contracting uterus. Generally, there will be some uterine fluid expelled during palpation. Vaginoscopy to assess and characterize uterine discharge sequestered in the cranial vagina is generally not needed but may be carried out if one is not sure about the nature of the discharge. It is

macrophages to the uterine lumen. Macrophage colony stimulating factor release from epithelial cells activates resident macrophages (M1) to release pro-inflammatory cytokines (IL1α, IL1β, IL6, IL8, TNFα) and assist neutrophils in phagocytosis. Epithelial cells may trigger mast cell degranulation by secreting prostaglandins. The damaged epithelial barrier of the postpartum uterus may allow PAMPS and DAMPS to penetrate into the subepithelial connective tissue and directly activate dendritic cells (DC), neutrophils, and resident macrophages. Activated dendritic cells secrete IL12 that can activate T-cells resident in either uterine tissue or associated lymph nodes to secrete pro-inflammatory cytokines (IFNγ, TNFα, IL6). Resolution of uterine inflammatory processes (b) may involve both epithelial cells as well as a variety of immune cells, including anti-inflammatory macrophages (M2), regulatory T-cells (Treg), natural killer (NK) cells, and possibly commensal bacteria. Epithelial cells may reduce inflammation directly by secreting antimicrobial peptides and fraction 3 of complement and indirectly by secreting IL33. IL33 secreted from epithelial cells and M1 pro-inflammatory macrophages in the later stages of inflammation promotes differentiation of macrophage toward an M2-type phenotype and promotes T-cell differentiation to Treg cells. B-cells respond to bacterial antigens by secreting immunoglobulins which are transported to the endometrial surface to facilitate bacterial opsonization and phagocytosis by neutrophils and macrophages. NK cells initially start with a pro-inflammatory profile and then progress toward an anti-inflammatory profile. Resolution of inflammation may also be supported by IL10 and transformation growth factor (TGF)β secretion from macrophages (M2 phenotype), Treg cells, and NK cells. *Source:* From [15], © 2017, Elsevier.

critical to assess cows with metritis for concomitant mastitis, hypocalcemia, ketosis, or displaced abdomen. These conditions are commonly encountered at the same time and reflect the systemic nature of metritis. The use of ultrasound is not necessary for diagnosing metritis and offers little value other than to visualize fluid and debris in the uterus. A complete blood count (CBC) and blood chemistry typically show leukocytosis with or without a left shift and increased haptoglobin, respectively [53, 54], as well as pain biomarker substance P if testing is available at the lab [54].

Treatment

The treatment of choice for metritis usually includes systemic administration of broad-spectrum antibiotics for curtailing bacterial infection and anti-inflammatory drugs to control fever and inflammation. Spontaneous self-recovery is reported to occur in one out of five cows affected with metritis [55]; however, currently there are no reliable means to predict which animals these will be. Clinicians should be aware that there are strains of *E. coli* [56] and *T. pyogenes* [57] associated with metritis that may be resistant to commonly used antibiotics. A prudent approach to the use of antibiotics might be to avoid antibiotic treatment in the absence of systemic illness and to base the choice of antimicrobial on culture and sensitivity results. Other supportive therapies such as intravenous or oral fluids to correct dehydration, intravenous or oral calcium to address hypocalcemia, and polyethylene glycol to treat ketosis should be administered as warranted.

Both penicillin [58] and ceftiofur [59, 60] are known to concentrate in the uterine tissues following systemic administration at levels that are higher than the minimum inhibitory concentration (MIC) required for bacteria causing uterine diseases. Penicillin administered at 22 000 IU/kg intramuscularly (i.m.) for five days has been observed to resolve metritis in cows [61]. Although the cost of treatment may appear less expensive, the associated milk (4 days) and meat (10 days) withdrawal times must also be considered. A meta-analysis of 23 published clinical trials has indicated that ceftiofur is the most commonly used antimicrobial to treat metritis [62]. Preference for the use of ceftiofur is supported by studies comparing the MICs for the third-generation cephalosporins, penicillin, and tetracycline against the common uterine pathogens [63, 64]. Ceftiofur and other cephalosporins have the lowest MICs against the uterine-specific strains of *E. coli*, *T. pyogenes*, *F. necrophorum*, and *P. melaninogenica*, while tetracycline has the highest MIC [64]. These MICs apparently vary between cows kept in tie-stalls [64] versus those on pastures [63]; however, the clinical significance of such a difference is unknown. Ceftiofur sodium, which is approved for use in dairy cattle at dose rates of 1 and 2.2 mg/kg in Canada/Europe and the USA, respectively, can be administered once daily for three to five days intramuscularly or subcutaneously. At the 1 mg/kg dosage rate i.m. and once daily, peak concentrations of ceftiofur in uterine tissues are reached after the third injection [59]. Therefore it is recommended that at least a five-day treatment protocol is required to treat metritis successfully. A distinct advantage of the 1 mg/kg dose of ceftiofur sodium is that there is no associated milk or meat withdrawal period. A sterile suspension of ceftiofur hydrochloride salt can be also used to treat metritis cases at 1.1 mg/kg (labeled dose) or 2.2 mg/kg (extra-label use) administered daily for five days, with the higher dose reported to have higher cure rates [65]. Alternatively, ceftiofur crystalline free acid at a dose of 6.6 mg/kg may be injected once in the base of the ear if repeated handling and treatment of animals is not an option. A single dose of ceftiofur crystalline free acid is, however, not usually effective for treating metritis; hence a second dose may be administered 72 hours after the first in the base of the opposite ear to improve the cure rate [66]. Appropriate care must be taken while injecting ceftiofur crystalline free acid, as the accidental intra-arterial injection can be fatal to the cow. Since this product is not labeled for the treatment of metritis in cattle, the manufacturer's instructions for appropriate meat and milk withdrawal periods need to be followed.

Intramuscular oxytetracycline is commonly prescribed for treating metritis in cows, yet clinical trials conducted to date have not demonstrated the efficacy of this drug. Furthermore, pharmacokinetic studies have not provided strong support for the use of systemic oxytetracycline. The highest concentrations of oxytetracycline achieved in the uterine tissues are only about a third of the desired MIC for the common uterine pathogens [67]. Another antibiotic that could be utilized to treat metritis is ampicillin, as it is effective against *E. coli* and Gram-positive bacteria [63]. At least one study has shown improvement in the metritis cure rates following treatment with ampicillin trihydrate (11 mg/kg i.m. for five days) [68].

Intra-uterine infusions of antibiotics and other compounds have been used alone or in combination with systemic therapy as treatment for metritis with variable results. A clinical trial comparing repeated intrauterine infusions of 1% povidone-iodine versus a commercial preparation of plant-origin phenolic compound, carvacrol, showed no difference in clinical cure or cow culling rates but lacked a negative control group [69]. Intrauterine infusion of procaine penicillin [68], oxytetracycline [61, 68], and chlortetracycline [70] were observed to have some beneficial effects; however, most of these studies also lacked appropriate negative control groups. Other concerns with intra-uterine treatment are that this route is not approved for most antibiotics; there is lack of

information regarding the required dosage per kilogram of body weight; there is variable tissue penetration from the uterine lumen [67, 71]; and some antibiotics are inactivated by cellular debris and bacteria. Moreover, the duration for which antibiotic residues are detectable in the milk and meat following intra-uterine infusion has not been reported except for procaine penicillin (up to three days in milk) [72] and oxytetracycline (up to eight days in milk) [73–75]. Blanket treatment of cows having retained fetal membranes with intra-uterine antibiotic preparations to prevent or treat metritis should be discouraged. Since most commercially available intrauterine preparations and historically popular veterinary clinic treatments contain oxytetracycline, this approach could result in the propagation of bacterial strains with antibiotic resistance. Similarly, the use of first-generation cephalosporin for intrauterine therapies should be discouraged, as they are not effective for the treatment of metritis.

Uterine lavage to flush the uterine contents using warm sterile saline, tap water, or other liquids is generally not recommended. The risks likely outweigh the benefits, since lavage is believed to increase the absorption of bacterial toxins due to hyperemia within the uterine wall and the escape of toxins into the peritoneal cavity via the oviduct. Uterine rupture can easily occur as a result of overfilling or rupture of the thin uterine wall by the tube, especially when its free end is beyond the clinician's reach.

Hormonal treatments such as oxytocin, estrogen, and PGF have been utilized as the primary or adjunct therapy to treat metritis based on their ability to facilitate the evacuation of uterine contents. Oxytocin receptor presence in the uterus has been reported up to seven days postpartum in cows; however, the functional status of these receptors is unknown [76]. Nevertheless, this period overlaps with the reactivation of ovarian follicular activity and development of the first dominant follicle that could act as a source of estrogen for the upregulation of oxytocin receptors in the uterus. Estrogen exerts its ecbolic effects directly or indirectly through oxytocin receptors [77], is known to increase the blood supply to the uterus due to vasoconstriction, and can enhance chemotaxis [78] and phagocytic activity of leukocytes [79, 80]. Accordingly, estradiol cypionate (ECP) was historically advocated for the treatment and prevention (when used to treat cows with retained fetal membranes without systemic illness) of metritis in cows, but it is not currently approved by the Food and Drug Administration for use in cattle in the USA. Use of ECP at a dose of 4 mg i.m. administered 24–36 hours post-calving to treat cows predisposed to metritis did not result in a reduction in the proportion of cows diagnosed with metritis at a later date [81]. To date, published studies have not shown any substantial benefits associated with treating cows with either oxytocin [82] or PGF [83] as a preventive or curative measure for the occurrence of metritis and there has been no difference in subsequent fertility parameters associated with their use. Although once believed to be beneficial, it is not surprising that various protocols employing PGF for the treatment of metritis have not survived scientific scrutiny, since we now know that cows with metritis already have elevated levels of PGF metabolites (PGFM) compared to cows undergoing an otherwise healthy postpartum period [84, 85].

Endometritis

Cows affected with endometritis have inflammation that is restricted to the mucosal and submucosal layers of the uterus. Unlike metritis, endometritis does not cause systemic illness, but affected animals might have associated cervicitis and vaginitis. New definitions of the disease led to the terms clinical and subclinical endometritis. It is important to recognize that endometritis should not be diagnosed in cows ≤21 days postpartum to avoid falsely classifying cows undergoing normal uterine involution. Classically, *clinical endometritis* has been defined by the presence and grade of the purulent vaginal discharge (PVD) (≥50% pus) in cows that are >21 days postpartum [86]. Discharge should be visualized either in the cranial vagina or at the ventral commissure of the vulva; however, it is noteworthy that PVD may not be observed in all cases of endometritis [87]. Some animals may have a closed cervix (luteal phase) at the time of examination [88], while others might be more effective at clearing uterine discharge. Subclinical endometritis is characterized by the presence of increased proportions of neutrophils in the uterine cytosmears using threshold levels that have been defined relative to the number of days in milk (see below).

Postpartum cows undergoing normal uterine involution processes have a peak infiltration of leukocytes (primarily neutrophils) during the first week postpartum, with neutrophil counts declining to zero by the fifth to seventh week postpartum. As shown in Table 54.1, certain factors can predispose cows to develop persistent endometritis and these may be aided by an inadequate mucosal immune response and synergism between uterine pathogens. In that regard, cows with a weaker uterine inflammatory response (lower neutrophil counts) during the first week postpartum are at a higher risk of being diagnosed with endometritis between five to seven weeks postpartum [89]. One research group reported that cows with subclinical endometritis had reduced proportions of phagocytosing neutrophils and monocytes both in the peripheral blood and in the uterus 18 days after the time of diagnosis when compared to non-endometritic cows [38]. However, the exact reason for this prolonged immunosuppression occurring in cows with

endometritis is unknown. It is possible that some of these cows had a negative energy balance and/or had a previous episode of metabolic disease(s) that could have adversely impacted the phagocytic and oxidative burst capabilities of innate immune cells. Reduced dry matter intake and increased NEFA concentrations in peripheral blood during the postpartum period have been associated with a lowering of immune cell functionality and an increased occurrence of subclinical endometritis in cows [90, 91]. It is noteworthy that the postpartum period is demanding on the cow's energy resources for milk production, uterine involution, and resumption of ovarian cyclicity.

The most common bacteria cultured from cows with endometritis is *T. pyogenes*. Infection of the bovine uterus with *E. coli* during the first week postpartum appears to predispose growth and propagation of *T. pyogenes* at three weeks postpartum. The induction of clinical endometritis in virgin Holstein heifers following intrauterine infusion of *E. coli* and *T. pyogenes* indicates further proof of this association between bacteria [92]. Additionally, the presence of *T. pyogenes* in the uterus at 21 days postpartum is highly correlated with the growth of *F. necrophorum* as well as *P. melaninogenica*, diagnosis of persistent endometritis at the fifth week postpartum, and decreased conception rates [89, 93, 94]. Interactions and interdependence between aerobic and anaerobic bacteria seem to be critical for the development of persistent endometritis. Such a synergistic association and domain-specific propagation of different bacteria have been highlighted by recent metagenomics studies as well [35, 95].

Diagnosis

Clinical endometritis can be diagnosed by the nature of mucopurulent discharge (≥50% pus) present at the vulva or in the cranial vagina in cows >21 days postpartum [86]. Contents present on the floor of the cranial vagina can be visualized either by vaginoscopy (Figure 54.3) or by scooping using either the Metricheck™ device (Simcro Ltd, Hamilton, New Zealand) or a sleeved hand and arm. The Metricheck device has been shown to be more effective as 10–17% more diseased cows were discovered that would have otherwise gone undetected [96, 97]. The belief is that the clinician can more consistently reach deeper into the vagina and is better able to scoop exudate as the device is withdrawn. Visualization of the vaginal contents with a speculum may be limited, especially in multiparous cows whose genital tracts may be suspended more cranioventral, creating a pool just caudal to the cervix where discharge tends to accumulate. Delaying the examination of vaginal contents until 28–30 days postpartum will decrease the number of cows undergoing normal uterine involution from being falsely classified as diseased (false positive) [98]. Dubuc et al. first proposed a broader term PVD to identify the postpartum cows that may or may not have an accompanying endometrial inflammation [99]. Cows identified with PVD include those affected with endometritis or cervicitis (enlarged and inflamed cervix) or vaginitis or a combination of these inflammatory conditions. Nevertheless, the observation of PVD in cows ≥28 days postpartum has been consistently associated with decreased first-service conception rates and poor reproductive performance [99–101].

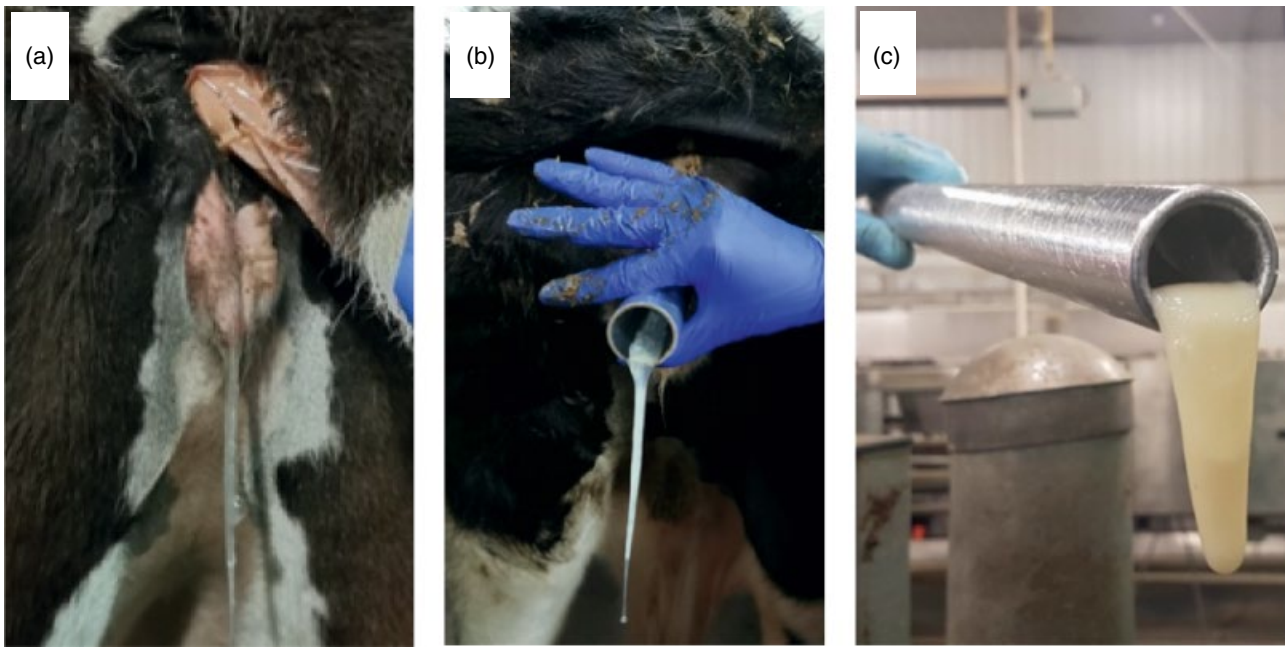

Figure 54.3 Different grades of vaginal discharge visualized on vaginoscopy and on the floor. (a) Slight cloudiness and few pus flakes (grade 1); (b) mucopurulent with 50% pus (grade 2); (c) purulent (grade 3).

Transrectal palpation of the uterus may yield some information regarding the asymmetry of uterine horns, the thickness of uterine walls, and/or the presence of fluid in the uterine horns; however, such information tends to be subjective. In our clinic, a transrectal examination is usually employed to detect cows that should have a more thorough ultrasonographic evaluation of their genital tract. Generally speaking, however, the transrectal examination is not considered to be a sensitive diagnostic tool [99].

Evaluation of uterine fluid volume and echotexture is beneficial for identifying cows with clinical endometritis (Figure 54.4). Most often, these cows will have echogenic inflammatory fluid accumulated at the tips of the uterine horns or in the most dependent part of the uterine horns. Small amounts of inflammatory fluid can be easily displaced by the pressure of a hand and probe, resulting in false negatives. If the cervix is open, the inflammatory fluid line can sometimes be seen to continue right into the cranial vagina. A recent study has indicated that concomitant use of the Metricheck device and ultrasonographic assessment of uterine contents might help decrease false negatives and false positives, respectively; however, this observation needs to be tested in a bigger dataset [102].

Histologically, endometritis is characterized by epithelial damage, infiltration of leukocytes (neutrophils, macrophages, and lymphocytes), the formation of lymphoid aggregates, and, in some instances, ablation or fibrosis of endometrial glands [87, 103]. The degree of these inflammatory changes indicates the severity or chronicity of the disease [104]. Uterine biopsy provides more information than cytology regarding the extent of the inflammatory response in the deeper tissues; however, a single biopsy sample is not representative of inflammatory changes involving the entire uterus and has a longer turnaround time for results. Studies have been equivocal regarding concerns of a potential negative impact that uterine biopsy may have on subsequent fertility [98, 105, 106].

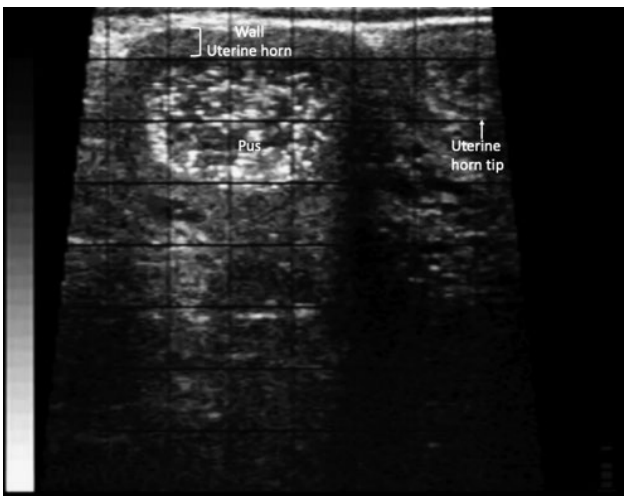

Figure 54.4 Ultrasonographic image of a dairy cow diagnosed with clinical endometritis 28 days postpartum. This cow had purulent discharge adhering to the vulva but there was no corpus luteum on either of the ovaries. Hyperechoic spots in the uterine contents indicate trapped air-bubbles as the cow was scanned after obtaining cytobrush samples to confirm increased neutrophils. Each gridline square equals 1 cm^2.

Since the early 2000s, fundamental research and clinical trials have demonstrated the immense value of uterine cytology as both a diagnostic tool and a means of improving our understanding of the pathophysiology of postpartum endometritis in cows. Uterine cytological samples can be obtained by low-volume lavage [107], cytotape [103], or cytobrush [88, 108]. Harvested samples are then smeared onto microscope slides, dried, and stained using modified Wright Giemsa stain or other commercial stains used for the differential blood cell counts. The proportion of neutrophils is determined by counting their number in relation to the number of other leukocytes and endometrial cells. It is important to exclude the endometrial cell casts from counting to avoid skewing the results. Several techniques have been described for counting; however, for the clinician, determining the proportion of neutrophils in a single 100-cell count of a well-prepared smear will be sufficient. The low-volume uterine lavage method has the benefit of getting a sample that is representative of the entire uterus; however, recovered cells are often distorted due to osmotic damage [107]. A uterine infusion pipette attached to a catheter tip-syringe is passed through the cervix into the uterine body. Once in place, 20–40 ml of sterile saline is infused, followed by gentle massage of the uterine horns to distribute the fluid. Next, using gentle manipulation of the infusion pipette, as much fluid as possible is reaspirated back into the syringe. The recovered fluid is centrifuged, the supernatant removed, and the sediment is used to make a smear on a microscope slide. Some cows may pose a challenge with the recovery of fluid with this technique [108].

Ready to use, double guarded cytobrush devices are available for veterinary use; however, in research settings we have learned to prepare our own. Our cytobrush device preparation first involves shortening the plastic handle of a 15-cm-long brush device designed for human use to enable it to be attached to a guarded stylet of a universal artificial insemination gun or similar device. By doing so, both the length and rigidity of the assembly are improved substantially. The assembly is then guarded using an infusion pipette and a plastic sleeve [88]. Once prepared, the cytobrush, stylet, and infusion pipette will survive sterilization in the autoclave. It is essential to withdraw the cytobrush into the outer barrel of the insemination gun to avoid any distortion of the plastic handle of the cytobrush due to autoclaving. The commercially available plastic sleeves, designed to provide protection when placed over insemination guns, can be applied

over the infusion pipette guard to provide an additional layer of protection just prior to use. The prepared assembly is passed into the uterus, similar to performing artificial insemination in cows. The stylet is pushed forward to introduce the cytobrush into the uterus, then is given two full 360° turns to brush off cells from the uterine wall and before being withdrawn back into the guard and removed from the uterus. It is important to note that no additional digital pressure should be applied to the cytobrush while it is being rotated to avoid excessive tissue damage and blood in the sample. Smears are made by gently rolling the cytobrush onto a slide and cytosmears are air-dried before staining.

A range of threshold proportions of neutrophils from 5 to 18% coinciding with the number of days postpartum when the samples are harvested have been used to identify cows with endometritis [88, 89, 107–109]. Despite the differences in techniques, smears obtained using cytobrush and low-volume uterine lavage have been shown to result in similar cell counts [108]. Our research and that of others supports a threshold of ≥18% neutrophils for samples collected between 28 and 35 days postpartum and ≥10% for samples collected after 35 days postpartum [88, 107]. The use of higher thresholds has decreased the risk incidence of false positives. Furthermore, these higher thresholds have been more consistently associated with increased gene expression of pro-inflammatory (IL1β, IL8, IL6, IL17α, TNFα) [88, 110] and regulatory cytokines (IL10 and IL1 receptor antagonist), again supporting the higher neutrophil threshold as a valid indicator of disease [88]. Despite these benefits, cytobrush cytology cannot yet be touted as a cow-side diagnostic test for endometritis due to the time required for cytobrush preparation, sampling, staining, and reading slides. Despite these limitations, it can be a handy tool to survey herds with reduced reproductive performance. The utility of cytobrush cytology in the future may evolve with modification of the assembly to harvest uterine secretions for the detection of inflammatory cytokines [111] or the detection of novel metabolites.

Treatment

Current treatment strategies for postpartum endometritis in dairy cattle employ PGF and intrauterine infusion of antibiotics. Clinical cure rates following these treatments have varied between studies, which have often been confounded by the definition of disease and clinical cure, the number of cows per treatment group, the timing of treatment, and the occurrence of spontaneous resolution. The proportion of cows undergoing spontaneous disease resolution between five and seven weeks postpartum can vary between 50 and 70% [10, 88, 112], which makes a comparison of the clinical efficacy for any treatment challenging.

Cephapirin benzathine, a first-generation cephalosporin, is the only antibiotic that is approved for intrauterine infusion in dairy cows for the treatment of endometritis, but not in all countries. The drug is available as a 19-g dose in a syringe containing 640 mg of cephapirin (Metricure™, Merck Animal Health) and has two-day meat and zero milk withdrawal period if used according to label instructions. In two large randomized clinical trials, postpartum cows, 28–42 days in milk, diagnosed with endometritis (PVD and/or cytological evidence of disease) showed an improvement in first service conception rates of 8–15% compared with their untreated counterparts [113, 114]. Other studies reporting that intrauterine cephapirin treatment did not improve the overall reproductive performance of cows were most likely confounded by the inclusion of PGF for presynchronization or by the timing of the intrauterine antibiotic treatment relative to the stage of the estrous cycle. It is noteworthy that intrauterine infusion of antibiotics in cows during the luteal phase may not be as effective as treatment during the proestrus and estrus periods. Steroid hormones are known to modulate innate immune responses. Since progesterone is immunosuppressive, the luteal phase would naturally be a supportive period favoring the colonization of bacteria in the uterus [92, 115]. In our practice, endometritic cows in the luteal phase are treated with PGF, followed by the infusion of Metricure three days later. These cows are marked for follow-up at the next herd health visit two weeks later. A second dose of cephapirin in 14 days is advised by the manufacturer; however, we have rarely observed a need to repeat the treatment (unpublished data).

Since the 1990s, single or double doses (14 days apart) of PGF have been used to treat uterine infections owing to PGF's ability to induce luteolysis [116] and uterine muscle contraction [117]. Induction of estrus brings about an estrogen-dominant hormonal status, enhancing neutrophil chemotaxis, mucus production, and uterine contractility, thus allowing immunological as well as physical clearance of bacteria from the uterus [115]. Initial meta-analysis on the use of PGF in postpartum cows proved an association with fewer days open; however, the first service pregnancy rates did not differ between treated and untreated cows [118]. A subsequent meta-analysis of published trials showed that PGF treatment of endometritic cows did not improve their reproductive performance [119, 120].

Non-specific immunostimulants such as recombinant granulocyte colony-stimulating factor and probiotic bacteria [121] need to be tested using more extensive randomized clinical trials to assess their benefit in the prevention and treatment of endometritis in postpartum cows. Such treatments, when available, would allow us to further minimize the development of antibiotic resistance in uterine pathogens.

Pyometra

Accumulation of purulent material in the uterus, presence of a persistent corpus luteum on one or both ovaries, a closed cervix, and anestrus are characteristic signs of pyometra in cows. The reported incidence of pyometra in postpartum dairy cows is less than 2% [122] and, in most cases, is believed to be a sequela to ovulation early in the postpartum period – at a time when many cows are still clearing the uterus of pathogens. Despite an increase in the serum levels of proinflammatory cytokines (TNFα, IL-6) and acute phase proteins (serum amyloid A and haptoglobin), cows with pyometra are not systemically ill [123]. The combination of bacterial synergism, altered immune defense mechanisms, and a closed cervix, due to the presence of corpus luteum, leads to the development of pyometra. A progesterone-dominant hormonal phase always favors the development of uterine disease. The life span of the corpus luteum in naturally occurring cases of pyometra is difficult to determine; however, artificial induction of pyometra resulted in luteal phases lasting >30 days [124, 125]. Both PGF and PGFM were shown to be elevated in the uterine fluid and peripheral blood, respectively, yet the corpora lutea persist. Presumably, the extended life span of the corpus luteum in pyometra cases is due to increased concentrations of prostaglandin E2 (PGE2) in the uterus, which being luteotropic is believed to override the luteolytic effects of endogenous PGF [123, 124, 126]. The exact source of the PGE2 is unknown but could be leukocytes, bacteria, or the uterine epithelium. Nevertheless, progesterone creates a favorable environment for bacterial growth and propagation in the uterus.

Commonly isolated bacteria include *T. pyogenes*, alone or in combination with the Gram-negative anaerobes, *F. necrophorum*, and *P. melanogenica* [125]. Typically, *T. pyogenes* is located in the uterine lumen or on the uterine epithelium, whereas *F. necrophorum* and *P. melanogenica* prefer to invade the endometrium, indicating synergism [127]. Cows with pyometra appear to have a decreased proportion of innate immune cells in both peripheral blood and the uterus [128]. This shift could be a function of bacterial synergism and progesterone-induced immunosuppression.

Diagnosis

Cows with pyometra are often diagnosed during routine herd health visits as having a fluid-filled uterus, no vaginal discharge, and a corpus luteum. Most often, only one uterine horn is involved, but the condition may involve both horns, particularly in long-standing cases. Usually, the wall of the uterus is palpably thicker early in the disease process and fluid can be pushed from one horn to another. An active inflammatory process likely causes the thickening of the uterine horns. As the disease progresses, the purulent material continues to fill the entire uterus, stretching out the uterine wall. An ultrasonographic examination will confirm the presence of a fluid with varying echogenicity, a corpus luteum, and the absence of pregnancy (Figure 54.5). Varying echogenicity is best described as fluid (black) with cellular material (gray speckles), which is very characteristic of purulent exudate. The presence of a fluid-filled uterus may be confused with the uterus of a pregnant animal; however, the cardinal signs of pregnancy – amniotic vesicle, fetal membrane slip, placentomes, and a fetus – are absent. Histologically, the endometrium shows signs of chronic inflammation (chronic endometritis) [125, 127] with or without the involvement of the distal oviducts (salpingitis) [127].

Treatment

The vast majority of cases of pyometra in cows will respond to a single luteolytic dose of PGF (dinoprost tromethamine, 25 mg, i.m.) or its analog (cloprostenol 500 mcg, i.m.). A PVD may be observed within one to two days of treatment. In our clinical experience, and as reported elsewhere [129], approximately 15–20% of cows treated for pyometra may need a subsequent treatment. Following successful treatment (clearance of purulent material from the uterus), roughly 65% of these cows conceived, requiring an average of 2.2 inseminations to become pregnant [129]. In our practice, cows with pyometra are administered two doses of PGF 14 days apart. With reproductive herd health visits at biweekly intervals, the timing of the second injection is coincident with a follow-up assessment to determine the effectiveness of treatment. Further, two induced estruses following PGF treatments facilitate the clearance of pathogens through an open cervix and by the activation of uterine defense mechanisms

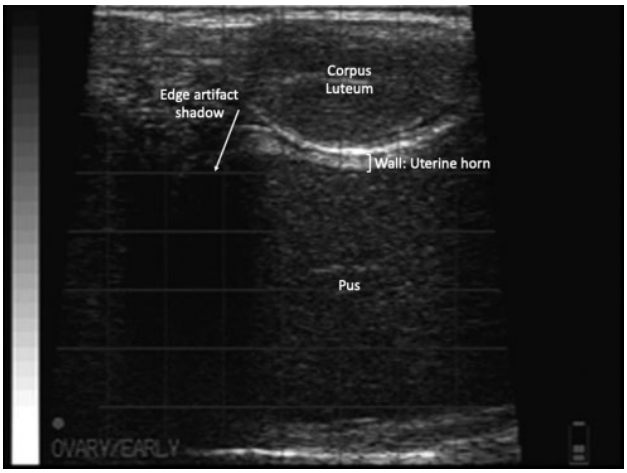

Figure 54.5 Ultrasound image of a dairy cow diagnosed with pyometra at 125 days postpartum. Each gridline square equals 1 cm^2.

during the estrogen-dominant phase. Usually, these cows would conceive following the second to fourth insemination (unpublished data), which suggests that these cows need time to resolve associated endometritis and/or salpingitis before the uterine environment is healthy enough to sustain embryonic development.

Surgery to Restore Fertility

Richard M. Hopper

Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

For cows of genetic merit or perceived to be of high value, urogenital procedures are typically performed with the goal of restoring fertility. However, a desire to extend the life of the cow so that a calf can be reared or a lactation completed, or simply to add condition prior to sale often justifies attempts at surgical correction as well. Additionally, while the ability to conceive and maintain a pregnancy and calf continues to be a standard measure for fertility, current assisted reproductive technology provides the opportunity to harvest embryos or oocytes from cows with varying degrees of damage to the caudal urogenital system or uterus. Thus, an attempted surgical procedure that maintains the viability of the ovaries, even if not successfully correcting the injury, is often warranted. The procedures that will be described can be performed on the standing animal with regional analgesia and sedation.

Repair of Injuries Occurring from Dystocia

Parturition is clearly one of the most dangerous events in the life of an animal, whether the dam or the offspring. Common injuries include trauma and tears of the uterus and caudal urogenital system. Tearing of the uterus, whether spontaneous or iatrogenic, can be life-threatening. At the very least, the resultant fibrosis and structural incompetence from perineal body, cervical, and vaginal tears typically results in infertility. Identification of the severity and the provision of a realistic prognosis are critical to the producer, so that an informed decision can be made with respect to treatment versus culling or even immediate salvage.

Repair of Uterine Tears

Most injures to the uterus are iatrogenic and occur during efforts to relieve dystocia. With few exceptions they occur on the dorsal aspect of the uterus (cranial to the cervix) when the obstetrician is attempting to repel a breech presentation or during the forced extraction of a large fetus. In the first case, repair is secondary to removal of the calf. If a cesarean section is performed, the uterine defect may be approached and repaired after the calf is delivered. This is almost always the case when dealing with a tear that occurred during repulsion of a breech position fetus. If the calf can be delivered vaginally following this type of tear or, as in the second case, in which the tear occurs during the delivery, a "blind" suture repair through the vagina can be performed.

I will first examine how these tears occur. In the case of the tear caused by "excessive" force in the obstetrician's attempt to repel the calf, the uterine wall was probably weakened by some level of pressure (ischemic) necrosis. This occurs when the tailhead of the fetus in the breech position is pressed for hours against the dorsal uterine wall. In the second situation, a large calf, a "dry" birth canal, and forced extraction combine to create an overfolding and subsequent shearing of the uterine wall. These tears are usually 5–30 cm in length, although some seem almost circumferential.

Regardless of the tear's etiology, repair may not be necessary if it is small and dorsal. Because of rapid uterine involution, tears smaller than the width of a hand will usually be satisfactory without repair. Treatment for these can be limited to repeated oxytocin injections for the first 24–48 hours and 7–10 days of antibiotics. If the tear is larger, it can be closed with a "blind" suture technique [1].

To perform a one-handed blind closure of a uterine rent, first thread an atraumatic needle (size and shape determined by preference) with 150 cm of #2 or #3 catgut. With

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

the needle at the halfway point of the suture (doubled), make a knot at the end (knot 1) and about 25 cm from the end (knot 2). Next introduce the needle into and through the vagina, guarding the point with the fingers until the tear is reached. Begin closure at one end of the tear. After piercing the uterine wall (about 1 cm lateral to the tear) run the needle between the doubled suture and cinch at knot 2 (the only purpose of knot 1 is to keep the two loose ends together). Then close the tear with a continuous pattern until the last bite is made 1 cm lateral to the other end of the rent. It is important to pull the suture tight with each throw. Then reverse and continue the closure back to the original site and tie to the suture tail. Uterine involution serves to cover small appositional problems. Recommended treatment includes antibiotics, non-steroidal anti-inflammatory drugs (NSAIDs), and oxytocin (Figures 55.1–55.4).

Alternatively, the uterus can be prolapsed to facilitate suture repair. To prolapse a uterus, the cervix must still be completely dilated. Therefore this procedure must be performed within 6–12 hours of parturition. Administer 10 ml of 1 in 1000 epinephrine intravenously very slowly. Traditionally, it was advised to dilute the epinephrine in a minimum volume of 250 ml saline. This does not appear to be necessary. Do not perform an epidural or administer oxytocin. The cow must be able to strain and the uterus must be flaccid. Immediately following administration, enter the vagina with an arm, reaching as far cranial as possible to grasp a placentome and pull slowly. This will invert the tip of a uterine horn and the presence of the arm along with the invaginated uterus will stimulate straining. Pull with the cow's straining, grasping other placetomes if necessary. The uterus will usually come out within minutes. At this time, if the rent or tear can be visualized, it can easily be repaired. The uterus is then cleansed and replaced.

It should be noted that this procedure has limited application in that many of the iatrogenic tears encountered as a result of, or during the management of, dystocia are very close to the cervix; after the uterus is prolapsed, the area of the tear will usually still be within the vagina, thus not allowing the accessibility desired. Additionally, some if not most of these tears are near circumferential, and manual prolapse may be synonymous with uterine extraction – because the uterus is held in place with only a small amount of tissue, upon prolapse it simply tears and falls off. Therefore careful evaluation of the tear and its location and severity is warranted prior to prolapse for repair. As with the "blind suture" repair, antibiotics, NSAIDs, and oxytocin should be given postoperatively.

Figure 55.1 With the suture "doubled," the first bite is made at the lateral edge of the wound most easily accessed.

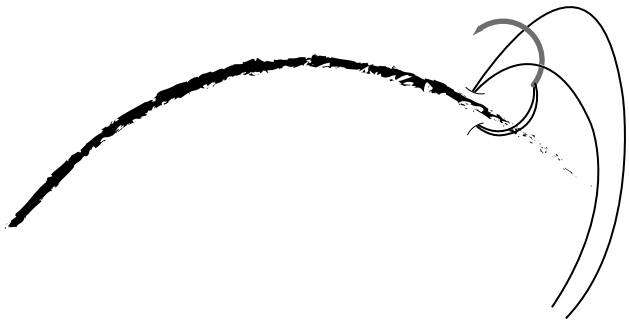

Figure 55.2 After first suture bite is taken, pull the needle through the loop created in the suture (this is not a knot, the suture is cinched).

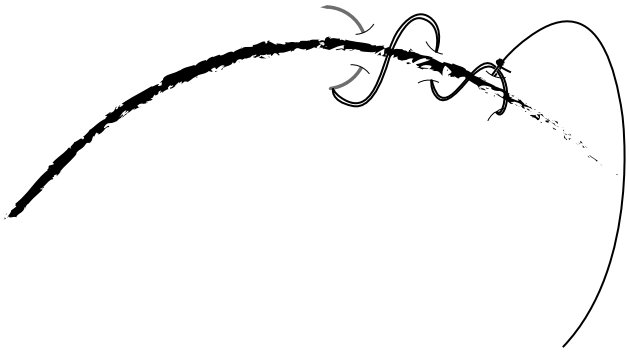

Figure 55.3 Continuous suture bites.

Figure 55.4 After reaching the end of the wound, return. This would look similar to a cruciate pattern and serves to correct the appositional deficiencies of the first row of sutures. When the pattern is complete, the suture is tied to the "tail."

Occasionally a cow will present two or more days following parturition with signs of peritonitis, depression, and anorexia. The cow may or may not have a history of obstetric intervention or even suspected dystocia. Examination may reveal a distal uterine tear which is likely the result of a spontaneous tear or, of course, an injury similar to the iatrogenic injuries previously described. Additionally, the peritonitis could be a complication following cesarean section. In any case, because of the duration of injury and peritonitis, surgical exploration of the abdomen via a flank approach should be performed. Treatment of the peritonitis begins with thorough abdominal lavage, which in turn is facilitated by the ventral placement of a drain.

Utilization of a rumen trocar placed from within the abdominal cavity at the ventralmost aspect will provide very efficient egress for the volume of fluid that is required (Figures 55.5 and 55.6). Also, because of the "siphon" effect that is created, debris (fibrin clots, necrotic material, and placental remnants) will be "pulled" to the drainage site and can be more efficiently retrieved. The rent in the uterus can then be repaired, the uterus lavaged, and finally the flank incision closed. This of course is accompanied by a guarded prognosis, so this level of effort is typically reserved for the cow of genetic merit or the involvement of a highly motivated owner.

Injury to the Vulva, Vagina, and Cervix

Tearing of the vulva, vagina, and cervix occurs almost exclusively during dystocia. Tearing and bruising can often occur during parturition in the absence of obstetric intervention; however, injury to these structures typically occurs during obstetric management of dystocia.

Figure 55.5 A rumen trocar placed from within the abdomen and directed outward at the ventral most location.

Figure 55.6 Fluid flow through the trocar cannula from the abdominal lavage.

Tearing of the vulva during the management of dystocia can be prevented by performing an episiotomy. This is an incision typically made at the dorsolateral (10 o'clock or 2 o'clock) aspect of the vulva. This incision will serve to either avoid or, at the very least, "guide" the tearing that occurs with the extreme stretching of the vulva during dystocia due to an oversized fetus. If an episiotomy is not performed, the tear will most likely occur at the most dorsal aspect of the vulva toward the anus and this in fact is the mechanism for grade 1, 2, and 3 perineal lacerations, a grade 3 being a rectovaginal tear.

Lacerations that involve only the vulva and even episiotomy incisions can be left unrepaired especially if the cow is to be culled. However, this often results in compromised vulvar competence, so these tears should be sutured immediately. A modified vertical mattress pattern can be used. Take a deep bite that includes the skin, fibrous tissue, and mucosal layers, and then the skin only for the superficial bite [2]. Although non-absorbable suture material is often recommended, #1 chromic gut can be used.

Vaginal tearing usually occurs in overfit heifers during the forced extraction of a calf. In these heifers, vaginal fat serves to decrease the cross-sectional area of the birth canal, thus serving as a contributing factor in the dystocia. During parturition, and specifically forced extraction, the vaginal wall will split, allowing the protrusion of this fat. This fat can and should be removed, but suturing the laceration is neither necessary nor recommended [2].

Occasionally the bruising that occurs during parturition will be so severe that the vaginal tissues will become necrotic. Depending on the severity, systemic illness will follow, but at the very least the cow will display tenesmus, a vaginal discharge, discomfort at urination, and vaginal prolapse. Treatment depends on severity and ranges from systemic antibiotics and vaginal lavage to surgical debridement of the affected tissue.

Trauma to the vagina can also result in severe and extensive adhesions. These can occur following dystocia or as a complication of vaginal or cervico-vaginal prolapse. If the adhesions completely occlude the vagina, fluid of a mucoid consistency will accumulate proximally. If this fluid has filled the uterus (mucometra), this is indicative of likely damage to the endometrium and therefore a poor prognosis for future fertility. If the condition is of short duration or if the uterus is not distended, attempts at treatment are warranted. Utilizing epidural anesthesia, insert a gloved hand into the vagina and attempt to break down the adhesions manually. The difficulty with which this is done and the depth of the lesions are prognostic indicators (deeper or more cranial lesions indicate poorer prognosis). Following this, the vagina should be lavaged with several liters of dilute carboxymethylcellulose.

Ensuring that the vagina remains patent after the adhesions are broken down is the key to successful resolution. An inflatable rubber beach ball (25 cm long deflated) with a grommet on one end has been recommended as a pessary [2]. Using #3 Braunamid suture, fix the grommet of the well-lubricated (petrolatum jelly and antibiotic ointment) deflated ball to the cervix. Then slightly inflate the ball. To ensure retention, the vulva is closed with vertical mattress sutures or prolapse pins. Remove the ball in 7–10 days, but continue the application of topical antibiotic ointment until healing. When a ball as described is unavailable, I have used a reusable latex palpation sleeve. The sleeve, closed at one end, is placed in the vagina, filled with loose cotton, and fixed in place.

Injuries to the cervix occur during dystocia and most are iatrogenic. If this is identified immediately, as in the case of an iatrogenic uterine tear or an extension of a uterine tear, it is managed basically as the uterine tear (one-handed "blind" suture). However, many injuries to the cervix are not noticed until artificial insemination (AI) is attempted. These injuries are for the most part not as amenable to correction as those that occur in mares. However, I have examined several cows with cervical injuries or scarring that did not conceive via AI but became pregnant after natural mating. Interestingly, cervical structure following the subsequent calving and involution appeared normal and the cows were again able to conceive following AI.

Rectovaginal Tears

Also termed third-degree perineal laceration, a rectovaginal tear exclusively occurs as a sequela to dystocia. It can be iatrogenic, but most occur naturally due to fetal oversize. In the cow, the constrictor vestibule muscle and cervix are able to provide an adequate anatomic barrier to prevent uterine contamination and infection [3]. Indeed, most cattle with rectovaginal tears or fistulas will continue to conceive and carry pregnancies to term.

Cases in which surgical repair is advisable would be the cow that has been presented as open after attempts at breeding or cows of high genetic merit, specifically the embryo donor cow, for which the owner/manager does not wish to leave the results of future use up to chance. In any case, allow at least four to six weeks following the injury before attempting repair [4].

Several techniques have been described for use in the mare and any of those would be appropriate. The procedure I have used and will describe involves the separate closure of the rectal mucosa, the perineal body, and the roof of the vagina much the same as a technique recently described for the mare [5]. Unlike the mare, the cow has typically soft manure, so dietary alterations prior to surgery are unnecessary. Likewise, it is a matter of choice whether to use a "rectal tampon," a stockinette (diameter 7.5 cm) filled with cotton and placed in the rectum cranially to the surgery site. Regardless, catheterize and empty the bladder, evacuate the feces from the caudal rectum, and administer epidural anesthesia. Alternatively, it is possible to utilize one of the regional blocks described in Chapter 17. Sedation depends on the cow's behavior. The restraint utilized can be either a chute or stanchion. The tail is tied to the side and the surgical site prepared. After cleaning the area, lavage with dilute Betadine solution and dry. I prefer Betadine scrub and solution for this area and do not use chlorhexidine-based products. The use of a chlorhexidine product is discouraged as these products are irritating to the vaginal mucosa and can result in luminal adhesions.

A transverse incision is made along the scar and deepened to a depth of 1–2 cm, carefully dissecting the newly formed "flaps" away from the lateral aspects of the vaginal wall. With careful attention to suture placement in the cranial-almost aspect, begin suturing the roof of the vagina. Various suture patterns and suture materials have been recommended for this procedure in mares, but a simple continuous pattern utilizing #1 chromic gut is adequate. The rectal mucosa should be closed with an interrupted horizontal mattress pattern in such a way as to avoid suture exposure in the rectal lumen. As the closure of the rectal mucosa is advanced caudally, stop every 3–5 cm to place a suture in the perineal body. This effectively closes the "dead" space as you go. The skin is closed with a vertical mattress suture pattern and a non-absorbable (Braunamid) suture.

The advantage of this technique over others, specifically the "6-bite" closure of all layers with one suture, is that it seems to create a thicker, stronger shelf. While this procedure is tedious, the results are usually very rewarding and, as alluded to earlier, it is a procedure reserved for an animal

of high value. Postoperative care consists of antibiotics and NSAIDs for five to seven days, as well as care during transrectal palpation for the next two to three months and perhaps attention at the subsequent calving.

Management of Iatrogenic Injury from Artificial Insemination or Embryo Transfer

Because of the physical structure of the vagina and cervix, iatrogenic injury to the vagina and cervix during the course of AI or embryo transfer (ET) is unlikely or at least rare. However, the uterus and specifically the endometrial lining are damaged easily. The most common injury related to AI is probably uterine puncture following passage of the AI rod completely through the cervix and aggressively continuing anterior passage. This injury in typically related to lack of experience of the technician, but is likely on the increase due to the utilization of "deep-horn" AI when utilizing semen with low sperm numbers, specifically sex-sorted semen or semen that has been evaluated and determined to have low number or low post-thaw motility. Another problem occurs when a straw is broken and the straw or portions of the straw are left in the uterus. Injuries from ET are also typically associated with the novice and include overextension of the Foley balloon, which results in rupture of the endometrium, or stylet-related uterine punctures which would be similar to those created by AI pipettes.

Because it is hard to ascertain how often punctures occur, little is known about the incidence of resultant infertility. Although these injuries likely heal successfully without intervention, a reasonable management tactic when presented with such a case would be a low-volume antibiotic infusion following the injury and then to "short-cycle" the cow [administration of a prostaglandin (PG)]. This would be done 7–10 days later following the AI attempt or immediately if occurring during ET. Cows managed such have conceived on the resultant estrus (note that it is not recommended to breed a cow on the next estrus following an ET flush, so this is applicable only for AI-associated injury).

A fragment of or an entire straw can inadvertently be left in the uterus. This can be the result of a prolonged and aggressive AI attempt by a novice, but can also occur when the subject is unruly and/or poorly restrained. These "foreign bodies" serve to function as excellent intrauterine devices and thus result in infertility. Depending on the duration of retention, it can be removed transcervically, which is best attempted during estrus, or surgically. Transcervical removal can be attempted with any long forceps, including an equine biopsy forceps. Often the straw becomes "embedded" in the endometrium. Removal in these cases can be facilitated by the use of a Foley catheter and the introduction of 80–150 ml of sterile lavage fluid. This serves to expand the uterus and help with removal. Surgical removal can be accomplished via a flank approach and I have utilized a colpotomy approach as well. In either case, if the straw appears intact it can simply be manipulated and forced out manually without an incision. If there are straw fragments, an incision must be made and the uterus lavaged following removal. Closure is with a disposable suture and pattern of individual preference.

Endometrial rupture during an ET flush is not uncommon and will occur following overextension of the Foley balloon, but also from unexpected and dramatic movement by the subject. In any case, it results in some level of hemorrhage, but also the inability to recover lavage fluid. Immediately stop flush attempts, administer 5–10 mg $PGF_{2\alpha}$ (Lutalyse®) intravenously via the tail vein, and decompress the Foley balloon. After 5–10 minutes have elapsed the flush can be resumed, this time replacing the catheter in a position anterior to the previous location.

Urovagina (Urine Pooling)

Urovagina is recognized as one of the most common reproductive disorders in the mare. Although there have been various reports that describe surgical correction of this condition in the cow [6–8], only relatively recently has work been published that describes risk factors, its effect on reproductive performance, and prevalence [9]. This work revealed that based on the evaluation of Holstein cows over a total of 344 lactations, this condition occurred at a prevalence of 26.7%. Urovagina was identified by vaginal speculum examination and classified as mild, moderate, or severe based on the amount of urine pooled within the vagina. Only moderate or severe categories of the condition resulted in a decrease in fertility and these in turn represented about half of the cases. Risk factors included poor body condition, a history of endometritis, and poor vulvar conformation.

This condition is therefore worthy of our attention and attempts at correction. Although risk factors have been identified, a specific etiology is less clear. A common case presentation at our referral clinic is that of urovagina in an aged donor cow with a likely iatrogenic etiology, specifically that being repeated treatment to induce superovulation. The reason I believe this is that most of the time these cows do not present with a torn or injured urethra or possess any of the identified risk factors, but instead a large vagina in which the cranial aspect falls over the floor of the pelvis. This condition of course can also occur following

injury, usually associated with dystocia, or is manifest as splanchtosis from multiple calvings. Perhaps because there is no single management or surgical procedure that is either easily performed or works in every case, several options will be discussed, the goal being to provide a comprehensive review and hopefully not that of either creating confusion or stimulating an argument on which is best.

One of the urethral extension procedures described for the mare can be utilized, although I have typically employed one of the easier alternatives. Regardless of etiology, if the case presented involves a cow to be used for ET and the client's desire is to simply get one more embryo flush, a long Foley catheter (20–24 French, 30-ml balloon) can be placed in the urethra at the initiation of the superovulatory regime and maintained through embryo flush/recovery. A one-way valve (finger of a latex glove with a small slit) is placed over the egress of the catheter to allow urine out but preclude air from entering. This will temporarily prevent urine from accumulating in the cranial vagina, but irritation to the bladder and urethra from the presence of the catheter limits its value as a long-term solution.

For a longer semipermanent correction, a circumferential suture placed in the vestibulovaginal junction (Figure 55.7) as described by Dr. González-Martín et al. [6] will allow several embryo recovery flushes or the maintenance of pregnancy (note that the suture should be removed prior to parturition). To accomplish this procedure the cow is restrained, epidural analgesia employed, the tail tied to the side, and the vagina and perineum prepared for surgery. Next, place a catheter into the bladder to prevent the inadvertent restriction of the urethra by the subsequent suture pattern. Introduce a hand into the vagina, utilizing either a hand-held curved cutting edge needle or a Deschamps needle (Figure 55.8) to place a subcutaneous suture cranial to the urethral orifice. The needle is introduced at the 4 o'clock position and exits at the 8 o'clock position. Then reintroduced at the same location (8 o'clock), exiting at the 12 o'clock position, and again reintroduce (same location – 12 o'clock), to finally exit at the original 4 o'clock location. Tighten the suture and tie. Note – a finger is placed in the lumen to provide a gauge for tightness of the cerclage. There should be ample opening for passage of an AI pipette or ET catheter. After several modification attempts of this approach the author has concluded that strict adherence to the procedure as described by González-Martín et al. will provide the best long-term results.

A technique described by Robert Hudson [10] that may offer permanent correction is the creation of a transverse dam across the floor of the vagina cranial to the urinary meatus, after which a Caslick procedure may be performed. The patient is prepared as with the other procedures, restrained, an epidural administered, and the vagina prepared with antiseptic lavage. Entering the vagina manually, a fold of tissue is grasped and rolled up at the level of the constrictor vestibuli muscle to create a transverse fold. Place an anchor suture with a half-curved, cutting-edge needle and either #3 or #4 catgut at the 4 o'clock position on the lateral wall, continuing with a mattress suture pattern in which you are alternately passing the needle cranially and caudally through the fold you created (Figure 55.9). Care should be taken to avoid the urethra and you should begin, proceed, and end the pattern keeping in mind the goal of incorporating 120° of the vaginal circumference and the creation of a semilunar dam of about 5 cm. Because of a "drawstring" effect that results from the mattress suture, there will not be a consistent height of the dam, but this does not affect the effectiveness. Adhesions should form within the tissues pulled together to form the dam, making this a permanent barrier to urine retention.

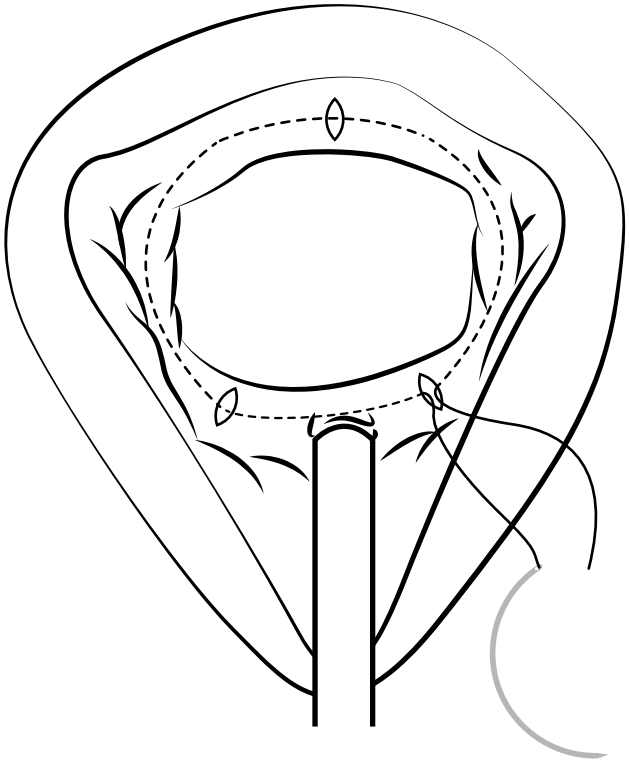

Figure 55.7 Suture placement for circumferential suture in the vestibule of the vagina. A catheter is placed in the urethra to avoid incorporating it into the suture. This procedure is described by González-Martín et al. [6]. *Source:* Image courtesy of McRae Hopper.

Additionally, the Minchev procedure or one of several of its modifications can be utilized. This is performed exactly as it is when utilized for vaginal or cervico-vaginal prolapse retention. It is effective for the resolution of urine pooling because it has the effect of both raising the vagina and pulling it caudally. This typically facilitates urine passage.

Figure 55.8 Deschamps needles. One of the instruments has been made longer. This may not be an improvement as this instrument is less stable and will bend under pressure.

Removal of a Mummified Fetus Via Colpotomy

A mummified fetus is an infrequent finding during routine herd pregnancy checks. Additionally, this condition is discovered when a cow is presented due to signs of anestrus or had been previously diagnosed pregnant and is overdue. Diagnosis can be made by per rectal palpation. An enlarged uterine horn with a palpably hard intrauterine mass, accompanied by a lack of fluid, is the most common finding, as well as the presence of a corpus luteum on the ipsilateral ovary. Utilization of ultrasonography is also of value (see Chapter 40).

Mummification of a fetus can occur any time after fetal ossification [11], typically between the third and eighth month of gestation. The condition is dependent on the maintenance of the corpus luteum and a closed cervix. Several etiologies for this condition are possible. Trichomoniasis and bovine viral diarrhea virus are the most common of the many infectious agents that cause early fetal death. Chromosomal abnormalities have been implicated as well as genetic anomalies. One genetic cause, an autosomal recessive gene for deficiency of uridine monophosphate synthesis (DUMPS), is known to cause embryonic and fetal death and was identified in the DNA extracted from two mummified fetuses [11].

Depending on the age of the cow and/or economic considerations, the cow may be immediately culled. If an attempt to treat the cow is chosen, conservative medical treatment should always be the first approach, this being the administration of a native or synthetic PG (Lutalyse®, Estrumate®) [12]. Depending on whether estrogen products are legally available for use in cattle in your country, a single dose of estrogen, either estradiol cypionate or estradiol benzoate (2–5 mg), can be given with or 24–48 hours after PG treatment with the goal of facilitating response by softening or "priming" the cervix. PGE available as a suppository used in human obstetrics, a compounded form, or Cytotec (misoprostol) tablets can also be used intracervically to aid in cervical dilatation. It is worthwhile to repeat medical treatment several times before resorting to either surgery or culling.

In cases in which there is no response to these treatments, a surgical remedy may be effective. A hysterotomy via either a flank approach or a colpotomy is recommended. In a retrospective study of cases not responsive to PG treatment [11], some mummified fetuses were removed by a combination of medical treatment (estradiol-17β, $PGF_{2\alpha}$, and oxytocin), followed by manual cervical dilation and manual extraction, and some by a flank approach hysterotomy. In this study 36% of cows became pregnant following a hysterotomy removal, while none conceived following the manual extraction.

A flank approach or a midline is recommended in cases in which the mummy is greater than 30 cm [13]. For those that are smaller, a hysterotomy via a colpotomy [14] approach can be performed easier and in less time. The cow is restrained in a chute. It is recommended but not absolutely

necessary to fast the cow, removing feed for 24 hours and water overnight. Sedation or tranquilization is dependent on the patient's personality. Administer an epidural and evacuate the rectum as effectively as possible. Then place a length of 7.5-cm stockinette packed with cotton within the rectum. Clean the vulva and prepare the vagina by lavaging with a dilute disinfectant (Betadine). Using dampened cotton pledgets, dry or at least remove water from the vaginal vault. Creating a pneumovagina by introducing or allowing air in will facilitate the procedure. With a blade carefully guarded between finger and thumb, introduce a hand into the vagina, and at a location in the anterior vagina that is dorsolateral (10 o'clock) to the cervix make a small stab incision. Alternatively, a specially made trocar can be utilized to make this stab incision. After an incision is made, the vagina is reentered and the incision is enlarged bluntly, first with the fingers and then the hand until a hand can be introduced into the abdomen. This should be performed aggressively and not gingerly, as overly cautious manual entrance serves to "tent" the peritoneum rather than push through it and this is actually more painful to the patient. Once the hand is inside the abdomen, the uterus is easily palpated; when the horn with the mummy is located, grasp and retract it out through the rent created in the vagina (Figures 55.10 and 55.11). Once it is exposed, make an incision into the uterus and extract the mummy. The lumen of the uterus is then lavaged to make sure that all foreign material is removed. Then suture the uterus with a continuous inverting suture pattern as you would a cesarean section hysterotomy. Rinse the uterus removing any debris or fibrin tags. Addition of carboxymethylcellulose to the saline used to both lavage the uterine lumen and cleanse the uterus before replacement is likely beneficial in reducing the possibility of adhesion formation. Then replace the uterus. Although suturing the rent created in the vagina is considered optional, I do not attempt to close colpotomy incisions on mares but I close it in cows. This can be done with a continuous pattern (the suture technique described for uterine tears can be utilized). If the decision is not to close the colpotomy incision, a Caslick should be performed.

Unilateral Ovariectomy

The indications for ovariectomy include neoplasia or the presence of severe adhesions, either of which affect the function of the ovary. There should be reasonable evidence that the contralateral ovary is normal and that fertility will be restored following removal of the abnormal ovary. An ovary that is small enough to be easily grasped during per rectal palpation can be removed via colpotomy. Larger ovaries or those with extensive adhesions should be removed via flank celiotomy.

Figure 55.10 The uterus (uterine horn containing a mummified fetus) exposed through a colpotomy incision.

Figure 55.11 Incision into the exposed uterine horn.

Ovariectomy Via Colpotomy

The colpotomy approach was described in a previous section. Once the abdomen has been entered, the chain loop of an écraseur is placed around the ovary. The chain loop is slowly tightened, making sure that the placement does not include the bowel. The loop is tightened further until the ovary's attachment is severed and the ovary can be removed. Although it is recommended that only smaller ovaries (those that can easily be held in the operator's hand) are to be removed by this technique, larger ovaries can be removed by carrying a sterile plastic bag into the abdomen, dropping the ovary into the bag, and then removing the bag with the ovary.

Ovariectomy Via Celiotomy

The left flank celiotomy approach is described in Chapter 52 and the only difference is that the incision for this should

be made slightly more dorsal and caudal. This approach is preferred over the colpotomy when the ovary to be removed is large, adhesions are severe, or there is concern relating to hemostasis.

Pregnancy Wastage

56

Fetal Disease and Abortion: Diagnosis and Causes

Wes Baumgartner

Veterinary Diagnostic Laboratory, College of Veterinary Medicine, University of Illinois, Urbana, IL, USA

Introduction

Reproductive failure is a significant problem in breeding management that arises from physiological, anatomical, inherited, and infectious causes. The inability to achieve or maintain a pregnancy may be divided into four main stages: failure to ovulate after estrus, failure of fertilization, embryonic death (prior to gestation day 42), and fetal death [1]. Pregnancy wastage, which probably comprises the largest portion of these losses, encompasses the combined embryonic, fetal, and neonatal deaths that achieve nothing. It has been estimated that about 75% of pregnancy wastage occurs in the embryonic stage [2, 3]. The majority of reproductive failure occurs in the first two weeks, at the time of development from a morula to blastocyst where the conceptus begins enhanced protein synthesis and placental development [3–6]. Despite the importance of wastage at this time of development, the mechanisms contributing to embryonic death are poorly understood and in most cases the cause is never established [1]. Factors typically thought to contribute to embryonic death include heat stress, infections of the uterus/gametes/embryo, local trauma, genetic factors, heavy lactation in dairy cattle causing energy imbalances, maternal illness, aged oocytes from persistent follicles, small follicles, fetal–maternal incompatibilities, twinning, postpartum breeding intervals, and abnormal progesterone levels due to estrus synchronization [1, 3, 6, 7]. Investigation into the causes of early loss are hampered by the rarity of available early conceptuses that are either expelled or resorbed and go unnoticed, only to result in a cow that returns to estrus or fails to deliver a calf.

Abortion typically refers to pregnancy loss in the fetal stage, between days 42 and 260. It is in this stage of gestation that the tissues of conception cannot be resorbed and, when expelled, are more easily noticed. During the fetal period there is a progressive decrease over time in the risk of abortion, with a slight increase in the last month [8]. Although losses during this time are a minority of overall wastage, the cost of investment by the cow and the manager is substantial. A mid-term abortion represents a loss of at least USD $600–1000 [8]. For practical purposes, unavoidable losses of 3% after pregnancy confirmation (six weeks' gestation), with 1–2% loss in the periparturient period, may be considered acceptable or typical, although opinion in this area varies [8–10].

This discussion will concentrate on fetal death and the approach to diagnosis, but will necessarily include some aspects of embryonic death, congenital abnormalities, and common gross findings. Additionally, a brief overview of anatomy and development are included to familiarize the reader with general concepts. A glossary of terms appears at the end of this chapter.

The investigation of abortion is a vital part of herd management and its importance is hard to overemphasize. Accurate diagnosis is the only path to the effective control of disease. It should go without saying that a focused, efficient, and thorough investigation technique with a definite purpose by prepared veterinarians is the only relevant way to identify and understand the etiologies of abortion. The necropsy itself contributes to this in several ways: by establishing definitive causes of death, identifying unsuspected findings, providing information concerning zoonotic disease, contributing to discovering new diseases and pathogenic mechanisms, and providing a means to test new diagnostic and treatment techniques [11].

Pathology

The expression of disease in the conceptus is remarkably varied in a general sense, in that it gives rise to bizarre developmental defects of potentially every sort. This is due

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

to the intricate physiology and morphology of fertilization and gestation that is shared between the dam and fetus. The sequential stages of organ system development in utero provide unique opportunities for infectious and non-infectious etiologies to manifest themselves at the gross level, if pregnancy is maintained. In addition, the placenta, a unique organ of gestational necessity, is a target of many disease-causing agents and can itself develop anomalous defects that in turn directly affect the fetus.

Despite this, in many cases, aborted tissues from infectious and non-infectious causes exhibit little if any recognizable changes of significance. This is partly due to autolysis in utero masking subtle changes; the relative ease and rapidity by which fetuses succumb to disease, allowing only a brief window for gross changes to manifest; and a rudimentary inflammatory response to injury [12]. Not only does the conceptus vary in its susceptibility to particular insults across the gestational period, but also the degree and duration of insult determine the outcome, whether it be life, death, malformation, or inflammation [9].

The physiology of pregnancy is well studied and dealt with in detail in preceding chapters. Despite our understanding of normal pregnancy, the physiology of abortion and the mechanisms involved are poorly understood. In many cases, abortion may be mediated through the same pathways that occur in normal parturition, but different mechanisms and pathways are also possible [8].

Categories of Reproductive Loss

The cause of abortion is often not known, which is a consistent source of frustration for managers and clinicians alike. In all species, abortion may be caused by infectious and non-infectious etiologies. Specific causes and agents are dealt with in detail later in this and subsequent chapters. Of these, infectious causes of abortion (bacteria, viruses, fungi, protozoa) are probably the best understood and characterized. It is common to see reports where the percentage of cases with a specific diagnosis is less than 50% [13]. Of these, at least half are due to infectious agents, with the majority of these due to bacterial infection [8].

Bacteria involved in abortions can be broadly grouped into those that are contagious and those that are opportunistic. The majority of bacterial abortions are caused by opportunists, and these may be further divided into those that are part of the natural flora, such as *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) and *Histophilus somni*, and those from the environment, such as *Bacillus* spp. and *Escherichia coli* [14]. The significance attached to abortion by opportunists depends on the situation in the herd. If these bacteria are only seen in isolated cases, the significance to the herd is minimal [14]. However, if these organisms are consistently associated with abortions, then further investigation is warranted.

Table 56.1 Disease-causing agents associated with endemic fetal losses.

Histophilus somni, *Listeria monocytogenes*, *Trueperella pyogenes*, *Leptospira* spp., *Ureaplasma diversum*
Bluetongue virus, bovine viral diarrhea virus (BVDV)
Neospora caninum, fungi, epizootic bovine abortion
Inbreeding, sire-derived lethal traits, chromosomal abnormalities
Feed estrogens (silage, poultry litter), progesterone aberrations (high pasture protein)
Protein, vitamin A, iodine, selenium deficiency
Protein/urea, copper, iodine excess
Endotoxins due to Gram-negative bacterial sepsis in dam
Endotoxin in Gram-negative bacterial vaccines, especially given during the first or last two months
Pine needle, broomweed, locoweed, narrow leaf sumpweed toxicosis
High plant estrogens
Aflatoxin, ergotamine, fusarium (zearalenone), nitrate fertilizer, organophosphate toxicosis

Source: [15].

Non-infectious causes of abortion are similar to those known to cause embryonic loss, including nutritional imbalances, malnutrition, stress, environmental toxins, teratogenic compounds, hormone imbalances, and genetic abnormalities. An expanded list of etiologic agents is shown in Table 56.1 and in the following chapters.

Pathophysiology of Injury to the Conceptus

Maintenance of the first half of gestation (the first 200 days) in cattle requires a persistent corpus luteum (CL), which is maintained by the fetus [9, 16]. Luteolysis may occur in pregnant cows due to excess prostaglandins (PGs) (exogenous administration or secondary to heat stress) or Gram-negative bacterial septicemia [17]. If the CL is destroyed at an early stage, death and rapid loss of the embryo with minimal degeneration may be seen [18]. If there is fetal death prior to luteolysis, the CL may regress, with eventual expulsion of autolyzed fetal tissues. However, in some cases the CL is maintained after fetal death, which can result in expulsion, resorption, or mummification [19]. Early abortions are typically not recognized; most are occultly expelled, severely autolyzed, or mummified.

The maintenance of late-stage pregnancy requires both the fetus and placenta. At this stage in development, sufficient fetal stress can induce parturition through natural endocrine mechanisms. In this way, chronically diseased fetuses can initiate their own premature delivery.

Fetal death often leads to abortion within a few days rather than immediately, allowing sufficient time for autolytic changes to occur. The mechanism for expulsion of dead fetuses is unknown but may share many similarities with normal parturition [19]. Autolytic changes include generalized edema, pallor, and hemoglobin-stained fluids in the body cavities. Visceral tissues become pulpy or semiliquid [19]. In some cases, the time between fetal death and expulsion may be characteristic for a pathogen, and may therefore be useful to the clinician. Fetal infections due to *Listeria monocytogenes*, *T. pyogenes*, non-septate fungi (*Absidia* spp., *Mucor* spp., *Rhizopus* spp.), and bovine herpesvirus (BHV)-1 may lead to fetal death with expulsion days later. Fetuses infected by *Campylobacter fetus* and *Aspergillus* spp. may be delivered alive [20].

It is important to recognize that infection of the conceptus does not necessarily lead to fetal death. The ability of a pathogen to injure the conceptus is influenced by the dam (general health, previous exposure), the stage of fetal development, and the virulence of the infectious agent. Fetal development is a continuum of organogenesis, physiological development, and immune development. Early stages of gestation are more prone to infection and severe disease, as the capabilities of the fetus are underdeveloped. The closer the fetus is to parturition, the stronger and more capable it is of defending itself from pathogens. Thus, infection at different stages of development will produce different outcomes in the fetus.

Bovine viral diarrhea virus (BVDV) infection is a good example of this. Infection in the first trimester often leads to fetal death and resorption, while infection in the second trimester may lead to developmental anomalies. The character of the developmental defects depends on which cells or tissues are susceptible to the virus at the time of infection. In the second trimester, cerebellar growth is maximal and BVDV infection at this time may lead to cerebellar necrosis and cerebellar hypoplasia. Also at this time, hair growth is highly active and BVDV infection may damage follicles, resulting in hypotrichia. By the third trimester, the immunocompetent fetus may react to BVDV infection by mounting a sufficient immune response with antibody production and virus elimination. The only evidence for such an infection would be fetal-specific antibody titers [21].

Other viruses, such as BHV-1, cause extensive cell necrosis and hemorrhage, leading to rapid fetal death. *Neospora caninum* infection in the third trimester may cause only mild inflammation, with the birth of asymptomatic calves.

Effects of Maternal Disease

Infectious pathogens may cause abortion either by directly infecting the conceptus or by affecting the dam such that severe physiological disturbance leads to abortion. Uterine disease has significant effects on the conceptus and potential future fertility; ovarian and uterine effects can be lasting despite resolution of the signs of active disease [22]. The dam is predisposed to infection through non-specific immunosuppression that occurs during pregnancy [23]. Fever (mastitis, pneumonia), circulatory disease (myocarditis, severe anemia), hypoxia, and endotoxemia (Gram-negative sepsis) are possible conditions that may cause abortion indirectly [21]. PGs may be elevated in febrile states, which can lead to luteolysis and abortion [24]. The likelihood of abortion probably increases with the number of pregnancies or previous abortions by the dam [8].

Routes of Infection to the Conceptus

In cases where infectious organisms invade the conceptus, four routes are likely [21]. Hematogenous spread from the dam to the placenta is commonly suspected in cases of infectious abortion, particularly due to *L. monocytogenes*, *Leptospira interrogans*, *Salmonella enterica*, *Brucella abortus*, fungus, BHV-1, or BVDV infection. Ascending infection from the vagina through the cervix can occur from primary vaginitis (characteristic of *Tritrichomonas foetus*) or contamination at insemination. The presence of pathogens within the uterus (endometritis due to *C. fetus*, *T. pyogenes*) and descent from the abdomen via the uterine tubes (mycobacteriosis) are also possible pathways for organisms to reach the conceptus.

Route from the Placenta to the Fetus

Once a pathogen reaches the placenta, it may proceed to the fetus through the blood, via the umbilical veins, or by contamination of the amniotic fluid [21] (Figure 56.1). For example, BVDV primarily infects the fetus hematogenously, whereas BHV-1 may first infect the placenta and then proceed to the fetus. Primary placental infection with subsequent amniotic fluid contamination is characteristic of fungal infections. In some cases, a pathogen need not infect the fetus, such as with *S. enterica* infection, where severe infection of the placenta may lead to generalized fetal hypoxia and subsequent death.

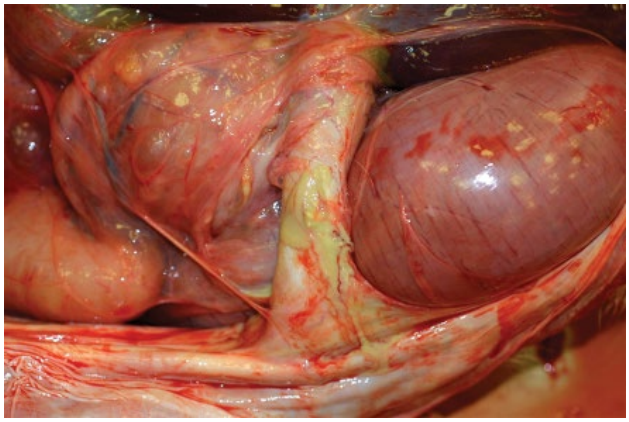

Figure 56.1 Fetus, omphalitis, and ascending bacterial infection from the placenta. Purulent material is easily expressed from the cord. *Source:* Photo courtesy of J. Edwards.

Lesions of the Placenta

Placentitis most commonly develops by one of three ways: hematogenous spread, extension from a diseased uterus, or an ascending vaginal infection. Gross placental lesions are characteristic of chronic bacterial and fungal disease, while viral infections generally produce no lesions [25]. Changes of significance may occur in both the cotyledons and/or intercotyledonary spaces. The presence of fibrin (yellow, stringy, friable material) on cotyledons is an indication of inflammation (Figure 56.2). Fibrin must be distinguished from necrotic inflammatory exudate or entrapped caruncle fragments (necrotic uninfected endometrial tissue). The presence of ecchymosis and extension of the changes to the intercotyledonary space are suggestive of an infectious inflammatory process. With chronicity, stereotypical changes of placentitis include (i) placental fibrosis and edema; (ii) cupping of cotyledons; (iii) exudate on chorionic surfaces; and (iv) necrosis of the cotyledons [12].

Fungal and bacterial inflammation of the cotyledons is often associated with necrosis, which imparts a firm to friable, tan, irregular or nodular consistency to the tissues with interspersed ecchymoses. Fungal organisms prefer to grow along and within blood vessels; this often leads to thrombosis, hemorrhage, and necrosis (Figure 56.3). Fungal organisms may be particularly abundant at the periphery of lesions rather than in the centers. A useful feature for interpretation is the extension of the pathologic process into the pericotyledonary chorioallantois. Such infiltrates may bridge cotyledons and often impart a leathery thickened texture. Another differential for such a change would be adventitial placentation (discussed in the section "Pathology"). Leptospirosis and BHV-1 infections may also produce a placentitis and appear similar to one another [26].

Ureaplasma diversum is known to produce a rather characteristic hemorrhagic amnionitis, where the membranes

are thickened, opaque, and ecchymotic with fibrin, necrosis, and fibrosis [27].

Lesions of the Fetus

Gross lesions of the fetus, aside from malformations, are generally uncommonly noticed. They may be inapparent for four reasons: (i) the fetal immune system is not of sufficient robustness to mount a response that is easily observed at the gross level; (ii) fetuses often die before lesions appear; (iii) lesions are masked by autolysis; and (iv) fetal pathology may manifest itself in ways that are difficult to recognize [15]. Table 56.2 lists some causes for commonly

Table 56.2 Possible causes for gross and microscopic lesions in bovine fetuses.

Lesion	Possible causes
Gross lesion	
Mummification	BVDV, *Neospora*
Ascites/anasarca	Congenital heart defect, nutritional myopathy/cardiac dilation, BVDV, *Neospora*
Arthrogryposis, musculoskeletal deformities	Akabane/Schmallenberg/bunyaviruses, reduced in utero motility, genetic
Fibrinous peritonitis/pleuritis	Bacteria (*Trueperella*, *Campylobacter*, *Bacillus*, *Brucella*, *Chlamydia*), fungi, EBA
Fibrinous pericarditis	*Bacillus*, *Campylobacter*
Icterus	*Leptospira*
Cerebellar hypoplasia	BVDV, Schmallenberg, BTV
Hydrocephalus, hydranencephaly, porencephaly	BTV, BVDV, SBV, other bunyaviruses, genetic anomaly, toxins (lupines), genetic
Microphthalmia	BVDV
Pulmonary/renal hypoplasia	BVDV
Dermatitis/hyperkeratosis	Fungi, EBA
Multifocal liver necrosis	*Listeria*, BHV-1, *Yersinia*, *Salmonella*
Splenomegaly/lymphadenopathy	EBA, HoBi-like pestivirus
Hepatomegaly	Chronic passive congestion, EBA, lipodystrophy
Placentitis, infarctions	Fungi
Placental exudate	Bacteria (*Trueperella*, *Campylobacter*, *Brucella*, *Leptospira*, Mollicutes, *Coxiella*), *Trichomonas*, BHV-1
Generalized petechiation/hemorrhage	BVDV, anthrax, HoBi-like pestivirus
Microscopic lesion	
Encephalitis	*Neospora*, BHV-1, BVDV
Meningitis	EBA, *Leptospira*, *Brucella*, other bacteria
Myocarditis	*Neospora*, BVDV
Suppurative bronchopneumonia	Bacteria
Bronchointerstitial pneumonia	*Ureaplasma*, *Brucella*
Multifocal hepatic necrosis	BHV-1, *Listeria*, *Salmonella*, *Yersinia*
Interstitial nephritis	*Neospora*, *Leptospira*
Abomasitis/enterocolitis	Bacteria, fungi
Conjunctivitis	Bacteria, *Ureaplasma*, fungi
Placentitis	Bacteria, fungi
Oxalate crystals, renal	Congenital metabolic defect, associated with anomalies, ingestion of oxalate-producing plants by dam
Liver: (1) Lipid; (2) fibrosis; (3) iron	(1) Lipid-toxin exposure, lipodystrophy; (2) fibrosis-aflatoxin, passive congestion; (3) iron-weak calf syndrome

encountered lesions in aborted fetuses. Other conditions are listed further in the text.

The most common finding in abortion is autolysis, the degree of which depends on the cause of death, the time from death to abortion, and the time from abortion to examination [26]. In experimentally induced, sterile, dead ovine fetuses, changes associated strictly with autolysis included (i) lack of odor, (ii) subcutaneous blood-tinged gelatinous edema, (iii) blood-tinged fluids in body cavities, (iv) renal cortex softening, (v) liver softening, (vi) abomasal content that was cloudy yellow to red, and (vii) uniform color (pink/red) of tissues [29] (Figures 56.4 and 56.5). By

Figure 56.5 Fetus and placenta. The fetus exhibits generalized red discoloration due to autolysis. *Source:* Photo courtesy of J. Cooley.

12 hours after death, the fetal corneas were cloudy, the liver and kidneys were friable, and abomasal content became cloudy with brown flecks. After 36 hours, the subcutis contained edema and the skin would slough. By 144 hours, progressive dehydration was obvious (mummification) [29]. Signs of fetal infection include fibrinous exudates in body cavities, white to tan foci in the liver or lungs, and evidence of abnormal development [26] (Figure 56.6).

Pathogens that invade the fetus via umbilical veins may produce lesions in the liver, as it is the first organ encountered (Figure 56.7). *L. monocytogenes*, BHV-1, *Yersinia pseudotuberculosis*, and *S. enterica* infections are often associated with liver necrosis. For pathogens that infect the amniotic fluid, exposure of the skin, lung, and intestines may occur. Skin lesions are particularly well known in cases of fungal infection, where pale patches of thickened skin are evident (Figure 56.8). Lung and pleural disease may be manifestations of hematogenous systemic spread or inhalation of infected amniotic fluid during fetal distress [21].

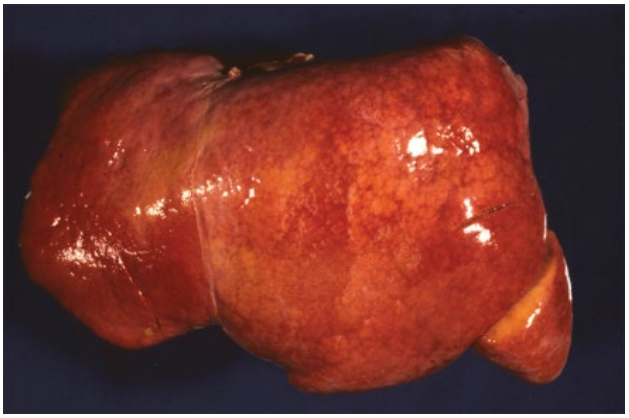

Figure 56.9 Fetal liver. The surface is tan and coarsely irregular. This change may be seen with chronic passive congestion (heart anomalies) or epizootic bovine abortion. *Source:* Photo courtesy of J. Edwards.

Epizootic bovine abortion (EBA) causes distinctive lesions in the fetal liver, lymph nodes, and spleen. The liver is irregular and nodular; however, this change may also be seen in cases of congenital heart disease where chronic passive congestion occurs (Figure 56.9). The spleen and lymph nodes are characteristically enlarged due to lymphoid and mononuclear cell hyperplasia [19]. Yellow/fatty, enlarged, and even fibrotic/cirrhotic livers may be seen in hepatic lipodystrophy, a poorly understood condition that may be related to selenium deficiency, toxin exposure (pyrrolizidine alkaloid, aflatoxin), or other genetic causes [30, 31]. Iron in the liver was reported in association with weak calf syndrome (possibly due to selenium deficiency) [32].

Outcome of Exposure to Abortifacient Agents

Fetuses exposed to abortifacient agents or conditions may die (resorption/abortion/stillbirth), they may be infected (with or without disease), they may be malformed (live/dead), or they may be normal [23].

Death in the embryonic stage leads to resorption. In the fetal stage the presence of skin and musculoskeletal structures, in addition to placental endocrine activity, prevents resorption. Instead fetal death leads to autolysis and expulsion, or retention with mummification/maceration. In late gestation, a sick or stressed fetus may precipitate its own premature delivery with one of three results: the fetus may be born and then die, it may be born and fail to thrive, or it may be born and thrive even if infected [21].

Disease may impair fetal motion, a necessary requirement for proper musculoskeletal development. In such cases, the calves may exhibit severe changes, including arthrogryposis, ankylosis, scoliosis, torticollis, and similar defects that lead to dystocia, stillbirth, or death in the perinatal period.

Teratology

Abnormal development (congenital defects) in the fetus may be caused by teratogens: toxic substances, infectious disease agents (particularly viruses), nutritional imbalances, endocrine imbalances, hypoxia, extreme temperatures, and inherited or spontaneous genetic mutations [33, 34]. The manifestation of these defects includes resorption/abortion, malformation, alteration of growth, and functional deficits (Figure 56.10). The late embryonic period and early fetal periods are the times of greatest susceptibility for the conceptus. During this time, each organ system is established in an orderly fashion with morphogenesis occurring in "critical periods." During these periods organs are at their most sensitive to teratogens.

In many cases congenital defects have no defined cause. Seasonal occurrence, history of stress, or maternal disease are often noted, with or without a familial component [35]. The genetic composition of the fetus as well as the nature and degree of insult figure largely in the outcome [13]. Genetic considerations are discussed in greater detail in Chapter 70.

In cattle, viral infections are well-known causes of defects. BVDV, infectious bovine rhinotracheitis (IBR), (BHV-1), Wesselsbron, bluetongue, Akabane (bunyaviruses including Schmallenberg), and Rift Valley fever (RVF) viruses are commonly associated with embryonic loss and neuromuscular defects [36, 37]. In addition, toxic plants such as lupines, *Conium maculatum*, and locoweeds are associated with defects [35]. Further discussion of such toxins is presented in Chapter 69.

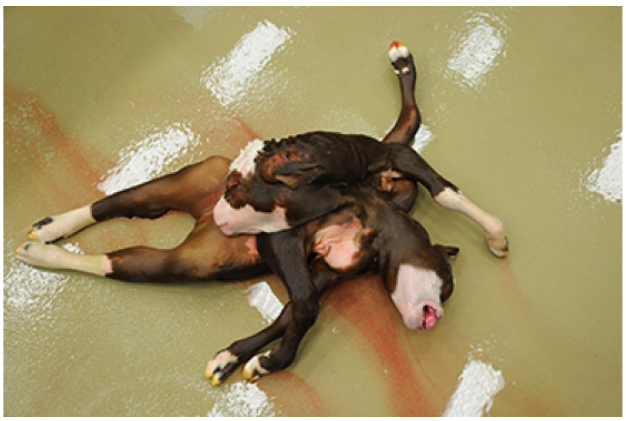

Figure 56.10 Fetal monster. A thoracopagus with shared viscera and four forelimbs.

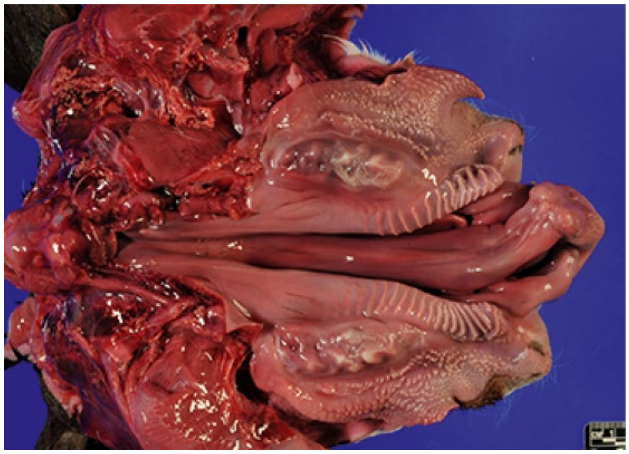

Figure 56.11 Palatocheiloschisis; cleft palate and lip (mandible removed).

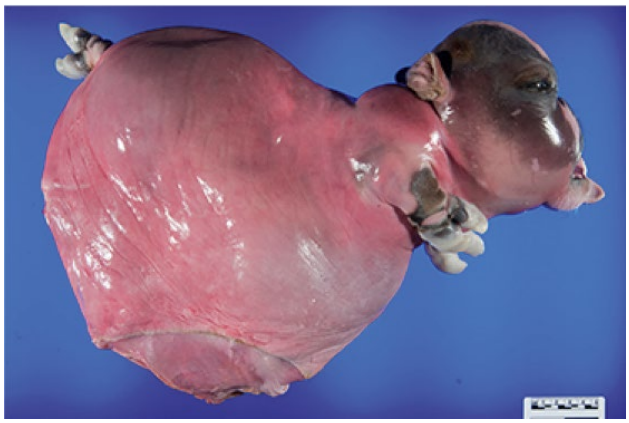

Figure 56.12 Chondrodysplasia; Dexter "bulldog" calf.

Calves with congenital defects often die during parturition or soon thereafter. In many cases the anomalies are grossly obvious, often affecting the neural and musculoskeletal systems (Figure 56.11). A wide range of malformations have been described, some of which have been intensively studied and a genetic component has been found (Figure 56.12). For the purposes of this chapter, relevant anomalies are generally discussed for those that are caused by infectious agents (BVDV, Akabane virus) or those that are not known to be inherited but are particularly puzzling when encountered (acardiac twins, moles). Reviews are available [13].

Neoplasia

Congenital tumors and neoplasms are rare in calves and are most often diagnosed as lymphomas, mesotheliomas, embryonic tumors, and hamartomas. They have been reviewed [31].

Anatomy

(See Figure 56.13 for identification of some anatomical terms.) The placenta is a transient metabolic organ derived from the fetal chorion and maternal endometrium to provide nutrition and metabolic exchange between mother and calf. Gestation can be divided into the embryonic stage with organogenesis and the fetal stage with fetal growth. The embryonic stage extends to around day 45; the fetal stage continues until delivery. Together, the chorioallantois and amnion form the extraembryonic fetal membranes.

After fertilization, the zygote undergoes cleavage to form a ball of cells (morula). With further division the morula develops into the blastocyst, which is an inner cell mass (the embryo proper) and a blastocoele (fluid-filled cavity) lined by the trophoblast cell layer. The blastocyst, now about 1.5 mm wide, hatches from the zona pellucida at 9–11 days after ovulation in order to attach to the endometrium of the uterus [38]. By 19 days, the bovine blastocyst trophoblast enlarges as a threadlike emanation/sac along the entire length of the uterine horn [37, 39]. At this time, defective embryos will die and be resorbed or expelled. Also, the CL is developing and producing progesterone [13].

The primitive endoderm from the inner cell mass migrates along the inner aspect of the trophoblast, lining the cavity that will become the yolk sac. The yolk sac provides nourishment to the conceptus and has developed on about day 20, but will quickly regress to an inapparent rudiment by day 30 [39–41]. At this time, prior to uterine attachment, the conceptus derives nourishment from the secretions of the uterine mucosal glands, known as histotrophe. This material is a yellow/white, opaque, thick secretion sometimes mistaken for purulent exudate [13]. Once the fetomaternal placental circulation develops, fetal nutrition is supplied by diffusion of nutrients from the blood across the placentome (hemotrophe) [37].

The primitive mesoderm migrates between the endoderm and trophoblast (now a trophectoderm), fusing with the latter to form the chorion (somatopleure). The chorion then rapidly expands as a transparent sac to fill the uterine lumen [42]. Around this time, dorsomedially migrating folds composed of mesoderm/trophectoderm surround the embryo between days 13 and 16, providing complete envelopment of the embryo in an amniotic cavity (vesicle) by day 35 [43]. The site where these folds meet, the raphe or mesamnion, persists as a broad attachment of the dorsum of the amnion to the chorioallantois in Bovidae. The amnion is therefore composed of an inner trophectoderm and subjacent mesoderm with extensive attachment to the allantois.

Between days 14 and 21, a diverticulum of the hindgut extends from the embryo into the mesoderm of the umbilicus to form the allantois (allantoic vesicle) and, along with

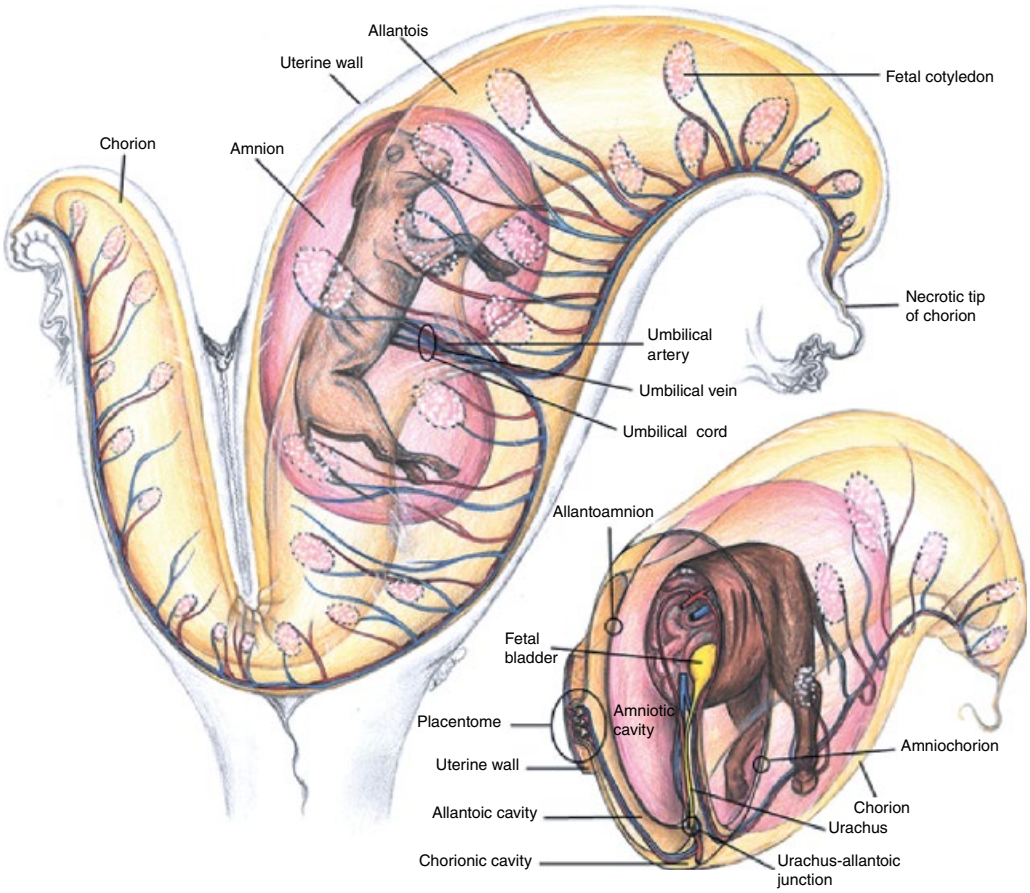

Figure 56.13 Schematic representations of the fetus in-situ during mid-gestation. *Source:* Images redrawn by Kirstin Cook from K. June Mullins and Richard Saacke *Illustrated Anatomy of the Bovine Male and Female Reproductive Tract*. Germinal Dimensions Inc., Cadmus Professional Communications, Science Press Division, Ephrata, PA, 2003.

it, the vasculature supplying the chorion and amnion [25]. The allantois continues to expand within the exocoelom to fill both uterine horns, with widespread apposition and eventual fusion to the chorion (chorioallantois). It is thus T-shaped, with the stem of the T as the allantoic stalk of the umbilicus and the other ends of the T as extensions of the chorioallantois into both uterine horns [37]. The chorioallantois attaches at four weeks' gestation to the uterus, forming irregular villous projections over the uterine caruncles, with eventual development into placentomes.

By days 30–35, three to four fragile attachments (early placentomes) are present in the pregnant horn; by day 40 a maximum of 20 attachments are present in both horns. At day 70, 80–90 placentomes are present, which will number 75–140 by mid gestation. Placentome size may vary widely, from 5 to 15 cm in diameter. The fetal cotyledon has a velvety red surface (Figures 56.14 and 56.15). Both the weight and size of placentomes increase during gestation, particularly in the pregnant horn [44]. Between placentomes, there is minimal chorioallantoic villous proliferation, which may be seen as fine red velvety spots occurring diffusely or in multiple, 5- to 10-mm-wide, regularly spaced foci. Such proliferation may cover non-gravid horns that contain no cotyledons.

Placentomes are usually arranged in two dorsal and two ventral rows along both horns, although an extra row or reduced rows may be seen (see Figure 56.13). They become progressively larger the closer they are to the fetus and the majority of cotyledons are present in the gravid horn. The largest placentomes are closest to the main arteries and become progressively smaller toward the periphery. In some cases all cotyledons are present in the gravid horn with few to no cotyledons on the non-gravid side. The cotyledonary rows may be interrupted by a circular bare area associated with the junction of the horns, near the cervix [45].

As development progresses, there is fusion of membranes to one another in the areas where they come into contact (see Figure 56.13). These attachments may be transient, but fusion of the allantois and chorion occurs around days 50–60 [43]. In early gestation, the amnion is relatively large and compresses the allantois laterally. As the amnion

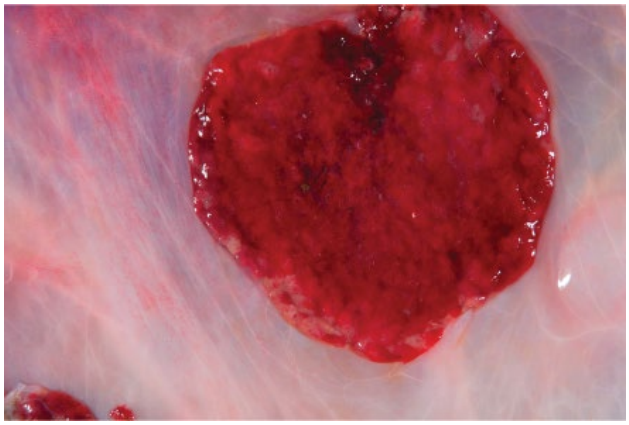

Figure 56.14 Normal placenta. Cotyledon has a red velvety surface. The intercotyledonary spaces are smooth, shiny, opaque, and white.

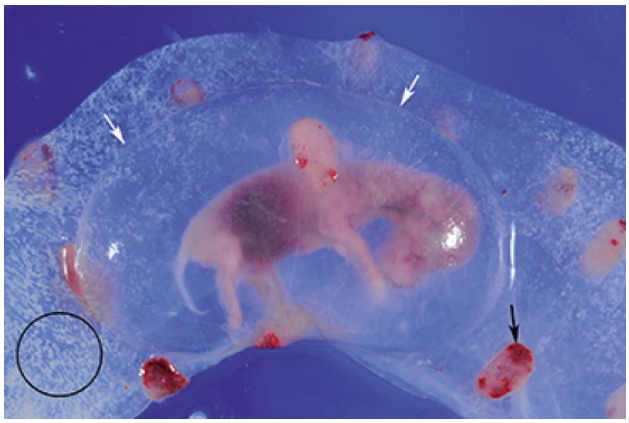

Figure 56.15 Normal fetus and placenta after 2 months' gestation. The calf is suspended in the amnion (white arrows), which is further surrounded by the chorioallantois. Cotyledons are evident (black arrow). White flecking in the intercotyledonary placenta is calcium deposition (circle), an incidental finding (see section "Mineralization").

grows and contacts the chorion, the amniochorion is formed; on the opposite side of the calf where the amnion contacts the allantois, the allantoamnion is formed. With maturity, the allantois increases in volume to almost entirely surround the amnion.Thus the fetus is immediately surrounded by the amniotic fluid, which is produced by transamniotic fluid fluxation, fluid from the fetal lungs, oral glands, and urination. Initially the amniotic fluid is watery, slightly yellow and clear; later in development it becomes viscous, translucent, opaque, and white or yellow. Urine throughout early development is excreted through the urachus and umbilicus to the allantois, but it may also be excreted through the urethra. The contribution of urine to the amniotic fluid after 240 days' gestation in cattle has not been conclusively decided; both increasing and decreasing late-term transurethral urination has been reported [25, 37]. Amniotic fluid in full-term cattle varies from 2 to 8 l, with reported averages at 2.2 or 5–6 l. Allantoic fluid at term ranges from 4 to 15 l, with an average of 9.5–10 l [13, 46].

The umbilicus is relatively short, being about one-quarter the length of the fetus, or about 30–40 cm [13]. As such, rupture of the cord occurs during parturition when the fetal pelvis passes through the dam's pelvis [47]. The umbilicus is exclusively within the amnion and is composed of two arteries, two veins (which merge into one prior to entering the fetus), the allantoic stalk, and rarely yolk sac remnants. The umbilical arteries and veins are sheathed in smooth muscle, which contracts during parturition due to stretching, stopping blood flow after birth [37]. The umbilical arteries arise from the caudal aortae, running cranioventrally along the urachus, exiting with the allantoic stalk to supply the chorioallantois. In necropsied neonates, it is common to see swollen, purple, thrombosed umbilical arteries at the level of the urachus; this is a normal inflammatory reaction to the severing of fetomaternal circulation (Figure 56.16). Thrombosis of umbilical arteries will be absent in stillborn calves [48].

By day 45, fetal organogenesis is complete and the fetal growth stage then begins. Average weights, crown–rump lengths, and external characteristics achieved during growth are summarized in Table 56.3.

Approach to the Problem

Fetal loss in a herd may be divided into four epidemiologic presentations, which may simplify and better direct investigations. These four include (i) baseline losses, (ii) endemic losses that exceed baseline and occur consistently and

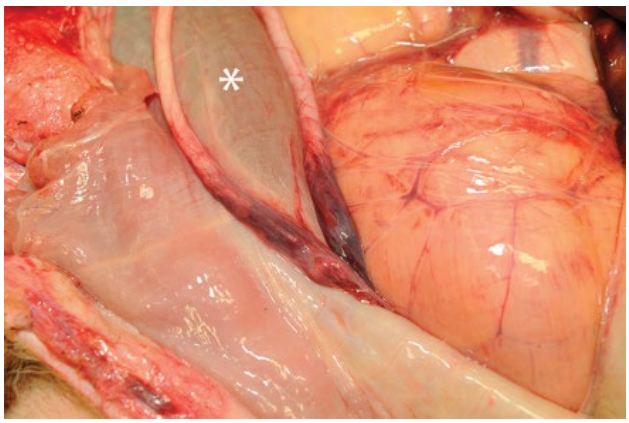

Figure 56.16 Calf with umbilical artery thrombosis. Bilaterally the arteries alongside the urinary bladder (asterisk) are focally swollen and red due to the tearing and thrombosis associated with parturition.

Table 56.3 Gestational age estimates of bovine fetuses.

Age (months)	Relative size	Crown–rump length (cm)	Weight	External characteristics
2	Mouse	6–8	8–30 g	Claw buds and scrotum present
3	Rat	13–17	200–400 g	Hair on lips, chin, and eyelids
4	Small cat	22–32	1–2 kg	Fine hair on eyebrows, claws developed
5	Large cat	30–45	3–4 kg	Hair on eyebrows and lips, testes in scrotum, teats developing
6	Small dog, beagle	40–60	5–10 kg	Hair on inside of ear and around horn pits, tip of tail, and muzzle
7	Dog	55–75	8–18 kg	Hair of metatarsal, metacarpal, and phalangeal region of extremities and beginning on back, long hair on tail tip
8	Large dog	60–85	15–25 kg	Fine short hair all over body, incisor teeth not erupted

chronically, (iii) epidemic losses characterized by high losses in a specific time frame, and (iv) fetal losses that are confused with conception failure or neonatal losses [15].

Baseline losses, as mentioned in the Introduction, are considered largely unavoidable and may be due to illness in the dam, lethal genetic make-up of the fetus, trauma, or physiological abnormalities. It is important to monitor such losses from a management standpoint as it will aid the discovery of endemic problems. While it is prudent to thoroughly investigate all abortions, it is also costly. However, with continued monitoring and testing, the manager and veterinarian have a clearer picture of herd health and are better prepared to identify endemic problems. Furthermore, upcoming epidemics may be identified at a stage where losses can be minimized [15].

Endemic abortions significantly affect herd productivity due to chronic excessive losses. It may be difficult to realize that there is a problem, but equally difficult to identify the source of the losses. Accurate record-keeping and routine pregnancy diagnosis are therefore vitally important in order to recognize these issues [15]. Table 56.1 lists many disease-causing agents that are associated with endemic losses in cattle. BVDV, *N. caninum*, and *Leptospira* spp. are of particular importance.

Epidemic abortion storms may be due to many of the same agents that cause endemic losses. BHV-1, *B. abortus*, and *Leptospira* spp. are well-known causes [23]. Herd health status, vaccination history, pathogen virulence, access to toxic agents, and clustering of pregnancies all have relevance in determining the likelihood of epidemic loss. Herds with tight pregnancy patterns are more susceptible to this type of outbreak. Investigations should make note of the particular time/season and area where the losses are occurring as this will aid in determining differentials [15].

Finally, managers should be encouraged to document and report all abortions, stillbirths, premature births, dysmature calves, and abnormal calves.

History/Background Investigation

The importance of a thorough history cannot be overstated; essential information is found in a systematic query of farm details. Abortion is both an individual and potential herd problem, and lack of investigation in both will severely hamper efforts to alleviate unacceptably high losses. Differentiating stillbirths from abortions will help clarify if more than one problem is present [48]. It is important to keep in mind that more than one agent may be involved in abortion. Similarly, although more than one infectious agent may be present in an aborted fetus, only one may be the cause of death. Organisms regarded as low virulence may be the cause of abortion, but are also commonly present as contaminants [20].

Sporadic abortions may be a manifestation of an ongoing herd problem or they may be the beginning of an outbreak; in either case investigation is warranted. Standard forms are used to reliably collect important cow and herd information (see Appendix); systematic evaluation of management practices will help direct investigations. Pertinent questions are listed below [49]. These questions and other information are incorporated into the investigation form provided. An expanded questionnaire has been published [50].

Aborted Calf

- When was it due? Is this a stillbirth (after day 260) or abortion?

- Was it born alive?
- Are fetuses mostly male or female?

Aborting Cow

- Breed, age, lactation/parity number, source, dam/sire, bred naturally or artificial insemination (AI), conception date/last service, date of last normal parturition, previous abortions, and any work-up done.
- Vaccination history, vaccine brand/lot number, vaccine handling, and storage.
- Deworming history.
- Any clinical signs?
- Parturient period – cow movement, calving location, observation, assistance rendered?

Herd

- Number of animals, number that are immature, number purchased in last year, health problems/body condition.
- Herd abortion history (sporadic/recurrent/recent, how many in last week/month/year, which trimester affected, affects older/younger/all cows, any particular time of year), problems with term calves (congenital defects).
- Are postpartum examinations performed routinely?

Nutrition

- Feeding regime, types of forage, concentrates, minerals, selenium.
- Any changes in management, housing, pasture?
- What is the quality of the forage?
- Water source/quality?

Environment

- Access of herd to other cattle, animals, predators.
- Nature and quality of pasture.
- Any toxic plants on pasture?
- Nutrient deficiencies in area pasture?

Examination of the Cow

In some cases, the health condition of the cow has direct implications as to the cause of abortion (plane of nutrition, respiratory/intestinal disease, *Anaplasma* sp., *Babesia* sp. infection). Any vaginal discharge or cervical mucus should be collected and sent to the diagnostic laboratory for microbiological analysis. Blood samples for serology should be taken from the dam as well as unaffected cows and those that have recently aborted. Serum should be acquired two to three weeks later in order to provide paired samples. Collecting serum from ten other herdmates (or 10% of the herd) will make serological assessment more meaningful [8]. Whole blood in ethylenediaminetetraacetic acid (EDTA) is useful for blood smear and serum chemistry analysis of the dam. Gloves are to be worn during all examinations, as zoonotic agents may be present. Samples for blood culture should be taken as well.

Examination of Tissues

A necropsy is an examination with a definite purpose in order to yield the maximum amount of information. As such, it is vitally important to be systematic so that a full complement of tissues is taken during each examination. Optimally one should send the entire fetus and membranes to a diagnostic laboratory for evaluation. It is of primary importance to send fetal membranes as these may be diagnostic. If this is not convenient, then a standard approach should be adopted, as described here.

Examinations should be directed toward suspected etiologies, but keep in mind that more than one pathogen may be present. Typical findings in aborted calves that died in utero include edematous red tissues that lack normal tinctorial distinction, clear red fluids in body cavities, pale soft livers, and friable autolytic kidneys. Digital photographs are an excellent way to document lesions and may be useful in communications with diagnostic laboratories.

Examination of the Fetus

It is important to verify the approximate time of death, which can be done based on gross findings. In antepartum fetal death, tissues are autolyzed or mummified and include the findings described above. Partum death is characterized by signs of life (localized head or limb edema, partial lung aeration, limb/rib fractures, subcutaneous shoulder hemorrhage, liver fractures with hemorrhage) in addition to appropriate fetal maturation/formation. Neonatal deaths are characterized by aeration of the lungs, umbilical artery thrombosis (swollen purple/red nodules along the arteries that run lateral to the urinary bladder), loss of the eponychium (soft fetal hoof keratin), and milk in the stomachs [51].

The method of necropsy for aborted fetuses is basically the same as for any animal. The degree of autolysis and weight of the fetus and placenta are noted. Even if severely autolyzed, fetal tissues may be of use for polymerase chain reaction (PCR) screening for pathogens. Estimation of gestational age can be accomplished by the following formula: $x = 2.5(y+21)$, where x is gestation age in days and y is crown–rump length in centimeters [9]. The crown is a point midway between the orbits

on a line traversing the frontal eminence; the rump is the base of the tail or first coccygeal vertebra [52]. In embryos, the greatest total length may be used instead of crown to rump. For stillbirths, fetal weight is useful in the diagnosis of dystocia due to fetal–maternal disproportion. Also, comparison of calf weight to thyroid weight in cases of suspect hyperthyroidism (goiter) may be useful. Reports of normal thyroid weight in calves vary from 6.5 to over 18 g [53]. Further discussion on this subject can be found in the section "Non-Infectious Causes of Abortion."

Most aborted calves have no gross lesions. Small white/tan foci in the lungs, liver, and kidneys may be present and indicate necrosis or inflammation. The presence of fibrin on organ surfaces is helpful for confirming inflammation. Meconium on the perineum or in airways/stomach indicates fetal stress and anoxia, typically associated with placentitis or dystocia (Figures 56.17). Hemorrhage and fractures of shoulder and hip joints are most often seen as a result of dystocia.

Slightly raised, white skin plaques that are firmly adherent, particularly around the eyes and face, indicate fungal infection. Sometimes calves will have scattered white mineral on the hair, which is easily removed; this finding is not significant but must be distinguished from adherent fungal plaques (Figure 56.18). In abortion/stillbirth, the lungs are uninflated; they are uniformly dull red/plum colored, heavy, and sink in formalin (see Figure 56.4). In cases of dystocia where fetuses may have taken a partial breath, there may be incompletely inflated lungs; assess lung aeration in sections of cranial and caudal lobes by degree of flotation in fixative/fluid. Make note of any milk in the stomachs, as this indicates colostrum consumption, which will interfere with bacteriological and serological findings [9].

Necropsy Method

It is best to have an abortion kit prepared beforehand; Table 56.4 enumerates materials to have in a kit [54]. Zoonotic pathogens may be present, so always wear gloves, protective clothing, and eye/face protection, and use careful technique when examining dams and fetal tissues. In addition, materials used in standard field necropsies are needed: clean water, bucket, brush, scale, and disinfectant. Make sure to disinfect contaminated sites and equipment. If there are questions as to which samples are best to take, contact the diagnostic laboratory to confirm which samples will be

Table 56.4 Contents for abortion kit.

Knife (15-cm boning) and steel
Nitrile/rubber gloves
String and ruler for measurements
Shears (small tree limb variety works well)
Culturette swabs
Overalls, washable apron, rubber boots
Alcohol swabs, syringes, needles to draw blood/fluids
Scalpel blades and handle
Lighter
Red-top glass vacutainer tubes, purple-top EDTA tubes
Hatchet/cleaver and hacksaw
Sterile rat-tooth forceps and scissors
Styrofoam box/cooler for temporary specimen storage
Sterile containers/whirltop bags/ziplock bags, permanent pen
Fixative (10% neutral buffered formalin), at least 500 ml in plastic sealable container/jar
Bucket, brush, disinfectant

submitted for advice. Taking photographs of lesions is a relatively simple and excellent practice which will aid diagnosis.

1) Measure crown–rump length along the vertebral ridge (see section "Examination of the Fetus") and weigh fetus and placenta separately. Examine skin for exudate and abnormalities, around the eyes and face in particular for signs of fungal infection. If skin lesions are present, perform scrapes for fungal culture/wet mount examination.
2) Note hair development/whiskers and muscle tone.
3) Examine the body for congenital abnormalities, umbilical hernias, cleft palates, facial anomalies, etc.
4) Examine for hemorrhages, fractures, hypopyon/hyphema, and lingual edema.
5) Wash the surface of the fetus with water to remove gross contaminants.
6) With the left side down, reflect right legs with a knife and continue the skin incision from cranial to caudal, reflecting the skin to the dorsal and ventral midlines. Collect any pooled blood between incised tissue planes with a syringe if available (for serology).
7) Open abdomen at the highest point along the caudal aspect of the ribs, being careful not to contaminate any peritoneal fluid or tissues. Aspirate any abdominal fluids with a sterile syringe, place in sterile tube, label, and refrigerate. Such fluids may be used as fetal sera. Continue the cut along the caudal aspect of the ribs, along the lumbar area, and cranial to the pelvis to expose the abdominal viscera. Note any lesions, and volume, character, and color of fluids.
8) Incise the diaphragm (noting if negative pressure is present) and cut the ribs at the costal angles and along the sternum; remove the chest wall. Aspirate any thoracic fluids with a sterile syringe, place in sterile tube, label, and refrigerate. Such fluids may be used as fetal sera. Note any lesions, and volume, character, and color of fluids. Pleural surface of the removed chest wall may be used as a makeshift cutting board/sterile field for dissection.
9) Aspirate fluids from the unopened abomasum with sterile syringe, place in sterile tube, label, and refrigerate. Note the character of the abomasal fluid. Take samples of any other suspicious fluids at this time.
10) Examine the body cavities and organs in situ, making note of fibrin, hemorrhages, or abnormally situated organs.
11) Remove thoracic viscera from tongue to lung (pluck). Examine the mouth; one may split the mandibular symphysis with a knife. Incise the esophagus along the entire length; incise the dorsal tracheal membrane from the larynx to the bronchi. Examine the chest for any fractures. Slice multiple lung lobes, examining the cut sections for changes in the lobules and airways. Examine the thyroid gland. Collect tissues, especially lesions (see numbers 18 and 19).
12) Examine the heart, making sure to inspect all four main valves and four chambers. Look for ventricular septal defects or other anomalies. Heart blood may be used for serology testing.
13) Collect visceral organs, examining gastrointestinal tract last. Identify the kidneys, ureters, and urinary bladder. Remove the gastrointestinal tract by incising the root of the mesentery and continuing the cut to the diaphragm along the dorsum, avoiding the urinary tract. The tract may then be lifted out of the abdomen, leaving the colon attached and uncut. Collect tissues, especially lesions (see numbers 16–18).
14) Remove the adrenal glands.
15) Remove the urinary tract, making multiple slices through the kidneys. Identify genital organs.
16) Serially section the liver and spleen.
17) Open the forestomachs and abomasum and examine for content. Continue into the intestine, making several incisions along each major section (duodenum, jejunum, ileum, cecum, colon). Examine content and the mucosa.
18) Collect organs (kidney, liver, lung, spleen, thymus, adrenal) in sterile bags (placenta kept in separate bag), and refrigerate.
19) *Collect in formalin for histopathology: lung, liver, kidney, spleen, heart, adrenal glands, skeletal muscle (three to four sections including tongue, diaphragm), thyroid, ileum, skin (including eyelid), thymus, and mesenteric lymph node in 5-mm sections.*
20) Remove the head from the body at the atlanto-occipital joint. Harvest the entire brain (can be done at the clinic), even if severely autolyzed, and place whole in formalin. If the fetus is severely autolyzed, take a swab culture of the brain tissue prior to fixation. The skull is relatively soft and can be easily opened with a saw, making two cuts along the inner aspects of the occipital condyles, cranially (and somewhat laterally along the curve of the calvaria) toward the inner aspects of the orbital rims. Make a third incision across the orbital ridge, connecting the first two cuts. Pry the cranium from the skull in one piece. Flip the head over, placing the dorsum of the brain in the palm of your hand and, with a scalpel, gently cut the nervous attachments of the base of the brain, allowing the brain to fall into your hand.
21) Collect ocular fluid with a needle/syringe for nitrate/nitrite levels if needed, and freeze. Collect eyelid and ear notch for histopathology.

22) Open several joints, looking for purulent exudate, fibrin, and hemorrhage.
23) Examine fetal membranes for exudates, lesions, and abnormalities (see next section for detailed instruction). Remove dirt/debris from the membranes prior to sampling.
24) Place two to three sections with cotyledons in a sterile bag, and refrigerate; make impression smears of any lesions.
25) Harvest the placenta for histopathology (at least three to four sections including cotyledons and intercotyledonary areas).
26) Collect amniotic fluid if available, refrigerate, and culture.
27) Collect dam blood in red-top tube for serology (herdmate blood samples may be collected as well; ten cows or 10% of the herd has been suggested). Blood in EDTA can be used for PCR.

Examination of the Membranes

Collect as much of the membranes as possible and carefully examine the chorioallantois and amnion, as lesions may be subtle, focal, and easily overlooked. In many cases, little if any placenta can be examined. It is important to try to verify if all membranes have been expelled. Because of the attachments of the amnion to the chorion, as well as the short umbilicus, calves will rupture and escape both the amnion and chorioallantois at delivery. Typically, membranes are found with cotyledons on the outside.

The fetal membranes may be laid out lengthwise to identify the umbilicus which is continuous with the internal aspect of the amnion. Examination of amniotic membranes and fluids is best done at this time. The umbilicus is composed of four muscular turgid vessels (arteries and veins) loosely enmeshed in slippery membranes. The gravid horn is easily identified as the larger half of the tissue and should have larger placentomes. Avascular chorionic tips (necrotic tips) should be identified and inspected carefully, as true placental lesions may be present in the gravid horn near the tip [19]. The umbilicus contains the umbilical arteries and veins, which form a useful longitudinal axis by which to orient the placenta. From there the internal aspect of the allantoic cavity may be examined, with attention to the nature of any fluids present, thickness and color of membranes, and peculiar odors. Allantoic calculi are typically found at this time.

By placing the umbilical vessels at one side of the tissue, a lengthwise incision along the opposite side of the placenta will allow the placenta to be opened and laid flat, with the umbilical vessels forming the central axis (Figure 56.19). The horns are unequal in size, the gravid horn being much larger. In this way, vessels and cotyledon rows (normally four) may be examined thoroughly. Fresh cotyledons have a red velvety texture with a mildly irregular surface. The size variation, shape, color, consistency, and degree of cotyledon mottling should be noted, as well as degree of autolysis. Occasional small tags of attached caruncular tissue may be seen. Cotyledon margins are typically sharply defined, and the intercotyledonary chorion is white, translucent, and smooth. Adventitial placentation is a frequent finding that appears as small cotyledons or villous tuft formations adjacent to the placentomes that may cover the entire placenta. Abnormalities in the placenta are described in the following sections.

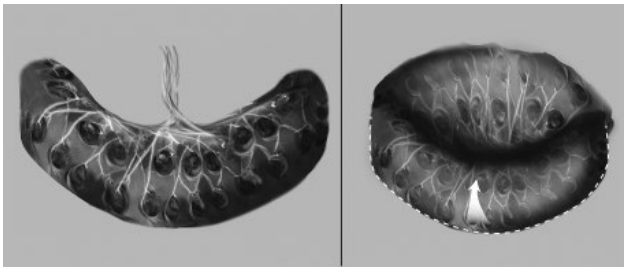

Figure 56.19 Placental membrane examination method. (*Left*) The long axis of the chorioallantois is arranged perpendicular to the umbilical stalk. (*Right*) An incision is made along the dotted white line, allowing the chorioallantoic sac to be opened (direction of white arrow) and laid flat. In this way, the vascular axis, cotyledons, and membranes can be thoroughly examined. *Source:* Courtesy of Rachael Fishman.

Sample Collection

A complete set of tissues should be collected in every case [55]. Depending on the etiologic agent (particularly bacterial), different organs may have significantly different recovery rates; lung, liver, and abomasal fluid should all be submitted for culture/examination to maximize success [56]. Biological specimens must be properly collected, prepared, stored, and transported, otherwise diagnostic accuracy will suffer. It is important to maintain aseptic technique despite apparent tissue contamination; this is necessary to maximize chances for diagnosis as well as for prevention of zoonotic infection. Microbiology samples should be kept chilled and sent to the diagnostic laboratory as soon as possible in a Styrofoam cooler with ice packs for overnight courier shipping. If fresh tissue samples cannot be sent within two to three days, freezing at −70 °C and delivering on dry ice is ideal [55]. If necessary, specimens can be placed at −20 °C until dry ice can be obtained. Conventionally frozen tissues (−20 °C) are often acceptable for PCR testing of many pathogens. Abomasal and thoracic/pericardial fluid samples should be sent in sterile

tubes without additives. Frozen fetal liver, lung, and kidney (2.5–5 cm chunks, −20 °C) should be kept for testing in case nutritional or toxicologic disease is suspected after initial examinations [49].

Chilled or frozen tissues should be placed in sealed bags (whirlpack-type bags often leak), preferably with a secondary bag around them. Fluids shipped in glass tubes require ample padding in tight-fitting containers. Absorbent materials should also be included in the package to prevent soaking of the exterior, which complicates and may delay the shipping process. Disposable diapers are an effective option [49]. Contact your diagnostic laboratory for proper packaging and shipping requirements for abortion samples, as they may contain infectious and/or zoonotic agents.

Viruses may have very specific tissue tropisms and therefore require certain tissues for isolation. Specimens need to be collected as soon as possible as autolysis can be very damaging to virions. Virology samples for abortions are typically pooled, although placing tissues in separate bags is ideal. Placental tissues should be bagged separately from fetal tissues. Do not pool samples from multiple abortions. Tissues should be kept cool but not frozen until arrival at the diagnostic laboratory. If tissues will not be immediately used, freezing at −70 °C is better than at −20 °C [49]. If live viruses are sent packed in dry ice for virus isolation, be sure to place samples in airtight containers as the gaseous phase of dry ice is carbon dioxide, which can lower sample pH and inactivate some viruses. Certain laboratories may have preferences for virological samples, particularly if a certain pathogen is highly suspected.

Bacteriology tissue samples should be 2.5–5 cm per side in order that surfaces may be heat seared for proper culture. External and gut samples should not be bagged with internal organs. If samples are contaminated, sending a swab culture (Culturette™) in addition to tissues may be helpful. For severely decomposed specimens, aseptically collected brain tissue may be useful for isolating pertinent organisms [26].

Fungal sampling should at least include affected cotyledons; however, it is best to send the entire placenta. Fetal infection is inconsistent, but lung, skin, and abomasal contents are useful.

For histopathology, sections approximately 5 mm wide in 10% neutral buffered formalin are best. The brain, however, should be immersed whole in formalin, without dissection. If the brain is liquefied, fix separately. For small lesions, several foci should be submitted. For large lesions, a few sections including the margin with normal and abnormal tissues should be collected. Identify clearly any lesions seen in order to alert the diagnostician.

Tissue smears from abomasal content or placenta may assist diagnosis; wet mount examination and preservation of air-dried smears can prove valuable for detecting bacteria, fungi, and protozoa.

At least 10 volumes of formalin per volume of tissue are needed for proper fixation. Tissues should be allowed to fix for at least 24 hours, preferably 3 days. The brain in particular requires ample fixative over 3–4 days. Addition of 1 part ethanol to 9 parts formalin (10% ethanol, 90% formalin) may be used to prevent freezing in cold climates [57]. If formalin is not available, 70% ethanol may be used. Tissues may be sent in formalin, otherwise fix tissues for 24 hours, drain, and send in bags with formalin-moistened gauze. Be sure to double-bag samples as containers may rupture in transit. Contact your diagnostic laboratory for instructions.

For blood samples, blood from the dam as well as the fetus is ideal. Fresh blood smears are particularly useful if anaplasmosis is suspected. Blood in EDTA is preferred for PCR testing. For serum samples, draw 8–10 ml of serum into tubes without additives, allow to sit for one to two hours until the clot begins to retract, then place in the refrigerator overnight. Centrifuge at 1000×*g* for 10 minutes and decant serum; send in a separate sterile tube. One may freeze the serum (do not freeze whole blood) until needed.

Table 56.5 lists typical sample storage conditions.

Table 56.5 Fresh specimens collected for fetal and neonatal diagnostics.

Test	Storage	Specimens	Notes
Bacteriology/mycology (culture, PCR)	Keep refrigerated *not* frozen unless PCR only	Stomach contents, pericardial fluid, liver, lung, brain, placenta	Collect stomach contents or pericardial fluid in a syringe with a large-gauge needle Package each specimen in separate containers. Placental culture results are often contaminated – evaluate critically
Virology (virus isolation, fluorescent antibody test, PCR)	May be frozen (at −70 °C if necessary)	Lung, liver, kidney, heart, blood, placenta	Package each specimen in separate containers
Nutrition, toxicology	May be frozen	Liver, kidney, ocular fluid	
Fetal/maternal fluids	Keep refrigerated	Dam serum/fetal fluids	Paired (acute and convalescent) if possible

Diagnosis

Arrival at an accurate diagnosis is the result of the cooperative efforts of the attending veterinarian and the diagnosticians at the laboratory. Even with the submission of proper samples, the establishment of a definitive diagnosis is problematic. Expulsion of a dead fetus often occurs hours to days after death; the resulting autolysis makes the difficult task of fetal lesion identification even more so. Fetal membranes, which may have the only significant lesions to be found, are often not present for examination. Also, in many cases examined tissues are severely contaminated, whether due to incomplete expulsion or from the environment. Finally, diagnostic laboratories run routine tests to identify well-known causes of abortion in a timely manner. As such, investigation of unusual or poorly understood etiologies is beyond their purview [20].

Keep in mind that the majority of pregnancy wastage occurs at earlier stages of development, when expelled tissues are least likely to be noticed. Early gestation abortions are often detected only weeks after the fact, making investigation and diagnosis all but impossible. The majority of tissues examined by clinicians and diagnostic laboratories are of large fetuses, which may bias the interpretation of a herd problem where losses occur at various gestation stages. Late-stage abortions may be the result of injury many weeks prior to expulsion; they may not exhibit important or telling changes that could be present in earlier aborted fetuses, preventing accurate diagnosis. Worse yet, in an effort to find a cause, other coincident agents may be erroneously blamed, depending on what is found in the submitted fetus [8]. A positive result for a pathogen using only one test modality may lead to error; serology, tissue smears, PCR, and histopathology should all be utilized in order to reach a confirmatory diagnosis [58]. PCR is an optimal first-line approach.

It is important to realize that more than one disease or management problem may be at work in a herd, complicating the resolution of endemic problems. Multiple pathogens may be present; some may not be obvious, while those that are readily evident may not be directly contributing to abortion. In these cases, determining the actual cause of abortion is challenging.

Serology results must be cautiously interpreted. A positive sample from a cow indicates exposure, which may or may not be relevant in light of vaccination status. Twofold to fourfold increases in titer over two weeks may be significant, particularly with herdmate samples for comparison [8]. However, it is likely that dam serum antibody levels have reached their peak by the time abortion occurs, so it is not unexpected to see a lack of rise in titer two to three weeks later [15]. Serology may be particularly useful in diagnosing BVDV, leptospirosis, anaplasmosis, and abortions where the agent is difficult to demonstrate by other methods [20]. The presence of a specific antibody in fetal serum does not mean that particular agent is the cause of abortion; BVDV and *N. caninum* are two examples. Serology results must be carefully weighed with microbiology, histopathology, molecular testing, and herd history data. Table 56.6 lists common diagnostic tests for specific pathogens.

Table 56.6 Summary of diagnostic tests for bovine abortion.

Agent	Preferred fetal tissues	Preferred fetal diagnostic test	Additional diagnostics
Bovine herpesvirus 1	Kidney, adrenal, liver, lung	FA (frozen tissue), IHC, VI	IHC of placenta if placentitis is present
Bovine viral diarrhea virus	Lung, heart, kidney, placenta, skin	FA, IHC, VI, PCR	Antigen-capture ELISA, RT-PCR
Bluetongue virus	Brain, spleen	PCR, VI	Fetal serology
Bunyaviruses (including Schmallenberg)	Brain	PCR	Fetal/precolostral serology; congenital abnormalities
Brucella	Placenta, lung, abomasal contents, uterine fluid	Bacterial culture	Culture of milk from dam; dam and fetal serology
Listeria	Placenta, lung, brain, abomasal contents	Bacterial culture, IHC	Gram's stain of freshly aborted tissues, PCR
Salmonella	Placenta, liver, lung, abomasal contents	Bacterial culture	

(*Continued*)

Table 56.6 (Continued)

Agent	Preferred fetal tissues	Preferred fetal diagnostic test	Additional diagnostics
Yersinia pseudotuberculosis	Placenta, liver, lung, abomasal contents, intestines	Bacterial culture	
Leptospira	Kidney, placenta	FA (fetal kidney smear), IHC, PCR	PCR of fetal urine; fetal and maternal serology
Ureaplasma	Lung, abomasal contents, placenta	*Ureaplasma* culture, PCR	
Campylobacter	Lung, abomasal contents, placenta	*Campylobacter* culture, IHC, darkfield microscopy	Silver staining of histology tissues, PCR
Epizootic bovine abortion	Thymus, spleen, lymph nodes	Modified Steiner's silver stain of histology slides, IHC	Elevated fetal serum immunoglobulins
Chlamydia	Placenta	PCR, IHC, FA	Macchiavello's, Gimenez, or modified acid-fast stains of histology slides
Coxiella burnetii	Placenta	PCR, IHC	Macchiavello's, Gimenez, or modified acid-fast stains of histology slides
Fungi	Placenta, abomasal contents, lung, skin lesions	Fungal culture, H&E	Direct identification by KOH wet mounts of skin or placenta or GMS and PAS stained histology slides
Tritrichomonas	Placenta, abomasal contents, lung	*Tritrichomonas* culture, Bodian's silver stain of histology slides, IHC, H&E	Darkfield microscopy of abomasal contents, PCR. Examination of maternal uterine discharge
Neospora	Brain, lung, kidney, skeletal muscle, liver, placenta	IHC, PCR	Fetal serology (IFA, microagglutination titer, ELISA). Maternal serology
Sarcocystis	Brain, lung, liver, kidney, skeletal muscle, placenta	IHC	Genomic probe; ribosomal RNA assays
Nutrient deficiency	Liver, heart, thyroid	Thyroid iodine assay Liver mineral (selenium)	Maternal blood-selenium, other
Congenital defects	Fetal hair	Fetal muscle	Teratogenic virus testing
Toxicosis	Liver, kidney, fat, urine, brain Abomasal/amniotic fluid, thoracic fluid	Gas chromatography mass spectrometry	

Source: Based on [28].
ELISA, Enzyme-linked immunosorbent assay; FA, fluorescent antibody test; GMS, Gomori–methenamine silver stain; H&E, standard histopathology stains; IFA, indirect fluorescence test; IHC, immunohistochemistry (usually formalin-fixed tissues); KOH, potassium hydroxide test; PAS, periodic acid–Schiff stain; PCR, polymerase chain reaction; RT-PCR, reverse transcription PCR; VI, virus isolation.

Specific Manifestations of the Conceptus Relating to Pathology

Mummification

Mummification is an uncommon event in which there is often no certain cause. It is the process of progressive dehydration and compaction of a sufficiently mature dead fetus in utero. In order for this to occur, bacterial infection (tissue lytic organisms) of the dead fetus must be absent, no air can be present in the uterus (closed cervix), and a functional CL must be present. The time course, which may take months, depends on the size of the fetus. This process generally occurs in the second and third trimesters, when fetal bones are sufficiently developed to resist resorption. As fetal fluids are absorbed, tissues become compressed, shrunken, red/brown, and sticky to dry, without odor. As the membranes atrophy and the uterus involutes, hemorrhage occurs between the uterus and fetal tissues, imparting the red "hematic" sticky material onto the tissues (Figures 56.20 and 56.21). This hematic type of mummification apparently is distinctly bovine [13, 36].

Figure 56.20 Opened uterus with mummified fetuses. Friable, non-odorous, hematic material obscures the fetuses. *Source:* Photo courtesy of J. Edwards.

Figure 56.21 Fetal mummy. The carcass is shrunken and contracted with diffuse red/brown discoloration, dry tissues, and sunken eyes. Tissues lack odor and emphysema. *Source:* Photo courtesy of J. Edwards.

The uterus tightly wraps around the fetal materials, compacting the mummy. The longer this proceeds, the drier and firmer the fetus becomes, remaining in utero for as long as two years. In the cow, mummification is most common at the end of the first and beginning of the second trimesters [60]. Various infectious and non-infectious etiologies have been implicated in their occurrence (BVDV, tritrichomoniasis), but the cause is usually unknown [12, 19]. Mummification may be associated with certain breeds (Guernsey, Jersey) or certain breeding/genetic combinations [13]. In cases of uncomplicated mummification, prognosis is good for return to fertility [36].

Maceration

Maceration describes the effect of dead fetal tissue softening due to fluid soaking and saprophytic digestion in utero

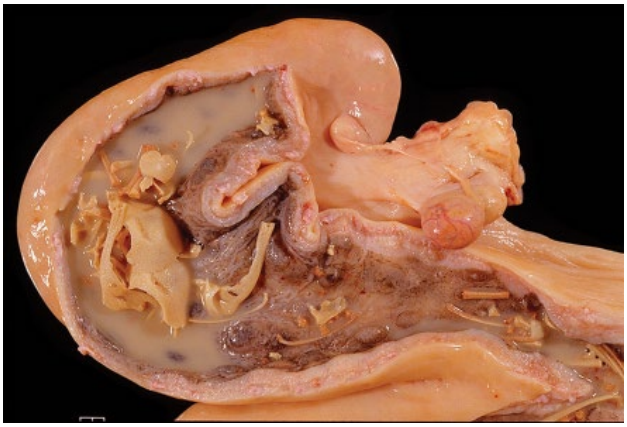

Figure 56.22 Opened uterine horn with a macerated fetus. Bone fragments in purulent fluid remain. The ovary has a retained corpus luteum. *Source:* Photo courtesy of J. Cooley.

(Figure 56.22). In cattle this is due to exposure of the retained fetal tissues to bacteria. This occurs when there is failure of fetal expulsion after death with retention of the carcass partially or entirely within the uterus. The bacteria may be those that caused fetal death or those that arrive through an open cervix [12]. Maceration is distinct from autolysis, which is digestion of tissues by endogenous enzymes and requires no bacteria. When bacteria gain access to a dead fetus in the reproductive tract, they are able to multiply rapidly at body temperature and are relatively insulated from the dam's immune system. Bacterial digestion of tissues and gas formation (emphysema) ensues. The uterus surrounds the fetus and there is an intense metritis.

In early gestation, macerated embryos are resorbed or expelled with little exudate. After the first trimester, the fetal skeleton is sufficiently formed to resist disintegration, and skeletal fragments may be retained. Bone fragments may become embedded in the uterus or may perforate the wall and remain free in the abdomen [60]. CL regression and cervical dilation may be found on palpation. Cows may display vague signs of illness due to a persistent and severe uterine infection [19].

Emphysema usually occurs when incomplete abortion or near-term dystocia allow putrefactive vaginal flora to invade the dead fetus. Incomplete abortion occurs when there is partial cervical dilation and insufficient expulsion of the fetus, which is partly or totally retained in the uterus [19].

Embryonic Death with Persistent Membranes (Moles)

Moles are not neoplasms, but are masses of hyperplastic or edematous immature placental tissue [61]. Once fertilization occurs, the blastocyst divides into embryonic and extraembryonic tissues; the latter becomes the trophoblast, which is

the forerunner of the placenta. Later in development, endodermal and mesodermal tissues from the embryo migrate along the inner aspect of the trophoblast to form the chorion, which is the outermost fetal tissue that is in contact with the uterus. Thus, embryonic mesenchyme contributes to the stroma of the placenta. This is an important point, for in order to form placental tissues, embryonic tissue must have been present [61, 62]. Thus it is not surprising to find fetal tissues in moles, even though it is rare.

Hydatidiform moles are defined in humans by macroscopic features and are termed (complete and partial) based on the degree of fluid accumulation. They are named hydatidiform for their abundant, bulbous, botryoid to polypoid villi, which are edematous with watery fluid-filled cisterns. Villous edema and trophoblastic hyperplasia are constant and characteristic features [61, 63]. The hydropic swelling seen in moles may also occur in unrelated gestational disorders, such as maldevelopment of the placental vasculature or edema following early fetal death [64].

In humans, complete moles are derived from an anucleate egg fertilized by one or two sperm, leading to a paternally derived (androgenetic) tissue, most often 46XX. Conversely, partial moles arise from the fertilization of an ovum by two sperm, generating a triploid conceptus [61]. Such anomalies lead to fetal loss, but membranes survive and proliferate (mole).

Moles in cattle are rare and have been reported as hydatidiform or cystic [19, 65–67]. Bovine placental masses similar to hydatidiform moles in humans have been reported to be between 40 and 60 cm wide and weighing up to 48 kg [66]. The masses are smooth, soft/firm, ovoid/irregular, and pale gray/tan with multiple pendulous nodules that appear fatty. They are often associated with twinning [66, 67]. Microscopic descriptions resemble descriptions in the human literature [67, 68]. Recently, a mole of androgenetic origin (60XX) was reported in association with a stillborn male calf [66].

More commonly, moles in cattle have been termed "cystic placental moles." They are thought to arise after fetal death, with or without resorption, where membranes persist as an empty cystic structure of a size similar to normal membranes at three to four months' gestation [19, 65]. The cyst is filled with clear gel-fluid and stroma. In some cases, the tissues become infected, leading to pyometra and expulsion [19].

Acardiac Twins

Acardiac twins (acardiac monster, amorphous globosus, holoacardius acephalus, holoacardius amorphous) are the most bizarre and severely malformed fetuses imaginable. They represent a twin whose development is completely disturbed and, unlike the name, may indeed have some cardiac tissue remnants. Despite this, a functional heart is absent. They develop in association with a twin that has sufficiently normal cardiovascular function to support the monster through placental vascular anastomoses [69]. Various theories as to their development have been proposed [70]. In cattle, such twins often manifest as globoid, hair-covered masses of soft tissue attached to an umbilicus (Figure 56.23). Other monsters have rudimentary limbs, faces, and teeth. In rare cases multiple monstrous anomalies may be present [13].

Adventitial Placentation

In some cases, particularly in older multiparous cows and those with a history of metritis, there is inadequate placentomal development due to uterine damage. To compensate, the intercotyledonary chorion develops bright-red to tan, fine, villous structures and small accessory cotyledons (adventitial placentation) (Figures 56.24 and 56.25). In some cases proliferation may be abundant [13]. Rarely, villous proliferation may appear as a diffuse process with few or no obvious placentomes due to destruction of caruncles [71, 72]. This process may be incidental, but excessive adventitial placentation may be associated with pathologic conditions such as hydrallantois [19, 73]. This condition indicates subnormal placental capacity and such cows, particularly if other stressors are involved, may not be able to maintain full-term calves, resulting in late-term abortions/stillbirth.

Dropsy of the Fetal Sacs (Hydramnios/ Hydrallantois)

Hydramnios and hydrallantois refer to excessive accumulation of fluids in the amnion and allantois cavities, respectively;

Figure 56.23 Acardiac monster with umbilicus. A hair-covered soft tissue globe. *Source:* Photo courtesy of J. Cooley.

Figure 56.24 Chorioallantois, maternal aspect, with adventitial placentation. Placenta (top) has been partially pulled away from the endometrium (bottom). Cotyledon proliferation is irregular but tissues are shiny, without fibrin, intercotyledonary hemorrhage, or necrosis. *Source:* Photo courtesy of J. Cooley.

Figure 56.25 Chorioallantois, fetal aspect, with adventitial placentation. Arteries and veins (white) arborize onto the coalescing placentomes. *Source:* Photo courtesy of J. Cooley.

edema of the chorioallantoic membrane may also be present. In most cases, aside from Dexter bulldog calves, fluid accumulation occurs in the last trimester [36]. Fetal swallowing partly regulates amniotic fluid volume in the second half of gestation; conditions that prevent or slow fetal swallowing may lead to fluid retention [45]. Allantoic fluid is a watery fluid generated by the fetal kidney. It is excreted through the urachus, reaching 8–20l at term. Amniotic fluid is more viscous and glairy (albuminous), due in part to fetal salivary secretions.

Hydrallantois is associated with placental dysfunction and is seen with uterine or placental disease. It is generally considered a maternal placentation problem and adventitial placentation is commonly present [74]. This condition is seen sporadically in dairy and beef cattle and has been reported with *Sida carpinifolia* toxicosis in Brazil [75]. It is more common in twin pregnancies. Membranes may be more fibrous than normal, but the character of the fluid is grossly normal. Fluid accumulation may reach 250l. [74] Fetuses are usually born dead or are small and may have ascites or anasarca (Figure 56.26) [19, 73]. A heritable condition was identified in Japanese Black cattle in which fetal polyuria led to hydrallantois and secondary pressure-induced hydronephrosis, a correlation which has been reported in other breeds [76, 77].

Hydramnios is much less common than hydrallantois. It is associated with fetal malformations that may be congenital or inherited. Congenital defects include any severe anomaly, such as schistosomus reflexus, that impairs normal swallowing. Inherited defects include Dexter bulldog fetuses (see Figure 56.12), hydrocephalic Hereford fetuses, Angus fetuses with osteopetrosis, and Guernsey fetuses with pituitary hypoplasia [13].

Fetal Dropsy

Fetal dropsy encompasses three main presentations: anasarca, ascites, and hydrocephalus. Fetal anasarca may be seen with dropsy of fetal sacs (Figures 56.26 and 56.27). It is sometimes associated with genetic defects such as pulmonary hypoplasia. Fluid accumulates in soft tissues, often enlarging the fetus such that cesarean section is required [78]. Fetal ascites may be commonly seen in cases of infectious abortion or developmental defects. Ascites or placental edema may occur as a rare accompaniment to *B. abortus* infection [13, 36].

Hydrocephalus

Hydrocephalus refers to an absolute increase in cerebrospinal fluid (CSF) within the brain ventricular system, within the meninges, or both (Figure 56.28). Congenital hydrocephalus

Figure 56.26 Fetus and placenta. The fetus is edematous (anasarca) with yellow/brown skin due to meconium staining. The allantois is markedly expanded by edema (hydrallantois). *Source:* Photo courtesy of J. Cooley.

Figure 56.27 Fetus with anasarca. *Source:* Photo courtesy of J. Edwards.

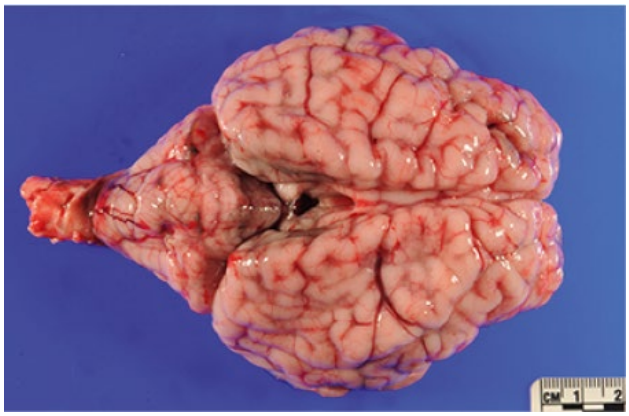

Figure 56.28 Brain, dorsolateral aspect. Hydrocephalus, with collapse of cerebral hemispheres and cerebellar coning.

occurs in two main forms: obstructive (hypertensive) and compensatory (normotensive). Obstructive hydrocephalus is associated with an inherited malformation, the most common of which is stenosis of the mesencephalic aqueduct [79]. Six such heritable forms have been described in Holstein, Jersey, Hereford, Charolais, Ayrshire, Dexter, and Whitebred Shorthorn breeds. Affected calves often have many other obvious defects [80]. Characteristically, there is marked doming of the skull with malformation of the bones of the cranium [81].

Compensatory hydrocephalus, on the other hand, arises as a result of CSF accumulation after severe brain necrosis. It is often associated with in utero infections with BVDV and Akabane, RVF, Wesselsbron, Schmallenberg, and bluetongue viruses. Hydranencephaly is a form of compensatory hydrocephalus where the neopallium (outer cerebrum) has been reduced to a very thin, almost translucent membrane with little to no parenchyma (see section "Bovine Viral Diarrhea Virus (BVDV) Infection"). Such lesions result from the aplastic and necrotizing effects of viral infection. The brainstem, cerebellum, hippocampus, and olfactory regions may be spared. The bones of the skull cavity are generally normal [79]. Other causes of congenital hydrocephalus include *Veratrum californicum* ingestion by pregnant cows and vitamin A deficiency [82]. The cause of hydrocephalus may be difficult or impossible to determine in some cases.

Amniotic Plaques

Amniotic plaques are normal, discrete, flat, white, 2–20 mm wide, round to irregular foci of squamous epithelium on the internal surface of the amnion (Figures 56.29 and 56.30). Immediately around the umbilicus they may become papillary or villous. They often resolve by six months' gestation, occur most often around the umbilicus, and are not found on the fetus. Plaques are not considered to be of pathologic significance and are not associated with

Figure 56.29 Fetus and placenta (amniotic surface exposed). The umbilicus and amnion are covered by amniotic plaques. *Source:* Photo courtesy of J. Cooley.

Figure 56.30 Placenta, umbilicus, and fetal aspect of amnion. Numerous coalescing amniotic plaques cover the amnion. *Source:* Photo courtesy of J. Cooley.

signs of inflammation. They are to be distinguished from fungal plaques. Their presence is useful for orientation of tissues for examination as they occur on the internal (fetal) side of the amnion [19].

Mineralization

Mineralization of the allantois or amnion appears as a network of white spots or streaks, typically associated with small vessels (see Figure 56.15). The material is not gritty but is soft, occurring most often in the second trimester [19]. After this time the mineral disappears and is probably incorporated into fetal bone [13]. Mineral may also be present on the coat of the calf which may be easily wiped from the hair (see Figure 56.18). The origin and significance of this finding is uncertain, but it must be differentiated from fungal dermatitis.

Necrotic Tips

Necrotic tips (Figure 56.31), or avascular chorion, is a normal area of necrosis occurring at the extreme tips of the chorioallantois of both horns. These areas are pale tan, shrunken, up to a few centimeters long, and clearly demarcated from the villous chorioallantois. Necrotic tips may be unilateral, particularly in the non-gravid horn. In some cases, necrosis of the non-gravid horn may involve as much as the entire horn [45].

Allantoic Calculi (Hippomanes in Horses)

Known since the time of Aristotle (*hippomane* means "horse madness"), these allantoic aggregates are composed of mineral and mucoprotein that deposit in progressive laminations around a nidus of cell debris (Figure 56.32) [83].

Figure 56.31 Chorioallantois with uterine horn tips. The horn at the top is avascular and shrunken. The lower horn tip is relatively normal. *Source:* Photo courtesy of J. Edwards.

Figure 56.32 Hippomane and avascular chorion tip. *Source:* Photo courtesy of J. Edwards.

Allantoic calculi are irregular, discoid, rubbery, tan masses with tapering margins, 3–15 cm wide and up to 4 cm thick [13]. They have been described in horses, donkeys, zebras, cattle, deer, goats, and ewes, among others [84]. In cattle they are common and may be multiple. They are not known to be of significance.

Meconium

Meconium is a combination of sloughed intestinal and epidermal cells, mucus, bile acids, and various other metabolites of fetal development. These contributed materials collect in the fetal colon, where water and electrolyte absorption forms thick, brown, tenacious feces that may develop into pellets. Calves will also shed hair into the amniotic fluid, which is then swallowed by the fetus and collected in the colon to be expelled as part of the meconium. As such, meconium pellets may be composed of abundant matted hair, which may be expelled into the amniotic fluid or may be ingested and found in the alimentary tract of the fetus [39, 85]. In cases of fetal stress/hypoxia, meconium may be prematurely expelled and aspirated, causing discolored amniotic fluid, smearing of meconium on the fetus, and meconium in airways (Figures 56.26 and 56.33).

Arthrogryposis

Arthrogryposis describes a condition where congenital joint contractures occur in one or many limbs and may be associated with scoliosis, kyphosis, lordosis, and torticollis. The limbs are rigidly fixed and variably bent in every sort of unnatural position. These changes occur as a result of decreased limb movement due to myogenic or neurologic abnormalities. As a result of neurologic disease in utero, muscles are underdeveloped and articular surfaces are

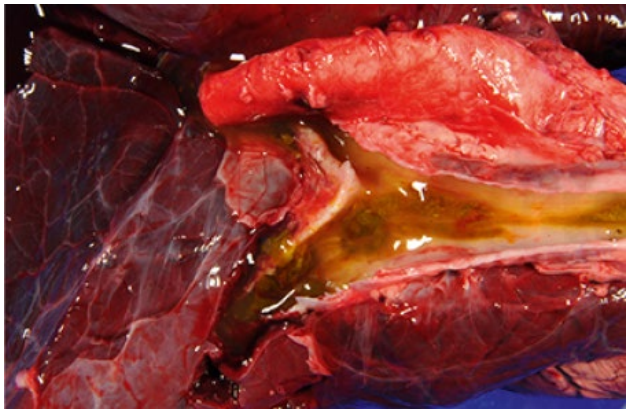

Figure 56.33 Meconium aspiration; stillbirth due to severe neurologic malformation (Chiari-like).

misshapen due to lack of proper stimuli. It may occur sporadically, in association with viral infection (bluetongue, Akabane, BVDV, Schmallenberg), or due to maternal toxin ingestion (lupines, poison hemlock, some types of tobacco). Breed-associated syndromes in cattle have been described. Arthrogrypotic fetuses are associated with stillbirth, hydramnios, and dystocia for obvious reasons [86].

Congenital Skin/External Lesions

A variety of abnormal conditions may present in the skin and can be hereditary, but not necessarily so. Hypotrichosis/alopecia, a less than normal amount of hair, is one of the best described and many heritable forms are known [87]. Non-genetic causes include iodine deficiency (fetal goiter), pituitary hypoplasia, maternal ingestion of *Veratrum album*, BVDV infection, and autoimmunity [88]. Calves may lack hair entirely or have thin, soft, and even curly hair. Affected areas are usually symmetric and the skin itself appears normal. The distribution can be patchy and calves may also have dental anomalies. A rare and distinctive condition is ichthyosis fetalis, in which generalized alopecia is combined with marked hyperkeratosis, resulting in fissures or plate-like folding of the skin over the entire body. Calves may be stillborn or die soon after birth; it is hereditary [87].

Defects, tears, and ulcers in the skin at birth can be due to various conditions. One of the more common is spina bifida (spinal dysraphism), a congenital defect in spinal development. In its most mild form calves have small areas of alopecic or glabrous skin on the dorsal lumbar midline (Figure 56.34). The underlying muscle, bone, and spinal cord have varying degrees of malformation, with a lack of the fusion normally seen in neuraxial folding. Lesions may bulge due to meningomyelocele formation. In some cases the spinal canal is continuous with the skin and in severe cases there are anomalies of the head as well.

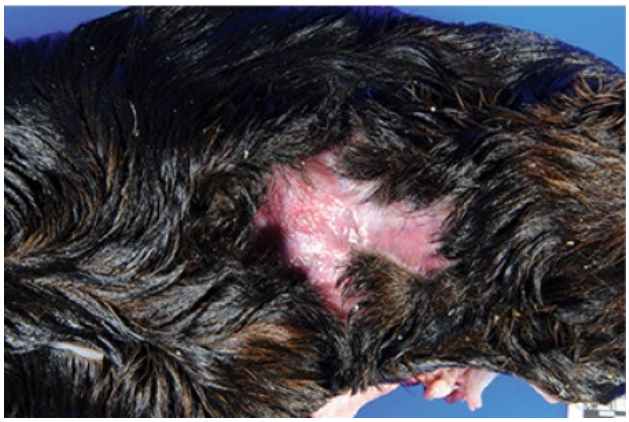

Figure 56.34 Spina bifida; failure of proper development of vertebra, spinal cord, and skin over lumbosacral area.

Figure 56.35 Hypospadia; failure of the ventral urethal fold to close from anus (far right) to prepuce (left).

Hypospadias are the failure of the urethral folds to join, and in severe forms may present as linear fissures from the perineum to the prepuce (Figure 56.35).

Epitheliogenesis imperfecta, an inherited absence of skin formation, presents as large red defects in the distal limb skin/hooves and additional oral lesions [89, 90].

Non-symmetrical skin defects can occur as a result of fragile skin collagen (asthenia/dermatosparaxis) or vesicobullous disease (epidermolysis bullosa, familial acantholysis of Angus calves, mechanobullous disease of Brangus calves). These conditions are hereditary and rare; definitive diagnosis requires histopathology and electron microscopy [87, 89].

Causes of Abortion

Embryonic Death

The early part of gestation is a time when fetal organ systems and extraembryonic membranes develop to achieve placentation, which is the point at which the chorion and endometrium attach. Prior to this, the uterus must be presented with

an embryo by days 15–17 in order to prevent luteolysis and maintain pregnancy [91]. Failure to do so leads to early embryonic death. Late embryonic death occurs after maternal recognition but prior to the fetal stage (days 42–260).

A variety of factors contribute to embryonic death, including heat stress, metritis, maternal endocrine abnormalities (progesterone), aged gametes, trauma, genetic abnormalities, nutritional deficiencies, and maternal–fetal incompatibilities [1]. Infectious disease is able to cause embryonic loss in three major ways: (i) the uterine environment of a febrile cow is also hyperthermic and may lead to loss; (ii) infectious organisms may directly infect the embryo or may interfere with the uterine environment; and (iii) endotoxin from Gram-negative bacterial infection may lead to premature luteolysis [1].

Fetal Death (Days 42–260)

Non-Infectious Causes of Abortion

Twinning is associated with higher rates (three to seven times normal) of stillbirth and abortion as well as retained membranes [92]. Abortion may occur at any time during gestation; rates of 30–40% have been reported for twin pregnancies [13]. In bovine twins, placental vessel anastomoses are almost always present, leading to fetal chimerism and freemartins.

Umbilical cord constriction is a rarely reported cause of abortion. This is largely due to three factors. Firstly, in the calf the umbilicus remains entirely within the amnion and is relatively short near term, such that rotation about the long axis (rolling over) is rarely possible. Secondly, the amnion is extensively fused to the chorioallantois, preventing rotation of the amnion within the chorioallantois, unlike the mare. Thirdly, at five to six months' gestation, the length of the calf exceeds the amnion width. By this stage, 95% of calves adopt an anterior presentation and cannot rotate around their transverse axes, preventing umbilical twisting and compression. In the mare, fetal anterior presentation is not firmly adopted until the ninth month [93]. If these assumptions are valid, then any constriction, twist, or entanglement should have occurred before the third trimester. Development would then proceed with relative normalcy until near term, when progressive umbilical constriction could impair venous and allantoic outflow. The result would be placental edema and possible abortion. Such a situation was suggested in a report of term abortion with placental edema in a Belgian White Blue calf, a breed in which it may be more common. Calves have had their cords wrapped around the abdomen, legs, or neck [94].

Abortion may be observed in association with severe abdominal trauma or stress, starvation, fetal hyperthermia or hypoxia, genetic abnormalities, and environmental causes (toxic plants, phytotoxins, mycotoxins, pharmaceuticals), and from iatrogenic intervention.

Toxic causes of abortion may be particularly difficult to diagnose, especially if they are not one of the better-known varieties. Specific lesions associated with certain toxins may be poorly described and therefore not easily recognized. Subclinical toxin exposure may lead to fetal death and abortion in an otherwise normal-appearing cow. Diagnosis in such cases is unlikely to be recognized by routine examination [20]. For specifics the reader is referred to Chapter 69 on the subject.

Therapeutic estrogenic compounds, PGs, or glucocorticoids may induce abortion [13]. Vitamin A is teratogenic, whether in deficiency or excess, and is associated with defective musculoskeletal and neural development which may lead to abortion [95].

Iodine deficiency has been reported in cases of fetal hyperplastic goiter in association with weak, alopecic, stillborn, and aborted calves [96]. Causes for hypothyroidism in cattle include forage/water low in iodine, selenium deficiency, ingestion of goitrogenic plants, or genetic reasons (Afrikaner cattle) [97, 98]. The thyroid gland in such cases is large and may weigh more than 30 g. Both iodine-deficient diets and high calcium intake have been implicated [99]. For suspected cases, removal of the entire thyroid gland is advised. Weigh the entire gland, fix half in formalin, and submit the rest fresh for iodine analysis. Gland weight above 30 g in addition to thyroid iodine concentrations below 1000 mg/kg (or thyroid iodine wet weight 0.03% or dry weight 0.01%) and consistent histological changes are necessary for diagnosis [98, 99].

Excessive dietary selenium has been associated with abortion or weak calves, with accumulation in the liver [100]. Conversely, selenium/vitamin A/E deficiency has been associated with poor fertility, cardiac mineralization, ascites, stillbirth, and abortion [101–104].

Finally, allergies or assumed anaphylactic reactions due to vaccines have been associated with abortion [13].

Infectious Causes of Abortion

The remainder of this chapter deals with contagious and non-contagious abortion-related pathogens. In Table 56.7 the approximate gestational stage of abortion is listed for various agents [105]. For each broad category of pathogen (bacteria, virus, protozoa, fungi), sequential preference is often given in order of perceived importance. Many pathogens are included in this section, partly due to their customary inclusion in other references concerning abortion, but

Table 56.7 Approximate stages of development when abortion occurs for specific pathogens.

Agent	Embryo	Early	Mid	Late
Anaplasma marginale				L

also for the sake of completeness and utility as a reference. Several of these organisms are discussed in other chapters and detailed information can be found therein. For those pathogens that are only mentioned in this chapter, further discussion is included in the following text.

Zoonotic pathogens include *B. abortus*, *Campylobacter* spp., *Mycobacterium bovis*, *L. monocytogenes*, *Coxiella burnetii*, *Leptospira* spp., and *Salmonella* spp.

Bacteria

Campylobacter fetus subsp. *venerealis* Infection

C. fetus is the cause of widespread venereal disease in cattle associated with infertility, embryonic mortality, and, uncommonly, abortion [106]. *C. fetus* is an obligate pathogen of the female reproductive tract, causing a mild transient endometritis [14]. After coitus, bacteria spread from the vagina to the uterus within two weeks. However, infection does not seem to impair fertilization and early embryonic development. Subsequent rapid bacterial replication in the uterus incites inflammation, leading to embryonic death between 30 and 70 days' gestation. This often occurs after maternal recognition of pregnancy, leading to prolonged estrus in cows. If bacterial replication in the uterus is slower, mid-gestation abortions are seen [14]. Non-venereally transmitted *C. fetus* subsp. *fetus* or *Campylobacter jejuni* infections are associated with sporadic abortion due to ingestion of infected material/tissues [106].

In infected herds, low fertility rates and abortion (<10%) are typical. Abortions are uncommon and occur most often at four to six months' gestation, but may occur in the last trimester; fetuses may be autolyzed, freshly dead, or even delivered alive [20, 27]. Gross fetal lesions are non-specific and include fibrinous pleuritis, pericarditis, and peritonitis [27, 107]. Membranes are not typically retained and may have lesions that resemble *Brucella* sp. infection, such as thickened leathery intercotyledonary spaces and variably necrotic cotyledons [19]. However, placental lesions are variable and often subtle or inapparent.

Darkfield examination of abomasal contents will reveal motile bacteria with rapid darting movements; this is characteristic of *C. fetus* or *C. jejuni* [14]. Organisms can be cultured from aborted tissues (lung, placenta, abomasal fluid), but isolation may be problematic as drying is highly detrimental to

viability. Several types of transport enrichment media are available; contact your local laboratory for preferred methods. Amies transport medium with or without charcoal is particularly useful for cultures [27, 106].

Leptospirosis

Leptospirosis is a worldwide infectious disease of many species (including humans), with highest prevalence in tropical areas [108]. Antigenically distinct serovars of *Leptospira* spp. (Icterohaemorrhagiae, Hardjo, Pomona, Grippotyphosa, etc.) may belong to more than one genomic species (*L. interrogans* sensu stricto and *Leptospira borgpetersenii*), since bacteria are classified into serogroups as well as genomic species [108, 109]. In cattle, *L. interrogans* serovar Hardjo type hardjoprajitno and *L. borgpetersenii* serovar Hardjo type hardjo-bovis are the most important causes of abortion, stillbirth, and reproductive failure [19]. These Hardjo types (hardjoprajitno and hardjo-bovis) are of particular importance in cattle; both are adapted/maintained in cattle (cattle are incidental hosts for Pomona and Grippotyphosa). Infection in maintenance hosts is characterized by efficient transmission, high incidence of infection, chronic disease, persistence in the urinary tract, poor antibody response, and few organisms in tissues [14]. The Hardjo strain important in the USA and found throughout the world is *L. borgpetersenii* serovar Hardjo type hardjobovis. The other, *L. interrogans* serovar Hardjo type hardjoprajitno, is a highly virulent organism found primarily in Europe [19]. The Pomona serovar is maintained in swine; cattle are incidental hosts. Serovar Pomona infections are associated with severe acute disease in adults, with hemolytic anemia, hemoglobinuria, mastitis, and abortion during the septicemic stage [110].

Bacteria are effectively shed in urine and may spread transplacentally, venereally, orally, via inhalation, and across conjunctiva [109]. Bacteremia follows a 4- to 10-day incubation phase, resulting in localization to the kidney and reproductive tracts. This in turn results in persistent shedding in urine and reproductive fluids. Maintenance of *Leptospira* spp. in the uterus may lead to fetal infection and abortion [14].

Pregnant cows generally abort in the last trimester or deliver weak infected calves; often abortion may be the only sign of infection in the herd [27, 109]. They may be sporadic or epidemic, occurring most often in the second and third trimesters [27, 111]. Abortion rates vary according to serotype; serovars Pomona and Grippotyphosa can approach 50%, while serovar Hardjo typically ranges from 3 to 10% [19]. Fetuses are often autolyzed and may be icteric [27]. In some cases the liver may have a green tinge due to cholestasis. Membranes may have intercotyledonary edema, and less commonly will have yellow/brown viscous fluid with diffuse cotyledonary necrosis (tan, uniformly affected) [26]. These changes are similar to those seen in BHV-1 infection.

Fresh specimens are essential for isolating the bacteria, as bacterial competition, desiccation, and acid pH are detrimental to leptospiral survival [109]. Pericardial fluid, abomasal fluid, and kidney are particularly good samples for finding bacteria. Bacterial lability and autolysis of samples makes isolation difficult and inefficient [27, 113]. Opportunistic bacteria (*T. pyogenes*, *Bacillus* spp.) may also be present in aborted specimens, obscuring leptospiral involvement [19].

One of the best methods for diagnosis is by serology using the microscopic agglutination test (MAT). Immunohistochemical tests are used for identifying bacteria in fixed tissues and fluorescent antibody (FA) tests may be used on frozen material. The kidney, lung, placenta, and adrenal glands are most useful for finding antigen [14, 19]. Refrigerated samples should be sent to the diagnostic laboratory promptly. PCR testing is available. For detailed discussion concerning diagnosis see Chapter 59.

Brucellosis

Brucella abortus is a highly contagious, zoonotic, intracellular bacterium that is an important cause of abortion and infertility in cattle. Cattle are the primary host of *B. abortus*, which is widespread in Africa, Asia, Europe, and Latin America [114]. In areas where cattle are housed with sheep or goats (western Asia, southern Europe), *Brucella melitensis* may infect cattle and cause abortions [115].

The cow is the source of infection, and the bacterium is mainly spread by placental tissue and uterine discharge, but spread via milk, contaminated feed, and in utero does occur. Uterine discharge may contain *B. abortus* for two weeks prior to and two to three weeks after calving or abortion [14]. Acute infection is characterized by abortion, delivery of weak or premature calves, retained fetal membranes, metritis, infertility, and sterility in cows and bulls [114]. Carpal hygromas can be common in certain areas and may be the only obvious sign of infection [115]. In managed vaccinated herds infection may be subclinical, whereas in fully susceptible herds abortion rates may be as high as 70% [116].

Bacteria penetrate the nasal/oral mucosa and incite a local or regional lymphadenitis, with enlarged lymph nodes that may be hemorrhagic. In time, bacteria spread hematogenously, with a bacteremia that may be recurrent and persistent. *B. abortus* has an affinity for the placental trophoblasts, in which they grow to large numbers, and is associated with persistent inflammation and necrosis. Infection then spreads to the fetus [19].

Abortion is the principal sign, occurring in the second half of gestation, after the fifth month. Infected cows may

abort only once, thereafter delivering term calves that may or may not be infected [116].

Placentitis is a consistent feature. Fetal membranes are often retained and contain yellow slimy exudate with gray/yellow flocculent debris between and especially surrounding the cotyledons [19]. Cotyledons are variably necrotic with thickening and fissures, or are soft to leathery, sometimes with sticky, brown, odorless exudate [19]. Intercotyledonary tissues may be similarly affected.

Fetuses are expelled one to three days after death; they are often autolyzed and may not have gross lesions [27, 116]. They may be edematous with serosanguineous cavity fluids and fibrinous pleuritis/pericarditis/peritonitis, pneumonia, and multiorgan hemorrhage [19, 114, 117]. Abomasal fluids may have yellow flocculent material [116]. Pneumonia in aborted calves is an important and outstanding feature; tissues are firm, sometimes presenting with a cobblestoned surface or small white foci [19, 116].

The gold standard for diagnosis is the isolation of *B. abortus* from the fetus or placenta (abomasal contents, spleen, lung), but this may be difficult. Serology is the best method to detect infection, using the milk ring test and card agglutination test. PCR methods are used to differentiate vaccine strains from wild-type bacteria. Organisms are plentiful in aborted tissues. Vaccination of pregnant cattle with strain RB51 is associated with abortion and should be avoided [115, 118]. For detailed discussion refer to Chapter 60.

Listeria Infection

L. monocytogenes and *Listeria ivanovii* are associated with disease in cattle, which takes the form of meningoencephalitis, neonatal septicemia, and abortion [119]. *Listeria* spp. are common in the environment, particularly in colder temperate climates. Disease in cattle is often associated with feeding spoiled silage where bacteria grow to large numbers. Hematogenous spread to the placenta 5–12 days later with subsequent fetal sepsis occurs. If infection occurs early in the last trimester, rapid fetal septicemia and death occurs. Abortion occurs a few days later, with partial masking of lesions due to autolysis [19]. Infections near term are associated with significant metritis and septicemia in the dam, with dystocia and retained membranes. In these cases, autolysis may be less severe, allowing better visualization of fetal lesions [19].

Abortions are sporadic and rarely exceed 15% [119]. They typically occur in the third trimester but may occur in the second. Fetuses die in utero and exhibit varying degrees of autolysis. Even if fetuses are well preserved, lesions may be few; the most commonly seen are pinpoint white/tan foci of liver necrosis that may mimic herpesvirus infection [120]. Small abomasal erosions, fibrinous serositis, pneumonia, and polyarthritis may also be seen [20, 51]. Placentas are often retained; changes include multifocal cotyledonary necrosis and intercotyledonary placentitis with gray/white to red/brown exudate [19, 119]. Aborting cows exhibit disease before, during, and after abortion, including weight loss, metritis, and septicemia [14, 19]. Recurrent abortion from year to year and in the same cow may be seen.

Organisms can be isolated from numerous fetal tissues; in some cases refrigerating specimens can aid in recovery of *Listeria* spp. [19]. Highly selective media are available. Gram staining of fetal fluids or tissue impressions reveal Gram-positive short rod bacteria in large numbers [14].

Histophilus somni (Formerly *Haemophilus somnus*) Infection

H. somni is a Gram-negative bacterial pathogen in cattle best known for causing pneumonia, arthritis, myocarditis, and thrombotic meningoencephalitis. It is a normal inhabitant of the male and female bovine genital tracts and is associated with infertility, abortion, and endometritis. Orchitis and epididymitis have been reported in bulls. Natural breeding spreads the bacterium. Transmission by AI is unlikely, as many strains are sensitive to the antimicrobials used to preserve frozen semen [19].

The association of *H. somni* with infertility is controversial; this bacterium is a normal inhabitant of the reproductive tract and research results are mixed [14]. As a cause of abortion, *H. somni* is not common; abortions are sporadic and infection rarely results in outbreaks. Typically, abortions occur in the second half of gestation. Placental lesions concentrate on cotyledons, where there is necrosis due to vasculitis and thrombosis. Such lesions are characteristic of this organism and indicate hematogenous spread from the vagina or respiratory tract. Fetal death is rapid and autolyzed carcasses are characteristic. Gross fetal lesions are uncommon; fibrinous bronchopneumonia may be seen [19].

Organisms may be cultured from abomasal contents and membranes. However, light bacterial growth from the placenta may be due to contamination from the birth canal. Culture must be interpreted in conjunction with necropsy findings [14].

Salmonella Infection

Salmonella spp. cause infectious and contagious disease in humans and livestock around the world. *S. enterica* subsp. *enterica* is divided into hundreds of serovars, of which Dublin is best associated with cattle abortion, although other serotypes may be involved, like *typhimurium* [121]. *Salmonella* Dublin is regionally distributed around the world and is known to persist on farms due to periodic fecal shedding, particularly around the time of parturition [121].

It is a cattle-adapted pathogen that causes enteric disease/dysentery, pneumonia, or polyarthritis in adults, but may also present with abortion as the principal sign [121]. Organisms survive in the environment for months to years and may be transported from farm to farm [122]. Bacterial infection in the dam leads to hematogenous spread to the placenta and subsequent placental failure and abortion, with or without fetal infection [19]. Abortion may be due to infection of the fetus, but as abortion may also occur in association with stressful events, pyrexia, and maternal enteritis may precipitate expulsion [19]. Abortions are typically sporadic to epizootic, occurring most often in the second half of gestation, often with retained membranes [121].

Aborted calves are often autolyzed and may be emphysematous. Pale foci of necrosis may be seen in the liver. Fetal fluids are fibrinous and amber colored; membranes are thickened and red/gray with yellow exudate and caruncular fragments on the cotyledons [19, 27]. Organisms can be recovered from placental tissues and abomasal contents [19].

Yersinia pseudotuberculosis Infection

This Gram-negative bacterium is associated with enterocolitis, caseous mesenteric lymphadenitis, and septicemia in calves. Apparently healthy cattle may carry the bacteria subclinically [123]. Sporadic abortion (often in the second half of gestation) has been reported, possibly due to uterine infection via transient bacteremia from the gut flora [124].

Fetuses typically have minimal autolysis; body cavities contain abundant fluid with fibrin tags, and livers may have multiple pale tan foci of necrosis [19, 27, 124]. Lungs may be firm due to bronchopneumonia [124, 125]. Microscopic lesions are characterized by abundant necrosis, vasculitis, and large bacterial colonies. Cotyledons are thickened, red/tan, with little exudate and caruncular tissue tags; intercotyledonary areas have fibrosis [19, 27]. Bacteria may be cultured from various tissues.

Trueperella (*Arcanobacterium*) *pyogenes* Infection

A common cause of suppurative inflammation in cattle that may act as a primary pathogen or a secondary invader, *Trueperella pyogenes* is a Gram-positive commensal organism in the respiratory, gastrointestinal, and urogenital tracts in healthy cattle. Tissue invasion leads to abscessation in any organ, causing a wide variety of clinical signs [126]. *T. pyogenes* is often isolated from aborted tissues and is considered to be a primary pathogen in cattle abortion [19].

Uterine infection occurs hematogenously or via ascending infection, which is often acquired in the postpartum period, in part due to retained membranes. Fetal infections are not consistently present. The ensuing endometritis is associated with discharge and pyometra, although the cow may appear normal [126].

Abortion can occur at any time throughout gestation, but the cow is often in the second half of gestation. Abortions are generally sporadic but may occur in clusters. Retained membranes are common; cotyledons are covered with yellow/brown exudate and intercotyledonary tissues are thick, opaque, and covered with similar exudate [27, 126]. Fetuses exhibit variable degrees of autolysis with fibrinous exudates on serosal surfaces; sometimes lungs are dark red with yellow foci or there is a characteristic hemorrhagic tracheal cast consistent with suppurative bronchopneumonia [19, 51] (see Figure 56.6).

T. pyogenes is readily isolated from fetal lung, abomasal contents, or membranes.

Various Opportunistic Bacterial Infections

Sporadic abortions in cattle may be caused by environmental and endogenous opportunistic bacteria, including *Bacillus* spp., *E. coli*, *Acinetobacter* spp., *Mannheimia haemolytica*, *Nocardia* spp., *Aliarcobacter* spp., *Pasteurella* spp., *Pseudomonas* spp., *Staphylococcus* spp., *Streptococcus* spp., *Helcococcus*, and *Serratia marcescens* [13, 127–129]. Almost any bacterium that can gain access to the dam's bloodstream has the potential to infect the conceptus.

Abortions occur most often in the second half of gestation. Fetal membrane retention and autolysis vary. Membranes are thickened with yellow/brown exudate (Figure 56.36). Fibrinous exudates may be found in body cavities. Fetal bronchopneumonia (white spotted lungs) is sometimes present [27].

Bacillus licheniformis is considered an important isolate associated with abortion, particularly in Europe. Outbreaks may be common. *B. licheniformis* apparently has little

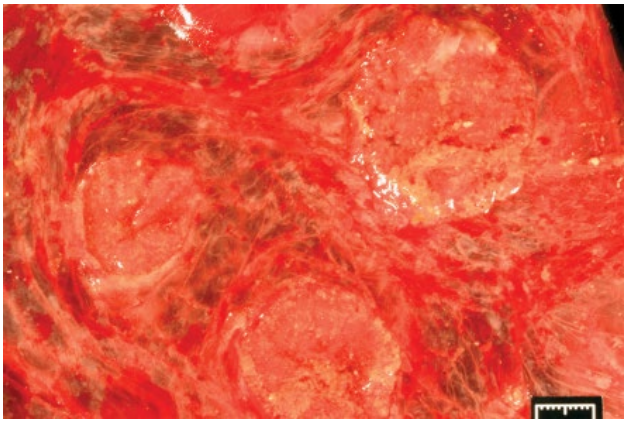

Figure 56.36 Chorioallantois with bacterial placentitis. Hemorrhage and fibrinous exudate cover the cotyledons and intercotyledonary spaces. *Source:* Photo courtesy of J. Edwards.

inherent pathogenic potential, and reports of disease often implicate coinfection, such as with *N. caninum* and BVDV [9, 130]. Fetal edema, fibrinous pericarditis, granulomatous hepatitis, bronchopneumonia, and placentitis have been reported [130]. Infected silage is implicated as a cause of cow infection, with a resulting bacteremia that may infect the cotyledons and spread to the fetus.

Cattle can develop subacute anthrax (*Bacillus anthracis*), with localized disease in the respiratory, gastrointestinal, and subcutaneous tissues. Pregnant cattle that survive infection may have fetoplacental infections as a result of bacteremia; gross fetoplacental lesions may be absent [131]. More severely affected cattle may present with protracted fever, subcutaneous edema, hemorrhagic vaginal discharge, an edematous fetus, bloody amniotic fluid, placentomal hemorrhage, and lack of typical lesions in the maternal liver, spleen, and kidneys [132, 133].

Mollicute Infection

The Mollicutes are bacteria that lack cell walls and have a preference for mucosal and serosal surfaces. They are known causes of chronic respiratory, urogenital, mammary, musculoskeletal, and ocular disease in ruminants. Coinfection with other pathogens is common. *Mycoplasmopsis* (prev. *Mycoplasma*), *Metamycoplasma* (prev. *Mycoplasma*), *Mycoplasma*, *Ureaplasma*, and *Acholeplasma* spp. have been associated with male and female reproductive disease in cattle, including abortion [134]. These species, including those known to cause disease, are often found in the mucous membranes and reproductive tracts of normal animals.

Endometritis, granular vulvovaginitis, salpingitis, infertility, seminal vesiculitis, epididymitis, and granular balanoposthitis occur with infection. Transmission may occur venereally, mechanically (including AI as they can withstand freezing), and by respiratory routes [134]. Disease is multifactorial and associated with intensive husbandry.

Mycoplasmopsis (*Mycoplasma*) *bovis*, *Mycoplasmopsis* (*Mycoplasma*) *bovigenitalium*, *Metamycoplasma* (*Mycoplasma*) *canadense*, *Mycoplasma leachii* (type 7), and *U. diversum* have been reported causes of abortion in cattle, but *M. bovis* and *U. diversum* abortions are the best known and characterized [134–138]. The association of these organisms with abortion in general is controversial and is not well understood. However, *M. bovis* is not a normal inhabitant of the reproductive tract and thus its presence in an abortion is significant. Mycoplasmal abortion is uncommon. Reported lesions include placentitis, fetal bronchopneumonia, and myocarditis [14].

U. diversum is the most important abortion-related pathogen in this group, causing embryonic death, abortion (often in the last trimester), stillbirth, weak calves, and neonatal pneumonia [19, 134]. Outbreaks of *U. diversum* infertility have been reported lasting up to six months, with conception rates as low as 20% [14]. Fetal membrane retention is common. Since few diagnostic laboratories attempt to culture this organism, there is wide regional variability in diagnosis frequency. In the USA many cases are reported from Canada [27].

Grossly, the amnion is often severely affected with thickening/fibrosis, mineralization, necrosis, hemorrhage, fibrin, and meconium staining [19, 139]. The chorioallantois may be similarly affected with white to brown exudate. Aborted fetuses are commonly fresh [120]. Fetuses and newborn calves may have firm poorly aerated lungs. The constellation of amnion, chorioallantois, and lung lesions is characteristic of *U. diversum* infection [19].

Definitive diagnosis requires culture of organisms from stomach contents, placental tissues, liver, or lung in addition to consistent lesions [140]. These organisms preferentially localize to the fetal–maternal interface (placentome). Specific media are required for culture; consult the diagnostic laboratory for preferred methods. Samples should be refrigerated and transported immediately. Deliver samples in frozen media (Stuart broth, Amies without charcoal), preferably in liquid nitrogen or dry ice rather than wet ice [141]. PCR methods for *M. bovis* and general *Mycoplasma* spp. are available.

Chlamydia-Like Organism Infection

Bacteria of the order Chlamydiales are obligate intracellular parasites, ubiquitous, infect a wide range of vertebrate species, and cause a wide variety of diseases [142, 143]. *Chlamydia abortus*, *Chlamydia pecorum*, *Chlamydia psittaci*, *Waddlia* spp., and *Parachlamydia* spp. are of interest in cattle production. Abortion in cattle is usually caused by *C. abortus*, but *C. psittaci* abortion has been reported [144]. *Chlamydia* spp. have also been associated with mastitis and infertility [14]. *C. pecorum* is associated with enteritis, pneumonia, neurologic disease, polyarthritis, and conjunctivitis. Infectious forms may be shed in feces, urine, semen, uterine fluids, and ocular/nasal discharges [145]. Ingestion or inhalation of the organism leads to infection.

Parachlamydia spp. and *Waddlia chondrophila* have been isolated from aborted calves in Europe and in the USA [146–148]. The overall contribution of *Waddlia* and *Parachlamydia* spp. to cattle reproductive disease is uncertain.

C. abortus is an uncommonly diagnosed cause of abortion in cattle [27, 149, 150]. Fetal loss is more sporadic than in sheep, but abortion rates of up to 20% can occur [149]. Although the prevalence of occult chlamydial infections may be high in some areas, currently the contribution of such infections to fetal losses is unclear [149, 151, 152]. The method of natural transmission of infection in cattle has not been verified but is probably through contact with contaminated fetal fluids and tissues, as in sheep [153].

Affected cows may show little sign of disease, delivering aborted, stillborn, or weak calves, sometimes with retained membranes [154, 155]. *C. abortus* abortions typically occur during six to eight months of gestation, often presenting with necrotizing placentitis, with or without vasculitis [146]. Tissues have leathery, reddish, opaque intercotyledonary patches and multifocal cotyledonary necrosis. Fetuses may have pink/red subcutaneous edema, ascites, thymic and subcuticular petechiae, and serofibrinous pleuritis/peritonitis, which in some cases may be severe [154, 155]. Chronically infected calves may have nodular mottled livers and enlarged lymph nodes [155]. *Parachlamydia* and *Waddlia* related abortions also exhibit necrotizing placentitis, but vasculitis is uncommon [146]. Experimental *W. chondrophila* infection led to placentitis but not abortion [156].

Diagnosis of chlamydial abortion requires examination of the placenta, where organisms multiply in cotyledons [153]. Cotyledons and uterine discharges contain abundant organisms [14]. Isolation is the gold standard for diagnosis, which is necessary to identify species and strains/serotypes/subtypes; such methods require specialized media and special expertise [157]. It is important to recognize that many cattle harbor chlamydiae in their intestinal tracts, which may contaminate aborted tissues and confound complement fixation tests and PCR, leading to false-positive results [153]. Exposure of cows may be common and single titers are of questionable worth, although a rise in titer is suggestive of significant infection as delivery of an infected fetus leads to a rise in titer two to three weeks after parturition [14]. Specific antibody in fetal thoracic fluid or tissues is confirmative [19]. The presence of placentitis with identification of organisms within lesions by immunohistochemistry (IHC) as well as PCR is diagnostic. Placental smears stained with Giemsa, Gimenez, or modified Ziehl–Neelsen acid-fast methods are useful for diagnosis [19, 155]. Chlamydial organisms should be considered as serious zoonotic agents and may cause abortion in humans [158].

Epizootic Bovine Abortion (EBA)

EBA is a regionally important and specific disease confined to the western USA. It is associated with certain pine ranges that sustain the argasid tick *Ornithodoros coriaceus* [159]. The etiologic agent, *Pajaroellobacter abortibovis*, is transmitted by the tick [159, 160]. Disease is typified by premature calving and abortion in otherwise normal cattle [27]. The disease in the fetus is a chronic one, developing over three months or more prior to abortion. Abortions occur sporadically or in severe outbreaks, often in the last trimester. Fetuses are expelled fresh; retained membranes are not typical. Lesions include petechiae in the mouth (particularly the ventral tongue), enlarged peripheral lymph nodes, ascites, splenomegaly, dermatitis, large and coarsely nodular livers, and small thymuses surrounded by edema and hemorrhages [27, 159]. The presentation and lesions are characteristic. Diagnosis requires compatible lesions and herd history in addition to elimination of other causes [159].

Coxiella burnetii Infection

The cause of Q fever in humans, *C. burnetii* is a Gram-negative, obligate intracellular rod bacterium that replicates within macrophages [161]. Organisms are hardy and resist desiccation, pH change, ultraviolet radiation, and disinfectants. Found worldwide except in New Zealand, *C. burnetii* is present in a wide variety of rodents, birds, wild and domestic animals (including reptiles, dogs, cats, pigs, horses), ticks, and domestic ruminants, the latter serving as reservoirs for human infections [161]. Prevalence is variable worldwide; in the USA prevalence in 316 bulk milk samples was greater than 90% [162]. Routine pasteurization kills the organism [110].

In endemic areas infected calves may clear the infection or become latently infected. During late pregnancy hormonal changes are thought to trigger *C. burnetii* replication in the uterus, fetus, and mammary gland [161]. Infected sheep, goats, and cattle are typically asymptomatic when they present for late-term abortion, stillbirths, and weak neonates [161, 163]. Abortion in cattle is uncommon to rare. The organisms are shed in feces, milk, urine, fetal fluids, and fetal membranes in large numbers [161]. Infection usually occurs through inhalation of infected aerosols, but spread through infected equipment, manure, and ticks is possible.

Approximately half of seropositive heifers shed *C. burnetii* at calving; there is reduced shedding with age. Chronically infected cows may shed organisms in milk, feces, and vaginal mucus intermittently for several months to years [164]. Gross lesions are confined to the placenta, where the intercotyledonary zones are covered by abundant, white, inspissated exudate, giving the tissue a thick leathery appearance [19]. Multifocal mineralization and pericotyledonary necrosis may develop [161].

Placental exudate smears stained with Gimenez or Ziehl–Neelsen acid-fast staining methods show numerous organisms, but these may be easily confused with *Chlamydia* spp. PCR and enzyme-linked immunosorbent assay (ELISA) are effective in diagnosis. The mere presence of *C. burnetii* in aborted tissues is not sufficient evidence for diagnosis; cows may carry the organism long term and they may be in placentas of subsequent pregnancies [19, 164].

Tuberculosis

Mycobacterium tuberculosis (syn. *M. bovis* and *Mycobacterium caprae*) has beenlargely eliminated from many countries around the world, yet remains enzootically or in limited

geographic areas in Central and South America, North America, Africa, Europe, Asia, and Oceania. Disease caused by *M. caprae* is not significantly different from that caused by *M. bovis*. *Mycobacterium* infection occurs in a wide range of hosts, including domestic livestock, cats, and dogs. The bacterium is a major economic problem in terms of trade and industry as well as being a zoonotic pathogen. One of the major problems encountered in terms of eradication is the prevalence of *M. tuberculosis* in wildlife reservoirs such as farmed and wild cervids, European badgers, buffalo, bison, brushtail possums, and European wild boars [165, 166].

Mycobacterium is typically spread by inhalation or ingestion. With reference to theriogenology, bull carriers may spread infection through coitus [13]. An initial site of infection may develop into a persistent focus of bacterial replication, with subsequent hematogenous spread to various organs. Disease is characterized by the presence of tubercles, which are discrete, pale tan granulomas of various sizes in virtually any organ. They may resemble abscesses, with abundant caseous necrosis. In adult cattle, tubercles are most common in the lungs and the lymph nodes of the mesentery, pharynx, and thorax; generalized lesions are uncommon. *Mycobacterium* reaches the uterus hematogenously or by peritoneal spread to the uterine tubes. Uterine infection may primarily affect the serosa/muscularis or may concentrate in the endometrium. The uterine tubes may be severely affected [167]. Abortion due to endometritis often occurs late in gestation [168]. Retained placentas and purulent to caseous uterine exudate may be seen [13].

Congenital tuberculosis occurs in about 1% of at-risk calves [168]. Transplacental transmission may occur hematogenously via tuberculous endometritis with umbilical spread to the fetal liver (hepatic primary complex) and lymph nodes [166]. Alternatively, fetal swallowing or inhalation of tuberculous amniotic fluid may result in enteric or pulmonary lesions, respectively [168]. *Mycobacterium avium* has been reported as a cause of abortion in cattle housed with infected chickens [13].

At least 10 g of fat-free affected tissue should be submitted for culture.

Anaplasma Infection

There are currently three species of anaplasmal bacteria that infect cattle: *Anaplasma marginale*, *Anaplasma centrale*, and *Anaplasma phagocytophilum* (previously *Ehrlichia phagocytophila*, *Ehrlichia equi*, and human granulocytic ehrlichiosis agent) [169]. *A. marginale* is the cause of anaplasmosis in cattle and can infect buffalo, bison, deer, and other hoofstock. This infectious but non-contagious agent is spread by arthropod bites, mechanical means, or transplacentally [169]. Anaplasmosis occurs in tropical and subtropical areas worldwide. *A. marginale* infects erythrocytes, leading to extravascular hemolysis, anemia, icterus, fever, and weakness [170]. Initial infections are the most severe, leading to chronic persistent infection that is often subclinical. *A. centrale* is a milder pathogen, usually employed as an immunizing agent against *A. marginale* [171].

A. marginale is rarely implicated as a cause of abortion. Suggested causes of fetal loss include pyrexia, severe anemia, or stress in the dam. Aborted calves show variable liver and lung petechiation with splenic enlargement [172].

A. phagocytophilum is the cause of pasture fever in cattle and tick-borne fever of sheep and goats in northern Europe, although the bacterium is distributed worldwide. While currently considered to be one species, *A. phagocytophilum* strains causing ruminant disease differ in distribution, disease, severity, and target hosts from those causing human granulocytic ehrlichiosis [173]. The organism infects circulating granulocytes and large lymphocytes, which are best seen during clinical illness [171]. Signs include fever, cough, nasal discharge, and leukopenia [170]. Although present in the USA, cases of clinical illness in cattle have not been reported. *A. phagocytophilum* has been known to cause abortions (and storms) during first exposure to infected ticks during late pregnancy [9, 173].

Diagnosis of *Anaplasma* spp. can be made on Giemsa-stained blood smears during the acute phase in cattle, but it is not useful for carrier states. Blood from live cattle should be collected in anticoagulant and refrigerated to be sent to a diagnostic laboratory. Smears from the liver, kidney, heart, lungs, or peripheral blood vessels can be made from dead animals and air dried for staining [174]. Serologic tests and PCR methods are available.

Viruses

Herpesvirus

Bovine Herpesvirus 1 (BHV-1, Infectious Bovine Rhinotracheitis Virus, Infectious Pustular Culvovaginitis Virus) Infection BHV-1 virus is an important worldwide alpha-herpesvirus pathogen of cattle, known to cause abortion, genital disease, respiratory disease, encephalomyelitis, and severe systemic disease in neonates [27]. Other ruminants, including deer, pigs, goats, wildebeest, and buffalo are susceptible [175]. Infected cattle shed virus from oculonasal and reproductive fluids. Like other herpesviruses, latency is established after infection through the genital or respiratory tract [175]. Respiratory infection in naive pregnant females is likely to lead to fetal infection and abortion [176]. Clinical signs in adults are generally mild, with conjunctivitis or respiratory tract disease. However, signs may be absent at the time of abortion, which typically

occurs several weeks after initial infection [27, 175]. Abortion is typically seen in the second half of gestation, anywhere from two weeks to two to three months after clinical disease; fetuses are expelled three to seven days after death [13, 175]. Abortions may be sporadic in herds with previous exposure, which includes modified live vaccines [176]. If naive pregnant cattle are exposed, storms affecting 25–60% may occur [27, 177].

The virus spreads hematogenously in the dam to the caruncle, where it invades the placenta and then the fetus. Herpesviruses induce widespread cell necrosis in multiple organs, leading to rapid fetal death [19]. Fetuses show advanced autolysis with few lesions; tissues are red due to hemoglobin staining and abundant reddish fluid may be present in body cavities [175]. Pinpoint white foci of hepatic necrosis may be present [27]. Less commonly, pulmonary and renal hemorrhage with necrosis is seen [19, 178]. Renal necrosis may be pronounced [179]. Diffuse placentitis similar to that seen in leptospirosis may be found and yellow/brown amniotic fluid may be evident.

Fetal lung, liver, spleen, kidney, adrenal gland, and placenta are good sources of virus; samples should be kept cold. Freezing at −70 °C is acceptable, but standard freezing (−20 °C) will inactivate the virus [175]. Histopathology may give a presumptive diagnosis, which can be confirmed by IHC, PCR, FA detection, immunoperoxidase tests, or virus isolation. Kidney and the adrenal gland are useful for FA testing [27]. Cows that abort typically have low titers at the time of abortion and fetuses die so rapidly that fetal antibody production may be poor or non-existent [19].

Bovine Herpesvirus 4 (BHV-4) Infection A widespread gammaherpesvirus in cattle considered minimally virulent or avirulent in adults, BHV-4 may be an important cause of abortion [177, 180]. Presence of the virus in abortions is often associated with other pathogens [19]. Associated disease includes pneumonia, keratoconjunctivitis, orchitis, sudden death in neonates, digital dermatitis, mastitis, encephalitis, diarrhea, vulvovaginitis, postpartum metritis, and abortion [177, 181]. The contribution of BHV-4 as a cattle pathogen at this point is mostly hypothetical, with the exception of the latter three conditions [180]. The role of BHV-4 in abortion is incompletely understood [182]. Abortion is reported to occur between five and nine months' gestation. Descriptions of lesions in the literature are few, with no gross fetal or placental lesions reported. Cytomegalic intranuclear inclusions are seen microscopically in multiple organs [183].

Bovine Herpesvirus 5 (BHV-5) Infection A pathogen typically associated with severe meningoencephalitis in young calves, BHV-5 outbreaks are seen in South America and sporadically in Australia, Europe, and the USA (Figure 56.37) [184]. Transmission may occur through the genital tract, with evidence suggesting possible negative embryological effects [185–187]. The virus has been isolated from an aborted fetus [188].

Bovine Viral Diarrhea Virus (BVDV) Infection BVDV is one of the most important infectious causes of reproductive loss in cattle worldwide. It is a pestivirus that uses the reproductive system for spread within herds. Negative effects on herd reproduction range from genital tract inflammation, reduced reproductive efficiency, and embryonic death to abortion storms, delivery of small calves, persistently infected calves, and congenital defects [19, 111].

Transplacental infection is likely in cattle [176]. Viremia leads to fetal infection as it is a primary target for the virus [189]. The manifestations of disease in pregnancy vary according to virus strain and stage of fetal development at the time of infection [176]. Fetal infection in the first and second trimesters often leads to embryonic death, resorption, mummification, or abortion [27]. Fetal calves infected with non-cytopathic viral strains between one and four months become persistently infected, immunotolerant calves that produce no antibody to the virus [111]. Those infected after four months may successfully eliminate the virus, but in some cases those infected between 100 and 150 days develop congenital anomalies [27, 111]. Such anomalies are quite variable but include central nervous system anomalies (hydranencephaly, hydrocephalus, cerebellar hypoplasia, microphthalmia, retinal dysplasia, cataracts), thymic hypoplasia, hypotrichosis, bone defects, brachygnathism, arthrogryposis, and pulmonary or renal hypoplasia/dysplasia (Figure 56.38). Necrotizing myocarditis leading to chronic passive hepatic congestion and

fibrosis with ascites as well as congenital diabetes mellitus have been reported (see Figure 56.9) [27, 190]. Individual herds may have only a few calves with congenital defects; consecutive calves may have the same defects [191]. More often, fully developed but small (50–66% normal size) calves are delivered [192]. Infections in the last trimester do not typically produce disease as calves are immunocompetent and produce anti-BVDV antibodies [189].

Fetal death and abortion typically occur in the first trimester, but can occur at any time. The abortion rate varies but is usually low [189]. There is a delay between fetal death and expulsion (as much as 50 days), which often produces autolyzed specimens from which it is difficult to detect the virus. Additionally, dams often seroconvert during this delay, making serum titers of little value [113]. Lesions aside from teratogenic changes are therefore difficult to appreciate and rarely noted. Enlarged spleens, lymph nodes, and nodular mottled livers may be seen [189]. Thrombocytopenia inducing strains (types 1b and 2) may cause widespread petechiation and hemorrhage [193]. Placental lesions are generally not seen [51].

The virus is fairly resistant and can survive in moist tissues for several days; preferred samples for virus isolation include lymphoid organs [189]. Various other diagnostic methods are used including IHC, FA, and ELISA [27]. BVDV is widespread, and molecular evidence of infection in an aborted fetus does not prove it to be the etiologic agent. Herd history and fetal lesions consistent with BVDV infection are necessary for diagnosis [27]. A history of ataxic, small, or blind calves in the herd is suggestive. Fresh specimens and often multiple fetuses are required before the virus can be identified [113]. Evidence for transplacental transmission includes detection of BVDV in fetal tissues or precolostral antibodies in fetal serum or fetal fluids. However, a persistently infected (non-cytopathic BVDV infection) fetus will not produce antibody. Infected dams that carry persistently infected calves may have high titers that continue to increase until delivery [194]. Contaminated modified live BVDV vaccines have been reported to cause disease and congenital defects [176].

Recently, another pestivirus (HoBi-like, BVDV-3) has been associated with abortion and respiratory disease in cattle in Brazil, Southeast Asia, and Italy [195–197]. The origins of this virus are poorly understood; hypotheses include viral emergence from South America or transmission from water buffalo to cattle. Natural infection has not been reported in North America, Europe, Australia, India, and Africa so far [195].

In natural cases, seromucous oculonasal discharge, tracheitis, bronchopneumonia, and gastroenteritis have been reported in infected calves. Abortions were seen in the second trimester [198]. Experimentally, hyperthermia, oculonasal discharge, and lymphopenia were seen in calves. Lambs also exhibit nasal discharge, while pigs show no signs but will seroconvert. Peak seroconversion occurs in calves by 21 days after infection; nasal and fecal shedding occur [195]. HoBi-like virus has been isolated from bull semen. In utero infection may produce persistently infected calves, similar to BVDV. Current testing is complicated by the similarity of the HoBi-like viruses to BVDV.

Cattle are susceptible to border disease virus (BDV) infection, which is a pestivirus generally associated with small ruminants. The virus can be transmitted between sheep and cattle, and abortions have been reported in association with infection. Infected cattle have signs similar to those of BVDV infection; they may develop diarrhea, and persistent infection in calves can occur [199]. Experimental infection caused growth retardation and hydrocephalus in calves [200]. Many antigen and antibody tests cannot discriminate between BVDV and BDV; specific PCR assays, with or without sequencing, are necessary for diagnosis.

Orbivirus

Bluetongue Virus (BTV) Infection

BTV is the cause of a widespread arthropod-borne orbiviral disease of domestic and wild ruminants, particularly of sheep [201]. Virus distribution is confined to areas where susceptible hosts (wild game, sheep, and cattle) are found and the *Culicoides* spp. biting midges are present for transmission [201]. BTV is generally considered non-contagious and infected animals shed little virus, except possibly in the semen of viremic bulls [19]. However, novel serotypes with

minimal virulence can be horizontally transmitted among sheep and goats [202]. BTV infection may be seasonal, depending on the climate and numbers of *Culicoides*; in temperate zones, late summer/early autumn is common [203]. The range of infection has increased since 2000, as a result of additional *Culicoides* spp. vectors, emergence of novel BTV serotypes, and changes in climate [202]. After infection, animals may be viremic for several weeks, but this does not lead to immunotolerance or persistent infection [176, 204]. Clinical signs in adult cattle are rare and mild, particularly in enzootic areas [177]. When clinical disease occurs, signs include the formation of ulcers in the mouth and tongue as well as on the muzzle. The coronary bands develop hyperemia and ulceration, and hoofs may slough [191].

After introduction into the skin, the virus is transported to local lymph nodes where it replicates. Subsequent hematogenous spread to secondary organs then occurs. BTV replicates in macrophages, lymphocytes, and vascular endothelial cells, causing host cell death. This results in widespread injury to small blood vessels which leads to vascular leakage, edema, subsequent thrombosis, and tissue infarction [205].

Infections during pregnancy cause congenital abnormalities more commonly than abortion; early embryonic death, mummification, and stillbirth also occur [19]. Congenital abnormalities due to BTV are sporadic and are known to occur principally in the USA and South Africa, where modified live vaccines are used. These vaccine strains were considered largely responsible for fetal malformations [206]. Abortions associated with BTV2 and 9 vaccines have been reported in Europe [207]. Until recently, transplacental transmission was thought to occur only in laboratory modified strains, although now serotype 8 (BTV8) in Europe has been shown to frequently cross the placenta [27, 208, 209]. BTV8 is unusual not only for its virulence in cattle, but also for its wild-type transplacental transmission and oral transmission in field and experimental reports [210–212].

Like BVDV, fetal disease is associated with gestational age at infection. Fetal infection prior to day 70 may lead to fetal death and absorption, while infection between 70 and 130 days can cause stillbirth, weak calves, hydranencephaly, or abortion. If infection is just prior to fetal immunocompetence, hydrocephalus or porencephaly may result. Fetal infection after 150 days can cause encephalitis or premature birth, but malformations do not occur [27, 206]. Abortions occurring in the last trimester have been associated with hydranencephaly [213].

Isolation of BTV is difficult and the virus is inactivated by freezing at −20 °C [176]. Virus may be isolated from blood (in anticoagulant: EDTA, heparin), spleen, or lymph nodes if tissues are sent refrigerated to an appropriate laboratory [204]. PCR techniques use whole blood in EDTA. Live attenuated and killed vaccines are available. Live vaccines are effective but are associated with abortion and congenital anomalies when used in pregnant females in the first period of pregnancy [204]. Fetal BTV antibody from serum or cavity fluids indicates in utero exposure [27]. Complementary lesions are needed for diagnosis.

Epizootic Hemorrhagic Disease Virus (EHDV) Infection

EHDV is an orbivirus transmitted by *Culicoides* midges that affects wild and domestic ruminants, particularly white-tailed deer [214]. Of the many serotypes found worldwide, Ibaraki virus, an Asian strain of EHDV serotype 2, has long been considered the only strain of significance to cattle. However, recent outbreaks of severe disease in cattle have been seen with serotypes 6 and 7 in Turkey and Israel [215, 216]. Disease in cattle mimics BTV; mortality is often low and morbidity varies [214]. Abortions and stillbirths have been reported in outbreaks of Ibaraki virus infection in Japan [217, 218].

Palyam Serogroup Orbivirus Infection

This group includes at least 15 viruses that are primarily found in Africa, Asia, and Australia and are associated with abortion and teratology in cattle [219]. *Culicoides* midges are natural vectors, but the virus has also been isolated from mosquitoes and ticks. Of these, the Chuzan (Kasba) virus is best known, causing hydranencephaly and cerebellar hypoplasia in calves [220, 221]. The presence of infection in herds is usually found after abortion and malformations are seen. Abortions may occur at any stage of gestation, being sporadic or epidemic [219]. Antibodies in precolostral serum are helpful in establishing a diagnosis [219].

Bunyaviridae

Rift Valley Fever Phlebovirus (RVF) Infection

RVF is the cause of severe disease in domestic ruminants and humans; the virus is largely confined to sub-Saharan Africa and Madagascar [222]. Mosquitoes are the main route of transmission, with many capable species, including some found in the USA [19, 222]. Disease is most severe in young ruminants. In calves, severe hemorrhagic diarrhea and liver necrosis (with icterus) develop over a rapid course, with mortalities ranging from 10 to 70%. Adult cattle may show only abortion, which can occur at any gestational stage and may reach 80–90% [177, 222]. Abortion is due to fetal death; specimens are autolyzed and exhibit liver necrosis [223]. Fetal livers are enlarged, soft, friable, and yellow/red with hemorrhages or subcapsular hematomas [224]. Placental lesions have not been described. Aborted tissues

contain large amounts of virus [19]. Hepatic lesions are considered diagnostic; differentials include BTV and Wesselsbron virus. The virus may be isolated from the liver, spleen, and brain; keep refrigerated or freeze and send on dry ice. Serological tests are available [225].

Akabane and Simbu Serogroup Orthobunyavirus Infection

This group includes about 25 viruses in the *Bunyavirus* genus that occur worldwide, including the Akabane, Aino, Tinaroo, Peaton, Shamonda, Shuni, and Schmallenberg viruses (SBVs) [226–230]. The Akabane virus, which occurs in Australia, Japan, China, Korea, the Middle East, and Kenya, is possibly the most important pathogen of this group, although SBV is now on the rise in Europe [19, 231]. Transmission is via *Culicoides* gnats and probably mosquitoes [230, 232]. Clinical disease in adult cattle may be mild or inapparent, with reduced milk yield, diarrhea, or inappetence [230, 233]. Clinical disease is more characteristic of SBV than in other viruses of this group [234]. Certain variants (genogroup Ia, Iriki strain) of Akabane virus are known to cause neurologic disease outbreaks (bovine epizootic encephalomyelitis) in calves and adult cattle in East Asia [191]. The Shuni virus has recently emerged as a cause of neurologic disease in calves and abortion in Israel [235].

Infection during pregnancy may produce abortions, malformations, mummies, and stillbirths [19]. Abortions occur in the third trimester and can occur as clusters or epidemics [230, 232]. Viruses in this group are neurotropic and are known to cause arthrogryposis, muscular hypoplasia, and hydranencephaly defects in domestic ruminants [233, 236–238]. Hydrocephalus, cerebellar hypoplasia, porencephaly, scoliosis, and cardiopulmonary defects are also reported [177, 233]. The gestational stage at which infection occurs determines the severity and outcome of infection, with decreased severity seen in later infections [230, 232].

SBV was first noticed in the summer of 2011 in northern Germany and the Netherlands as a febrile syndrome in adult cattle; signs included fever, decreased milk production, and diarrhea [234]. SBV is the first outbreak of a Simbu serogroup virus in Europe and has now spread across much of Western Europe [239]. The virus is associated with abortion and congenital malformations in cattle, sheep, and goats. The losses in cattle due to decreased milk production and return to service may be more costly than losses due to malformed calves, which in the Netherlands' outbreak occurred in 1–3% of farms [239].

SBV antibody seroprevalence was 72% in cattle from the Netherlands between November 2011 and February 2012; a high seroprevalence in red deer, roe deer, and mouflon was also found. Current evidence suggests that biting midges (*Culicoides* spp.) are involved in horizontal transmission, but the details of horizontal transmission and its significance are poorly understood [239, 240]. SBV has been found to be shed in semen, unlike Akabane virus, and vertical transmission occurs [241]. The susceptibility of non-ruminant species to SBV is unclear [239]. SBV is unlikely to pose a risk to humans [242].

Virus can be isolated from blood and various fetal tissues and fluids [19]. PCR and immunochemical methods are available for detection in tissues. For SBV, brainstem tissue for PCR and pleural fluids for antibody testing have been reported as an optimal combination for diagnosis [243]. Differentials for arthrogryposis/hydranencephaly include BTV, BVDV, Chuzan, Wesselsbron, SBV, genetic causes, and toxins such as lupines.

Wesselsbron virus infection is caused by a mosquito-borne flavivirus primarily found in Africa. Disease is most severe in young small ruminants. Infection in adult cattle is typically subclinical [244]. Pregnant cattle may sporadically abort, deliver weak calves, or deliver apparently healthy calves. Certain viral strains can produce encephalitis, porencephaly, and cerebellar hypoplasia [19].

Bovine Parvovirus (BPV) Infection

Bovine parvovirus (BPV) is widespread in the USA and worldwide. Often associated with diarrhea in calves, it is an uncommonly diagnosed cause of abortion [19, 192, 245]. Virus can be transplacentally transmitted to developing fetuses [246]. Experimental data indicate first and second trimester fetuses are most susceptible [246]. If infected between days 107 and 150, fetal cerebellar hypoplasia may be seen [19]. Fetuses infected in the last trimester can respond immunologically, preventing death. BPV should be considered in herds with abortion and repeat breeding problems [245].

BPV is present in multiple fetal visceral tissues and in membranes [19, 246]. BPV can be grown in cell cultures, but care should be taken that supplemental sera do not contain BPV antibodies. Serum from fetuses infected in the third trimester will have specific antibody to BPV [247].

Miscellaneous Viruses

Bovine enterovirus (picornavirus), adenovirus, pseudorabies virus (Suid herpesvirus 1), parainfluenza virus 3 (PI3), lumpy skin capripoxvirus, malignant catarrhal fever (gammaherpesvirus), foot and mouth disease virus (picornavirus), and bovine leukosis virus have been associated with abortion [13, 192].

Bovine PI3, generally considered a common mild respiratory pathogen, has been diagnosed uncommonly in abortions. Abortion calves have red rubbery lungs [248]. Prevalence in herds is high, and association with abortion may be incidental or contributory with other pathogens. Experimental infection

may cause bronchiolitis and interstitial pneumonia. Abortion due to PI3 is rare [27, 249].

Fetal antibodies to bovine enterovirus have been detected in high percentages of aborted fetuses tested in two studies [250, 251]. This virus has been associated rarely with significant enteric disease in adult cattle, and experimental reproduction of illness in calves has been difficult [252, 253].

Protozoa

Neospora caninum Infection

N. caninum is a common worldwide infectious apicomplexan parasite of domesticated livestock, dogs, and some species of deer [254]. Dogs (including coyotes, dingoes, and gray wolves) are definitive and intermediate hosts. Currently there is no evidence for infection in foxes [255]. Livestock are intermediate hosts that harbor tachyzoites that form tissue cysts [256–258]. Tachyzoites may be found in a variety of cell types, but tissue cysts are almost exclusively found in the nervous tissues, including brain, spinal cord, eye, and nerves. Infection occurs in both beef and dairy herds and it is a major cause of dairy cattle abortion in the USA and the UK [259–261]. Vertical transmission is a common and highly efficient route of infection in ruminants and can progress through multiple generations in congenitally infected heifers [256, 262]. Cattle may also become infected by ingestion of sporulated oocysts from canid feces.

Maternal seroprevalence is highly variable; seropositive cattle are more likely to abort than seronegative cattle [27, 263]. Antibody titers in infected cows may fluctuate or decline over time and many may be persistently infected, making interpretation of sample results difficult [27]. Serum samples from precolostral calves are useful for determining infection in suspect cows, due to the efficiency of transplacental transmission [264]. For abortions, specific antibodies in fetal serum (after 100 days' gestation) or brain/spinal cord tissue are indicative of infection but do not prove *N. caninum* as the abortigenic agent. Similarly, negative titers do not rule out neosporosis since fetal antibody formation depends on exposure level, gestational age, and duration of infection [27, 254, 265, 266].

Abortion is the only clinical sign in cattle, occurring from three months' gestation to term, but predominating at five to six months, a hallmark pattern of this pathogen [256, 259, 267, 268]. Abortions may be sporadic, endemic, or epidemic [269]. Calves may be stillborn, mummified, malformed, or born alive; calves may rarely show neurologic signs [73, 254]. They may also be small for their age, ataxic, or have flexion/hyperextension of the limbs [19]. In most cases of infection, asymptomatic congenitally infected calves are produced [267].

For definitive diagnosis an examination of the fetus is necessary. Fetuses are typically autolyzed with serosanguineous fluid accumulation. No consistent gross lesions are seen, although pale streaking in skeletal or cardiac muscle may be present [267]. Cotyledons may be necrotic and areas of malacia (soft, pitted, darker areas) may be seen in the brain or brainstem [19]. Submitting the entire fetus with placenta is optimal. Fetal brain is the most consistently affected tissue for finding lesions. IHC is highly useful for diagnosis since organisms may be few and difficult to find in autolyzed tissues [254]. The results of such methods should be viewed cautiously, as fetuses infected later in gestation may only have a mild *N. caninum* infection but die from a secondary pathogen [27]. Congenitally infected calves often have high precolostral titers, but antibody levels vary and may even be undetectable [9, 19].

Tritrichomoniasis

This is a worldwide venereal disease of bull-bred cattle due to *T. foetus* parasitism. Commercial AI services in the USA often screen for this pathogen, although custom-collected semen may be contaminated. This flagellated protozoan is an obligatory inhabitant of male and female genital tracts, occurring in both beef and dairy herds. Concurrent infection with *C. fetus* subsp. *venerealis* may be common. Females of all ages exhibit equal susceptibility and present with a history of bull-bred infertility due to embryonic death.

Infection typically causes vaginitis that may progress to endometritis; such infections may cause embryonic death and abortion (5 to >20%) in the first half of gestation, with uncommon later-stage abortions. The majority of pregnancies are probably lost by day 17. Fetuses aborted in mid pregnancy may be macerated and expelled with membranes. Cows may develop pyometra due to retained fetuses, which may present as multiple pyometras in a bull-bred herd. Uterine fluids are copious with little odor and can vary from watery and flocculent to red/brown and inspissated. Embryonic death after recognition of pregnancy (17 days) can lead to irregular cycling and return to estrus 60–90 days after breeding.

Placentas show little evidence of pathology aside from edema or the presence of white flocculent material and mild cotyledonary hemorrhage. Fetuses present in varying stages of autolysis, from fresh to macerated, and in many cases show no gross pathologic changes. Mild rumenitis with plaque formation can be seen occasionally [107]. In late-stage abortions bronchopneumonia and necrotizing enteritis have been seen.

Diagnosis depends on finding organisms in fresh fetal fluids/abomasal contents and pyometra fluids (directly from the uterus) where they are often plentiful. Tissues older than 48 hours are poor specimens. Commercial media are preferred for transport and culture (In-Pouch TF Bovine, Biomed Diagnostics, OR, USA) and samples should be

maintained between 22 and 37 °C. Buffered saline solutions (physiologic saline, lactated Ringer's) can be used, but samples should be kept cool (not frozen) and delivered as soon as possible (<48 hours) to a diagnostic laboratory. Positive identification of *T. foetus* may be complicated by other flagellated protozoan species. Immunohistochemical methods are also available to detect organisms in fixed tissues.

T. foetus infections may mimic *C. fetus* subsp. *venerealis* infections [9, 13, 19, 27, 269–272].

Sarcocystis Infection

Sarcocystis cruzi, *Sarcocystis hirsuta/Sarcocystis bovifelis*, and *Sarcocystis hominis* are coccidian protozoal parasites that commonly infect cattle. Carnivores are the definitive hosts while herbivores are the intermediate hosts. Cattle are infected by ingesting sporulated oocysts in carnivore feces. Once ingested, sporozoites are released into the gut, where they penetrate the mucosa and develop in arteries as meronts. The parasites are released from vessels as merozoites that then infect capillaries throughout the body. After a second round of replication, merozoites infect mononuclear cells and enter muscle and neural tissues to encyst. Clinical disease is uncommon in adult cattle but is associated with hemorrhage and edema due to the effects of intravascular maturation [273]. Signs include fever, ptyalism, lymphadenopathy, anemia, and abortion, with experimental oral infection [274].

Abortion is rare and has been reported in the third trimester; fetal hypoxia due to dam anemia, premature parturition due to $PGF_2\alpha$ release, pyrexia, or direct infection of the fetus are suggested etiologies [13, 19]. Parasitic cysts may be present in the placenta or the fetus, but this is not typical. Gross lesions may resemble *N. caninum* infection or be inapparent [19, 27]. Microscopic lesions are typically plentiful, consisting of necrosis in soft tissues and tissue cysts [27].

Miscellaneous Parasites

Abortion in herds infected by *Trypanosoma vivax* has been reported, likely a result of anemia and overall ill-health in the cow [275]. *Babesia bovis* and *Babesia bigemina* are associated with abortions as a result of pyrexia and fetal infection. Infected aborted fetuses are anemic and icteric, with swollen icteric livers [276]. *Theileria orientalis*, a cause of benign/non-transforming theileriosis, is associated with severe anemia and abortion in Australia, New Zealand, and Japan [277].

Fungi

The incidence of mycotic abortion varies widely [278]. In some areas fungal abortion is the most common abortion diagnosis [279]. Losses are sporadic as these organisms are not contagious. The degree of environmental contamination may increase the risk of fetal infection [27, 280].

A variety of ubiquitous environmental fungi cause abortions in cattle worldwide. Prevalence of fungal types and commonality of fungal abortion varies geographically. *Aspergillus* spp., *Zygomycetes* (*Absidia*, *Mucor*, *Rhizopus*, *Mortierella*), *Candida* spp., and *Pseudallescheria boydii* are among the more frequently reported [19]. *Aspergillus fumigatus* and other *Aspergillus* species are reported as the most common causes of mycotic abortion, with *Zygomycetes* the second most common [278]. It is thought that primary maternal disease in the respiratory or gastrointestinal tract leads to hematogenous spread to the placentomes, as lesions are first seen there and are most severe. Clinical signs in the dam are typically not seen. However, fetal abortion with *Mortierella wolfii* is associated with a severe post-abortion pneumonia in the dam [27, 280].

Abortions occur in the last trimester and they generally do not exceed 10% incidence in a herd [280]. They may be seasonal in association with increased environmental exposure. In the northern hemisphere, the winter and spring are most often associated with abortion [280]. Retained membranes are common. Infection causes severe thickening of cotyledons with extension into the intercotyledonary areas, imparting a cracked or leathery appearance to tissues. Cotyledons may have entrapped shreds of maternal caruncular tissue (see Figure 56.3). Fetuses may have minimal autolysis.

Placentitis develops slowly, interfering with fetal nutrition and often leading to fetal death. However, normal live calves may be born in cases of mild or even severe placentitis [13]. Fungal infection then extends to the fetus by infection of amniotic fluid. Fetuses may have numerous irregular tan epidermal plaques, particularly on the face, back, and sides (see Figure 56.8) [19]. Infections due to septate fungi (*Aspergillus* spp.) often cause raised, dry, and wrinkled skin lesions, while infections due to nonseptate fungi *(Mucor* spp., *Rhizopus* spp.) may cause flat, moist, white/red foci [20]. Because of the chronicity and severity of infection in placentomes, incarceration of cotyledons may prevent membrane detachment for up to 10 days. At this stage, complete placentomal necrosis may ensue, with retention of necrotic tissues, maceration, and/or pyometra [13].

Gross lesions are distinctive (see Figure 56.39). Placental lesions may mimic *B. abortus* or *Campylobacter* sp. infection [280]. Organisms may be cultured from the placenta, abomasal fluid, or lung. Placentas or, less commonly, abomasal fluids may have incidental fungal contamination. Diagnosis requires compatible lesions in addition to the presence of fungi.

Figure 56.39 Placenta with fungal placentitis and *Aspergillus* sp. Placentomes are swollen with abundant fibrinous exudate. *Source:* Courtesy University of Illinois Veterinary Diagnostic Laboratory.

Definitions

Asterisk denotes definitions from an authoritative source [52].

Abortion Expulsion of a conceptus incapable of independent life.* Calves born after day 260 are generally thought to be able to survive independently. Expulsion of the entire conceptus (complete abortion) or portions (incomplete abortion) may occur.

Allantois A secondary outgrowth of extraembryonic splanchnopleure from the ventral hindgut. The mesoderm is vascular.*

Amnion Extraembryonic somatopleure that is inverted around the embryo such that the ectoderm lines a cavity filled with amniotic liquor. The mesoderm is avascular.*

Birth Expulsion of a live fetus.

Blastocyst The stage in development after the morula, where the cells form a hollow sphere with an inner cell mass.*

BVDV Bovine viral diarrhea virus (bovine pestivirus).

Calf A live-born bovine.

Caruncle (plural carunculae) Discrete, monomorphic, regularly placed fleshy elevations of the inner uterine wall.

Chorion Extraembryonic somatopleure that is composed of an outer ectodermal trophoblast and is not part of the amnion. The mesoderm is avascular.*

Conceptus An inclusive term denoting the embryo or fetus and membranes.

Congenital Present at birth.*

Cotyledon Discrete, monomorphic, regularly placed elevations of the chorioallantois that are directly apposed and adhered to the uterine caruncles.

Embryo An animal in early development that does not have a form recognizable as a particular species.

Embryonic death Death of the conceptus prior to day 42.

Endemic abortion Abortion in a continuous pattern, at a rate greater than 5% throughout the year.

Epizootic/epidemic abortion A storm of abortions where greater than 10% of at-risk cattle abort in a short period of time, usually within two to three months.

Fetal death Death of a fetus prior to complete expulsion from the dam, subdivided into antepartum and intrapartum.*

Fetal period The stage of development between days 42 and 260, divided into early (days 42–120), middle (days 120–180), and late (days 180–260).*

Fetus An animal in development that has identifiable features of a given species.

Gestation The period of pregnancy; breeds typically vary in length, from 278 to 293 days.

Hamartoma A focally excessive overgrowth of mature normal cells in an organ that typically contains those cells.

IBR Infectious bovine rhinotracheitis virus (bovine herpesvirus 1).

Inner cell mass The group of cells in the blastocyst at one pole that develop into the embryo.*

Morula The early stage when eight or more cells are arranged in a solid mass without organization.*

Periparturient (peripartum) With reference to the dam, the time span occurring during the last 10% (30 days) of gestation to the first few weeks of calf life.

Placenta The fetal and maternal specialized organs of transfer between mother and offspring. The fetal placenta is the chorioallantois, while the general term "fetal membranes" includes the amnion as well.

Placentome The union of chorionic villi (cotyledon) and caruncle.

Premature parturition Delivery of an immature viable calf prior to completion of normal gestation (about 260 days).

Somatopleure The lateral and ventral body wall of the embryo composed of an outer ectoderm and an underlying mesoderm.

Splanchnopleure The embryonic layer formed by the fusion of the visceral mesoderm to the endoderm (definitive yolk sac wall).

Sporadic abortion Individual or small numbers of abortions occur at irregular intervals and typically do not exceed 3–5% annually.

Stillbirth Delivery of a dead fetus within the time of expected viability (after day 260).

Teratogen Anything, infectious or otherwise, that causes abnormal development in a conceptus.

Trophoblast The outer cellular layer composed of extraembryonic ectoderm through which all physiological exchange takes place.*

Zona pellucida The non-cellular layer surrounding the ovum.

Zygote A diploid cell formed from fusion of male and female pronuclei lasting until the first cleavage is complete.

Infectious Agents: Campylobacter

Jessica B. Rush[1] *and Misty A. Edmondson*[2]

[1]*Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA*
[2]*Alabama Department of Agriculture and Industries, Montgomery, AL, USA*

Introduction

Campylobacter fetus subsp. *venerealis* is the etiologic agent of bovine venereal campylobacteriosis and is an important cause of infertility, death of the late embryo or early fetus, and sporadic abortion in cattle. This organism was first recognized in the early 1900s as a cause of abortion in cattle and was initially called *Vibrio fetus* [1]. Based on differences in clinical presentation the agent was further classified as *Vibrio fetus* subsp. *intestinalis* and *Vibrio fetus* subsp. *venerealis*. *Vibrio fetus* subsp. *intestinalis* was associated with sporadic abortions due to bacteremia from the intestinal tract of the pregnant cow. *Vibrio fetus* subsp. *venerealis* was also associated with occasional abortions, but the primary importance of infection was a significant decrease in herd fertility. However, in the 1960s there was evidence that many of the *Vibrio* species were sufficiently different to warrant classification under a separate genus, *Campylobacter* [2]. Consequently, *Vibrio fetus* subsp. *intestinalis* was renamed *Campylobacter fetus* subsp. *fetus* and *Vibrio fetus* subsp. *venerealis* was renamed *Campylobacter fetus* subsp. *venerealis*. "Vibrio" is still a commonly used term to refer to the venereal disease caused by *Campylobacter fetus* subsp. *venerealis*.

Etiology

C. fetus subsp. *venerealis*, a slender, motile, Gram-negative, comma-shaped or S-shaped rod that appears as "seagull wings" in silhouette, requires a microerophilic environment for growth [2, 3]. *Campylobacter* spp. require an atmosphere of 10–20% CO_2 with reduced oxygen concentration at 5% or less and optimal growth occurring at 37 °C [2]. There are two biotypes within the subspecies, biotype *venerealis* and biotype *intermedius*. These biotypes are differentiated by the production of hydrogen sulfide with lead acetate strips when organisms are grown in media containing cysteine. Biotype *intermedius* produces hydrogen sulfide, whereas biotype *venerealis* does not. Both biotypes are capable of causing disease; however, biotype *intermedius* appears to be less pathogenic than biotype *venerealis* [4].

Pathogenesis

C. fetus subsp. *venerealis* is primarily transmitted by the venereal route. Bulls serve as carriers and are the major mode of transmission of the organism through a naive herd. The rate of transmission from infected bulls to naive cows is quite high, approaching 100%. The bacterium may be spread to cows and heifers at the time of artificial insemination (AI) with infected semen. Direct transmission from cow to cow is unlikely, although contaminated insemination equipment may act as a fomite, allowing for transmission of the organism [5]. Campylobacteriosis may be spread from bull to bull if contaminated semen collection equipment is not sufficiently cleaned between bulls [4]. In addition, transmission has been reported to occur from bull to bull due to contaminated bedding [6].

Bull

The role of bull age in the course and duration of disease is unknown. One study demonstrated no difference in duration of infection between bulls 5.5–6 and 3.5–4 years

of age [7]. However, another study revealed a higher incidence of infection in bulls greater than 6 years of age [8]. It has been speculated that younger bulls may be more resistant to infection and more likely to clear infection, and clear infections within a few weeks. In addition, it has been speculated that older bulls are more likely to become persistent carriers due to an increase in the number and depth of crypts in the preputial epithelium [4]. However, more recent work evaluating the surface architectural anatomy of bulls revealed no differences in penile and preputial epithelial anatomy between young and old bulls [9].

The prepuce of bulls serves as the natural reservoir of infection to naive cows through natural mating [10]. The addition of carrier bulls poses a significant risk to a naive herd, although the disease is most commonly seen in newly introduced cows and heifers in herds where bovine campylobacteriosis is endemic [11].

Cow/Fetus

Venereal campylobacteriosis causes low reproductive efficiency, resulting in severe economic loss to a cattle operation [12]. This is associated with temporary infertility with mild endometritis, death of the early embryo or early fetus (30–70 days of gestation), and sporadic abortions [13, 14]. After exposure the bacteria colonize in the mucosa of the anterior vagina and cervix of cows [10]. The infection then spreads to the uterus and oviducts under the influence of progesterone. Fertilization and development of the embryo are not directly affected by *C. fetus* subsp. *venerealis*. The resulting inflammatory response in the uterus and/or oviducts results in early embryonic death. The majority of pregnancy loss occurs between 30 and 70 days of gestation [13, 15]. Reactions associated with heat-stabile endotoxins produced by *C. fetus* subsp. *venerealis* are thought to be responsible for the occasional mid-term abortion [4]. *C. fetus* subsp. *venerealis* has the ability to reach the placenta and the amniotic fluid and cause severe placentitis and fetal hypoxia [16]. Cows and heifers are normally capable of mounting an immune response, clearing the infection, and returning to normal fertility four to eight months after the initial infection [13].

Immune Response

Infection with *C. fetus* subsp. *venerealis* in cows and bulls does not produce significant systemic antibodies during or after infections [17]. Unlike bulls, cows and heifers infected with *C. fetus* subsp. *venerealis* produce a local antibody response in the vagina and uterus. Heifers challenged with *C. fetus* subsp. *venerealis* had transient agglutinating and immobilizing immunoglobulin (Ig)M antibodies followed by persistent IgA and IgG antibodies in vaginal secretions and predominantly IgG antibodies in uterine secretions [17, 18]. Both IgA and IgG antibodies to *C. fetus* subsp. *venerealis* surface antigens immobilize and mediate neutrophil and mononuclear cell killing of the bacteria [19]. The production of IgG in the uterus directs clearance through opsonization and phagocytosis. In the lower reproductive tract, the IgA produced helps to immobilize the bacteria and block adherence of the organism. Conversely, IgA may also be responsible for blocking opsonization and promoting persistent colonization of the lower genital tract. Because of the stronger antibody response in cows and heifers, prolonged infections in females are not as persistent as they are in bulls [18, 20]. However, in the rare case of the chronic carrier cow, the bacterium may be able to elude the immune response and be maintained in the cervix through a full gestation, although this is quite unusual (<1% of infected females) [6]. Persistence of infection in the cervix and vagina in the presence of an immune response may be partly due to antigenic changes in the organism that allow for avoidance of the host immune response. Antigenic changes in the S-layer, a regular array of high-molecular mass surface proteins that compose the outermost part of the cell envelope, result in the expression of different immunodominant epitopes and persistence of the organism [4].

Clinical Signs

Herd

A herd history of poor conception rates, infertility, or second trimester abortions is commonly one of the first indications that bovine venereal campylobacteriosis could be a problem. Trichomoniasis, poor detection of estrus, and bull subfertility or infertility should also be considered as possible differential diagnoses. A confirmatory diagnosis of bovine venereal campylobacteriosis should be attempted through laboratory evaluation of samples obtained from the herd. Samples for diagnosis include tissues from aborted fetuses, placenta, vaginal mucus samples, vaginal washings, and preputial scrapings.

When beginning a diagnostic evaluation of a herd, it seems advantageous to begin with the breeding males in the herd due to the fewer number of males and the self-limiting type of infection associated with females. Thus preputial scrapings should be obtained from all herd bulls. If bulls are not available, vaginal mucus samples should be obtained from a representative sample of cows and heifers and submitted to the diagnostic laboratory.

Cow

In females the main clinical signs are related to infertility. Venereal campylobacteriosis is characterized by repeat breeding, irregular estrous cycles, prolonged calving seasons, and reduced calf crops [13, 21]. The average number of services per conception is extended to 2.5–3.5. When infection is introduced into a naive herd, the initial pregnancy rates are quite low. As the breeding progresses, the conception rate of the herd improves as females clear the infection. However, the resulting calving season is extended as more cows conceive later in the season. Infected cows show few clinical signs of infection. Most infected cows do not exhibit vaginal discharge; however, a mucopurulent secretion may be detected in the occasional cow [4]. As previously stated, the majority of pregnancy loss occurs between 30 and 70 days of gestation; the uncommon midterm abortion, four to eight months of gestation, due to *C. fetus* subsp. *venerealis* has also been reported [13, 15]. Abortions appear to be more commonly associated with biotype *intermedius* than with biotype *venerealis*. When midterm abortions due to *C. fetus* subsp. *venerealis* are reported, there is typically a recent history of infertility in the herd [4].

Bull

Infection with *C. fetus* subsp. *venerealis* in bulls is not apparent as bulls do not exhibit clinical signs of infection. Although genital infections in mature bulls may persist for months or years, there are no alterations in semen quality or production [22–24].

Pathology

The pathology associated with infection of *C. fetus* subsp. *venerealis* is limited to the reproductive tract. Endometritis, mild cervicitis, and salpingitis are usually the only lesions seen in cows and heifers [25]. Grossly the cervix may appear reddened and the uterus may produce a small amount of mucopurulent exudate that can extend through the cervix into the vagina. Histologically, the lesions have mild infiltration of inflammatory cells (plasma cells and foci of lymphocytes in the stroma) with slight desquamation of the superficial epithelium with no significant vascular changes [25]. Involvement of the endometrial glands is minimal, although cystic glands with slight periglandular fibrosis have been noted on clearance of infection [25].

No gross abnormalities are observed on the penis and prepuce of infected bulls. Histologically, there is only a diffuse infiltration of mononuclear cells within the lamina propria of the penile and preputial epithelium [22]. Plasma cells are located in clusters at the apex of the dermal papillae [7]. However, the infiltration of subepithelial lymphocytes and plasma cells has been found in both infected and uninfected bulls [22, 24, 26].

The most common fetal lesions associated with *C. fetus* subsp. *venerealis* are neutrophilic bronchopneumonia and interstitial pneumonia [16]. Other commonly observed lesions include non-suppurative interstitial enteritis, hepatitis, pericarditis, myositis, myocarditis, serositis, occasional abomasitis, and meningitis [16, 27, 28].

Diagnosis

It is important to be able to differentiate *C. fetus* subsp. *venerealis* from *C. fetus* subsp. *fetus*. The natural habitat for *C. fetus* subsp. *fetus* is the intestinal tract of cattle, but it can also cause sporadic abortions [29]. Differences in the epidemiology and clinical relevance of these bacteria make accurate detection imperative. The traditional means for differentiating between both species, and the recommended international standard, is based on tolerance to 1% glycine [30]; *C. fetus* subsp. *venerealis* is sensitive to glycine whereas *C. fetus* subsp. *fetus* is tolerant to glycine. However, the glycine tolerance characteristic may not be completely reliable for differentiation of the two subspecies as it has been demonstrated that glycine tolerance can be acquired by transduction or mutation [31]. In addition, glycine-tolerant variants of *C. fetus* subsp. *venerealis* have been described and designated as *C. fetus* subsp. *venerealis* biotype *intermedius* [30, 32]. Glycine-sensitive *C. fetus* subsp. *fetus* isolates have been detected as well [33]. Another method of differentiation between the two organisms is a hydrogen sulfide production test, as *C. fetus* subsp. *fetus* produces hydrogen sulfide and *C. fetus* subsp. *venerealis* does not [34].

Sample Collection

Bull

A simple method for collecting preputial smegma is to take a preputial scraping. The most common method for collecting a preputial scraping involves using a plastic AI pipette, which is fast, easy, and inexpensive [14]. The tip of the AI pipette is placed into the proximal preputial fornix. Scraping of the prepuce should be somewhat vigorous in an effort to loosen epithelial cells from the penile and preputial surfaces and include 10–15 strokes. A 12-ml syringe should be attached to the distal end of the AI pipette, and the clinician should apply negative pressure to the pipette throughout the scraping procedure [14]. A small amount

of hemorrhage may be seen following preputial scraping but usually does not indicate any harm to the bull. As the pipette is being withdrawn from the preputial cavity, the negative pressure on the pipette should be released gently. An adequate sample consists of a 2- to 5-cm column of cloudy smegma within the pipette. A plastic sheath may be used to minimize contamination prior to introducing the pipette into the preputial cavity. The Pizzle Stick (Lane Manufacturing) provides an alternative collection tool to the traditional AI pipette. This tool is used in the same manner as the AI pipette; however, the corrugated grooves located on the tip of the stick allow for the collection of smegma. Historically, other methods of collecting smegma from the preputial cavity of bulls include preputial lavage (douching) and swabbing the penile and preputial epithelium with the penis held in extension.

Cow

A cranial vaginal mucus sample can be obtained from the cow by using an AI pipette with a plastic sheath to minimize contamination. A 12-ml syringe is placed on the distal end of the AI pipette, which is then placed into the cranial vaginal fornix of the cow. Negative pressure is placed on the syringe while the pipette is gently moved within the vaginal fornix. Collection of vaginal mucus samples should be performed around the time of estrus. Culturing of vaginal mucus samples is considered most useful diagnostically when samples are obtained early in the course of infection before immunity develops [4].

Fetus

Samples that should be collected from an aborted fetus include abomasal fluid, lung, liver, heart, intestine, and placenta. Abomasal fluid from aborted fetuses serves as the best diagnostic sample. Fetal membranes may also be useful, but diagnosis is often complicated due to the presence of contaminating bacteria [4].

Sample Transport

Proper handling of preputial scrapings, vaginal mucus samples, or samples from aborted fetuses and fetal membranes is critical for accurate diagnosis of *C. fetus* subsp. *venerealis*. In order to optimize recovery of the organism, it is best to have samples at the laboratory within six hours of sample collection. *Campylobacter* spp. require a complex support medium, antimicrobials to suppress growth of commensals and contaminants, and near-anerobic conditions [35]. The success of culture of *Campylobacter* spp. is directly related to the choice and availability of media. Several different transport enrichment media (TEM) are available for isolation and culture of samples for *C. fetus* subsp. *venerealis*. These TEM include Weybridge medium, Cary–Blair medium, Clark's selective medium, Australian TEM, Blaser–Wang medium, Lander's transport medium, Campy-Bac, and Thomann transport and enrichment medium [3, 14, 36, 37]. It is best for clinicians to contact their local diagnostic laboratory for preferred media and sample handling prior to collection and submission of samples. In many cases the laboratory will supply the transport media and instructions for its use. Once in the TEM, the sample is safe, to some degree, from small changes in temperatures. If an inoculated TEM is to be in transit more than four hours, it is recommended that the sample not be incubated above room temperature until it reaches the diagnostic laboratory [14, 38].

Samples can be pooled to decrease the cost of testing animals when permitted by the diagnostic laboratory. Sensitivity of the quantitative polymerase chain reaction (qPCR) has been shown to be comparable for the pooling of up to five samples with that of a single unpooled sample [39]. However, care should be taken to contact the local diagnostic laboratory before pooling samples, as not all allow pooled samples or, if they do, many prefer to pool the sample themselves.

Temperature during transport may be more critical depending on the time it takes for the sample to arrive at the diagnostic laboratory. It has been shown that sensitivity of qPCR is highest for short-term transport (2–48 hours) when shipped at either 4° C or 30° C, but long-term transport (96 hours) has the highest sensitivity at −20° C [39].

Diagnostic Techniques

Antigen or Antibody Detection

Antigen detection techniques are most often used to identify an active carrier of venereal campylobacteriosis in bulls, although antibody detection may be more useful for detection of the organism in cows. The detection of antigen includes the fluorescent antibody test, which is most commonly used for preputial scrapings from bulls [36]. The sensitivity and specificity are reported to be 93 and 88.9%, respectively [40]. An immunohistochemical technique has also been developed, with a sensitivity of 94% for detecting *C. fetus* in aborted fetal tissues [41].

Systemic antibody responses are not helpful because they are often due to non-pathogenic *Campylobacter* spp. One specific antibody detection method is the vaginal mucus agglutination test to detect antibodies in preputial

scrapings, vaginal mucus, and aborted fetal fluids [42]. However, due to the low sensitivity of the test, it is best used for herd evaluation utilizing vaginal mucus samples collected between 37 and 70 days after infection [3]. In addition, the specificity of this test may be negatively affected by the presence of blood or an unrelated inflammation [4]. A vaginal mucus sample that causes complete agglutination at a dilution of 1 : 25 is considered a positive diagnosis [4].

Specific IgG antibodies have been detected via enzyme-linked immunosorbent assay (ELISA) in order to measure the humoral immune response in cattle following vaccination against *C. fetus* [43, 44]. An ELISA has also been used to detect IgA antibodies in vaginal mucus from cows following abortion [45], and a monoclonal antibody-based ELISA has been developed as a screening test for detecting *C. fetus* subsp. *venerealis* in preputial scrapings and vaginal mucus samples [46, 47].

Isolation in Culture

Campylobacter spp. are not easily cultured and isolated due to the organism's fastidious nature and special requirements for growth in media [3, 48]. Once at the laboratory the TEM is streaked onto selective media and incubated in a microerophilic atmosphere (6% O_2, 7% CO_2, 7% H_2, 80% N_2) at 37 °C. The media plates should be incubated for at least six days before being called negative. In many cases, colonies of *C. fetus* subsp. *venerealis* will be visible within three days of inoculation. Colonies are round, raised, and 1–3 mm in diameter. These colonies may initially appear clear but become opaque on further incubation. Phenotypic characteristics are most commonly used for identification. *C. fetus* subsp. *venerealis* isolates are oxidase positive, catalase positive, resistant to nalidixic acid but sensitive to cephalothin, and grow at 25 °C but not at 42 °C. It is imperative to differentiate between *C. fetus* subsp. *venerealis* and *C. fetus* subsp. *fetus* due to potential sample contamination. These two subspecies of *C. fetus* only differ in that *C. fetus* subsp. *venerealis* does not grow in the presence of 1% glycine whereas *C. fetus* subsp. *fetus* does grow in 1% glycine [4]. As previously mentioned, the glycine tolerance characteristic may not be completely reliable for differentiation of the two subspecies as it has been demonstrated that glycine tolerance can be acquired by transduction or mutation [31]. A passive filtration technique during culture may increase the recovery rate of *C. fetus* subsp. *venerealis* while decreasing the contamination from other organisms. This is accomplished by applying a mixed cellulose ester membrane filter over the top of a blood agar plate and inoculating with the sample. The plate is incubated right side up at 37° C for 30 minutes, allowing for motile organisms to cross the filter into the media. The filter is then discarded and the plate returned to the same environment for an additional 72 hours of culture [49].

Direct examination via darkfield microscopy and Gram's staining of abomasal contents from aborted fetuses may be a useful additional tool for diagnosing abortions due to *C. fetus* subsp. *venerealis*. Darkfield microscopy may allow observation of the morphologic traits and darting motility of *C. fetus*. Gram staining reveals a Gram-negative, comma-shaped or S-shaped rod that appears as "seagull wings" [2, 3]. *Campylobacter* spp. are more easily visualized by Gram's stain when counterstained with carbolfuchsin rather than safranin, the standard counterstain [2–4]. Darkfield microscopy and Gram staining may not be as beneficial for other samples.

PCR

Molecular methods for differentiating between *C. fetus* subsp. *venerealis* and *C. fetus* subsp. *fetus* have been developed to validate the results of phenotypic differentiation in order to avoid misidentification [29]. Most of these polymerase chain reaction (PCR) assays use the colonies grown from the cultured vaginal mucus or preputial scrapings [14]. However, Thomann transfer and enrichment medium was developed for the enrichment of *C. fetus* subsp. *venerealis* and to allow direct PCR amplification from media if overgrowth with contaminants occurs [37]. Differentiation of *C. fetus* spp. is achieved by a specific PCR assay [50]. This assay utilizes a species-specific 764-bp amplicon that is produced with primers MG3F and MG4R with the DNA of both species of *C. fetus*. Subsequently, primers VenSF and VenSR are used for differentiation. The identification of *C. fetus* subsp. *venerealis* is based on the presence of a 142-bp amplicon that is not formed by *C. fetus* subsp. *fetus* [50]. However, the reliability of this PCR assay has been called into question [30] due to misidentification in up to 10% of strains [51]. Therefore this PCR assay may best be used to confirm traditional phenotypic characterization of *C. fetus*.

Other studies have focused on the use of a multiplex PCR for differentiation of *C. fetus* spp. [51]. Multiplex PCR consists of multiple primer sets within a single PCR mixture. These primer sets produce amplicons of varying sizes that are specific to different DNA sequences, which are observed as distinct bands when visualized by gel electrophoresis. However, utilization of multiplex PCR will require further validation with regard to a larger pool of clonal strains [52, 53].

Cloning and nucleotide sequencing, with and without PCR, are becoming more useful methods for genotyping bacterial isolates [54]. In fact a novel 5′ *Taq* nuclease PCR assay using a 3′ minor groove binder DNA probe has been developed for the direct detection of *C. fetus* subsp. *venerealis* in clinical samples from cattle [55]. Molecular methods to

discriminate between the two subspecies of *C. fetus* have also utilized the discovery of an 80-kb genomic sequence (consisting of type IV secretion system [T4SS] components, putative plasmid genes, and other proteins) and an insertion element (ISCfe1) unique to *C. fetus* subsp. *venerealis* [56, 57].

Prevention, Control, and Treatment

Prevention

Vaccination programs are the most effective means of preventing campylobacteriosis in a cattle herd and should include vaccination of bulls as well as cows and heifers [13]. Initial immunization of females requires two injections of bacterin, with the second injection coming within three weeks of breeding. Annual boosters should also be administered within three weeks prior to breeding [14]. This prebreeding schedule of vaccination increases antibody levels (IgG_1 and IgG_2) at the time when exposure is most likely to occur and helps protect against uterine infection [14].

Many different *C. fetus* vaccines are available for use in cattle, including both oil-adjuvanted and aluminum hydroxide-absorbed vaccines [13]. Bacterins in oil adjuvant are more effective and provide a longer duration of immunity and protection after a single dose [58]. Two commercial aluminum hydroxide-absorbed vaccines were evaluated in herds in Argentina and were found to be ineffective at preventing reproductive loss due to *C. fetus* [13, 59]. Subcutaneous administration of a single dose of an oil-adjuvanted *Campylobacter* vaccine demonstrated protection in heifers from reproductive losses. However, oil-adjuvanted vaccines cause localized granulomas and granulomas at the injection site [13].

Vibrin™ (Zoetis) is the only oil-adjuvanted *C. fetus* bacterin available in the USA that has been evaluated in bulls [13]. Two 5-ml doses, which is 2.5 times the dosage recommended for vaccination of cows, should be administered subcutaneously to breeding bulls at four-week intervals beginning eight weeks prior to the breeding season. Annual revaccination at the same dose is recommended four weeks prior to the breeding season [13, 60].

Control

Elimination of natural breeding and the use of AI is the best means of controlling bovine venereal campylobacteriosis. However, producers often find this a difficult recommendation to follow. If AI is used the semen should be adequately screened for *C. fetus* subsp. *venerealis* and have antibiotics added to the semen extender to ensure that contaminated semen does not allow reintroduction of the bacterium into the herd. If AI is not possible, the previous battery of bulls should be replaced with virgin bulls [14]. The entire bull battery should be tested at the end of the breeding season, with all positive bulls being culled.

Treatment

Because of the lack of availability and effectiveness of certain antibiotics (streptomycin), the treatment of animals infected with *C. fetus* subsp. *venerealis* has focused on immunotherapy to clear the infection, which involves immunizing animals with an appropriately adjuvanted antigen. Systemic immunization of cows that have been actively or passively immunized with *C. fetus* subsp. *venerealis* has cured these animals of the vaginal carrier state [24, 61, 62]. In addition, systemic immunization may cure, or clear infection for nine weeks or more, in some bulls infected with *C. fetus* subsp. *venerealis* [23, 63, 64]. Immunization induces both local and systemic IgG antibody production, which prevents microbial adherence, immobilizes the bacteria, activates complement, and opsonizes bacteria for phagocytosis [24]. The oil-adjuvanted vaccine preparations are most often used for therapeutic immunotherapy.

Infectious Agents: Tritrichomonas

Katelyn Waters and Julie Gard

Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

Trichomoniasis is a venereal disease in cattle. The causative agent is an extracellular protozoal agent, *Tritrichomonas foetus*. Infections occur in female and male cattle. However, the bull is the asymptomatic carrier, while the cow experiences clinical signs manifested as embryonic death, abortion, metritis, pyometra, and transient infertility. Older bulls are often unable to clear the infection and become chronically infected carriers [1]. A routine breeding soundness examination does not include *T. foetus* testing, so a *T. foetus* infected bull may pass such an examination. Both "trichomoniasis" and "trichomonosis" are commonly used to describe *T. foetus* infections in cattle [2]. Additionally, *T. foetus* is able to survive the freezing process used when freezing semen. Therefore only bulls that are tested and determined to be negative for *T. foetus* are utilized in certified bull studs. Using frozen semen from *T. foetus* negative bulls is considered a method of control. During the last century, the reported number of cases of *T. foetus* has increased dramatically. This increase is most likely associated with increased movement and demand, drought, and the development of improved modalities of identification of *T. foetus* infected animals. Swift identification and eradication of positive animals is the current control modality. With the identification and removal of infected animals being key to control of this disease, many states have implemented rules and regulations regarding the testing and movement of *T. foetus* positive animals. The economic losses seen with herd outbreaks of *T. foetus* can be devastating. In the USA there is currently no approved treatment for trichomoniasis in cattle; however, new therapy methods are currently being investigated.

Organism

The identification of *T. foetus* is credited to an Italian scientist Mazzanti in 1900, when he identified the organism in two cows and one heifer that were slaughtered due to infertility [3]. At the approximate time of the discovery of *T. foetus*, the disease brucellosis emerged and most likely became the predominant focus of research at the time [3]. In the 1920s work with *T. foetus* reemerged in Germany. In 1928, Riedmüller while studying aborted fetuses identified trichomonads in several of the affected fetuses. Following this study the name *Tritrichomonas foetus* was coined [3]. The first identified case of trichomoniasis in the USA was reported in Pennsylvania in 1932 from vaginal smears of several cows experiencing reproductive failure [3]. The organism has been identified in six of the seven continents, the exception being Antarctica, and is considered endemic in the USA west of the Mississippi River [2, 4].

T. foetus is an extracellular protozoan and an obligate parasite of the reproductive tract of cattle. *T. foetus* belongs to Trichomonadea, which comprises a class of amitochondriate protists belonging to the phylum Parabasalia [5]. *T. foetus* is a small flagellate whose size ranges from 10 to 25 μm long and 3–15 μm wide with a single well-developed laterally located undulating membrane spanning the length of the entire organism [6, 7]. Additionally, *T. foetus* has three less well-developed anteriorly located flagella and one posteriorly located flagella [6, 7]. Also, *T. foetus* undergoes two lifestyle stages, the pseudocyst and the trophozoite. The pseudocyst usually forms in times of unfavorable environmental conditions, such as following a decrease in nutrients, administration of drugs, or abrupt changes in temperature [5]. The trophozoite internalizes the flagella and the organism rounds up forming pseudocysts with no cyst wall surrounding the

Companion website: www.wiley.com/go/hopper/bovine

cell. These *T. foetus* pseudocysts are able to adhere to host cells and the pseudocyst adhesion rate is reported to be even higher than for the trophozoite form [8]. Reversibility assays have found that the pseudocysts can revert to the trophozoite form when conditions are favorable [5].

T. foetus is reported to infect other species such as domestic cats and colonize the colon, resulting in chronic irritation and diarrhea [9]. Additionally, *T. foetus* and *T. suis* are described as inhabitants of the porcine gastrointestinal system and the nasal mucosa [5]. It is believed that *T. foetus and T. suis* are synonymous [10]. Care must be used when identifying trichomonads microscopically as fecal trichomonads are extremely similar in size, shape, and characteristic movement and may even be the same. These similarities decrease the specificity of culture to accurately identify *T. foetus*, and so testing utilizing polymerase chain reaction (PCR) is necessary to truly differentiate different trichomonads. Prevention of disease within a herd is best done by institution of biosecurity protocols including testing of all non-virgin bulls and replacements and removal of infected animals, establishment of a closed herd, utilization of artificial insemination, and vaccination.

Transmission and Clinical Signs

As with the majority of sexually transmitted diseases, the male is the asymptomatic carrier, while the female experiences the reproductive losses. Transmission can occur via infected male to female or infected female to male during coitus. Transmission from infected female to infected female via uninfected bulls is possible if breeding occurs within the narrow time frame of 20 minutes [11, 12]. Infection of the female by an infected male requires only one breeding; however, the infection of an uninfected male by an infected female can require up to six breedings [4]. Infection via the use of contaminated artificial insemination guns and vaginal speculums is rare but has been reported [13]. In the bull, *T. foetus* inhabits the epithelium of the prepuce and penis [11]. Additionally, *T. foetus* has been isolated in the distal urethra of the bull [11]. It was previously speculated that there is an increase in the depth of the epithelial folds within the prepuce of aging bulls, usually referred to as "crypts." The presence of increasing depth of the epithelial folds of the prepuce has since been disproven via a study by Strickland et al. [14], which found that there were no significant differences observed in the preputial histology of bulls less than two or greater than five years of age.

In the cow, *T. foetus* inhabits the cervical mucus and eventually spreads throughout the entire reproductive tract [11]. Infection occurs following breeding with an affected bull. Once *T. foetus* is present in the cervical mucus, the organism moves from the cervix and vagina to the uterus during estrus and within weeks the entire reproductive tract is colonized [15]. *T. foetus* can be identified in the tract of a female as soon as four days post infection, with no apparent negative impact on conception or maternal recognition of pregnancy associated with the presence of *T. foetus* [13]. The number of parasites present in the cervicovaginal mucus fluctuates depending on the stage of the estrous cycle. The numbers of trichomonads are highest several days before estrus is observed [16]. Inflammation associated with infection of *T. foetus* can result in vaginitis and cervicitis. Infection ultimately leads to reproductive failure in the female, with embryonic death and abortions occurring most often within 95 days of exposure [13, 17]. Less than 1% of infected cows become chronically infected [18, 19]. Chronically infected females are defined as females that have remained infected for up one year post-infection [19]. These chronic carriers can serve as a source of reinfection for bulls and other cows [16].

Infected bulls do not suffer from any penile or preputial lesions and there are no reported negative impacts on libido [11]. However, there is a negative impact on motility according to a study by Ribeiro et al. [20]. This study found that *T. foetus* released cytotoxic substance, resulting in a significant decrease ($P \leq 0.05$) in progressive motility [20]. A study conducted in Florida documented that the mean age of infected bulls was 5.5 years $\pm$ 1.6, with the mean age of uninfected bulls being approximately 1.5 years younger [13]. Routine bull breeding soundness examinations (BBSEs) cannot identify infected bulls via the spermiogram as there is no negative impact of the trichomonads on semen morphology and motility may be lower but considered adequate. Annual BBSEs are an ideal time for collection of preputial smegma for testing of *T. foetus*. If the producer maintains a closed herd, has experienced no reproductive losses or decreased calf crop, and a previous negative trichomoniasis test had been obtained, it is less vital but remains a good recommendation to retest bulls every year.

Infection with *T. foetus* can cause a variety of reproductive issues in the female such as embryonic death, transient infertility, metritis, pyometra, and abortions [21]. The majority of embryonic death occurs at approximately day 17, at which time maternal recognition of pregnancy has occurred [16]. Although abortions occurring after three months of gestation are uncommon, placental lesions have been reported [22]. A clinical sign often noticed by the producer is an increased interestrus interval, which ultimately leads to a prolonged breeding season and a stretched out calving season. As most of the reproductive loss is manifested as embryonic loss, very few fetal abortions will be visualized. If a controlled breeding season is not already implemented, then affected herds can go undetected for

several months and even an entire calving year. A prolonged calving season will then occur, with most calves born late in the season. Economic losses from embryonic loss and lower weaning weights due to decreased time for average daily gain can be devastating. The effect of the prolonged calving season and late calving dates can be felt years later as the same cows will continue to have calves late in the calving season. In herds where trichomoniasis has gone undetected for a period of time, the results may be less dramatic because of temporary herd immunity. In such cases, the calf crop may only be reduced 5–10%. However, this loss is still enough to have a substantial economic impact on feeder calf breakeven price and profit per brood cow [23, 24]. The economic impact attributed to direct, secondary, and indirect losses is approximately USD $650 million annually in the USA and $300 million in the state of Texas alone [12, 25, 26].

Figure 58.1 Infusion pipette and Pizzle Stick used for collection of smegma from bulls potentially infected with *T. foetus*.

Sample Collection, Testing, and Diagnosis

As there is no currently approved treatment for *T. foetus* in the USA, control is reliant on the prompt identification and removal of positive bulls, followed by the institution of strict biosecurity. Identification of the organism is performed via the collection of preputial smegma in bulls and cervicovaginal secretions in female cattle [27]. Identification of the organism is also possible in aborted placental and fetal abomasal fluids; therefore all abortions should be investigated [16]. The rationale for obtaining samples from whole herds of cows is not logical due to the limited window of presence of the trichomonad in the vaginocervical mucus after infection, which ranges from 12 to 20 hours post-infection [28]. The preputial smegma from the bull is the most readily accessible and most reliable sample to obtain.

Prior to collection of preputial smegma, the bull's preputial hairs should be examined and cleaned of any debris to decrease the risk of fecal contamination of the sample. There are currently several methods of preputial smegma collection, including the Pizzle Stick® (Lane Manufacturing, Denver, CO), mare infusion pipette with attached 10-ml syringe, TRICHIT™ (Morris Livestock Products, Delavan, WI), microscope slide, gauze collection, and preputial wash. For the sake of ease, the most utilized collection methods are those that do not require extension of the penis, such as but not limited to the mare artificial insemination pipette and the Pizzle Stick, as shown in Figure 58.1.

Regardless of the collection method utilized it is imperative to ensure an adequate sample is collected from the prepuce, level with the midshaft of the penis, extending all the way to the fornix of the prepuce. Proper collection requires equipment in which the bull can be safely restrained with adequate access to the penis and prepuce. A study performed by Parker et al. [29] showed that choice of the side of collection was more important than the number of scrapes along the prepuce and shaft. This study stated that the most adequate samples are obtained when the practitioner collects from the side from which their dominant hand is located; therefore a right-handed individual should attempt to collect the bull from the right side [29]. For best ease of passage of the collection device, the thumb of your non-dominant hand is placed at the ventral aspect of the preputial orifice. Once your thumb is in place it acts as a guide for the collection device for placement into the preputial cavity (Figure 58.2). The hand can be moved from the preputial orifice and the collection device gently guided to the preputial fornix. Once the device is positioned at the fornix of the prepuce, the non-dominant hand massages at the level of the fornix (Figure 58.3), while the dominant hand manipulates the collection device five to ten times to ensure an adequate sample is collected.

Samples should be immediately placed in a collection device containing Modified Diamond's media. Media containers include a two-chambered pouch (In Pouch®) and a trichomoniasis transport tube containing Modified Diamond's media (Figure 58.4).

The sample should be free of gross debris to help ensure no fecal contamination occurs. If it is grossly contaminated the sample should be discarded and a new sample collected. It is important not to leave the sample in direct sunlight or place in a cooler or refrigerator as hot and cold will kill the organism. The death of the organism is less of a problem since the development of PCR, which will identify

Figure 58.2 Positioning of smegma collection device in preputial orifice of a bull.

Figure 58.3 Positioning of smegma collection device at preputial fornix of a bull.

the organism's DNA. However the dead organisms will not be identifiable on culture. Testing accuracy depends on the relative sensitivity and specificity. Sensitivity is defined as the ability of the test to correctly identify the positive animals with a positive test result. Specificity is defined as the ability of a test to correctly identify negative animals as truly negative.

Diagnostic testing for identification of *T. foetus* includes culture in Modified Diamond's media with bright field microscopic identification and PCR [1]. Culture alone relies on the microscopic visualization of the organism's characteristic jerky, rolling progressive movement [16]. Direct visualization of the organism is possible (Figure 58.5); however, due to the variable number of organisms present, a 25% decrease in sensitivity is appreciated [16]. Overall sensitivity of culture is lower than PCR due to the possible contamination of fecal trichomonads as the size and shape are almost visually undistinguishable. The PCR alone possess a

high degree of sensitivity with the ability to identify as few as 50 trichomonads per milliliter of sample [6].

The gold standard for identification of the organism has been PCR following a 48-hour culture period. The combination of *in vitro* culture followed by PCR has increased the sensitivity of the testing modality [6]. However, new tests have been developed and currently the most accurate determination of *T. foetus* positive bulls is through collection and testing of preputial smegma for nucleic acid through employing a direct reverse-transcription quantitative real-time PCR (direct RT-qPCR) utilizing smegma [30]. The specific test developed by Ginter Summarell et al. eliminated the need to use culture medium. The direct RT-qPCR exhibited 100% diagnostic sensitivity and 100% specificity, whereas the currently employed qPCR (culture PCR), which utilizes cultured samples, exhibited 95% diagnostic sensitivity and 100% specificity [30]. Agreement between direct RT-qPCR and culture qPCR was found to be 98. Moreover, direct RT-qPCR identified three more positive samples and exhibited lower quantification cycle (Cq) values among positives by culture reading than did culture qPCR (direct RT-qPCR Cq range = 14.6–32.3 vs culture qPCR Cq range = 18.7–37.4) The direct RT-qPCR enables simplified sample collection, elimination of culture medium, faster results, applicability in cows, and lower cost than culture qPCR, making this new test more efficacious for control programs.

Treatment and Vaccination

Although there is no approved treatment for trichomoniasis in cattle in the USA, a study by Love et al. from 2017 suggests that treatment with metronidazole at a dose of 60 mg/kg of 0.5 μg/ml resulted in elimination and prevention of new growth of *T. foetus* [31]. The study was performed on a bull that tested positive for *T. foetus* on culture for five consecutive weeks. After treatment with intravenous metronidazole at a 24-hour interval for two treatments, the bull tested negative on culture for five weeks post treatment [31]. Although these results are promising, PCR was not included in this study, so further testing to confirm the ability of metronidazole to eliminate infection with *T. foetus* in cattle is likely warranted. Also, it must be noted that the use of drugs from the nitroimidazole family, which includes metronidazole, is banned in food animals in the USA. In human medicine, metronidazole is utilized for treatment of *Trichomoniasis vaginalis*. However, approximately 5% of strains of *T. vaginalis* in humans are resistant to metronidazole [32]. Additionally, metronidazole is an important antibiotic in the treatment of *Clostridium difficile* infections in humans and anything that will potentially add resistance to this serious toxin-forming bacteria is most likely not going to be taken off the prohibited list [32–35]. culture trails have been promising and *in vivo* trials are in progress to identify approved food-animal drugs that might be utilized for treatment of trichomoniasis.

At this time there is only one United States Department of Agriculture (USDA) approved vaccination for *T. foetus* in the USA, TrichGuard® (Boehringer Ingelheim). TrichGuard is a killed vaccine that requires two doses, administered two to four weeks apart and at least four weeks before the breeding season begins. This vaccination when administered correctly has been proven to decrease the severity of clinical signs associated with *T. foetus*. Additionally, vaccination against *T. foetus* decreases the time it takes females to clear the infection, thus returning them to cyclicity more quickly. Vaccination for *T. foetus* has been shown to promote production of vaginal, cervical, and uterine immunoglobulin (Ig) G1 and IgA antibodies in cows [16]. Cows able to clear the infection experience a transient resistance to reinfection [16]. In a 2017 study by Edmondson et al. 40 beef heifers were inoculated with either TrichGuard (20 heifers) or a sterile saline sham vaccination (20 heifers). The heifers underwent an estrous synchronization protocol and were inoculated vaginally with cloned *T. foetus*. Three days post-inoculation the heifers were maintained with three *T. foetus* negative, unvaccinated bulls for a 49-day breeding season. Cervical mucus samples were taken at designated dates and *T. foetus* positive cultures were obtained in all the heifers. Pregnancies were seen in both the TrichGuard (95%) and the sham vaccination group (70%). Heifers from both groups gave birth to live calves, with the TrichGuard group and the sham vaccination group only having a 50 and 20% live calf rate, respectively. Embryonic loss was observed in both groups, with the sham vaccination group experiencing a significantly higher loss (71%) versus the TrichGuard group (41%) [17]. Although the vaccine does not prevent infection with *T. foetus*, these results suggest that vaccination can significantly decrease the embryonic and fetal loss seen with *T. foetus* infections [17]. Two studies showed that 80% of vaccinated heifers challenged with *T. foetus* were negative within two weeks after a 15-day breeding cycle, as compared to 80% of non-vaccinated heifers still infected four weeks after a 15-day breeding cycle; in addition, 60% of non-vaccinated heifers remained infected 10 weeks following a 15-day breeding cycle [36, 37]. Hence, a vaccinated cow or heifer that is subsequently infected with *T. foetus* will clear the infection sooner and either maintain her pregnancy or be ready to rebreed weeks or months sooner than a non-vaccinated animal. Vaccination of bulls has been more closely evaluated in studies by Cobo et al. who found that immunoglobulins directed against *T. foetus* appeared in the preputial secretions of bulls vaccinated with *T. foetus* antigens [38, 39]. These and other studies

have evaluated the cellular and antibody response in the lower genital tract of bulls [38, 39]. These studies demonstrated that TrichGuard prevented colonization of the preputial and penile epithelium [38, 39]. In well-managed herds with firm vaccination protocols or herds that have experienced previous trichomoniasis outbreaks, vaccination is recommended.

Control and State Regulations

As there is no current legal treatment in the USA, many states have regulations in place for the movement and sale of bulls into, through, and out of their states. The current regulations in many states require bulls, virgin or non-virgin, that are greater than 18 months of age to test negative for *T. foetus* within 30 days prior to entering the state. In Texas bulls must be tested if they are 12 months of age or older. The bulls must be negative on PCR prior to entry into the state. If the bull is allowed to commingle with other cattle between the time of testing and the time of entering the state, the bull must be retested. The bull must be identified via a USDA issued ear tag, a registry brand, or registry tattoo. In addition to verifiable identification, the bull must have a current Certificate of Veterinary Inspection (CVI) that includes the test results, date, lab used for testing, address of both the consigner and consignee, and the signature of the accredited veterinarian associated with the CVI. Specific incidences may exempt animals from *T. foetus* testing; these include rodeo and exhibition bulls that will not commingle with cattle during their temporary stay in state and will leave the state immediately after the event. Also exempt are virgin bulls that are less than 18 months of age (but have CVI confirming age), bulls going directly to slaughter, and bulls that are strictly being transported through the state and will not commingle with female cattle. Every state has specific regulations regarding *T. foetus*, so it is imperative to check the requirements of shipping cattle to the particular state of interest at least two weeks prior to shipment.

Impact on Other Species

In addition to cattle, *T. foetus* can cause chronic infections in felines, with the predilection site being the gastrointestinal tract [4]. Colonization of *T. foetus* can occur in the stomach, cecum, and nasal passages of swine with no apparent clinical significance [40]. Although colonization in swine can occur, a study by Mueller et al. suggests that transmission between bovine and swine via swine fecal environmental contamination is unlikely [40]. In cats, *T. foetus* infections are characterized as large bowel diarrhea, with the organism colonizing on the mucosal surface of the colon [40, 41]. A study in 2007 by Stockdale et al. compared the effects on the reproductive tract of heifers experimentally inoculated with *T. foetus* of bovine or feline origin. This study revealed varying degrees of pathology in both the feline and bovine groups, suggesting that regardless of the organism's origin the same pathologic lesions are seen [41]. The largest difference in the pathologic lesions were seen in the heifers inoculated with bovine *T. foetus*, which were all devoid of an intact endometrial surface epithelium, whereas only one of the feline *T. foetus* inoculated heifers experienced endometrial epithelium damage [41]. The variation of the damage of the endometrium is suggestive of differing parasite interactions with the host [41]. This variation in the endometrial effects also suggests that feline *T. foetus* may not be associated with infertility in the bovine. The same study confirmed that although similar, feline *T. foetus* is not identical to *T. foetus* associated with bovine trichomoniasis [41].

Summary

Trichomoniasis is a venereally transmitted disease that can be economically devastating to a naïve herd. A bull infected with *T. foetus* is typically asymptomatic and becomes a chronically infected carrier. However, the cow experiences a transient infection manifested as embryonic loss and abortion and can develop immunity to *T. foetus*. The current standard of control is the identification and immediate removal of *T. foetus* positive bulls and prevention of exposure of infected animals to uninfected animals. Currently there are no approved treatments available in the USA. There are experimental treatments with promising results. Eradication is unlikely, but control with regular testing and strict biosecurity measures is vital to the success of prevention of further spread of trichomoniasis in cattle.

Infectious Agents: Leptospirosis

W. Isaac Jumper

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

Leptospirosis is a zoonotic bacterial disease considered to be an important cause of bovine reproductive failure worldwide. Caused by a motile, Gram-negative, obligate aerobic, spirochete bacteria in the genus *Leptospira*, infections may result in one or more of several different disease outcomes. In ruminants, disease forms may include relatively benign, chronic infections of the renal tubules and genital tract, or severe, acute disease of the renal, hepatic, or central nervous system, and reproductive inefficiency or abortion [1].

The taxonomy and system of classification of organisms in the genus *Leptospira* is complex and based on both genetic and serologic characteristics. Understanding the taxonomy of *Leptospira* requires familiarity with the hierarchical nature and meaning of terms such as serovar, serotype, and serogroup. Such terms have become necessary when describing leptospires due to the magnitude of both antigenic and genomic diversity found within the genus *Leptospira*.

The current standard for determining species of *Leptospira* is DNA sequencing and currently 20 different genomospecies (e.g. *Leptospira borgpetersenii*) have been identified [1–3]. The term serovar denotes an intraspecies classification of organisms based on serologic characteristics such as similar surface antigen expression [1, 3]. Serovars have been suggested to be the basic systematic unit of *Leptospira* spp. classification, with over 250 pathogenic serovars described [1–3]. Several different species are now known to include both pathogenic and non-pathogenic serovars. Each serovar may occur in more than one species (e.g. the serovar Hardjo occurs in the species *L. borgpetersenii*, *Leptospira interrogans*, and *Leptospira meyeri*) [2, 4]. Further differentiation among serovars is accomplished by serotype (e.g. *L. borgpetersenii* serovar Hardjo type hardjo-bovis). Serogroups are often used to group serovars with homologous antigen expression. Serogroups have no official taxonomic status, but are often useful for epidemiological studies involving similar populations or geographical regions [1–4]. Evidence exists for horizontal transfer of genetic material responsible for characteristics such as lipopolysaccharide (LPS) surface antigen expression between species of *Leptospira*, meaning neither serovar nor serogroup is currently predictive of the species to which an individual leptospire will belong [3, 4].

Although there are numerous species, serovars, serotypes, and serogroups within the genus *Leptospira*, the focus of this chapter will be on those most commonly implicated in reproductive inefficiency and failure in cattle.

Epidemiology

Prevalence

Members of the genus *Leptospira* are thought to be the most widespread zoonotic pathogens in the world [2]. Endemic serovars vary depending on geographical location; however, numerous studies have shown serovar Hardjo to be the most commonly isolated leptospire from cattle in the USA [5–8]. Two genetically distinct types of serovar Hardjo exist: *L. borgpetersenii* serovar Hardjo type hardjo-bovis and *L. interrogans* serovar Hardjo type hardjoprajitno. Serovar Hardjo type hardjo-bovis has a nearly global distribution [7, 9], while type hardjoprajitno is primarily found in the UK, and has not been identified in the USA [6].

Limited studies in the USA estimate herd prevalence of serovar Hardjo to be near 60% in dairies [10] and 40% in beef herds [6]. In Ontario, Canada, 8% of dairy herds and 44% of beef herds surveyed that were not vaccinated against leptospirosis were found to have cows serologically positive

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

for serovar Hardjo [11], whereas in western Canada seroprevalence appears to be much less in the beef herds surveyed there [12]. Herd prevalence may vary regionally, with higher prevalence more likely in temperate climates [6, 13]. In a large survey of cull cows sampled at slaughter in 49 states, the percentage of cattle serologically positive for a *Leptospira* serovar was much higher in southern tier and west coast states than other areas of the USA [5]. In studies of individual adult cows, seroprevalence of serovar Hardjo ranges from 10 to 30% in both the USA and Canada. Higher seroprevalence rates can be expected in individual herds that are endemically infected. One study performed in New Zealand of 95 beef herds totaling 1886 cattle found herd-level seroprevalence of serovar Hardjo to range from 79 to 90.5%, depending on whether the seropositive for a herd was defined as having one, two, or three animals seropositive in the herd [14]. A similar study conducted by Irish researchers found a beef herd-level prevalence of serovar Hardjo to be 82.29% over 288 herds [15]. These studies illustrate that broad variations exist in the seroprevalence of serovar Hardjo, and that these variations are likely due to differences in environment, management, and production system.

In the USA, serovars Hardjo, Pomona, and Grippotyphosa have been reported as the most prevalent in renal infections of cull cows [5]. Other serovars such as Canicola, Icterohaemorrhagiae, and Bratislava have been identified as causal agents in individual cases of bovine reproductive failure as well. A 2018 study conducted at harvest of fed cattle (<30 months of age) showed that 7.2% of 600 animals sampled were actively excreting leptospires in their urine prior to harvest. Of those, serovar Hardjo was the most commonly isolated, followed by Bratislava, Icterohaemorrhagiae, Grippotyphosa, and Pomona. Historically, exposure to serovar Bratislava among US cattle has been considered rare in occurrence. Although limited in scope, this study suggests serovar Bratislava may be increasing in prevalence [8].

Risk factors for individual animal and herd-level infections with *L. borgpetersenii* serovar Hardjo have been reported [6, 14, 16, 17]. Differences in risk factors reported among studies are likely due to variations in geographical region, environment, management, production system, etc. Although specific risk factors differ among studies, similar factors associated with *Leptospira* infection may be observed. Herd size has consistently been related to presence of *Leptospira* within a herd, with larger herds having greater odds of being seropositive for serovar Hardjo [14, 16, 17]. Other variables implicated in risk of seroprevalence include length of breeding season, higher mean annual temperatures [6], vaccination status [14], access to bodies of water [6, 14, 17], feeding on pasture, and no veterinary involvement [17]. Factors that should be considered when managing leptospirosis outbreaks include population size and density, environment, management system, and production goals.

Maintenance Versus Incidental Hosts

Animals infected with *Leptospira* can be classified as either maintenance hosts or incidental hosts of *Leptospira*. Different *Leptospira* serovars are associated with one or more maintenance host(s), which serve as reservoirs for transmission. Animals may be maintenance hosts of some serovars but incidental or accidental hosts of others. In a maintenance host, the disease is maintained by chronic infection of the renal tubules [2]. Transmission of the infection among maintenance hosts is efficient and the incidence of infection is relatively high at a population (or herd) level. Incidental hosts may become infected by direct or indirect contact with the maintenance host and are not important reservoirs of infection. Transmission of the infection from one incidental host to another is inefficient and uncommon. Examples of important maintenance hosts for different *Leptospira* serovars that commonly cause infection in cattle are listed in Table 59.1.

The terms "host-adapted" and "non-host-adapted" may often be used to describe infections or serovars of *Leptospira* in bovine hosts. Serovar Hardjo, including both types hardjo-bovis and hardjoprajitno, is the bovine host-adapted serovar, meaning the organism is adapted to surviving and reproducing within the bovine maintenance host. Maintenance infections in cattle would therefore by definition involve a host-adapted serovar, while incidental infections would involve a non-host-adapted serovar. Typically, host-adapted infections, or maintenance host infections, result in colonization of the urinary and reproductive tracts causing a chronic infection with no or mild clinical disease. In contrast, *L. interrogans* serovars Icterohaemorrhagiae, Bratislava, Canicola, Pomona, and Grippotyphosa are host-adapted to other species (see Table 59.1). Thus, when infections with these serovars occur in cattle they are described as non-host-adapted infections. Non-host-adapted infections in cattle may be more severe, but are often shorter in duration. The consequences of *Leptospira* infection in cattle may differ depending on if the serovar of *Leptospira* is host-adapted to cattle or another species.

Transmission

Both direct and indirect methods of transmission are important in *Leptospira* infections of cattle. Direct methods of transmission most often occur in infections involving

Table 59.1 Important maintenance hosts for different *Leptospira* serovars that commonly cause infection in cattle in the USA.

Leptospira species	*Leptospira* serovar	Maintenance host
L. borgpetersenii	Hardjo type hardjo-bovis	Cattle, deer [1, 9]
L. interrogans	Hardjo type hardjoprajitno	Cattle [1]
L. interrogans	Bratislava	Pigs, mice, horses [1, 2, 10]
L. interrogans	Canicola	Dogs [1, 2, 10]
L. interrogans	Grippotyphosa	Raccoons, opossums, skunks [1, 2, 10]
L. interrogans	Icterohaemorrhagiae	Rats [1, 10]
L. interrogans	Pomona	Pigs, raccoons, opossums, skunks [1, 2, 10]

serovar Hardjo, while indirect transmission most commonly occurs in incidental infections of cattle involving other serovars [18].

Direct transmission of bovine host-adapted serovar Hardjo occurs when uninfected cattle are directly exposed to contaminated urine, postpartum or postabortion uterine secretions, semen, or fetal membranes. Vertical transmission of serovar Hardjo may also occur, resulting in the birth of weak, *Leptospira*-infected calves. Shedding of leptospires from the urinary and reproductive tract may occur for months to years post infection with serovar Hardjo [1, 9, 18–20].

Indirect transmission is more prominent in non-serovar Hardjo infections. Bovine infections with non-host-adapted serovars of *Leptospira* such as Pomona, Icterohaemorrhagiae, and Grippotyphosa often result from environmental contamination with urine of other maintenance hosts such as rats, pigs, etc. Bovine non-host-adapted serovars often enter the environment through the urine of their maintenance host and survive until contact with a bovine incidental host occurs. Environmental contamination is often the cause of non-serovar Hardjo infections in cattle, rather than direct transmission from their maintenance hosts [18]. *Leptospira* organisms are able to survive in the environment for extended periods of time, particularly in warm and wet climates, and have been reported to survive in pond water for up to six months [7]. However, leptospires do not survive in hot and dry or freezing conditions. Cattle infected with non-host-adapted serovars typically shed low levels of the organism for a shorter time of weeks to months compared to infection with host-adapted serovars [1, 9].

The bovine host-adapted serovar Hardjo is very efficiently spread both directly and indirectly within a herd. Colonization of the urinary and reproductive tracts leads to continual shedding of the organism into the environment. Continual shedding lowers the importance of favorable environmental conditions, such as ponds and swampy areas, to maintain the infection in the herd and allows transmission to occur in confined housing or pasture situations [7, 18].

Pathogenesis

Leptospira organisms enter the body by penetrating mucous membranes of the eye, mouth, nose, or genital tract or through abrasions in the skin. Local proliferation at the site of entry occurs during an incubation period of 2–20 days. As the *Leptospira* organism proliferates, it enters the blood stream, leading to multiorgan infection, including colonization of the urinary and genital tracts. Leptospiremia typically lasts 7–14 days, during which signs of acute clinical disease may be present. Circulating antibodies against *Leptospira* organisms may reach peak levels at three to six weeks post infection. Antibodies can be detected in serum soon after leptospiremia begins and coincides with the clearance of *Leptospira* from blood and most organs. Upon cessation of the leptospiremic phase by *Leptospira* neutralizing antibodies, a convalescent phase begins in which low titers may be detectable for years in some animals. The humoral response is effective in clearing *Leptospira* organisms from most tissues in the body; however, colonization of the mammary gland, kidney, and gential tract continues as the organism appears to be protected from the immune response in these locations [1, 9]. Organisms can persist in the kidneys for several weeks in an incidental host or for six months or more in a maintenance host [7, 10]. *Leptospira* can also persist in the genital tract of a maintenance host for similar periods of time [10]. *Leptospira* excretion in urine is variable and may last weeks in incidental hosts and months in maintenance hosts. In cattle, serovar Pomona shedding has been observed for up to 15 weeks under experimental conditions [21], while serovar Hardjo is typically shed for 6–8 months [22] but has been reported to be as long as 18 months [23]. Adverse effects on reproduction in cattle may therefore be observed during the acute leptospiremic phase of disease due to invasion of the reproductive tract or systemic illness, or during the convalescent phase due to the lingering colonization of the genital tract.

Table 59.2 Summary of clinical differences between infections with Hardjo and non-Hardjo serovars.

	Hardjo serovar	Non-Hardjo serovar (e.g. Pomona, Grippotyphosa)
Presentation in adult cows	Subclinical to mild signs	Subclinical to mild signs
Persistence of infection	6–18 months	<6 months
Infertility	Common	Uncommon
Abortion	Occurs with initial infection	Occurs with initial infection
Time to abortion after infection	Months after infection	Weeks after infection
Herd presentation of abortion	Sporadic abortions	Sporadic abortions or abortion storms
Stillbirths	Yes	Yes
Weak calves at birth	Yes	Yes
Persistent infection in newborn calves	Yes	Yes

Clinical Disease

Clinical outcomes of *Leptospira* infections in cattle depend primarily on the serovar involved. Differences in the clinical manifestation of disease may be seen for bovine infections involving host-adapted serovars (e.g. Hardjo) when compared to non-host-adapted serovars (e.g. Pomona, Grippotyphosa). Level of host immunity may also influence the consequences of infection in cattle. A summary of clinical reproductive differences between bovine infections involving Hardjo and non-Hardjo serovars is presented in Table 59.2.

Infections with serovar Hardjo are typically subclinical or result in mild clinical signs. Clinical signs observed with serovar Hardjo infections are the result of persistent or long-term infection of the urinary and reproductive tracts. The most significant outcome of serovar Hardjo infection is decreased reproductive efficiency. Initial infections with serovar Hardjo during pregnancy can result in abortion, stillbirth, or birth of weak calves. Abortions may occur many weeks after infection of the dam and are usually not associated with any obvious illness in the cow. Infected but apparently healthy calves may also be born [20]. Abortions due to serovar Hardjo infection tend to occur sporadically as opposed to abortion "storms" which may occur as a result of infection with other non-Hardjo serovars such as Pomona or Grippotyphosa.

Persistent infection of the reproductive tract with serovar Hardjo can lead to infertility and early embryonic death. In infected herds, increased services per conception and prolonged calving interval have been described [18, 19, 24–26]. Studies in other species suggest that inflammation altering the uterine environment and direct invasion of the embryo by the *Leptospira* organism may be mechanisms by which persistent infection of the reproductive tract by serovar Hardjo decreases reproductive efficiency in cattle [27].

Infections with non-Hardjo *Leptospira* serovars are typically subclinical in adult cattle. If infection occurs during pregnancy, it can result in abortion, stillbirth, or birth of weak calves. Abortions are more common with non-Hardjo serovar infections. Abortion of autolyzed fetuses typically occurs one to four weeks after infection and without any overt clinical signs in the dam. Infections with non-host-adapted *Leptospira* serovars in calves, however, may result in severe systemic disease, including hepatitis, nephritis, and meningitis. Some serovars (i.e. Pomona and Icterohaemorrhagiae) produce hemolysins that result in acute intravascular hemolysis, leading to anemia, hemoglobinemia, and hemoglobinuria [1, 9].

Diagnosis

Accurately diagnosing leptospirosis as the cause of reproductive failure or inefficiency can be challenging for the practitioner and the producer. The effects of leptospirosis may not be observed for weeks to months after infection, such as in cases of estrus repetition or early embryonic death leading to an extended calving season or open cows. In other instances, producers may observe evidence of abortion (i.e. aborted fetus or fetal membranes) only after the decomposition process has begun, or they may not notice evidence of abortions at all. Even in cases of sudden "abortion storms," diagnosing leptospirosis as the definitive cause can be difficult.

Diagnosing leptospirosis as the cause of reproductive failure requires the practitioner to assess the clinical history of the reproductive-related complaint, clinical signs apparent within the individual or herd, underlying risk factors contributing to disease, and potential biosecurity risks (recent herd additions, exposure to wildlife, etc.). Critical evaluation of diagnostic testing results is also necessary to identify potential causes of false positives (vaccine type

and timing, etc.) or false negatives (sample contamination, improper sample handling, etc.). In cases where leptospirosis is suspected to be the cause of reproductive failure in a herd, risk factors that may have led to increased exposure to the organism or increased susceptibility to infection should be evaluated judiciously. Depending on the test performed, a positive result may only indicate carrier status and may be unrelated to the clinical problem. All diagnostic testing results should be interpreted within the context of the case history and the results of a thorough investigation into other potential risk factors for leptospirosis and reproductive failure. A summary of commonly used diagnostic testing methods for leptospirosis in cattle is presented in Table 59.3.

When investigating cases of suspected *Leptospira*-related reproductive failure, diagnostic testing methods for *Leptospira* involve detecting an immunological response to the organism (i.e. antibodies), or detecting the *Leptospira* organism or its DNA in tissues or body fluids of cattle [19]. Advantages and disadvantages exist for both schemes of testing; therefore utilizing a combination of testing modalities offers optimal diagnostic sensitivity and specificity [19]. Testing methods for serovar Hardjo focus on determining infection status of the herd. Repeated sampling is often needed to increase test sensitivity because of intermittent shedding in carrier hosts. Assuming a typical prevalence of 20–30% in herds endemically infected with serovar Hardjo, approximately 15 individuals would need to be tested to detect one infected individual with 95% confidence [32].

Serology is a commonly used and widely available method of *Leptospira* diagnostic testing that is inexpensive and reasonably sensitive [19]. The standard serologic assay is the microscopic agglutination test (MAT). The MAT involves mixing appropriate dilutions of serum with live *Leptospira* organisms belonging to relevant serovars found in the particular country or region where the testing is occurring [9, 19, 30]. If at the time of testing, high titer levels are observed with concurrent clinical disease and history consistent with leptospirosis, a diagnosis may be made. When cattle experience abortions as a consequence of infection with non-host-adapted serovars (i.e. Pomona, Grippotyphosa, Canicola, or Icterohaemorrhagiae), agglutinating antibody titers in the dam often exceed 1:1600. However, cattle infected with serovar Hardjo often show a poor antibody response following infection (i.e. titers ≤1:100), and at the time of abortion, serovar Hardjo titers may be low or negative [19].

Cross-reactivity among *Leptospira* serovars is not uncommon and can create confusion regarding the infecting serovar in individual animal tests. Cross-reactivity occurs when antibodies produced by an animal in response to infection by a particular serovar react with other serovars during the MAT. These cross-reactions may be equal to or higher than the reaction with the infecting serovar [9, 19]. Interpretation of serology may be complicated in animals vaccinated for *Leptospira*, as vaccines may induce a low-level antibody response that is detectable by MAT. In contrast to the high titers seen in natural infections, cattle typically develop titers that range from 1:100 to 1:400 in response to vaccines and these titers may persist for one to three months [19]. False positives are not common with MAT, as *Leptospira* surface antigens are not commonly shared with other organisms [29].

Table 59.3 Summary of commonly used diagnostic tests for detection of leptospirosis in cattle.

Test	Sensitivity	Specificity	Sample	Best use	Serovar differentiation
Detecting immune response					
MAT	Decreases as time from infection increases [9]; poor for serovar Hardjo [28]	Good [29]	Serum	Herd screening for exposure [30]	No [30]
ELISA	Depends on antigen used in test preparation [9, 30]	Depends on antigen used in test preparation [9, 30]	Serum	Herd screening for exposure or individual case confirmation [30]	Yes (LPS-based test) [9, 30]
Detecting *Leptospira* agent					
Culture and identification[a]	Poor due to fastidious growth requirements [29, 30]	Good [29, 30]	Urine, fetal tissue, and fluid	Individual case confirmation [30]	Yes [30]
PCR	Good (decreased by contamination) [30]	Exquisite [30, 31]	Urine, fetal tissue, and fluid	Individual case confirmation [30]	No [9]

[a] Isolate identification following culture requires a specialized reference laboratory and is beyond the scope of this text.

Serology is most sensitive when diagnosing the acute phase of leptospirosis, the sequelae of which is often abortion in cattle [9]. Because antibody titers are often highest at the time of abortion and may persist for months, paired serology performed post-abortion often does not demonstrate meaningful differences in titer levels. Paired serology initiated prior to abortion would likely demonstrate noticeable changes in titer levels; however, abortions may be the only clinical sign observed by the producer. The sensitivity of serology is less when serovar Hardjo infections are involved, because antibody titers are often low or absent. Serology is not appropriate when screening individuals for carrier status, because cattle chronically infected with serovar Hardjo may be seronegative while continuing to shed leptospires in urine [28]. Therefore leptospirosis should not be ruled out based on low antibody titers alone, especially when serovar Hardjo infection is suspected [19].

Enzyme-linked immunosorbent assays (ELISAs) offer the ability to detect antileptospiral antibodies following infection. The primary antigen preparations used for ELISA development include outer membrane protein (OMP) preparations and whole-cell preparations. Specificity of the ELISA is dictated by the antigen used. Recombinant OMP-based ELISAs produce reactions to numerous pathogenic leptospires and lack the ability to differentiate between *Leptospira* serovars. Cattle infected with serovar Hardjo produce little response to OMPs, making OMP-based ELISAs of no use in control programs where host-adapted infections are involved. LPS antigen-based ELISAs are capable of differentiating between serovars and are more useful for epidemiological investigations and herd control programs. ELISA tests are not useful in vaccinated herds, as *Leptospira* vaccines stimulate antibody production leading to false positive reactions. The MAT has historically been used to validate ELISAs. This method of validation is problematic, however, as the MAT can have sensitivities of 50% or lower in chronic *Leptospira* infections. Although ELISA-based testing may provide benefit in some situations, lack of availability of OMP-based ELISAs as well as concerns regarding test validation make ELISA-based testing impractical in most circumstances [9, 30].

Detection of *Leptospira* organisms or their DNA may be accomplished by immunofluorescence, immunohistochemistry, culture, and polymerase chain reaction (PCR) assays performed on tissues or body fluids. Often a combination of at least two of these techniques can be used to overcome issues with sensitivity that individual tests may encounter [33]. Immunofluorescence can be used to directly identify organisms within tissues such as fetal liver, lung, kidney, or placenta, or in urine sediment. *Leptospira* can be identified histologically by evaluation of formalin-fixed tissues if special stains are applied. When samples are available following abortion, fetal placenta, lung, liver, and kidney may be submitted for histopathological evaluation. Necropsy samples taken from adult kidney may also be useful in detecting *Leptospira* through histopathology [19].

Bacteriologic culture of *Leptospira* organisms is difficult due to the fastidious nature of its growth requirements; however, culture does provide a definitive method for the diagnosis of leptospirosis and identification of the infecting serovar. Culture may be performed on tissues harvested from necropsy of aborted fetal tissues or from urine voided from animals with clinical signs or suspected of having leptospirosis. Leptospires can typically be found in the urine of cattle for 10 days following the onset of clinical signs (i.e. abortion) [19]. Although culture of the organism provides near 100% specificity, the technical difficulty of the culture process for leptospires results in poor sensitivity [9]. Intermittent shedding in carrier hosts also lowers sensitivity of culture. Administration of the diuretic furosemide prior to urine collection increases the number of organisms present in the urine by increasing glomerular filtration rate, thereby improving the sensitivity of diagnostic methods [34]. Additionally, urine dilution enhances the survival of *Leptospira* for culture purposes [19]. A negative culture of urine or tissue should not be relied upon solely to rule out leptospirosis.

PCR is also available as a tool to aid in the diagnosis of leptospirosis and its use is increasing. The benefits of PCR include favorable sensitivity, the ability to detect early infections, and that it does not require a live organism. Variations in procedure between laboratories may affect the accuracy of PCR [33]. A positive PCR indicates the presence of genetic material from pathogenic leptospires, but serovar identification is not possible with most methods [9]. Leptospires may be detected by PCR performed on tissue samples from the aborted fetus, but urine from the dam typically provides a more reliable result [19]. Performing PCR on the stomach contents of an aborted fetus may also aid in diagnosis of leptospirosis abortion [35]. As with any diagnostic test, inaccurate results may be encountered when using PCR. False negatives are often seen because tissue samples may contain inhibitors to the amplification process [19]. False positive results may occur from contamination with foreign genetic material, as complex PCR assays can be extremely sensitive [31]. Failure of PCR to detect organisms in urine does not rule out infection, as the animal may not have been shedding the organism when the sample was collected [9]. As with bacteriologic culture, furosemide can be used to increase leptospire numbers in urine [34].

Control

Given the widespread exposure to wildlife and domestic animals that may be carriers of leptospirosis and the high prevalence of serovar Hardjo infection in cattle, prevention of all exposure to leptospirosis is virtually impossible in most dairy and beef operations. Therefore control of leptospirosis in cattle requires a comprehensive approach that includes reducing the risk of *Leptospira* exposure by interrupting direct and indirect routes of transmission, vaccination, and selective antimicrobial treatment to clear carriers of serovar Hardjo when indicated.

Limiting direct and indirect contact between cattle and carriers of *Leptospira* should be a priority. Strategies would include controlling wildlife and domestic species known to be maintenance hosts of serovars that commonly infect cattle (Table 59.1). Strategies should focus on reducing access of both wild and domestic animals to cattle feeds, especially stored feeds such as hay, grain, and other commodity feedstuffs. Control measures should also attempt to limit cattle access to standing surface water such as swamps or ponds to which wildlife commonly have access. Quarantine procedures can be implemented to reduce the risk of introducing serovar Hardjo into a herd through purchase of infected cattle. During quarantine, antimicrobial treatment and vaccination can be used to eliminate convalescent serovar Hardjo infections in new cattle and reduce the risk of reinfection and shedding.

Vaccination is commonly practiced in the USA to prevent leptospirosis. Currently available vaccines appear to be effective in limiting the shedding of serovar Hardjo in urine [36]. Whole-cell bacterins containing serovars Pomona, Canicola, Icterohaemorrhagiae, Grippotyphosa, and Hardjo ("five-way" vaccines) are widely available and commonly used. In general, these vaccines provide good protection against disease induced by each of the serovars, except serovar Hardjo [20, 37]. New-generation leptospirosis vaccines specifically targeting serovar Hardjo have demonstrated superior ability to prevent renal infection, urinary shedding, and fetal infection [27, 38]. Single dosing regimens and dosing regimens that included a booster four months after the initial dose have both proven to create a significant serologic response and prevent renal colonization [39]. These new monovalent vaccines induce a strong and long-lasting cell-mediated immune response compared with cattle naturally infected with serovar Hardjo and cattle vaccinated with non-protective serovar Hardjo vaccines [40, 41]. A general vaccination strategy for leptospirosis would include a whole-cell bacterin directed against serovars Pomona, Canicola, Icterohaemorrhagiae, and Grippotyphosa and a new-generation vaccine directed against serovar Hardjo. Recent studies, however, indicate that concurrent use of new-generation monovalent vaccines for serovar Hardjo used in conjunction with systemic oxytetracycline did not improve reproductive performance in dairy [42] or beef [43] herds where traditional "five-way" vaccines were already being used. The herds in these studies were not experiencing reproductive losses, however, so in instances where serovar Hardjo is suspected to be a source of reproductive inefficiency, a new-generation monovalent vaccine is recommended. Immunity should be induced in replacement breeding cattle following the manufacturer's recommendations and then revaccination is recommended every 6–12 months.

Antimicrobials can be used to treat cattle harboring persistent serovar Hardjo infections, as well as those with non-host-adapted *Leptospira* infections. Currently, there are no antibiotics approved for treatment of leptospirosis in dairy or beef cattle in the USA. Antibiotic selection for extralabel treatment of leptospirosis should consider potential milk and meat withdrawal times. Antibiotic treatment stops urinary shedding and is likely to improve clinical signs associated with persistent colonization of the reproductive tract with serovar Hardjo. Long-acting forms of oxytetracycline, tilmicosin, tulathromycin, and ceftiofur have been shown to be effective in the treatment of serovar Hardjo infections [44, 45]. One study showed that a single dose of tulathromycin (2.5 mg/kg, SC) resulted in clearance of leptospires from the urine, kidney, oviduct, and uterus as demonstrated by culture and PCR [45]. Another study found that a single dose of oxytetracycline (20 mg/kg, IM) resulted in no evidence of urinary shedding detected by PCR, culture, or immunofluorescence [44]. Caution should be exhibited when using any antimicrobial at extralabel doses and the Food Animal Residue Avoidance Databank (FARAD) should be consulted for appropriate withdrawal times. Antimicrobial treatment should be combined with vaccination to prevent reinfection from occurring.

Infectious Agents: Brucellosis

Valerie E. Ragan

Center for Public and Corporate Veterinary Medicine, Virginia-Maryland College of Veterinary Medicine, Blacksburg, VA, USA

Introduction

Brucellosis is a zoonotic disease caused by various species of *Brucella*, a Gram-negative facultative intracellular bacterium [1]. The disease severely impacts human health and livestock productivity in much of the world, especially in low-income countries, which has led the World Health Organization (WHO) to classify brucellosis as one of the world's top "neglected zoonotic diseases" [2]. While animals are the primary hosts of brucellosis, the disease is readily transmitted to humans primarily through the consumption of unpasteurized milk and dairy products and by direct contact with infected animals [3].

Evidence of brucellosis has been present for centuries, with the first recorded descriptions of disease characterized by fevers in 1859 [4]. The disease was discovered in Malta, where it was infecting British military officers and the local population. A researcher, Dr. David Bruce, traveled to Malta and was able to culture the bacteria causing the disease, which was eventually called brucellosis [5]. Subsequently, Themistocles Zammit was able to determine the connection between infected goats on the island and the transmission of brucellosis, primarily through milk [5].

Brucellae have varying host preferences and pathogenicity [6]. The *Brucella* species of particular importance to humans and livestock worldwide include *Brucella abortus*, *Brucella melitensis*, and *Brucella suis*, whose primary hosts include cattle, sheep and goats, and swine, respectively [7]. All of these *Brucella* species, along with *Brucella canis* (dogs), are also pathogenic for humans [8]. Although brucellosis is primarily host specific, cross-species transmission can occur with enough exposure, and cattle can become infected with *B. suis* or *B. melitensis* when they share facilities or pastures with infected pigs, sheep, or goats [9].

In addition to the "classical" *Brucella* species, other species exist and continue to be discovered. *Brucella ovis* in sheep causes ewe abortion, epididymitis in rams, and lamb neonatal mortality [10]. *B. ovis* is not known to be a human pathogen and therefore is not routinely included in brucellosis eradication programs. *Brucella neotomae* is known to affect rodents, and is also not a human pathogen [11]. Novel species more recently discovered include *Brucella ceti* which affects porpoises, dolphins, and whales, and *Brucella pinniedialis*, which affects seals. Additionally, *Brucella microti* (red foxes, common voles) has been isolated. The significance of these novel species is unknown, although they have the potential to be human pathogens. None of these novel species is known to affect cattle [11].

The facultative intracellular characteristic of *Brucella* allows the organism to largely evade the host immune system [12]. When cultured, *Brucella* has either a smooth or rough colony morphology, based on the composition of the lipopolysaccharide (LPS) molecule, which is the major inducer of antibody responses [13]. The naturally rough types (*B. ovis* and *B. canis*) tend to have less virulence to other than their host species (sheep and dogs) than the smooth types more commonly associated with livestock [13]. The difference in compositions of the LPS molecule between the smooth and rough types plays a role in serologic diagnostic testing [13].

Brucellosis is considered one of the most economically important zoonoses globally, with economic impacts attributable to human, livestock, and wildlife disease [14]. In high-income countries such as the USA, brucellosis has been successfully controlled or eliminated in most livestock populations, yet may persist in wildlife populations such as feral swine or bison and elk. In low-income countries it is often endemic, with large disease and economic burdens on both human and animal populations [14].

Etiology

Brucella abortus

B. abortus is the primary cause of brucellosis in cattle. There are seven biovars of *B. abortus* occurring in the world, the most predominant one being Biovar 1 [9]. *B. abortus* was initially isolated in 1895 from aborted materials from cattle by Bernard Bang, a Danish veterinarian [15]. As a result of that discovery, brucellosis in cattle is sometimes referred to as "Bang's disease" [16].

Cattle infected with *B. abortus* often exhibit placentitis and abortion [17]. *B. abortus* has a great affinity for the pregnant uterus, and often localizes in the reproductive tract of both male and female cattle [12]. Abortions in affected animals most commonly occur in the third trimester of gestation [18]. It has been determined that cows infected with *Brucella* are three to four more times likely to abort than non-infected animals [19].

Although the most common clinical sign of brucellosis in newly infected animals is abortion, the infected cow is often asymptomatic when not pregnant [19]. However, when such animals calve or abort, they become highly efficient transmitters of brucellosis via birthing materials and products of parturition [20]. Aborted fetuses and fetal membranes and fluids contain high levels of bacteria and therefore cause environmental contamination, resulting in a high risk of infection of susceptible animals [12]. Up to 10^{10} *Brucella* organisms per gram have been measured in placental samples from abortions caused by brucellosis [21]. Abortions may also be followed by long-lasting vaginal discharge, further leading to environmental contamination [22]. After contracting brucellosis, approximately 80% of cows normally abort only once. In subsequent pregnancies, infected cows may give birth to weak calves or may have apparently normal calvings [19]. However, when an infected cow calves, there is heavy shedding of bacteria through fetal fluids and the placenta, and such animals are sources of infection for other animals [19]. In between pregnancies, the *Brucella* tend to localize in lymph nodes and mammary glands [9].

Orchitis, epididymitis, and seminal vesiculitis may be seen in bulls, thus resulting in impaired semen production and infertility [12]. In cattle, natural breeding is not a major route of infection [23], although artificial insemination with contaminated semen may result in transmission to cows [12]. Hygromas and arthritis may also be seen in cattle [9].

Cattle most commonly become infected with brucellosis by ingestion of the *Brucellae* in contaminated pastures, feed, or fodder. Cows commonly lick newborn calves, afterbirth, and fetuses, all of which often contain a large number of bacteria and are major sources of infection [9].

The control of brucellosis in cattle is complicated by the role that heifers play in maintaining the disease in affected populations. Exposed heifer calves have been shown to be negative to serological tests, yet abort or have an infective first calving [24]. In addition, a small but important percentage of heifer calves born to seropositive dams have been found to be seropositive long after being isolated from potential other exposure. Those heifers are referred to as "latently" infected and are a risk for reinfection of herds [24]. The percentage of latently infected heifers has been estimated to be about 2.5% [25].

Brucellosis caused by *B. abortus* causes severe economic losses to cattle producers due to abortion losses, culling losses, and production losses [7]. It is estimated that brucellosis causes a 20–25% loss in milk production [9]. In addition, economic losses due to regulatory control and eradication programs requiring testing and removal of positive animals [26] and the impact of associated quarantines can be significant.

Brucella suis

Brucellosis in swine is caused by *B. suis*, which was first isolated by Traum from aborted swine fetuses in 1914 [12]. Swine brucellosis has a worldwide distribution, and both domestic and feral swine are hosts for *B. suis* [6]. In the USA, *B. suis* has essentially been eradicated from domestic commercial swine, yet remains endemic in feral swine [27]. The range of feral swine across the USA is expanding rapidly from its initial ranges of the southern part of the country [28]. As the expansion of feral swine continues, the risk of the spread of *B. suis* also increases.

Although swine can be transiently infected with other *Brucella* species, *B. suis* is the only *Brucella* species that can cause generalized systemic infection in pigs, resulting in reproductive failure [12]. In affected sows, abortion is most commonly observed and can occur at any stage of gestation, but most frequently between days 50 and 110 [18]. In herds that are chronically infected, infertility may be the most clinically apparent sign [18]. Other clinical signs in swine include orchitis in boars, posterior paralysis, and lameness [18, 29].

Transmission of *B. suis* usually occurs through direct contact with infected swine, and through the consumption of feed contaminated by abortion products or uterine discharges [18]. The boar is commonly incriminated as an important means of spread. In swine, unlike in cattle, brucellosis is a sexually transmitted disease and can be readily transmitted through breeding and the use of semen from an infected boar during artificial insemination [30].

Diagnosing brucellosis in swine is challenging in that the sensitivity and specificity of diagnostic tests in swine are

lower when compared to the detection of brucellosis in cattle, because serological tests used were developed for the detection of the *B. abortus* O side-chain in infected cattle [31]. In one study, a panel of serological tests conducted on infected feral swine only correctly identified 52% of those animals as infected [31]. In another study, 17% of culture-positive swine were negative on all serological tests [31]. Therefore serological tests for brucellosis in swine are usually interpreted at a herd level as opposed to an individual animal level [31].

Cattle grazing on pastures in close proximity with infected feral swine have also become infected with *B. suis* [32]. Although infection with *B. suis* does not result in abortion or decreased production in cattle, serologic titers of cattle infected with *B. suis* cannot be distinguished from those infected with *B. abortus* [32]. Therefore significant economic losses may result from an incident of such cross-species infection as a result of subsequent trace-back investigations, whole herd testing, and removal of positive animals required to definitely determine which *Brucella* is involved [32].

B. suis is also a serious human pathogen, with a higher degree of pathogenicity than *B. abortus* [29]. Therefore humans who have exposure to infected swine, such as hunters, wildlife biologists, and abattoir workers, are at an increased risk for transmission [29].

Brucella melitensis

B. melitensis is the causative agent of brucellosis in sheep and goats, and has significant impact on both the livestock industry and human health worldwide [33]. Of all the *Brucellae* known to affect humans, *B. melitensis* is the most virulent species, causing significant debilitating disease [33]. In 1905, a Greek physician was able to build an epidemiological link between the consumption of goat milk and "Malta Fever" in humans [33]. However, there is historical evidence that *B. melitensis* has been present for centuries [33].

Characteristic clinical signs of brucellosis in a sheep flock or goat herd are associated with an extensive negative impact on production, and include middle- to late-term abortion, stillbirths, and the birth of weak offspring [34]. The disease in males commonly causes impaired semen quality and therefore loss of fertility [12].

The USA is free of *B. melitensis*. However, in 1999, *B. melitensis* was discovered in Texas in four cows and traced back to an associated infected herd of meat goats, which was subsequently depopulated. That was the first time *B. melitensis* had been confirmed in a cow in the USA. The source of the *B. melitensis* infection was never definitively determined, but is thought to have been imported goats from Mexico [35].

Pathogenesis

The most common portal of entry for *Brucella* in the bovine is through the ingestion of aborted materials such as placentas and birthing fluids, by licking aborted fetuses or newborn calves from infected cows, or by ingesting feed or water contaminated by those products [19]. Once ingested, the *Brucella* invades the mucous membranes of the mouth, throat, and regional lymph nodes (suprapharyngeal and mandibular), where it localizes during the incubation period [20]. During the incubation period, *Brucella* replicates intracellularly in phagocytes [36]. This is followed by a brief bacteremia leading to systemic infection, with the bacteria localizing preferentially in the pregnant uterus, mammary gland, and male genital organs [36]. *B. abortus* thrives in the uterus during the last trimester of gestation. Although controversial, this is believed to be due to the high concentration of erythritol, which is metabolized by *Brucellae* as a source of energy and carbon [36]. The multiplication of *Brucellae* results in vasculitis, trophoblastic necrosis, infiltration of inflammatory cells, and ulceration of the allantochorion, thus compromising fetal–maternal metabolic exchanges and resulting in abortion [36]. *Brucella* bacteria also localize in the udders of animals, thus resulting in the production of contaminated, infectious milk [21].

Brucellae reside within and replicate within macrophages, dendritic cells, and trophoblasts [12]. The intracellular nature of *Brucella* organisms allows the bacteria to evade the host's cellular response and makes it difficult to eliminate by the use of antimicrobial drugs [37]. This allows for retention of the sequestered *Brucellae*, often resulting in subsequent relapse of infection [37].

Approximately 60–70% of calves born from infected dams are themselves initially infected. However, almost all recover within months of removal from the infective source and very young calves are known to be more resistant to infection. A small percentage of these exposed calves harbor latent infection yet remain negative to diagnostic tests until they abort their first pregnancy. These heifers are a significant threat to the success of control and eradication programs [19].

Susceptibility to brucellosis and the incubation period are quite variable, depending on factors such as age, pregnancy status, and sex of the animal, and the amount of bacteria to which the animal is exposed [25]. Although very young animals are relatively resistant to sustained infection with brucellosis, heifers that have reached sexual maturity increase in susceptibility, becoming extremely susceptible as they advance in pregnancy.

Immune Response

Exposure to *Brucellae* induces both cellular and humoral host immune responses. While host resistance to *Brucella* spp. is not completely understood, cell-mediated immunity appears to play a major role in the immune response to infection with virulent *Brucellae* [1]. This cell-mediated immunity involves activation of the bactericidal mechanisms of macrophages and dendritic cells and the expansion of antigen-specific T-cell clones [38]. The humoral response is limited and not protective, yet it is important from a clinical perspective in the detection of antibodies induced by *Brucellae* which are commonly used in serology for the diagnosis of brucellosis in humans and livestock [38].

As with other diseases, the innate immune system serves as the first line of host defense for brucellosis, responsible for preventing replication of the bacteria, reducing the initial number and killing of the bacteria, and creating conditions for generating an effective adaptive immune response [17]. Although there are countless components of the innate immune system to infection by *Brucellae*, they are not sufficient to overcome the infection [17]. The development of an adaptive cell-mediated immune response is necessary to control the disease [17].

An effective cell-mediated immune response against intracellular infections such as brucellosis is characterized by the predominance of a T helper type 1 (Th1) cell response that includes the secretion of interferon (IFN)-γ [17]. Activation of macrophages by IFN-γ is an important factor in the control of brucellosis [39]. Activated macrophages play a key role in the elimination of *B. abortus* [17, 39].

The exact contribution of humoral immunity in resistance to brucellosis probably plays a secondary role as it is also seen in other intracellular infections [17]. The major virulence factor of *Brucella* is the LPS in the outer membrane of the bacteria, which plays a role in cell entry and immune evasion [40]. The LPS O-side chain (OPS) is the primary immunogenic component of smooth *B. abortus* strains, and the majority of the antibody response in both human and animal infections is directed against the OPS antigen [17]. Brucellosis diagnostics are primarily based on serology, with agglutination tests being based on reactivity of antibodies against the LPS [40].

Diagnostics

The definitive diagnosis of brucellosis in livestock depends on laboratory testing, as clinical signs are not pathognomonic [6]. Laboratory diagnosis methods include serology, bacteriology (isolation of the bacteria), and molecular assays.

Unfortunately, there is no current diagnostic test sufficiently sensitive and specific enough to be capable of detecting all stages of infection in live animals [41]. The diagnostic "gold standard" is considered to be bacterial culture and isolation; however, that is not always practical in that samples are difficult to obtain, and isolation often is not successful due to the facultative intracellular nature of the bacteria. There is also a risk of infection to laboratory personnel [42]. The choice of samples for culture may include vaginal secretions, milk, colostrum, or mammary tissue, aborted fetuses (lung, stomach, or spleen), fetal membranes, and certain lymph nodes (oropharyngeal, scapular, iliac, and supramammary/testicular) [6]. However, because of the lack of sensitivity of most culture procedures and the associated drawbacks, serology is usually used for the diagnosis of brucellosis in animals [43].

The first agglutination test for the detection of antibody to *Brucella* was reported over 100 years ago [44]. Since then, diagnostic methods and accuracy have improved and new assays have been developed. However, the diagnostic sensitivity and specificity of serological tests vary widely, and there is debate in the literature over the value of different tests. Different serological tests measure different antibody classes [45], so several serological tests are usually used when making a diagnosis.

Serological tests are generally either primary binding assays, which directly measure the interaction between antibody and antigen, or the more conventional tests which measure secondary reactions, such as agglutination or activation of complement [44]. The primary binding tests, such as fluorescence polarization assay (FPA) and competitive enzyme-linked immunosorbent assay (C-ELISA), were developed to be more sensitive and specific than conventional agglutination tests [44], yet require specialized equipment or kits. The more conventional or secondary binding tests, such as the Card test, the Rose Bengal test (RBT), the rivanol test, the buffered acidified plate test (BAPA), and the complement fixation test (CFT), are dependent on being able to see the biological interaction of antibodies with antigen with the naked eye. These tests measure the consequences of antigen–antibody union such as agglutination, precipitation, or complement fixation.

Traditionally, highly sensitive, inexpensive, fast yet not necessarily highly specific serological tests (such as the Card test, RBT, or BAPA, and may include the FPA and ELISA) are used as initial screening tests [44]. Samples showing reactivity to screening tests are then subjected to confirmatory tests, which must be both sensitive and specific [46]. Such serologic tests may include the CFT, FPA, or ELISA. However, serological tests cannot determine which *Brucella* species is present in the host as only antibodies are measured.

Supplemental culture and isolation or DNA detection by PCR allows for a definitive diagnosis [6].

Once brucellosis is identified in livestock, state and/or federal animal health officials will become involved to control and eliminate the disease from the affected population(s).

Brucellosis in Wildlife

In the USA, brucellosis has been essentially eliminated from cattle. However, there are two primary reservoirs of *B. abortus* remaining: elk (*Cervus elaphus*) and free-ranging bison (*Bison bison*), both in the Greater Yellowstone Area (GYA – Yellowstone National Park and areas surrounding it) [27]. The risk of the spread of brucellosis between wildlife, livestock, and humans is a legitimate concern that creates serious challenges for wildlife management and conservation in those areas, especially near the boundaries of national and state parks and elk feeding grounds in the vicinity [47]. Although originally considered a spillover disease from cattle to bison and elk, brucellosis now regularly spills back from elk to cattle in the GYA. Bison to cattle transmission has not been documented in the GYA under natural conditions, most likely because of rigorous management to keep cattle and bison separated, although transmission has been demonstrated experimentally [47]. Transmission from bison to cattle has also been demonstrated when the species are pastured together [48].

B. suis is present in feral swine populations in the USA, although it has been essentially eliminated from domestic swine. The high incidence of *B. suis* in feral swine has resulted in transmission to domestic swine when raised in outdoor pens, and also to domestic cattle, causing serologic titers that are indistinguishable from those induced by *B. abortus* [31]. There is a risk to public health if raw milk is consumed from *B. suis* infected cattle, which are generally asymptomatic yet may shed high levels of bacteria in milk [31]. In addition, although *B. suis* does not result in abortion or decreased production in cattle, the detection of serologic titers as a result of *B. suis* infection causes economic losses incurred as a result of the subsequent disease investigation, including whole-herd testing, removal of infected animals, and trace-back investigations [49].

Brucellosis Regulatory Programs

Efforts to eradicate brucellosis in cattle in the USA were initiated in 1934 due to the Great Depression and concurrent drought conditions resulting in a need to reduce the number of cattle. At that time, brucellosis was the most significant livestock disease problem in the USA, with 11.5% of cattle tested in 1934–1935 determined to be infected [20]. In 1954, after recognizing the magnitude of the brucellosis problem and its impact on human health and the cattle industry, Congress appropriated funds for a national program to eradicate brucellosis from cattle [20]. As of 31 December 2000, for the first time, there were no brucellosis-affected cattle herds in the USA. As expected due to the variable incubation period, an occasional additional affected herd was disclosed after that time and quickly eliminated [20]. Currently, although there are occasional spillover cases from elk in the GYA to cattle, there have been no other cases of brucellosis caused by *B. abortus* in cattle in the USA since 2010 [50].

Surveillance

For a disease eradication program to be successful, an essential first step is to have an effective and ongoing surveillance system. It is imperative to be able to find, contain, and eliminate the disease before it spreads to other susceptible populations [20]. A recent review of the brucellosis control or eradication programs in 23 countries found that even if all the tools needed to eradicate brucellosis were available, an efficient brucellosis surveillance system is critical to program success [51]. Effective surveillance for brucellosis must be ongoing and utilize multiple methods [20]. In the USA, surveillance in the early stages of the brucellosis eradication program included down-the-road testing of herds. Later, the surveillance system was expanded to include the collection of blood samples at slaughter, testing of cattle at the first place they were assembled (such as stockyards and livestock markets), change of ownership testing, and milk ring testing of dairy herds. Additional surveillance methods included wide area testing in the vicinity of affected herds and testing of high-risk herds identified through epidemiologic investigations [20].

Since the USA has been essentially free of brucellosis for a number of years (other than occasional spillovers into cattle from elk in the GYA), national surveillance methods have recently been modified. Currently, around two million animals are tested annually at slaughter. This level of surveillance is sufficient to detect one affected herd out of 100 000 herds at a confidence level of 95%, with an estimated prevalence of 0.002%. This level is higher than what is required by the World Organization of Animal Health (OIE) and is intended to document disease-free states [50]. Federal or state animal health officials may also implement targeted surveillance activities as needed in areas determined to be high risk [52]

Control and Eradication Programs

Brucellosis is a regulated disease in the USA, meaning once a suspected case is identified, it is investigated by state or federal veterinarians. The US brucellosis eradication program historically consisted of several components, including serologic testing at the first point of assembly of cattle, trace-back of reactor animals to the herd of origin, quarantine of infected herds, test and removal of seropositive animals or whole herd depopulation, and vaccination of heifers [53]. Once brucellosis has been diagnosed in a herd, control measures are generally based on the principles of test and slaughter, vaccination, and sanitation [54]. In the USA, historically herds were tested every 30–180 days as part of a herd plan that also included herd management, until the herd was determined to be free of disease, and positive animals were removed to slaughter. As the country approached becoming free of brucellosis in domestic cattle, affected herds were generally depopulated [20]. However, in some cases and in some parts of the world, depopulation is not an option. In those cases, successful elimination of the disease depends on the development of a herd plan of action that will combine sound epidemiological practices with good animal husbandry practices, with the goal of eradicating the disease in the herd [55]. This involves far more than just blood testing the herd and removing reactor animals. Control and subsequent elimination of brucellosis from a herd or community is based on interruption of transmission, by minimizing exposure and the dose of bacteria to which animals are exposed. An effective herd plan should be designed to manage the disease problem and should include more than just a testing schedule. Its purpose is to eliminate the disease within the herd and to prevent reintroduction of disease into the herd. Since brucellosis is spread at the time of abortion or calving, management to prevent transmission during these times is essential. As pregnant animals are the ones that are most likely to continue spreading the disease, those need to be intensely managed [56]. In order to effectively control and eventually eliminate brucellosis from a herd and a community, calving management, heifer management, testing schedules, vaccination plans, and the management of replacement animals must all be addressed. Herds become infected with brucellosis through three primary ways: community spread from infected neighbors (including elk in the GYA), the introduction of incubating animals (tested or untested), and the retention of infected heifers. All three of those possible routes should be managed to prevent the reintroduction of brucellosis to negative herds.

Vaccination

The use of vaccine has been a critical component of most programs for the control or eradication of brucellosis in livestock caused by *B. abortus* or *B. melitensis*, but not for other *Brucella* spp. [54]. Vaccination has been a major factor in the success of the brucellosis eradication program in the USA. The ability of a vaccination program to reduce prevalence of brucellosis is generally dependent upon the proportion of vaccine-eligible animals within the targeted population that are vaccinated [54].

An ideal vaccine for brucellosis has been described as one that (i) does not induce antibodies that interfere with diagnostic serological testing; (ii) is attenuated and does not cause disease in animals or is not pathogenic to humans; (iii) does not lead to seroconversion with revaccination; (iv) is a live vaccine and able to provide a strong Th1 immune response; (v) is able to induce a strong and persistent protection against systemic and uterine infection; (vi) is stable and does not revert to virulence either *in vitro* or *in vivo* and (vii) is easy to produce and administer and inexpensive [57]. Although there have been research efforts toward developing killed vaccines, those vaccines have been found to not adequately stimulate cellular immune responses, and thus are not as efficacious as modified live vaccines [54].

However, there is no perfect vaccine for brucellosis, as no vaccine has been proven to provide 100% protection under field or experimental conditions [54]. The use of vaccination alone has been shown to reduce disease prevalence, but it is not likely to completely eliminate brucellosis from an infected herd. Exposure to high doses of *Brucella* can overwhelm protection from vaccine [54]. Although vaccination alone is insufficient to eliminate the disease from a herd, it plays an important role in that it increases resistance to infection and reduces both the risk of abortions and the number of bacteria shed by an infected animal [58].

In the USA, *B. abortus* strain 19 (S19) was introduced into the official Brucellosis Eradication Program for cattle in the 1940s [59]. Although the vaccine was an effective tool in the eradication program, there were challenges with the vaccine in that it interfered with diagnostic tests and was infectious for humans [59]. After many years of research, a new vaccine, *B. abortus* RB51 (RB51), was approved by the United States Department of Agriculture (USDA) and became commercially available in 1996. RB51 is now the official bovine brucellosis vaccine used in the USA [59].

In addition to strain 19 and RB51 for cattle, *B. melitensis* Rev. 1 (Rev. 1) vaccine is used for the prevention of brucellosis

in sheep and goats [60]. There are no brucellosis vaccines available for swine [60] at this time, nor are there brucellosis vaccines available for humans [61].

Brucella abortus Strain 19

S19 was first isolated from the milk of a Jersey cow in 1923. After the culture was maintained at room temperature in a laboratory for a year or more, it was found to have become attenuated [13]. In 1930, Buck reported the apparent lack of virulence and protection in a few heifers. After further studies on safety and efficacy, S19 was introduced for field usage in 1941 [53].

Since S19 is a smooth strain, it has the potential to induce antibody responses in most brucellosis serological tests that cannot be differentiated from that caused by infection with field-strain *B. abortus* [62]. A small percentage of animals will become persistently infected with S19 into adulthood, causing persistent titers that interfere with serological surveillance [63]. Brucellosis vaccine-induced antibody responses do not correlate with long-term protective immunity in animals [64]. High serological titers in S19 vaccinated animals correlate with chronic infection rather than resistance [65].

Vaccination with S19 does not induce full immunity, but it does increase resistance to *B. abortus* and has an efficacy estimated to be about 70–90% [61, 66]. However, because of the complications caused by residual antibody titers that interfere with surveillance and because S19 vaccination can cause abortions in some pregnant animals, vaccination was initially limited to calves, which received a full dose [$2.5–12 \times 10^{10}$ colony forming units (CFU)] of vaccine [57]. Following calfhood vaccination, S19 is usually cleared from superficial cervical lymph nodes within 10–12 weeks [57].

In the USA, due to difficulties in eliminating brucellosis from some herds and due to economic considerations, vaccination of adult cattle with S19 was explored. As a result, the Brucellosis Eradication Program was amended in 1977 to allow for the vaccination of adult cattle with a reduced dose of S19 [67]. A reduced dose administered subcutaneously to adult animals was an effective alternative that produced protection without a persistent antibody response and reduced the risks of abortion and excretion of vaccine-strain bacteria in milk [61].

Additionally, S19 is pathogenic to humans and thus requires the use of personal safety equipment such as gloves and protection glasses [57]. Since 1996, S19 vaccination has been replaced in the USA by RB51, primarily to eliminate persistent infection and titers that complicated diagnosis and surveillance efforts.

Brucella abortus Strain RB51

RB51 was first prepared commercially in 1996 and is now the brucellosis vaccine of choice for cattle in the USA [59]. RB51 is a rifampin-resistant rough mutant of virulent *B. abortus* strain 2308, derived by serial passages on media containing rifampin [60]. Since it is a rough mutant, RB51 is essentially devoid of the LPS 0-side chains on the bacterial surface [61]. These 0-side chains, that are present in field strains and S19, are the immunodominant antigens in the production of antibrucella antibodies. Since RB51 lacks this antigen, vaccination does not produce antibodies that react in the routine serologic tests for brucellosis, thus allowing the ability to distinguish vaccinated animals from those naturally infected [61] – an extremely important component of a disease eradication program. RB51 has been shown to induce a protective cell-mediated immune response against experimental challenge with the virulent strain 2308 [63].

Numerous studies have shown that RB51 offers significant protection from abortion, although there is no significate difference in effectiveness between RB51 and S19 [59]. In the USA, calfhood vaccination with RB51 is licensed for non-pregnant heifers 4–12 months of age. The vaccine must be administered by a state or federal animal health official or by an accredited veterinarian, and calves must be identified as vaccinated by an official eartag and a vaccination tattoo placed in the right ear [68].

Although cases are rare, RB51 can infect humans and is rifampin resistant. As a consequence, although rifampin is one of the drugs recommended for postexposure prophylaxis, it cannot be used for exposure to RB51 [69]. Therefore veterinarians should also use personal protective equipment such as gloves and glasses when vaccinating with RB51.

Brucella melitensis Rev. 1

Rev. 1 vaccine was developed to protect goats against *B. melitensis*, based on research conducted in Malta in 1956, and is the vaccine of choice for use in small ruminants [62]. Recommendations are to administer the vaccine subcutaneously in young animals (less than four months) and conjunctivally in older sheep and goats, avoiding those that are pregnant as the vaccine may induce abortions [64]. Since Rev. 1 is a smooth strain, it can induce serological titers that interfere with surveillance. Administering the vaccine conjunctivally reduces the likelihood of serological responses, without significantly reducing the protective effects of the vaccine [62].

Similar to other live *Brucella* vaccines, Rev. 1 is virulent for humans and precautions must be taken to avoid exposure [61]. At this time, since the USA is free of

brucellosis caused by *B. melitensis*, Rev.1 vaccine is not used in the country.

Human Infection

Brucellosis is a zoonotic disease, with a major impact on public health worldwide. Brucellosis in humans is also commonly known as undulant fever or Malta fever [70]. Annually, more than 500 000 human cases are reported worldwide, but it is suspected that human brucellosis is significantly underreported due to the non-specific clinical signs in humans and inadequate laboratory diagnosis in many countries [71]. Human brucellosis presents with a wide spectrum of clinical signs, thus complicating diagnostics as it often mimics many other diseases [72]. The disease is characterized by fever, anorexia, malaise, and profound muscular weakness [72]. In addition to those mostly non-specific symptoms, humans with brucellosis often suffer serious complications such as *Brucella* endocarditis, neurobrucellosis, or spondylitis. Chronic disease and relapses are frequent [71].

Although *Brucellae* are primarily host specific, four species of *Brucellae* are pathogenic for humans [8]. Those are *B. melitensis*, which causes the most severe disease in humans, *B. suis*, *B. abortus*, and *B. canis* [73]. Isolating and identifying the *Brucella* species involved in a human case can provide a clue as to the likely source of infection due to the limited number of preferred natural host animals [8].

There are several primary methods of transmission of brucellosis to humans. Studies have shown that a human's risk of contracting brucellosis are closely linked to food habits, standards of hygiene, and animal husbandry methods [74]. Human brucellosis is often the result of occupation-related exposure, primarily affecting adult men engaged in some aspect of the livestock industry [8]. This includes farmers, slaughterhouse workers, and laboratory workers who may be exposed through contact with infected animals or their products, or via aerosolized bacteria or entry of the bacteria through cuts and abrasions of the skin [73]. Veterinarians may also be infected by accidental inoculation with live *Brucella* vaccines [72]. Ingestion of contaminated dairy products is another very common method of transmission in much of the world and can affect a much broader segment of the population, primarily due to the consumption of fresh, raw milk and cheeses made from unpasteurized milk [72].

In the USA, human brucellosis cases decreased during the course of the brucellosis eradication program in livestock, with a dramatic drop in cases starting around the mid-1940s [20]. Currently, about 100 cases of human brucellosis per year are reported to the Centers for Disease Control and Prevention (CDC). Those cases are most often associated with international travel and the consumption of unpasteurized milk and dairy products from animals infected with *B. melitensis* [20]. Therefore if a case of human brucellosis is suspected in the USA, it is important to obtain a history of international travel and the consumption of dairy products abroad [8].

However, there is still a risk of *B. suis* infection to humans in the USA, primarily hunters and slaughterhouse workers, due to the prevalence of brucellosis in feral swine [30]. As the geographic spread of feral swine increases, there is an increasing threat of both recreational and occupational human exposure to swine brucellosis [75].

There have been three cases of human brucellosis caused by RB51 in the USA from the ingestion of raw milk from vaccinated cows [76]. Although very rare, with only three such cases identified in 2017 and 2018 despite extensive use of RB51 in the USA since 1997, these cases indicate there is a slight risk of acquiring vaccine-associated brucellosis from the consumption of raw milk.

Human brucellosis is routinely treated with long-term antibiotic therapy using a combination of agents [72]. Antibiotics are usually used in dual or triple combinations and may vary depending on the organ system involved and other factors. Antibiotics commonly used include doxycycline, streptomycin, rifampicin, and ciprofloxin [77].

Due to the risk of human infection, precautions should be taken when dealing with animals and animal products potentially infected with brucellosis. Standard personal protection such as gloves and protective clothing should be used, and personal hygiene such as carefully washing hands and other exposed areas of the body with soap and water should be utilized. The consumption of unpasteurized milk and dairy products should be avoided [73].

Future Research Directions

Brucellosis has been present in human and animal populations for centuries. Although there has been significant progress in the knowledge of the disease and the development of diagnostics and vaccines to control it, much work still remains to be done.

One of the challenges to future research is that *B. abortus*, *B. melitensis*, and *B. suis* could potentially be used as bioterrorism agents, and thus they are classified as "select agents" by the US Government [78]. "Select agents" are "biological agents that have the potential to pose a severe threat to animal health and safety, plant health and safety, or to the safety of animal or plant products (Select Agents)" [79]. The CDC and USDA Animal and Plant Health Inspection Service (APHIS) share regulatory

responsibility for some agents, including *Brucella* spp., because they potentially threaten both humans and animals [79]. Therefore any work with those pathogens must be registered with those agencies, accompanied by the appropriate permits, and closely regulated [78]. Most countries also require Biosafety Level 3 containment for animal facilities or laboratories conducting research with *Brucella*, thus limiting progress in research due to the expense of building and operating such facilities [80]. Striking an appropriate balance between the facilitation of *Brucella* science and national safety and security remains a challenge for the future of brucellosis research [80].

Infectious Agents: Infectious Bovine Rhinotracheitis

Benjamin W. Newcomer

Veterinary Education, Research, and Outreach Center, West Texas A&M University, Canyon, TX, USA

Introduction

Bovine herpesvirus-1 (BoHV-1), also known as infectious bovine rhinotracheitis virus (IBR), is a common pathogen of cattle responsible for significant economic losses due to respiratory and reproductive disease, pregnancy wastage, and the implementation of control measures. The virus affects cattle across the globe, although certain geographic areas have successfully eradicated the virus from local domestic cattle herds. BoHV-1 is recognized as an important pathogen in the bovine respiratory disease complex; clinical syndromes range from subclinical infection to severe disease. Infection also results in diseases of the reproductive tract, including abortion and genital syndromes. Due to the ubiquitous nature of the pathogen, its control in cattle populations is paramount to animal health and productivity.

Etiology

BoHV-1 is a virus of the Herpesviridae family and, as such, consists of a large, double-stranded, linear DNA genome. As a member of the subfamily Alphaherpesvirinae, BoHV-1 is characterized by a relatively short reproductive cycle and the tendency to establish latency primarily, but not exclusively, in the sensory ganglia. Three subtypes of BoHV-1 are recognized based on genetic analyses of clinical isolates [1]. Respiratory disease is generally caused by BoHV-1.1. The predominant strain in the USA, BoHV-1.1 may also cause abortions and infertility, often following infection of the respiratory tract. Genital infections are caused by BoHV-1.2. This subtype is further divided into BoHV-1.2a, which is abortifacient and occurs more frequently in South America, and BoHV-1.2b, which has not yet been associated with abortions and occurs in Australia, Europe, and the USA. The clinical syndromes associated with BoHV-1.2 infection are dependent on the route of transmission. Venereal transmission with BoHV-1.2 results in genital infections, whereas nasal infection can be followed by respiratory signs and transmission to other calves via the respiratory route. Therefore the manifestation of clinical signs is determined not only by the infecting viral strain, but also by the route of transmission. While differences have been noted in clinical syndromes caused by the different subtypes, genetic analysis remains the only definitive way to determine viral subtype.

The virus is sensitive to environmental inactivation. It is susceptible to ultraviolet light, desiccation, heat, and alterations in pH. Organic solvents and many disinfectants are effective against BoHV-1. The virus can survive the cryopreservation process for semen, and artificial insemination using contaminated semen can serve as a route of transmission in susceptible cattle [2].

Epidemiology

Disease associated with BoHV-1 infection is relatively common in almost all countries in which cattle are raised, with the current exception of some regions that have implemented strict control and/or eradication programs. Seroprevalence rates vary widely between countries, but may range from 10 to 70% depending on vaccination status, management practices, and the degree of contact with infected cattle. The virus is considered endemic throughout the USA. While seroprevalence rates may differ between beef and dairy herds within the same geographical area, these differences are more likely a reflection of different management programs than inherent breed differences [3].

Latently infected cattle serve as the reservoir for the disease, although a number of domestic and wild ruminants

Companion website: www.wiley.com/go/hopper/bovine

may also harbor the virus. Among others, natural infection has been described in goats, wildebeest, pronghorn antelope, and a variety of cervid species. While sheep and camelids may become infected with the virus, they are unlikely to play a major role in viral transmission [4, 5].

Morbidity rates in unvaccinated feedlot cattle generally approach 20–30%; morbidity in dairy herds and cow-calf operations usually tend to be slightly lower. Occasionally, outbreaks with near 100% morbidity may occur depending on the viral strain and the immune status of the cattle. Uncomplicated infections with BoHV-1 are not usually associated with high mortality. Most deaths are due to secondary bacterial tracheitis and bronchopneumonia. The case fatality rate may reach 3–5% in an outbreak with a particularly virulent strain but more typically does not exceed 1%.

Pathophysiology

Direct nose-to-nose contact is the primary means of BoHV-1 transmission; aerosol transmission of the virus in nasal secretions and respiratory droplets over short distances has also been demonstrated. After infection through the respiratory mucous membranes and local replication of the virus, a primary viremia allows spread of the virus to the respiratory, reproductive, and ocular tracts; retrograde axonal spread allows further dissemination of the virus through the nervous system, even in the presence of humoral neutralizing antibodies. Viral infection and replication is not always prevented in young calves despite adequate colostral intake, which may result in latency and subsequent recrudescence after a decline in colostral immunity.

Infection resulting in the genital forms of the disease is acquired through venereal transmission and the genital carrier state is the primary reservoir for outbreaks of genital BoHV-1 disease. Venereal transmission may occur through natural service or artificial insemination. Virus shed in semen is due to viral replication in the mucosa of the prepuce, penis, and urethra rather than the gonads or accessory sex glands [2]. Genital shedding of BoHV-1 can be seen as early as two to seven days following infection and bulls may intermittently shed virus throughout life without showing clinical signs of infection. Infection is not believed to negatively impact sperm motility or semen quality [6] directly but may cause changes as a result of generalized illness.

Infection with BoHV-1 is characterized by viral latency. As with all Alphaherpesvirinae, latency occurs in the neurons, most commonly in the trigeminal ganglion in cases of BoHV-1.1 [1]. Latency also occurs in the germinal centers of the pharyngeal tonsils. Following venereal transmission, the site of BoHV-1.2 latency is usually the sacral ganglia. The virus may remain latent in the animal indefinitely or recrudesce following periods of stress such as transportation or the administration of exogenous corticosteroids. Latently infected animals do not consistently shed virus and do not always have detectable levels of neutralizing antibodies in serum. Therefore detection of infection in these animals is achieved by viral detection following administration of dexamethasone and recrudescence of the virus. Vaccination of animals with latent infections does not prevent shedding of the field strain already present. Due to latency, animals from endemic herds should always be considered as potential reservoirs of BoHV-1 and potential sources of infection to naïve herdmates.

Clinical Presentations

Abortion

In the USA and elsewhere, BoHV-1 is the most commonly diagnosed viral cause of bovine abortion. In Europe, BoHV-1-induced abortion is less commonly observed but could be underestimated [7]. Abortions due to BoHV-1 generally follow systemic (e.g. respiratory tract) infection, with subsequent spread of the virus from the site of primary infection to the fetus. Spread to the fetus is believed to occur hematogenously by peripheral leukocytes via the umbilical vein [8]. Fetal infection is generally fatal and the abortus is usually expelled within a few weeks of fetal death, although in some cases expulsion may be delayed for weeks or months; a delay in expulsion may result in fetal mummification. Abortions are most commonly seen in late gestation (five to eight months). Gross lesions are often absent from the aborted fetus, although placental lesions including blanched and degenerate cotyledons are common. Placental degeneration is considered to be secondary to fetal death rather than the instigating cause of the abortion. The virus may lie latent in the placenta for up to three months without transmission to the fetus; abortion may occur subsequent to activation of the virus and infection of the fetus.

Genital Forms

Genital infection with BoHV-1.2 causes infectious pustular vulvovaginitis (IPV) and infectious balanoposthitis (IBP) in the cow and bull, respectively. Genital infections occur following venereal transmission of the virus. In both syndromes, clinical signs are usually observed one to three days following infection and include fever, anorexia, depression, restlessness, and frequent posturing to urinate. Inflammation of the vulva and vagina in cows, or of the preputial or penile surface in bulls, can be quite painful and result in hyperemia and the development of small raised pustules. The pustules may coalesce and form ulcers as the

disease progresses. Preputial prolapse can be observed in bulls and both sexes are susceptible to secondary bacterial infection leading to purulent discharge. Of particular concern in the bull, preputial adhesions may form as a result of the lesions and hinder future fertility. Treatment is generally not required and lesions usually resolve on their own within two weeks. Purulent vaginal discharge may persist in affected cows for several weeks. Likewise, libido in bulls may be decreased and resumption of normal breeding behavior delayed for several weeks [8].

Respiratory Disease

Infection with BoHV-1 results in inflammation of the upper respiratory tract, and hence the alternative name for the virus, IBR. Severity of clinical signs varies widely based on the strain virulence, host immunity, and environmental factors. Severe hyperemia of the nasal mucosa leads to the common moniker of "red nose." Other clinical signs include marked pyrexia, anorexia, ocular and nasal discharge, and focal necrosis of the mucous membranes of the nares. Necrotic foci may progress to large hemorrhagic and ulcerated areas covered by a diphtheritic membrane. Congestion and hemorrhage may be widespread throughout the trachea when visualized at necropsy or on endoscopic examination. Abnormal tracheal sounds can be readily auscultated and may not be accompanied by abnormal lung sounds unless there is secondary bacterial involvement that develops due to widespread inflammation and depression of innate immune functions of the upper respiratory tract. Development of bacterial bronchopneumonia is of higher consequence than viral infection alone as clinical disease following viral infection alone is often relatively mild, particularly in the USA. Secondary infection increases both the severity of clinical signs and overall mortality.

Other Clinical Syndromes

As with the other alphaherpesviruses, BoHV-1 has been implicated in clinical syndromes outside the reproductive and respiratory tracts. Conjunctivitis often occurs in conjunction with rhinotracheitis but may be the primary, or sole, clinical sign following viral infection. Conjunctivitis due to BoHV-1 may be unilateral or bilateral. In contrast to pinkeye, lesions are usually limited to the conjunctiva which is reddened and edematous; corneal ulcerations are not observed, although secondary corneal edema may be. Ocular discharge is common and is usually serous unless secondary bacterial pathogens are involved. Encephalitis in calves is occasionally associated with BoHV-1 infection but is more commonly seen with BoHV-5 (formerly BoHV-1.3) [9]. Systemic disease in newborn calves may be severe and characterized by high mortality. Calves less than 10–14 days of age may develop sudden anorexia, fever, rhinotracheitis, and conjunctivitis, particularly in herds with poor or diminished herd immunity and a lack of passive transfer of colostral antibodies.

Diagnosis

Virus Isolation or Detection

Isolation of the virus or detection of the viral genome using PCR in clinical samples can be used to demonstrate viral infection. Virus isolation has historically been considered the "gold standard" diagnostic test but has been largely replaced by PCR in many diagnostic laboratories due to the quick turnaround time of PCR analyses and the expense of cell culture programs required for virus isolation. The sensitivity of both virus isolation and PCR is relatively high [10]. Virus can be detected in a variety of samples including nasal, conjunctival, and vaginal swabs, preputial washings, bovine fetal serum, nasal secretions, and tissues samples, including those from an aborted fetus. Virus can also be detected by PCR in contaminated semen [11]. Other methods of viral detection include various immunofluorescence techniques, immunoperoxidase assays, and electron microscopy, although these are uncommonly utilized outside of research settings.

Serology

Evidence of BoHV-1 infection can be demonstrated by the detection of a serum antibody titer to the virus. Positive serology samples cannot differentiate between natural infection and vaccinal exposure using conventional vaccines such as those that predominate in the US market. Paired serology samples will help establish recent infection, as evidenced by at least a fourfold rise in titers between the acute and convalescent phases of infection. Antibody titers can be detected with either a virus neutralization test or enzyme-linked immunosorbent assay (ELISA). The primary immune response generally results in a detectable serologic titer by day seven post-infection.

Diagnosis of BoHV-1 Abortions

Diagnosis of bovine abortion can be challenging for the practitioner, as a definitive cause of abortion is not obtained in the majority of cases; the percentage of successful diagnoses increases when a full complement of diagnostic samples is submitted to the laboratory. For a complete

discussion of the diagnostic workup, the reader is referred to Chapter 56. Submission of the aborted fetus and the entire placenta provide the best opportunity for establishing a diagnosis of viral abortion. Admittedly, poor availability of either sample, particularly the placenta, may preclude submission, but the client should be advised of the benefit of locating and submitting both samples when possible. Diagnosis of BoHV-1 abortion is primarily based on histopathologic changes in the abortus and placenta. Moderate to severe autolysis of the fetus with focal hepatic necrosis may be present, but other gross changes are usually lacking. Intranuclear inclusion bodies may be visualized on tissue slides. Demonstration of viral antigen or genetic material in the abortus supports a diagnosis of viral abortion.

Prevention and Control

In the USA, vaccination is the primary means of controlling BoHV-1. However, the importance of designing and implementing an effective biosecurity program should not be overlooked, particularly relating to the introduction of new herd additions and the shipment of cattle that will eventually return to the home farm, as in the case of show cattle or certain breeding stock. Eradication programs have been successful in eliminating the disease from several European countries, and other countries within the European Union are in various stages of progressing toward complete abolition of the virus from domestic herds [12].

The goals of vaccination are to prevent clinical disease in the vaccinate as well as to protect fetal infection in animals that are, or will become, pregnant. Vaccination against BoHV-1 stimulates a strong antibody response in cattle. Both inactivated and modified-live virus (MLV) vaccines are widely available commercially, often in combination with other viral respiratory pathogens. Inactivated vaccines are often selected for their increased safety, while MLV vaccines are chosen for their rapid immune response, long-lasting immunity, and development of both local and mucosal immunity. Currently, parenteral MLV vaccines labeled for vaccination of pregnant cattle are available commercially; however, concerns have been raised that the vaccine may be associated with fetal loss following vaccination in isolated cases [13]. Consequently, one may consider pairing primary vaccination with an MLV vaccine and booster vaccination with inactivated vaccines in order to capture the benefits of both vaccine types while minimizing the risk of adverse side effects on the fetus [14]. Intranasal BoHV-1 vaccines are commercially available for use in both calves and adult cattle. They generally provide rapid local immunity and can be used in the face of an ongoing outbreak [15].

Serological assays cannot be used for the differentiation of infected from vaccinated animals (DIVA) when conventional vaccines are used. In Europe, genetically modified marker vaccines with a deletion in the glycoprotein gE gene are widely used as part of regional or federal control programs. Marker vaccines are DIVA-adherent in that serological detection of gE-specific antibodies denotes natural exposure since vaccinates will not have gE-specific antibodies. This principle also holds true for calves fed colostrum from dams vaccinated with the marker vaccine [16]. Marker BoHV-1 vaccines are currently not commercially available in the USA currently.

Summary

BoHV-1 remains a significant pathogen of cattle around the world, resulting in significant economic losses. Seropositivity rates are relatively high where eradication programs are not in place, although most infections do not result in severe clinical signs. The main manifestations of disease in the USA are abortion in breeding herds and as a component of the bovine respiratory disease complex in growing calves. Genital manifestations of IPV and IPB are more commonly reported in Europe. Less commonly, conjunctivitis, encephalitis, and systemic disease of neonates may result from infection.

Control of the disease is made difficult by the ability of the virus to become latent in the neural tissue and recrudesce following times of stress or immunosuppression. Strict eradication programs have eliminated the virus from some European countries; in the USA, vaccination and biosecurity are the core principles of most control programs. Vaccination is widely practiced and stimulates a strong antibody response. The use of MLV BoHV-1 vaccines in pregnant cattle should be balanced with an understanding of the potential risks to the fetus. Control of BoHV-1 is likely to remain a significant concern for cattle producers for the foreseeable future; an understanding of the vaccine types available coupled with knowledge of the management scheme of the individual producer will allow formation and implementation of the best control program for the virus.

Infectious Agents: Bovine Viral Diarrhea

Thomas Passler and Manuel F. Chamorro

Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

Bovine viral diarrhea virus (BVDV, now referred to as pestivirus A or B) is a pathogen of cattle and other artiodactyls with substantial impact on the health and well-being of affected livestock. Originally described by two North American research groups in 1946 [1, 2], infections with BVDV are still cause for enormous financial losses to the cattle industry worldwide. While the two earliest reports on BVDV described a disease that was mostly of severe acute nature, less severe subacute cases were also observed [1, 2]. In the decades following their original descriptions, BVDV infections in immunocompetent animals were reported to be mainly subclinical, and it was estimated that 70–90% of acutely infected animals did not display clinical signs [3]. The perception of BVDV as a mainly apathogenic bovine virus changed in the early to mid-1990s following the description of two new BVDV-associated syndromes, hemorrhagic syndrome and severe acute BVD, that were responsible for severe clinical signs with mortality rates of up to 100% [4, 5]. Genetic sequencing of BVDV isolates from severe outbreaks led to the description of a second genotype of BVDV (BVDV 2) based on its genetic dissimilarity of greater than 30% from classic BVDV strains [5, 6]. Subsequent retrospective genetic typing revealed that BVDV 2 had been present in Ontario as early as 1981 without causing severe disease symptoms [4]. Variation in the severity and observed clinical signs among BVDV-associated disease outbreaks emphasizes the influence of the tremendous genetic variability of BVDV isolates.

BVDV is an RNA virus and is the prototypic member of the genus *Pestivirus* within the family Flaviviridae. Recent revisions to the taxonomic classification of the genus *Pestivirus* added seven new species, and the genus now contains eleven recognized species: BVDV 1 (pestivirus A) and 2 (pestivirus B), classical swine fever virus (CSFV; pestivirus C), border disease virus (BDV; pestivirus D), pronghorn pestivirus (pestivirus E), Bungowannah virus (pestivirus F), giraffe pestivirus (pestivirus G), HoBi-like pestivirus (pestivirus H), Aydin-like pestivirus (pestivirus I), rat pestivirus (pestivirus J), and atypical porcine pestivirus (pestivirus K) [7]. The lack of strict host specificity and antigenic relatedness of pestiviruses has caused difficulties with the traditional methods of classification based on the host from which a strain was isolated, and more accurate taxonomic information is now based on monoclonal antibody binding assays and phylogenetic analysis of genomic sequences [8–11]. Although sequence variations are located throughout the entire genome, the 5′ untranslated region (UTR) is most commonly used for the differentiation of pestiviral species [8–10, 12].

Pestiviruses are enveloped viruses with a single-stranded RNA genome that is approximately 12.5 kb in length and contains a single large open reading frame flanked by UTRs at the 5′ and 3′ termini [13]. During replication of BVDV in the host cell cytoplasm, mutation and variation occurs readily, with an approximate mutation frequency of 10^{-4} base substitutions per base site [14]. At this high mutation frequency, at least one point mutation occurs per replication cycle of the viral RNA [15]. Frequent mutation is the consequence of error-prone viral RNA polymerases and results in variation of each progeny virus from the infecting parent virus [14]. Although millions of varying progeny virions are produced daily during the peak of infection, only copies with a selective advantage and without deleterious mutations will progress in the course of an infection [14, 16]. Consequently, a swarm of mutant virions exists in the host during a BVDV infection [14]. The virions of this mutant swarm are similar in base sequence and are referred to as a quasispecies [14]. The existence of BVDV as a quasispecies

with frequent mutation events offers a significant advantage to viral survivability, as viral mutants that are readily available are capable of adapting to adverse conditions, such as the host's immunity. With respect to virulence, adaptation to either lower or higher virulence may benefit viral survivability. While low virulence and host survival, as are common for host-adapted viruses, enable prolonged shedding, viral mutations that increase rates of replication and virulence allow for a burst of viral shedding [14, 17].

BVDV isolates can be classified as non-cytopathic or cytopathic, and this classification is based on the effects of an isolate on cultured cells. Cytopathic isolates cause cytoplasmic vacuolation and death of cultured cells, but infections with non-cytopathic isolates are inapparent [18, 19]. The categorization into biotype is not associated with the virulence of a BVDV isolate, and mild or severe disease can be observed with either biotype. The non-cytopathic biotypes are more prevalent in nature, and 60–90% of isolates from specimens at diagnostic laboratories are non-cytopathic [20, 21]. Only non-cytopathic BVDV strains can induce persistent infections, and these non-cytopathic strains are believed to be the most common source for cytopathic BVDV strains following homologous or heterologous recombination in the NS2–3 genomic region [14]. A third biotype of BVDV, the lymphocytopathic biotype, has been proposed and refers to BVDV isolates that have cytopathic effects only on cultured lymphoid but not epithelial cells [22]. Lymphocytopathic isolates are BVDV 2 strains that were associated with severe clinical disease [14].

Prevalence

Following the initial descriptions in North America, BVDV has been detected in cattle populations worldwide. The prevalence of seropositive animals depends largely on the management of cattle, including type of husbandry, use of vaccination protocols, addition of new herdmates, and presence of persistently infected (PI) animals [23, 24]. In North America, serosurveys demonstrated seropositive rates between 40 and 90% [25–27]. The individual seroprevalence rate among unvaccinated dairy heifers in Canada for BVDV 1 and BVDV 2 was 28.4 and 8.9%, respectively, and the herd-level prevalence was 53.4% for BVDV 1 and 19.7% for BVDV 2 [28]. In feedlot cattle, seroconversion to respiratory pathogens including *Pasteurella haemolytica*, *Mycoplasma* spp., and BVDV following arrival occurred in 40% of cattle [29, 30], but significant variation between groups is observed [30]. Similar seroprevalence rates have been detected in cattle herds worldwide, but the observed range varies widely among countries, reflecting global differences in cattle management and disease prevention practices.

In contrast to seroprevalence rates, the prevalence of PI cattle is considerably lower and is generally believed to be less than 1% of all cattle. PI cattle may be found in clusters within groups of cattle, elevating the prevalence within populations [31]. The prevalence of PI calves arriving at feedlots was demonstrated to be between 0.1 and 0.3%, and this rate is similar to the reported rate of 0.17% for beef cow-calf operations in the USA [30, 32–34].

Host Range

Pestiviral infections have been identified in various species of the mammalian order Artiodactyla, and lack of host specificity may play an important role in the pestiviral survival strategy [35, 36]. Among pestiviruses, BVDV has been the species most intensely studied as an infectious agent of heterologous hosts. Evidence of BVDV infection exists in over 50 species of cloven-hoofed animals (Artiodactyla) [35]. The implications of heterologous pestivirus infections are twofold. First, heterologous BVDV infections may hamper the success of control strategies, as are in progress for BVDV in cattle and CSFV in swine. Second, heterologous BVDV infections may threaten the health and well-being of other mammalian hosts, such as free-ranging and captive wildlife. The role of heterologous infections in the epidemiology of BVDV is incompletely understood, but evidence for interspecific transmission and BVDV-associated disease has been reported in various species.

BVDV in Small Ruminants

The close phylogenetic relatedness of small ruminants to cattle and associated greater possibility of permissive infections may promote a unique role of sheep and goats in the ecology of BVDV. Sheep and goats often have closer contact with cattle compared with other artiodactyls, especially in certain management conditions such as subsistence agriculture, alpine farming, or hobby farming. While one report did not identify a positive correlation between BVDV seropositivity of sheep flocks and presence of cattle [37], other studies have reported significantly greater seroprevalence rates in sheep on farms with cattle, especially where communal alpine pasturing of sheep, goats, and cattle was practiced [38].

Worldwide, infection of small ruminants with BVDV is common and many serological surveys have demonstrated antibodies against BVDV in small ruminants. Seroprevalence rates among evaluated flocks or herds varies widely, depending on associated risk factors. Due to cross-reactivity of BVDV antibodies with other pestiviruses, it is important to determine which pestiviral species caused the infection to accurately determine measures of prevention and control [39].

Various serosurveys that further evaluated the infecting pestiviral species by virus neutralization assays determined infections with BDV to be more common in small ruminants [40, 41], but several others demonstrated BVDV as the more frequent infecting viral species [37, 38, 42].

Infections with BVDV in domestic small ruminants result in clinical signs of border disease. In a recent study from China, 17.5% of goats with diarrhea, respiratory disease, or mucosal inflammation were positive for BVDV, indicating that infection and clinical disease are not uncommon in some small ruminant populations [43]. As in cattle, postnatal BVDV infections of non-pregnant small ruminants typically cause mild clinical signs, including pyrexia anorexia, tachycardia, pneumonia, and leukopenia [44, 45]. In contrast, infection of pregnant sheep and goats results in uteroplacental pathology, pregnancy loss by fetal resorption or abortion, and birth of mummified or stillborn fetuses [46]. BVDV and related pestiviruses are important causes of abortion and congenital disease of sheep and goats worldwide [47–50]. Fetal death and non-viability are common sequelae of transplacental BVDV infections; however, reports of viable PI offspring exist [51–54].

BVDV in Swine

The close antigenic relationship between ruminant pestiviruses and CSFV has important implications for diagnostic testing and control of CSFV. Currently, examination of blood samples for CSFV antibodies relies on a combination of enzyme-linked immunosorbent assay (ELISA) and virus neutralization techniques, and considerable efforts are necessary in establishing a CSFV-specific diagnosis [55]. During the CSFV outbreak in the Netherlands in 1997/1998, 26.5% of CSFV ELISA-positive samples were caused by the presence of antibodies to ruminant pestiviruses [55]. While BVDV seroprevalence rates in swine are typically lower than detected in other livestock [56–59], infection rates are greater in some production systems. A study from China identified BVDV in 26.8% of pigs exhibiting clinical signs of fever, diarrhea, abortion, or piglet mortality [60]. Risk factors associated with BVDV infection of swine include the presence of cattle on the same farm, high density of small ruminants near swine populations, vaccination with BVDV-contaminated vaccines, age of tested swine, and failure to follow biosecurity measures [57, 61–63]. Postnatal BVDV infections in non-pregnant swine rarely result in clinical signs [64, 65]. Experimental infection of eight-week-old pigs with either BVDV 1 or BVDV 2 did not result in clinical signs or increases in body temperature in any group, despite the use of a BVDV 2 isolate that was demonstrated to be virulent for cattle [65]. Experimental inoculation of pregnant pigs with BVDV does not consistently induce transplacental infection [66, 67]; however, reports of reproductive failure and congenital disease exist [68–71]. Similar to congenitally infected ruminants, piglets can be born PI with BVDV; however, seroconversion and clearance of infection after several weeks to months is also possible in some congenitally infected pigs and is termed "chronic infection" [68, 71].

BVDV in New and Old World Camelids

BVDV infections were identified through detection of antibodies as early as 1975 in Old World camelids (OWC) and 1983 in New World camelids (NWC) [72, 73]. While initial seroepidemiologic and experimental infection studies suggested that BVDV, while able to cause infections in NWC, did not pose a serious risk in these species, the first description of a PI alpaca following natural exposure of its dam [74] changed this perception. Several cases of PI alpacas have since been reported in North America and the UK [75–77], prompting prevention and control measures focused on improved biosecurity and detection of PI animals.

The BVDV antibody prevalence rates in NWC in European, North American, and South American studies is generally lower than those of other livestock species, with an individual prevalence of approximately 5% detected by most studies [78–85]. In contrast, most studies investigating BVDV infections in OWC detected much greater seroprevalence rates, suggesting widespread BVDV infection in camels [86–92].

Postnatal infection of camelids with BVDV following experimental inoculation did not result in clinical signs; however, viremia, nasal shedding, and alterations of the leukogram were documented [93–95]. In contrast, infection of pregnant OWC and NWC may result in reproductive disease including abortion, stillbirth, weak calves, early neonatal death, and neonatal hemorrhagic disease [74, 96]. In one study, BVDV was detected in approximately 15% of aborted camel fetuses [48], indicating that the virus may have a significant impact on camel production. Another possible outcome of BVDV infection in pregnant camelids is birth of congenitally infected offspring. Interestingly, like pigs, congenitally infected alpaca crias may be PI or chronically infected [97]. Congenitally infected crias are affected by low birthweight, failure to thrive, inappetence, lethargy, chronic diarrhea, and chronic recurrent infections especially of the respiratory tract [74, 76, 97, 98]. As in other species, BVDV is shed readily by PI camelids, and shedding of BVDV in semen from a camel was also documented [99]. Therefore sound biosecurity practices, such as preventing movement of animals between farms for breeding purposes, are important to prevent intraspecific transmission of BVDV.

BVDV in Wildlife

Serologic evidence for BVDV infection exists in many species of free-ranging and captive wildlife, encompassing at least 7 of the 10 families in the mammalian order Artiodactyla, including Antilocarpidae (pronghorn antelope) [100], Bovidae (e.g. European and American bison) [101, 102], Camelidae (e.g. vicuña) [83], Cervidae (e.g. mule deer) [103], Giraffidae (giraffe) [104], Suidae (e.g. Eurasian wild boar) [105], and Tragulidae (e.g. lesser Malaysian mousedeer) [106]. Additionally, BVDV antibodies were demonstrated in a few non-artiodacyl hosts, including in the European hare and European rabbit [107, 108]. While these studies demonstrate widespread exposure of wildlife to BVDV, they typically cannot provide information about the source and importance of the detected BVDV infection. Contact with infected cattle is a likely source for BVDV and greater BVDV rates were demonstrated in some wildlife populations that have contact with cattle [109, 110]. Transmission of BVDV from cattle to white-tailed deer was demonstrated in a cohabitation experiment [111]. In that study, BVDV was efficiently transmitted from PI cattle to white-tailed deer and resulted in seroconversion in all adult deer and birth of PI fawns from four of seven pregnant does [111]. In contrast, independent circulation of BVDV not related to contact with cattle has also been demonstrated [112, 113] and is further suggested by high seroprevalence rates identified in some wildlife populations [103, 114–116]. Maintenance of BVDV within a cervid population without presence of cattle was suggested by the presence of antibodies in over 60% of caribou that had not been in contact with domestic ruminants for over 25 years [117].

Independent circulation of BVDV in wildlife would likely depend on the presence of PI animals, which have been described in different wildlife species, including common eland (*Taurotragus oryx*), lesser Malayan mousedeer (*Tragulus javanicus*), mountain goat (*Oreamnos americanus*), mule deer (*Odocoileus homionus)*, and white-tailed deer (*Odocoileus virginianus*) [106, 115, 118–120]. While shedding of BVDV by acutely infected and PI wildlife has been demonstrated [120–124], only a few studies have examined the transmission potential of infected wildlife to cattle or conspecifics [121, 123, 125–128].

Few reports on the clinical outcome of BVDV infection in wildlife exist, but reported clinical signs are similar to BVDV infections in cattle. Experimental inoculation with BVDV NY-1 did not result in clinical signs in four mule deer and one white-tailed deer, despite evidence of viremia and nasal shedding [124]. Similar findings were made in yearling elk that were inoculated with either BVDV 1 Singer or BVDV 2 24515 [123]. In two young reindeer, loose, bloody, and mucoid feces, transient laminitis, or coronitis were observed after inoculation with BVDV Singer and mild lesions were detected at necropsy [129]. Naïve white-tailed deer fawns developed moderate pyrexia and marked to moderate decreases in lymphocyte populations in response to either BVDV 1 or BVDV 2; and lethargy or coughing was observed in individual fawns [130, 131]. Similar to other species, reproductive failure may be the most important consequence of BVDV infections in wildlife. Depending on the stage of gestation, infection of pregnant white-tailed deer with BVDV may result in fetal mummification, stillbirth, and abortion [120, 132]. Currently, insufficient data exist to determine whether BVDV infections negatively affect populations of free-ranging wildlife, as has occurred with BDV, a closely related pestivirus which has decimated some populations of Pyrenean chamois (Rupicapra pyrenaica pyrenaica) populations in Spain, France, and Andorra [133–135].

Transmission

Several direct and indirect routes of transmission have been described for BVDV within and between cattle herds [136]; however, PI animals are considered the principal reservoir of the virus and the main source of BVDV transmission in cattle populations [137]. Direct contact of susceptible cattle with PI animals results in higher BVDV transmission rates compared with direct contact with acutely infected animals [136]. Lower amounts and shorter duration of viral shedding have been described in cattle acutely infected with BVDV compared with PI cattle [138, 139]. Considerable virus concentrations are present in oculonasal secretions, saliva, feces, urine, uterine discharges, semen, and milk of PI cattle [23, 136, 140]. Therefore continuous shedding of BVDV in secretions from PI cattle results in increased transmission rates to susceptible animals [136, 137].

Transmission of BVDV is highly efficient when PI animals are born or introduced into the herd [137]. In one study, all susceptible cattle that came in contact with a single PI animal became seropositive in less than three months [141]. The purchase of a PI animal or of a pregnant heifer carrying a PI fetus represents the greatest risk of introduction of BVDV into susceptible herds [137, 142, 143]. Purchasing pregnant heifers from facilities or operations that commingle many cattle from different origins facilitates the maintenance and dispersal of BVDV within cattle populations [142, 143]. The risk of introducing BVDV into a naïve herd through the purchase of a PI animal (including a PI fetus from a pregnant heifer) when buying cattle of unknown origin and without testing is estimated between 33 and 47% [137, 142]. Introduction of BVDV to naïve herds through the purchase of acutely infected cattle can also result in BVDV transmission. In one study, the risk

of introduction of an acutely infected animal when buying 20 cattle of unknown origin or testing status was estimated to be 8% [136, 137]. However, factors such as virulence of the BVDV strain and severity of clinical signs may affect the dynamics of viral spread and transmission [137].

While PI animals are the major source of BVDV, transmission in the absence of PI animals has been described [141, 144], indicating that other transmission routes are important in the epidemiology of the disease. The birth of non-surviving PI fetuses, fence-to-fence contact with infected cattle, contact with infected heterologous hosts, use of contaminated semen or vaccines, use of contaminated fomites, airborne transmission, and hematophagous insects have been demonstrated to be alternative routes of BVDV transmission [137, 144–148]. Transfer of embryos from or to PI or acutely infected cattle is an effective route of introduction of BVDV into susceptible cattle herds [136]. Use of contaminated fetal calf serum for embryo washing procedures is also an effective route of BVDV transmission through embryo transfer. Although it has been suggested that appropriate embryo washing eliminates the risk of BVDV contamination, one study demonstrated that recommended washing procedures were ineffective for removal of BVDV from an *in vitro* fertilization system [137, 149].

Clinical Disease Syndromes

Infections with BVDV may result in a wide variety of clinical manifestations as the outcome of infection depends on the triad of host-associated factors, environmental stressors, and viral characteristics [150]. Host-associated factors include (i) immune status and immunocompetence, (ii) pregnancy status, and (iii) gestational age of the fetus at the time of infection. Viral characteristics that influence the outcome of an infection include the biotype of the infecting strain and genotypic variation that determine virulence and antigenicity. Infections with both species of BVDV may result in a broad spectrum of clinical manifestations, but severe acute BVD, thrombocytopenia, and hemorrhagic syndrome, as reported in North America, were associated only with BVDV 2 [4, 5, 151].

Postnatal Infections in Immunocompetent Cattle

Postnatal infections in cattle that are able to immunologically respond to the BVDV infection are referred to as "acute" or "transient" infections and the severity of clinical signs depends on the infecting BVDV strain. After infection of susceptible cattle, the tonsils and respiratory tract are the first sites of BVDV replication. Subsequently, the pathogen disseminates to other epithelial and lymphoid tissues, resulting in infection of gastrointestinal, integumentary, and respiratory tissues [152, 153].

The majority of BVDV infections in immunocompetent seronegative cattle proceed subclinically [3]. However, close observation of infected animals usually reveals mild signs including hyperthermia, leukopenia, and decreased milk production. Affected animals develop neutralizing antibodies [154]. Symptomatic infections are most commonly observed in 6- to 24-month-old cattle following waning of maternal immunity, in colostrum-deprived calves, or in seropositive cattle as a result of infection with a heterologous BVDV strain [155]. Clinical signs in affected animals include pyrexia, lethargy, leukopenia, ocular and nasal discharge, oral erosions and ulcers, blunting of oral papillae, diarrhea, and decreased milk production. More virulent BVDV strains can also cause epithelial erosions at the interdigital spaces, coronary bands, teats, or vulva. Although BVDV-associated immunosuppression can result in pneumonia, the tachypnea observed in acutely infected animals is likely the result of hyperthermia and other nonpulmonary factors [155].

In the 1990s, severe acute BVD was described in cattle herds in the USA and Canada [5, 151]. The outbreaks were characterized by a peracute course and caused unusually high rates of morbidity and mortality in all ages of cattle. The described clinical signs and postmortem findings were principally those of mucosal disease, with severe diarrhea, fever, ulcers, and erosions of the upper alimentary tract [4]. Histopathologic findings included a dramatic lymphocytolysis and lymphoid depletion of Peyer's patches, necrosis of intestinal crypt epithelium, and diffuse ulcerative lesions in the upper alimentary tract. Sudden death without premonitory clinical signs, abortions, and pneumonia were also prominent findings in some affected herds. Interestingly, the gross and histopathologic postmortem changes were more pronounced and more likely to be observed in older animals, which is in contrast to most previous descriptions of transient BVDV infections [4]. The viral isolates from all reports of severe acute BVD were determined to be different from traditional BVDV isolates in genotype and monoclonal antibody binding patterns, prompting the designation BVDV 2 [5, 10, 156].

Another form of severe acute BVD associated with BVDV 2 is the hemorrhagic syndrome, which is characterized by marked thrombocytopenia. The hemorrhagic syndrome is observed only in a minority of cattle with severe acute BVD, contributing to a diverse clinical picture in an outbreak [155]. Clinical signs in affected cattle include petechiation and ecchymoses of mucosal surfaces, epistaxis, bloody diarrhea, bleeding from injection sites, trauma, fever, and death [151]. The marked thrombocytopenia and leukopenia of affected animals is accompanied by altered

function of platelets, and thus quantitative and qualitative platelet defects contribute to the observed hemorrhagic diathesis [157].

In addition to direct effects on the host organism, BVDV suppresses the number and function of various innate and adaptive immune components, further damaging tissues by enabling infections with secondary pathogens. BVDV-induced immunosuppression is especially important in polymicrobial diseases such as the bovine respiratory disease complex of feedlot cattle and dairy calves. The synergistic action of BVDV and BHV-1, BRSV, *Mycoplasma bovis*, and *Mannheimia haemolytica* in inducing severe respiratory disease in cattle has been previously documented [158–160]. Infection of cells of the innate immune system may result in impairment of function and decreases in the number of circulating leukocytes. The microbicidal, chemotactic, and antibody-dependent cell-mediated cytotoxicity was impaired in neutrophils that were infected with BVDV [161]. Infected monocytes may undergo apoptosis, and a reduction of 30–70% in the number of monocytes has been observed after BVDV inoculation of calves [162–164]. Infection with BVDV diminishes the ability of antigen-presenting cells to present antigens to T-helper cells by reduction of Fc and C3 receptor expression and downregulation of major histocompatibility complex (MHC)II and B7 molecules [162, 165–167]. A strain-dependent inhibition of function with reduced ability to kill bacterial and fungal pathogens was observed following BVDV infection of cultured macrophages; however, significant functional inhibition was induced only by virulent strains of BVDV [166].

Similar to innate immunity, adaptive immune responses are affected quantitatively and qualitatively by BVDV infections. Upon infection with BVDV, circulating lymphocytes are reduced and lymphocytes in lymphoid tissues are depleted, and this depletion is strain-dependent [162, 168]. Of the T-lymphocyte subpopulations, CD8+ cytotoxic T-lymphocytes are most dramatically depleted, followed by CD4+ T-helper cells, with little reduction of circulating γ/δ T-cells [169]. In addition to lymphocyte depletion, functional alterations of $CD4^+$ cells are pronounced, and non-cytopathic BVDV infections result in a shift toward the Th2 response, with reduced cell-mediated but high levels of humoral immunity [170–172]. Virulent BVDV isolates can cause reductions in MHCI expression of infected cells, thus affecting cytotoxic $CD8^+$ cell function; however, this reduction appears to be strain-dependent [166].

The humoral immunity to BVDV infection depends largely on the quantity of neutralizing antibodies and the antigenic relatedness of the infecting strain with that of the original exposure. Although an amount of cross-reactive protection is conferred by vaccination against heterologous strains, and even between BVDV 1 and 2, superior protection from infection appears to result from homologous exposure [173, 174].

Infections of the Reproductive Organs

While BVDV-associated immunosuppression and respiratory disease are causes for the greatest losses in feedlot and stocker operations, susceptible cow-calf and dairy herds suffer considerable economic damage from BVDV-induced reproductive failure. Reproductive losses as a result of BVDV infection can occur throughout gestation, and BVDV infection at the time of breeding can result in reduced conception rates and embryonic losses. In heifers experimentally infected with BVDV nine days prior to insemination, a conception rate of 44% was detected compared with 79% in control animals [175]. In the same study, other heifers were infected four days after artificial insemination (AI), resulting in a conception rate of 60% by day 20; however, significant embryonic loss was detected by day 79 when only 33% of animals were still pregnant. Detrimental effects of BVDV infection on fertility were also reported in field studies, in which poor conception rates, early embryonic losses, and pregnancy losses were detected [176–179]. In contrast, heifers exposed to PI calves for 220 days beginning 50 days prior to the breeding season had the same pregnancy rates as unchallenged control heifers, due to development of protective immune responses prior to breeding [180]. Highlighting the benefits of a controlled breeding season, this study demonstrated that BVDV infections can be self-limiting in certain herds, when all animals are protected from BVDV during gestation and PI calves are not born [180].

Both male and female gonads and the entire female reproductive system are permissible for BVDV replication [181]. In postpubertal heifers experimentally infected with a non-cytopathic BVDV, the virus was isolated from the corpora lutea of two animals, and BVDV-antigen staining was detected predominantly in the stroma of ovarian cortex. In that study, prolonged antigen staining and associated chronic lymphocytic oophoritis were detected from 6 to 60 days following intranasal inoculation [182]. Similarly, experimental inoculation of susceptible heifers with cytopathic BVDV resulted in chronic oophoritis for days 5–61 after infection, and BVDV was detected in the ovaries of a subset of cattle immunized with a commercial vaccine containing cytopathic BVDV [182, 183]. Ovarian inflammation may alter ovarian cytokine concentrations or disrupt tissue macrophages, thus interfering with normal ovarian dynamics, and while the effects of BVDV on ovarian function remain incompletely understood, alteration of follicular formation and inhibition of ovulation were demonstrated following BVDV infection [182]. A decrease in the number of subordinate follicles and retarded growth of dominant anovulatory and ovulatory follicles were observed in heifers experimentally infected with BVDV, but the infection did not result in alterations of peripheral estradiol or progesterone patterns [182]. In contrast, experimental infection with

non-cytopathic BVDV two days prior to estrus resulted in significantly reduced plasma estradiol concentrations but did not affect progesterone secretion or plasma prostaglandin F2α concentrations [181]. While the average number of follicles in each size-category was not affected in BVDV-infected superovulated heifers, infection resulted in the absence or delay of the preovulatory surge of luteinizing hormone, reduced number of corpora lutea and recovered ova/embryos, and oophoritis with necrosis of granulosa cells [184–186]. Alteration of sex hormone concentrations with potential for disruption of ovulatory follicles to form a competent corpus luteum was also detected in heifers experimentally inoculated nine days before synchronized ovulation [187]. Collectively, these studies suggest that transient BVDV infections can interfere with normal ovarian dynamics and result in transiently or prolonged reduced reproductive ability [186, 188]. Other causes for reproductive losses associated with BVDV infection at the time of breeding have been proposed and include disruption of the hypothalamic–pituitary–gonadal axis, deficiency of gonadal leukocytes, and incompatibility of the oviductal and uterine environment for embryonic development [181, 188]. Infection with BVDV was demonstrated in oviductal cells following intravenous inoculation with non-cytopathic BVDV and intrauterine infection with cytopathic BVDV resulting in salpingitis for 21 days [189, 190]. In uterine flushes from a subset of experimentally infected heifers, BVDV was isolated on days 8 and 16 following infection with BVDV, demonstrating a potential risk for the developing embryo in the uterine environment [190].

Widespread BVDV infection of the reproductive system and reduced reproductive performance are described in PI cattle. Extensive BVDV immunostaining and pathoanatomical abnormalities including significantly reduced follicular structures and ovarian and follicular hypoplasia were described in PI cows [191]. In addition to ovarian structures, including follicular epithelium, theca cells, cumulus oophorus, stromal macrophages, and walls of small ateries, BVDV antigen is present in oviductal epithelial cells, uterine glandular, and luminal epithelia, arterial walls, and smooth muscle of PI cattle [192, 193]. While oocytes in primordial and secondary follicles did not contain BVDV antigen in one study, approximately 20% of oocytes in all stages of follicular development contained BVDV antigen in another report [181, 193].

Infections of the Conceptus

Infections with BVDV can have deleterious effects on the pregnancy, and infections before the third trimester are most harmful. BVDV is highly efficient in crossing the placental barrier, and fetal infections are common with either biotype [138]. Increasing rates of fetal infection of 33, 33, 86, and 100% were detected in cows experimentally infected at 4, 11, 18, and 30–34 days post-insemination, respectively [194]. In ewes infected with BVDV on day 18 of gestation, the virus was detected by reverse transcription polymerase chain reaction (RT-PCR) and immunohistochemistry (IHC) in fetal tissues approximately 100 hours following infection, and BVDV-positive cells were more numerous in fetal than maternal tissues [195]. Fetal infections occur in an orchestrated fashion, beginning with infection of fetal membranes by 72 hours, followed by infection of bulbis cordis and fetal aorta by 7 days, and subsequent spread to many fetal tissues by day 10–14 [195, 196]. Further dissemination through fetal tissues can be observed as the infection proceeds, and a primary target organ of fetal BVDV infection is the brain [197]. While viral antigen can be detected in most tissues from PI fetuses, histopathologic changes are primarily detected in the brain, liver, and spleen [198]. Invasion of the fetal brain may occur in a "Trojan horse" mode of invasion, in which BVDV enters the central nervous system (CNS) within infected microglial precursors [199].

To date, the mechanism of BVDV entry into the fetus is poorly understood. Infection of pregnant cows with non-cytopathic BVDV results in pronounced upregulation of interferon (IFN)-stimulated genes such as ISG15 in the first week after infection, and blood concentrations return to baseline by 45 days post-infection [200, 201]. In heifers carrying PI or transiently infected fetuses, BVDV infection results in measurable serum IFN-I concentrations, but this antiviral activity is not capable of preventing fetal infection [201]. This may be due to failure of maternal IFN-I and antibodies to enter the fetal bloodstream as a result of the blood–placental barrier [201]. Likewise, BVDV infection results in measurable IFN responses in the fetal blood, which is pronounced in fetuses infected after the susceptible window for development of persistent infection [202]. While IFN responses are also present in PI fetuses and resulting PI calves, these responses are moderate and unable to eliminate the infecting BVDV in the absence of specific adaptive immune responses [202, 203].

The outcome of fetal infection depends on the viral virulence and biotype, and the gestational age. Fetal death and abortions can occur at any gestational age, but are most common during the first trimester [188]. Fetal death during early pregnancy may result in fetal resorption or mummification (Figure 62.1) and expulsion of the fetus may occur up to 50 days following exposure to BVDV [204]. Of four heifers infected between 29 and 41 days of pregnancy, two abortions and two fetal resorptions were observed [205]. While infections in the preimplantation phase (before day 40 of pregnancy) result in large numbers of pregnancy losses, fetuses that survive infection with non-cytopathic BVDV of low to moderated virulence from approximately

Figure 62.1 (a) Mummification of a bovine fetus following exposure of a pregnant cow to cattle persistently infected with BVDV between 70 and 100 days of gestation. *Source:* Courtesy Dr. Paul Walz, Auburn University. (b) Similar appearance of a mummified white-tailed deer fetus, as found in birthing nest. Fetal death was estimated to have occurred at 94 days of gestation, approximately 50 days after BVDV infection of the dam. The mummified fetus was born together with a viable persistently infected fawn after completion of the full gestational period. (c) Fetal membranes removed.

40 to 125 days become PI [206, 207]. Persistent infections can only occur with non-cytopathic BVDV strains [207, 208]. Experimental inoculation of seronegative cattle with non-cytopathic BVDV at 75 days of gestation results in persistent infection in up to 100% of fetuses, and this gestational age is commonly used to induce persistent infection in research studies [201, 203, 209, 210]. The pathophysiology of persistent infection is incompletely understood, but this phenomenon occurs in fetuses before completion of immune system development, when viral antigens are recognized as self antigens, resulting in negative selection of BVDV-specific lymphocytes [188]. The negative selection of reacting $CD4^+$ lymphocytes is highly specific and the exchange of a single amino acid in the BVDV antigen may be sufficient to stimulate immune responses in $CD4^+$ lymphocytes from PI cattle [211]. The lack of immune responses results in widespread distribution of BVDV throughout the host's tissues, and PI cattle shed BVDV in multiple secretions and excretions, including nasal discharges, urine, semen, colostrum, milk, and feces [212].

Fetal infections during the period of organogenesis (approximately 100–150 days of gestation) may result in congenital malformations usually associated with abnormal development of nervous tissues. Defects of the CNS include cerebellar hypoplasia (Figure 62.2), hydranencephaly, hydrocephalus, porencephaly, microencephaly, spinal cord hypoplasia, and a variety of ocular changes such as cataracts, optic neuritis, retinal degeneration, and microphthalmia [188, 213, 214]. Less commonly, congenital BVDV infection can cause CNS hypomyelination, which has been reported with both species of BVDV [215, 216]. In addition to CNS abnormalities, congenital BVDV infections can

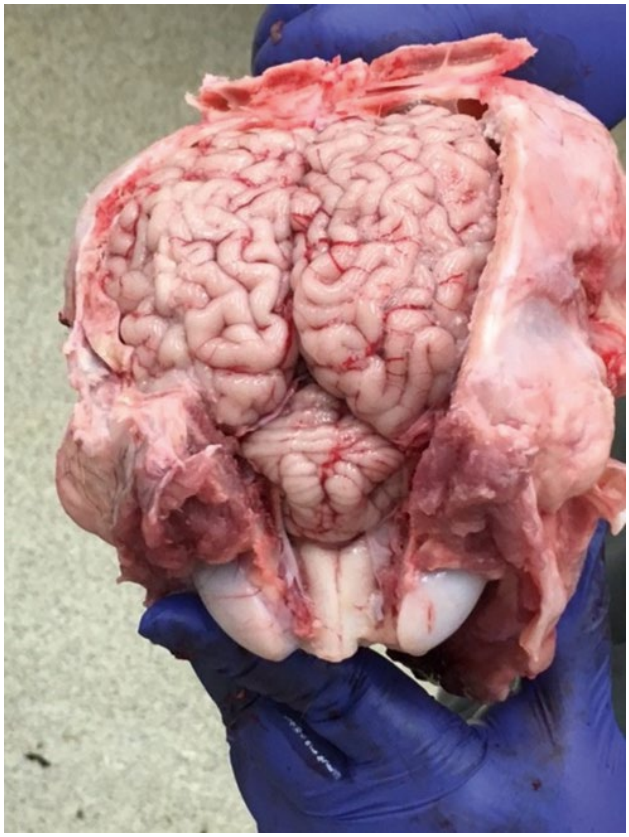

Figure 62.2 Cerebellar hypoplasia in a two-day-old Holstein calf. The calf had clinical signs of cerebellar disease including wide-base stance, intension tremors of the head, and bilateral horizontal nystagmus.

result in brachygnathism, osteopetrosis, thymic aplasia, hypotrichosis, hair coat abnormalities, pulmonary hypoplasia, and growth retardation [188, 212, 213, 217].

While abortions are still possible in later stages of gestation, congenital infections following the completion of organogenesis and immunocompetence (>150 days of gestation) result in effective immune responses and clearance of the virus. These calves are born with precolostral serum antibody titers and usually appear normal at birth [188]. However, one study suggested that calves born with precolostral antibodies against BVDV are more likely to develop severe illness during the first months of life, indicating that late gestational infections with BVDV may not be benign [218].

Infections in Persistently Infected Animals (Mucosal Disease)

Although PI calves may survive to reproductive age, many are born weak and stunted, and die shortly after birth [150]. PI cattle have a 50% greater risk of leaving the herd before the first year of age, dying, or being slaughtered due to unthriftiness as compared to normal cohorts, which may be partly due to a poor immune response and susceptibility to opportunistic infections [219, 220]. An additional risk for PI cattle is the development of fatal mucosal disease, which develops when cattle that are PI with a non-cytopathic BVDV become superinfected with a cytopathic strain. The severity of the developing clinical signs depends on the homology between both strains, and mucosal disease can be classified as acute, chronic, or delayed onset [221].

Acute mucosal disease occurs when the superinfecting cytopathic strain has close genetic homology with the PI strain, which most commonly is the result of mutational events that alter the PI strain's biotype [222]. Because of the close homology of both strains, acute mucosal disease results in case fatality rates that approach 100% [155]. Because acute mucosal disease affects only PI cattle, the disease is characterized by a low morbidity but very high mortality [155]. However, in groups of cattle with multiple PI animals infected with similar BVDV strains, outbreaks of mucosal disease have been reported [223]. Clinical signs of acute mucosal disease include fever, anorexia, tachycardia, polypnea, nasal discharges, and profuse foul-smelling diarrhea with mucosal shreds, fibrin casts, and blood. In addition, erosion and ulcers are commonly present on the alimentary epithelia (Figure 62.3), coronary bands, prepuce, and vulva [155].

Superinfections with heterologous cytopathic strains may result in chronic forms of mucosal disease that are not fatal but result in chronic clinical signs. The source for heterologous cytopathic strains is commonly vaccine-strains in modified-live vaccines [221]. Clinical signs include anorexia, weight loss, diarrhea, bloat, lameness, and erosive and ulcerative lesions on epithelial surfaces [221]. Sufficient heterology between the PI strain and the cytopathic strain may result in an immune response that clears the superinfection, enabling the animal's recovery from mucosal disease but not persistent infection [221]. Under experimental conditions, the incubation period of acute fatal mucosal disease is 7–14 days [224].

In contrast, delayed-onset mucosal disease occurs in PI cattle several weeks to months after inoculation with the cytopathic strain [225]. Similar to chronic mucosal disease, delayed-onset mucosal disease is caused by a heterologous cytopathic strain from an external source, but clinical signs occur after RNA recombination events between the PI strain and the heterologous cytopathic strain. This RNA recombination creates a homologous cytopathic strain and fatal mucosal disease [226].

Infections of Bulls

Both persistently and acutely infected bulls shed BVDV in semen, but the duration and level of shedding is much greater

Figure 62.3 Severe esophageal erosions and ulcers in a steer with acute mucosal disease. *Source:* Image courtesy of Dr. Jenna Bayne, Auburn, Alabama.

in PI bulls. In experimentally infected bulls, viral titers in semen (expressed in cell culture infectious dose [$CCID_{50}$]) ranged from 5 to 75 $CCID_{50}$/ml, and virus isolation was similarly effective from raw and extended semen [227]. In a group of heifers experimentally inseminated with contaminated semen from an acutely infected bull, approximately 5% became systemically infected [228]. While this initial rate of infection was low, it was sufficient for further transmission to susceptible heifers and maintenance of BVDV in the herd [228]. Under field conditions, AI with semen from two acutely infected bulls resulted in infection rates in exposed cows of 15.4 and 1.8%, respectively [229].

Semen from PI bulls can contain large quantities of BVDV (10^3–10^7 $CCID_{50}$/ml) [230, 231]. Insemination of susceptible heifers with semen from PI bulls consistently results in infection [230–232]. Semen quality from PI bulls ranges from normal on the basis of concentration, motility, and morphology of spermatozoa to abnormal, with morphological abnormalities of spermatozoa and low concentration and motility [230, 233].The use of semen from PI bulls usually affects conception rates negatively, which is likely due to a combination of factors, including lower quality semen, ill-thrift of affected bulls, and effects of BVDV on the reproductive tract of exposed cows [188, 230, 234].

In acutely infected bulls, formation of neutralizing antibodies results in viral clearance from most organ systems, but chronic infections of testicular tissues despite formation of serum antibodies are described [235]. This phenomenon was first described in a seropositive non-viremic bull that consistently shed BVDV in semen, suggesting an acute BVDV infection prior to completion of a functional blood–testes barrier [236]. Insemination of seronegative heifers with the bull's semen containing less than 2×10^3 $CCID_{50}$/ml of BVDV resulted in infection and seroconversion [146]. Localized and prolonged testicular infections have also been experimentally produced following intranasal inoculation and subcutaneous vaccination of peripubertal bulls with BVDV [237, 238]. Viral RNA was detected in semen for 2.75 years following BVDV exposure, and infectious BVDV was isolated from testicular tissue for up to 12.5 months after BVDV exposure [239]. Semen from a bull with prolonged testicular infection resulted in BVDV transmission when given intravenously to a seronegative calf [237]. However, artificial or natural insemination did not result in transmission of BVDV, indicating that the chronic presence of BVDV in testicular tissues could be of limited epidemiologic importance as a result of neutralization of infectious virus by humoral immunity in the ejaculate [235, 239].

BVDV and *in vivo* and *in vitro* Derived Embryos

Potential introduction of BVDV to *in vivo* and *in vitro* derived embryo production systems can result from three sources – donor cows, recipient animals, and materials of animal origin such as fetal bovine serum – and all three have to be free from BVDV to prevent transmission [240]. The World Organisation for Animal Health (OIE) states that "BVDV is a particularly important hazard to embryo transfer and the manufacture of biological products for other diseases due to the high frequency of contamination of batches of fetal calf serum" [241]. *in vivo* derived embryos could be exposed to BVDV if they were collected from acutely infected or PI cattle, or if contaminated sera were used in embryo collection, culture, or cryopreservation media [240]. However, BVDV appears to present a more serious threat in the production of embryos via *in vitro* production than via *in vivo* derived embryos. The virus can be introduced via serum or abattoir-origin oocytes and somatic cells used in *in vitro* embryo production. Hence unrecognized infections with non-cytopathic isolates could lead to amplification of the virus throughout *in vitro* maturation of oocytes, *in vitro* fertilization, and *in vitro* culture of embryos [242]. Furthermore, the virus

readily adheres to the zona pellucida of *in vitro* produced embryos, rendering the embryo washing and trypsin treatment procedures even less effective than they are for *in vivo;* derived embryos [243]. Production of embryos by somatic cell nuclear transfer presents even more unique hazards than that of *in vivo;* derived or *in vitro* produced embryos. Introduction of BVDV via serum used to culture both cytoplast-donor cell lines and the resulting embryos can readily occur. The cultured embryos are especially vulnerable because the zona pellucida has been either broken or removed to facilitate the process of cell fusion. Moreover, cumulus–oocyte complexes are usually collected at abattoirs from donors of unknown BVDV status and cell lines are often of fetal origin, creating enhanced opportunities for introduction and amplification of BVDV as embryos are produced and develop [242]. Therefore BVDV still continues to be a concern in embryo technologies and a more detailed discussion on this topic is included in Chapter 86.

Diagnosis, Prevention, and Control

As for other infectious pathogens, the main principles of BVDV control are the elimination of pathogen reservoirs and the prevention of transmission from infected to susceptible animals. Any BVDV control program should focus on three major principles: (i) identification and elimination of PI animals, (ii) enhancement of immunity through vaccination, and (iii) improvement of biosecurity to prevent exposure of susceptible cattle [244]. PI cattle are considered the most important source for BVDV and are central in the epidemiology of the virus. Ideally, detection of PI cattle should occur before entry into a herd, and all new herd additions including breeding bulls should be screened. In herds using a controlled breeding season, all calves, replacement heifers, open cows, and breeding bulls should be tested simultaneously before the beginning of the breeding season [244]. If pregnant dams are present, they should be segregated and their calves tested as soon as possible. All newborn calves should be tested as soon as possible to prevent exposure of susceptible animals. Because PI calves can be born to acutely infected or PI cows, the dams of PI calves must be retested.

When attempting BVDV control on a herd level, diagnostic assays should have a high sensitivity to detect BVDV, use an easily obtainable sample, and be highly specific for PI status. For this purpose, antigen-capture ELISA or IHC assays utilizing skin biopsy samples (ear notches) are well suited. While various diagnostic tests are available to detect infection with BVDV, not all available tests are applicable to each clinical problem. Additionally, genetic and antigenic variation of BVDV might affect the performance of detection assays [245]. Therefore test selection should correspond to the status of each herd, the tests available in different diagnostic laboratories, and economic considerations. Lack of rational use of detection methods hampers efforts in solving production problems caused by BVDV [246]. Principally, all available diagnostic assays can be grouped into methods that culture BVDV in tissue cells, detect antigen in diagnostic specimens, amplify the RNA genome of BVDV, or detect the presence of antibodies in serum or milk [246].

Virus Isolation

The isolation of BVDV from various specimens, including serum, buffy coat, nasal swabs, and tissue samples, remains the "gold standard" of diagnosis [246–248]. For BVDV diagnostics on live animals, white blood cells are the preferred sample for virus isolation as there is no interference by serum neutralizing antibodies and the virus is highly cell-associated. Tissues of the lymphoid system including spleen, thymus, and lymph nodes are the preferred sample from postmortem examinations or aborted fetuses [246]. BVDV grows readily in various cell lines, including those of other species, and this may result in difficulties when using BVDV-contaminated cell cultures [249–251]. Successful culture of cytopathic BVDV strains is indicated by vacuolation and cell death within a few days of virus inoculation. For non-cytopathic strains, immunofluorescence or immunoperoxidase staining techniques are utilized to visualize cellular infection with BVDV [252, 253]. Virus isolation may also be used as a herd screening test in the form of the immunoperoxidase monolayer assay [254]. Although economical, this test uses serum as the diagnostic sample and is not ideal for detection of acute infections or testing of cattle less than three months of age that have acquired colostral immunity. Failure to detect PI cattle with the immunoperoxidase monolayer assay has been reported, although at an extremely low rate of detection error [255].

Antigen Detection

Direct detection of BVDV antigen allows more rapid and economic testing of samples compared with virus isolation. Antigen detection can be performed by immunofluorescence, IHC, and ELISA techniques. In general, the analytical sensitivity and specificity of antigen detection assays are less than those of virus isolation, which accommodates the detection of PI cattle rather than of acute infections. In contrast to the traditional laboratory identification of PI cattle using two positive virus isolations performed three weeks apart, commercially available ELISA kits and IHC are used to identify PI cattle with a single

sample [256]. Several studies have demonstrated excellent results for antigen-capture ELISA and IHC for use as screening tests for PI cattle [257–260]. False-positive results after antigen-capture ELISA and IHC testing due to acute BVDV infections are rare but have been previously reported [261]; however, the antigen-capture ELISA and IHC tests can be utilized to test calves before waning of colostral immunity and after vaccination with modified-live BVDV vaccines which usually interfere with other assays [262–264]. Antigen detection is most frequently performed on ear-skin biopsies, but various samples including tissues, whole blood, serum, milk, and nasal swabs are suitable after appropriate sample preparation [246]. Unlike other BVDV tests, antigen-capture ELISAs cannot produce accurate results when pooled in more than two samples [265]. In addition to laboratory-based ELISA tests, a chute-side individual sample ELISA test is available, which can be used on ear-notch or serum samples to detect PI animals in 20 minutes [266].

RT-PCR

The description of the genomic sequence of BVDV and the development of suitable probes and commercially available kits has enabled the widespread use of RT-PCR as a routine diagnostic method [267]. The technique is highly sensitive and can be utilized for various diagnostic samples including skin (ear notches), milk, urine, tissues, serum, whole blood, semen, and embryos [268–273]. Although RT-PCR techniques can be used on diagnostic specimens that are fixed in formalin, RNA fragmentation occurs and reduces assay sensitivity [274].

The sensitivity of RT-PCR exceeds that of virus isolation, and the assay can detect the viral RNA of a single viremic sample in a pool of 100 negative sera [275]. The ability to pool samples such as ear notches, milk, or serum for RT-PCR BVDV testing offsets the initial greater cost of the assay and allows economical screening for PI animals. Pooling strategies using skin biopsies or blood samples rather than bulk-tank milk do not abolish the need to collect a sample from each animal in the herd [276]. In milk, BVDV was detected by RT-PCR in samples that were serially diluted to 1 : 640 [277]. Using ear notches, one study reported detection of one positive sample in a pool of 100 negative samples; however, the optimal number of samples used for pooling has been controversial, and pools of 30 samples to 100 samples have been recommended [271, 276, 278]. The economic and competitive benefits of sample pooling decrease when BVDV prevalence rates exceed 3% [279]. Testing initial pools of 20 samples followed by subsequent pools of 5 samples prior to individual testing was recommended as the pooling strategy in dairy herds with greater BVDV prevalence rates [279].

Serology

The detection of serum antibodies directed against BVDV can be performed by various assays, but the ELISA and serum neutralization tests predominate and have replaced indirect immunoperoxidase or indirect immunofluorescence techniques [280]. With appropriate application, serologic tests allow the assessment of vaccine efficacy and compliance with established vaccination protocols, the detection of herd exposures to BVDV, and the association of clinical signs with BVDV infection [281]. Difficulties exist in determining the etiology of detected antibodies, as seroconversion may be the result of acute infections, vaccination, or transfer of maternal immunity through colostrum. Commercial blocking ELISA assays that detect antibodies directed against the NS3 protein of BVDV are unable to differentiate antibodies derived from natural infection or vaccination, and marker vaccines are currently unavailable for BVDV [282]. Serologic testing of previously unexposed sentinel animals can be utilized to detect the presence of PI cattle in herds [283]. However, the analysis and comparison of serologic titers do not allow a clear distinction between PI-free herds and those with PI cattle [284].

Testing Strategy

Identification and elimination of PI cattle is the single most important step in the control of BVDV infection; however, the expense of control strategies should not exceed the cost associated with infection and disease. Whole herd testing using proper diagnostic tests is an effective method to identify and eliminate PI animals from cattle operations but may not be economically beneficial if the prevalence of BVDV in such operations is low [285]. Consequently, the strategy of testing should be developed based on the estimated prevalence of BVDV in each herd. When the prevalence of BVDV in a given herd is determined to be low (<0.47), strategies that include testing of new additions, newborn calves, aborted fetuses, and sick/dead cattle are probably more cost-effective than whole herd testing. In contrast, when herd prevalence is estimated to be greater (>0.47), whole herd BVDV testing is economically beneficial [285]. A two-test strategy could maximize the value of individual animal testing for identification of PI cattle especially when testing animals of high genetic value [261, 285]. Antigen-capture ELISA and IHC ear-notch tests can be confirmed

with RT-PCR or virus isolation (VI) in blood samples 30 days after initial testing [261].

Vaccination

In the USA, BVDV modified-live and inactivated vaccines are widely available, most commonly in the form of multivalent vaccines containing other respiratory and reproductive pathogens. While modified-live vaccines stimulate a broader immune response in vaccinated animals, are less expensive, and provide some protection after administration of a single dose, inactivated vaccines are utilized when safety concerns exist. However, failure to administer the necessary second booster dose during initial immunization can result in breakdown of BVDV control programs using inactivated vaccines [286].

Because of the antigenic diversity of BVDV strains and failure of some animals to adequately respond to immunization, vaccination efficacy cannot be 100%. Therefore vaccination programs must be part of a control strategy that includes removal of PI animals and measures of biosecurity [287]. Traditionally, only BVDV 1 strains were used in vaccine production, but the antigenic diversity between both BVDV species has prompted the inclusion of BVDV 2 in most vaccines. Studies have documented protection from BVDV 2-induced disease in cattle vaccinated with BVDV 1-containing modified-live or attenuated vaccines [288–290], but antigenic diversity of BVDV and resulting failure of cross-protection continues to be of concern. A meta-analysis concluded that multivalent vaccines containing BVDV 1 and BVDV 2 provide better protection against heterologous BVDV strains when compared with monovalent vaccines [291].

While protection of each individual animal from BVDV-induced disease is the desirable goal of vaccination programs, the increase in herd immunity and prevention of viral spread following accidental introduction are more reasonable objectives in BVDV control. Effective vaccination against BVDV should prevent viremia and spread of the virus to target organs. Additionally, vaccination should protect against clinical disease, fetal infection, abortion, and generation of PI calves. Identical immune mechanisms are stimulated to achieve these goals; however, the greater humoral and cell-mediated immune protection induced by modified-live BVDV vaccination has proven to be more effective in reducing morbidity and mortality compared with vaccination with inactivated vaccines [292]. Additionally, results from several studies demonstrated that modified-live vaccines are superior to inactivated vaccines in protecting susceptible cattle against abortion, fetal infection, and generation of PI offspring following experimental infection with BVDV [291, 293–295].

Cattle should be vaccinated to afford greatest protection during an anticipated exposure to BVDV. Therefore adequate humoral and cell-mediated immunity should be present during weaning, commingling, arrival to feedlots, and prebreeding [296]. The presence of high BVDV-specific antibody titers before experimental challenge/exposure to BVDV is associated with reduction of viremia and clinical signs [297–299]. In contrast, calves arriving at the feedyard with low antibody titers against BVDV and other respiratory pathogens have decreased economic returns, increased morbidity rates, and increased treatment costs [296, 300]. Increased morbidity rates and treatment costs were associated with inappropriate timing of vaccination close to delivery of calves or lack of a booster dose in programs using inactivated vaccines, emphasizing the value of adequate preconditioning programs [300]. Commonly, preconditioning programs as implemented in cow-calf herds require weaning of calves 45 days prior to shipment, and include dehorning, castration, bunk-training, and the administration of anthelmintics and vaccines. Calves vaccinated at 30 and 17 days before shipment to a feedlot using a multivalent modified-live vaccine did not become viremic or shed BVDV when exposed to PI penmates [301]. While modified-live vaccines are able to rapidly confer clinical protection and protected calves from experimental challenge as early as three to five days after vaccination under field conditions, complete protection cannot be expected this promptly [302, 303].

When planning a BVDV vaccination protocol for calves, blocking of protective immune responses by the presence of maternal antibodies is of concern, especially in early-weaned calves [304]. Two-week-old calves vaccinated with a modified-life vaccine in the presence of high titers of colostral antibodies were not protected from heterologous BVDV-induced disease at four months of age, in contrast to calves BVDV-seronegative at vaccination [305]. Additionally, considerable variation between individual maternal antibody titers exists, causing difficulty in estimating the ideal time of initial vaccination in calves [306, 307]. However, different investigators have recently demonstrated that vaccination of young calves in the face of maternal antibodies can result in cell-mediated and humoral anamnestic immune responses and protection from BVDV-induced viremia and disease [297, 298, 308, 309]. The results from these studies suggest that vaccination in the face of maternal immunity can be efficacious when early exposure to BVDV is expected [297, 298, 310].

In cow-calf herds, vaccination against BVDV should prevent fetal infection and birth of PI offspring, thus interrupting the endemic cycle of BVDV. Protective immunity should be achieved at least 30 days before

breeding and vaccinations should not be administered in the immediate prebreeding season to avoid adverse effects of vaccine strains on fertility [311]. In various studies, experimental intranasal challenge of vaccinated dams resulted in protection from fetal infection of up to 100%; however, complete protection was often not demonstrated [312–316]. A lower extent of protection was observed in other studies when vaccinated pregnant cattle were exposed to PI cattle, which is considered a more rigorous and realistic challenge model [293, 317–319]. While prolonged and complete protection from development of PI calves was demonstrated in a study using PI cattle as the challenge model [317], under field conditions success of vaccination to prevent fetal infection depends on various factors including timing of vaccination, nutritional and immune status of animals, cross-protection of vaccine and field strains, and number of vaccinations administered before breeding.

Biosecurity

Adequate biosecurity measures based on a practical and effective plan to identify and eliminate BVDV infected cattle are a key management factor in the prevention of introduction and transmission of BVDV in cattle herds [320]. Biosecurity measures should include isolation and testing of all purchased cattle and their offspring, using semen only from negative bulls, quarantining, testing of animals leaving the herd for shows, and separation of young stock from adults [142, 320]. Testing of all embryo transfer recipient cattle and embryo transfer collection supplies such as fetal bovine serum (FBS) is also important.

Introduction

In August 2011, an unknown disease observed in dairy cows in North Rhine-Westphalia (Germany) close to the Dutch/German border was first described [1–3]. At the same time, a similar case was reported from the Netherlands. Diseased cows displayed non-specific symptoms such as fever, diarrhea, and decreased milk production [4]. In late 2011/early 2012, lambs were born that showed different degrees of malformation [5]. Laboratory tests were all negative for classical bovine endemic and emerging viruses such as bovine viral diarrhea virus 1 & 2 (BVDV 1 & 2), bovine herpesvirus 1 (BHV1), foot and mouth disease virus (FMDV), bluetongue virus (BTV), epizootic haemorrhagic disease virus (EHDV), Rift Valley fever virus (RVFV), and bovine ephemeral fever virus (BEFV). Blood samples were collected from animals with clinical signs and subjected to metagenomic analysis. The results revealed a novel orthobunyavirus [1]. Because the virus was found in a pooled sample from cows from a dairy farm near the German town Schmallenberg, North Rhine-Westphalia, the new virus was named "Schmallenberg virus (SBV)" [1]. Since its first detection, the virus quickly spread all over Europe, and then continued to spread into Asia and Africa. North-, Latin-, and South America are still considered SBV free. Where SBV came from and how the virus was first introduced is still not known [3]. However, since its emergence, SBV has had significant economic impact on the cattle and small ruminant industries in countries where SBV is endemic due to direct (e.g. reduced prolificacy, malformed or dead offspring) and indirect (trade restrictions on animals and semen) losses [3].

Etiology

SBV is part of the Simbu serogroup of the genus *Orthobunyavirus* within the family Peribunyaviridae (order Bunyaviridae). Akabane virus (AKAV) [6, 7], Aino virus [8, 9], and Shamonda virus [10, 11] cause similar symptoms as SBV and are widespread in Oceania, Australia, Africa, and Asia. SBV is an enveloped virus with three negative-sense single-stranded RNA segments (small, medium, large; Figure 63.1) [12] with presumably limited antigen drift, high genetic stability, and low mutation rate [13, 14]. Only the M segment coding for two surface glycoproteins seems to be variable [3].

SBV is relatively instable in the environment or the vectors, as it does not survive outside its natural hosts for a very long time [15]. Also, it is susceptible to standard disinfectants such as 70% ethanol as well as glutaraldehyde and formaldehyde [15]. Moreover, infectivity is significantly reduced or lost at 50–60 °C for at least 30 minutes [15].

Hosts

Ruminant Species

SBV primarily infects ruminants, which includes all domestic species, i.e. cattle, sheep, and goats, but has also been found in wild and exotic ruminants such as alpaca, llama, elk, water buffalo, bison, various species of deer, mouflon, chamois, and camelids [3]. Wild ruminants may play a role in SBV transmission. However, clinical disease has not been confirmed in either wild or exotic animals [3].

Non-Ruminant Species

There is no evidence that SBV can infect humans. In one study conducted by the Robert Koch Institute in Berlin, Germany, and in another conducted by the National Institute for Public Health and the Environment in Bilthoven, the Netherlands, personnel working in infected sheep and goat flocks as well as in cattle barns, and the responsible veterinarians, were tested for antibodies against the virus [16, 17]. None of the tested people was positive for virus-specific antibodies. However, there are several other species that have tested SBV positive either serologically or for virus RNA. These include wild boar, dog, onager, zebra, elephant, and babirusa [3]. Clinical disease does not occur, except in one report of an SBV positive puppy that had developed torticollis and degenerative encephalopathy [18]. Domestic pigs experimentally infected with SBV transiently seroconverted, but SBV-RNA was not detected and no clinical disease was observed [19]. There is one report of SBV infection in horses from Iran, but caution is required when interpreting this result as, for example, cross-reactivity with other Simbu group viruses endemic to this area may have occurred [3, 20].

Distribution and Seroprevalence

The geographical origin of SBV is still unknown [3]. The SBV epidemic in Europe occurred quickly within a very short time period, i.e. 2 1/2 years [3]. Almost all European countries are now affected [1, 5, 21–31]. Spread continued into Russia [32] as well as neighboring countries such as Azerbaijan [33], China [34], and Turkey [35], and into Arabian (Iran [20]; Lebanon [36]) and African countries (Mozambique [37]; Namibia [38]; Ethiopia [39]). No cases of SBV infection have yet been reported from North-, Latin-, or South America.

After initial herd exposure, SBV has been demonstrated to reemerge in several European countries, albeit at lower levels compared to the first outbreak, likely due, at least in part, to the virus's ability for overwintering [40–48]. Pregnant ewes infected with SBV between days 45 and 60 of pregnancy have shown to harbor SBV in the placenta for at least 100 days post infection, which might explain overwintering in cold seasons [3, 49]. Overwintering may also occur in midges through transovarial transmission and in adult midges that are less sensitive to low temperatures such as those of the *Culicoides obsoletus* group [3, 50].

Three years post first detection, i.e. until March 2014, SBV was observed on 1,478 cattle farms as well as in 973 sheep and 53 goat flocks in Germany [51]. Generally, the prevalence of SBV infection in dairy herds is high, and higher than in sheep and goats [3]. Initial studies conducted in the Netherlands and Belgium in 2012 revealed a prevalence at farm level of 95.5 and 99.76%, respectively [52, 53]. Moreover, the intra-herd prevalence was 86.3% in the Dutch study [52]. At the same time, Spain reported a prevalence of 70.6% [54] and Turkey of 39.8% based on slaughterhouse material collected between 2006 and 2013 [55]. In a recent study from Ethiopia [39] from 2018, a prevalence of 56.6% was reported. A high between-herd seroprevalence of 98.03% was also found in sheep flocks in the Netherlands [56]. Within a flock, 58.7–84.31% of the sheep were found seropositive [56, 57]. In goats, the intra-herd prevalence was, for example, 40.68% in Belgium, 36.7% in the northwest part of Germany, and 43.8% in Lower Saxony, Germany [56–58]. In Turkey, slaughterhouse material was found to be SBV positive in 1.6% of sheep and 2.8% of goats [55].

Epidemiology

SBV is transmitted by biting midges (*Culicoides* spp.). The virus was detected in several *Culicoides* spp. (e.g. *C. obsoletus*, *Culicoides dewulfi*, *Culicoides chiopterus*, *Culicoides scoticus*, *Culicoides punctatus*, *Culicoides nebeculosis*, *Culicoides imicola*) across Europe [27, 59–62]. As with other aboviruses, a SBV transmission cycle starts with midges biting and sucking blood from an SBV-infected ruminant host. SBV then replicates within infected midges to be at transmittable levels (extrinsic incubation period, which takes 9–41 days) [63], and if infected midges then bite non-infected naïve animals, they transmit the virus via saliva. An intrinsic period follows (this takes 2–6 days) [1]. Mosquitos and black flies do not seem to be able to transmit SBV [64, 65].

Vertical transmission of SBV, i.e. through the placenta into fetuses of an infected viremic animal, is another route of infection. This route of infection causes congenital malformations to occur (see section "Pathogenesis and Clinical Signs"). The exact time window of pregnancy when animals are susceptible for vertical transmission is assumed to be between days 28 and 60 of gestation in small ruminants [66] and days 80 and 150 in cattle [7], similar to what is seen with AKAV. Moreover, assuming that SBV behaves like AKAV, infections outside these susceptible time windows may still cause effects such as embryonic/fetal death, but congenital malformations are then unlikely to occur [67].

Horizontal transmission through animal contact is unlikely, although experimentally subcutaneously inoculated cows were found virus-positive in fecal, oral, and nasal specimens [68]. In contrast, orally SBV inoculated cows did not become infected [68], and sentinel cattle kept in the same compartment as inoculated cows remained virus-negative and seronegative [68].

SBV can be detected in semen of infected bulls [69–71]. For instance, bulls subcutaneously inoculated with SBV exhibited viremia two to four days post inoculation, and highest amount of virus was detected between days four to seven post inoculation [71]. In contrast, experimentally infected goat bucks did not shed SBV in semen [72]. The role of venereal transmission of SBV therefore remains to be investigated further.

Pathogenesis and Clinical Signs

SBV pathogenesis is still not well defined. If a naïve pregnant animal is bitten by an infectious midge within the window of susceptibility and subsequently develops viremia, SBV may colonize and replicate in placentomes. However, efficient replication seems to be dependent on the maturity of the placentomes. For instance, extraembryonic material and lamb organs were more often SBV positive in sheep if experimentally infected at day 60 compared to day 45 of gestation [73]. As shown for AKAV, the susceptibility of embryos/fetuses to become infected may also be dependent on gestational stage, as no pathology was detected within the first three weeks of gestation in small ruminants and the first two months in cattle [3, 7, 66].

Generally, there are only weak or unspecific clinical symptoms in the adult pregnant and non-pregnant domestic ruminant animal associated with SBV, such as fever (up to 41 °C), decreased milk production, and diarrhea [3, 4]. Symptoms may last for up to six days (concurrent with the time period of viremia that also lasts for up to six days) [3, 4]. SBV can affect reproduction in cattle as abortions, stillbirths, and mummified fetuses have all been observed, as has reduced fertility (increased embryonic mortality, more returns and inseminations/cow, short gestations) [3, 74–77]. Similar SBV-attributed effects have been documented in sheep [74, 78–80] and goat [58, 74] flocks. However, clinical signs may also be lacking, as observed in experimentally infected goats and bucks [72]. The stage of fetal development may be of importance; ovine embryos have shown to be more susceptible before the blood–brain barrier is developed (i.e. before days 50–60 of gestation) [3, 81].

Clinical disease is most evident in calves, lambs, and goat kids after in-utero infection at the critical stage of pregnancy, causing congenital malformations belonging to the "arthrogryposis–hydranencephalia–syndrome (AHS)" (Figures 63.2 and 63.3) [3]. AHS is presented with one or more of the following malformations: arthrogryposis, vertebral malformations, brachygnathia inferior, ankylosis, torticollis, and scoliosis. In addition, malformations of the central nervous system (CNS) can occur, including hydranencephaly, porencephaly, hydrocephalus, cerebellar hypoplasia, and micromyelia [82–84]. Most of the malformed newborns are stillbirths. Survival is, however, possible, but affected offspring are then usually non-viable. Since there is indication that SBV has tropism to the musculoskeletal as well as CNS of developing embryos (with neurons in the cerebral cortex, brainstem, and spinal cord being targeted cells) [3, 81, 85], SBV infected calves and lambs may be born with unspecific symptoms that include inability to suckle and weakness in lambs [5, 86], as well as hypertonicity, hyperreflexia, depression, blindness, strabismus, and inability to stand in calves [23]. Those newborns are unviable and an immediate reason for euthanasia. Moreover, as reported for sheep, malformations may cause dystocia that would require obstetrical intervention, and also obstetrical injuries of, for example, the uterine wall [87].

Figure 63.2 Calf (a) and lamb (b) congenitally infected with Schmallenberg virus born with severe arthrogryposis of all four limbs, torticollis, kyphosis, and skeletal muscle hypoplasia. The lamb also presented without brachygnathia inferior. *Source:* Images courtesy of Dr. Benjamin Schade, Bavarian Animal Health Service, Poing-Grub, Germany.

SBV has also been shown to reduce white and red blood counts in experimentally infected calves, but this is certainly not specific enough to be utilized as a means for diagnostic testing [88].

Histological findings of the CNS included cerebral lesions and cerebral dysplasia associated with dilated lateral ventricles and a reduction of gray and white matter [89]. Viral nucleocapsid protein was detected in CNS neurons together with a moderate, non-purulent encephalitis, lymphohistiocytic vasculitis, and perivasculitis [89]. Cerebellar dysplasia and hypoplasia with either disorganization of the cerebellar cortex or multifocal to diffuse reduced thickness of the molecular layer and a reduction of Purkinje neurons may occur [89]. Skeletal muscle hypoplasia was associated with a decreased number and diameter of myofibrils occasionally in conjunction with cross-striation and fatty replacement [83, 90].

Diagnosis

SBV can be detected by real-time reverse transcription quantitative polymerase chain reaction (RT-qPCR) or by virus isolation using different cell lines [3]. RT-qPCR is certainly the most versatile method, as it would allow different specimens to be analyzed. Specimens of malformed neonates such as brain stem, placenta, spleen, meconium, or amniotic fluid are appropriate [3, 91]. Native as well as processed (extended, frozen) semen can be analyzed [69–71, 92, 93]. In blood, the best time for virus detection would the period of viremia (i.e. within the first week of infection) using an ethylenediaminetetraacetic acid (EDTA) stabilizer or serum.

SBV-specific antibodies can be detected by virus neutralization, indirect immunofluorescence test, or enzyme-linked immunosorbent assay (ELISA) (there are several commercial antibody ELISA kits available). Among all tests, virus neutralization seems to be the most sensitive test and more highly specific than the S-segment-based ELISA tests [94–96]. Antibodies can be detected in blood serum of adults [97] and milk of lactating females [98], and in different liquid specimens of ideally malformed stillborn or born-alive offspring (e.g. in blood, precolostral serum) [99–101]. Interestingly, antibody titers in milk were higher than in serum of individually collected cows [102], and were also highly predictable in bulk tank milk samples, making the latter an ideal matrix for surveillance programs [103].

Control and Prophylaxis

There is currently no treatment available for SBV-caused disease [3]. Control of SBV infection can only be achieved by vaccination, but the availability of vaccines varies by country. In Europe, there are three vaccines available to be used in both sheep and cattle: Bovilis® SBV (Intervet UK Ltd, Milton Keynes, UK), SBVvax® (Merial SAS, Lyon, France), and Zulvac SBV® (Zoetis, Parsippany, NJ, USA). All three vaccines contain inactivated virus. According to the labels, sheep are to be vaccinated at four months or older only once, while in cattle two vaccinations are required at an age ≥ two months and again three weeks later. A clear antibody response can be usually observed three weeks after the first (sheep) or second (cattle) vaccination. While it is not yet known how long protection lasts, it is assumed to be ≥12 months. Currently, there is no commercial vaccine available for use in goats.

Another preventative measure is to use repellents and pyrethroids directed against the vector, i.e. biting midges, thus reducing the risk of transmission to susceptible animals, but its sustained effect has been questioned based on a recent case control study [3, 104].

Another approach is to breed animals in colder times of the year (e.g. in late autumn or winter) when vector activity is low, in order to reduce transmission at times when fetuses are most susceptible to infection. However, this approach may have serious negative consequences to breeding management practices which may then override possible benefits by moving the breeding period, especially in areas with seasonal production systems [3, 78].

To what extent it is possible to reduce some of the risk factors, e.g. related to confinement (i.e. outdoor-kept animals are more susceptible then those confined indoor) [3], remains to be elucidated.

Finally, management practices regarding replacement animals may be employed to facilitate vector-induced infection before first breeding. Considering that immunity after natural SBV infection lasts for two to three years, those "naturally immunized" animals will then be protected at the time of first pregnancy. However, as recently summarized, this method by itself is not likely to be reliable, and a combination of different measures is required to reduce the risk of SBV infection in domestic livestock [3].

Infectious Agents: Bovine Epizootic Abortion

Jeffrey L. Stott, Myra T. Blanchard, and Mark L. Anderson

School of Veterinary Medicine, University of California, Davis, CA, USA

Introduction

Epizootic bovine abortion (EBA), commonly referred to as "foothill abortion," was first recognized in the early 1950s in California [1]. EBA is characterized by late-term abortions, or birth of weak calves, delivered by dams grazed in foothill regions of California, Nevada, and southern Oregon during their first and second trimesters of pregnancy. The disease has been, and continues to be, the leading cause of abortion in beef cattle in the state of California; estimates are not available for Oregon and Nevada [1–4].

Etiology

Multiple quests to identify the etiologic agent of EBA span 50 years. These efforts produced a number of candidate microbes as being the causative agent including a chlamydia, an uncharacterized virus (C-type-like particles), *Borrelia coriaceae*, and an uncharacterized spirochete [5]. Development of a reproducible method for experimental disease transmission in 2000 facilitated efforts to identify the etiologic agent. Inoculation of naïve pregnant heifers at ~100 days' gestation with cryopreserved fetal thymus homogenates, derived from select EBA-diseased fetuses, provided a reliable mechanism to predictably transmit the pathogen to the developing fetus with concomitant development of classical EBA. Antibiotic susceptibility studies were employed using disease-transmission experiments in pregnant heifers; aggressive treatment at the time of heifer infection with penicillin and/or tetracycline abrogated subsequent development of fetal disease, providing strong evidence that the etiologic agent was a prokaryote [5]. Application of molecular biology techniques to diseased fetal necropsy tissues ultimately identified the agent in 2005 as being a deltaproteobacterium. 16S rRNA sequences derived from the pathogen established an 89.4% homology to that of *Polyangium cellulosum* (i.e. *Sporangium cellulosum*), a member of the order Myxococcales [6]. The only other mammalian pathogen currently recognized in this class of prokaryotes is *Lawsonia intracellularis*, a deltaproteobacterium primarily associated with enteritis in pigs. The bacterial agent of EBA (aoEBA) has recently undergone additional characterization and been coined *Pajaroellobacter abortibovis* [7]. A revised 16S rRNA phylogenic analysis between *P. abortibovis* and *S. cellulosum*, taken together with the fact that *P. abortibovis* infects arachnids and is a mammalian pathogen, warrants it being in a genus separate from *Sorangium* [7].

Diagnosis

EBA was historically diagnosed with a combination of unique fetal pathology, elevated levels of immunoglobulin in fetal serum, and history of the dam being grazed in areas considered endemic for the disease during pregnancy [2, 3]. Gross and microscopic pathology associated with EBA is typically dramatic. Aborted fetuses are usually in excellent condition (not autolyzed) and present with a variety of gross abnormalities that can include extensive ascites with excessive fibrin (Figure 64.1a) resulting in a distended abdomen, swollen liver, enlarged spleen and lymph nodes (Figure 64.1b), skin lesions (Figure 64.1c), and petechial hemorrhages on mucosal membranes (oral cavity, tongue, and eyelids) (Figure 64.1d) and in the thymus (Figure 64.2a). Microscopically, lesions are widespread and have a vascular orientation characterized by infiltration with lymphocytes and mononuclear phagocytes [2, 3]. Focal necrotizing lesions may be present in organized lymphatic tissues and

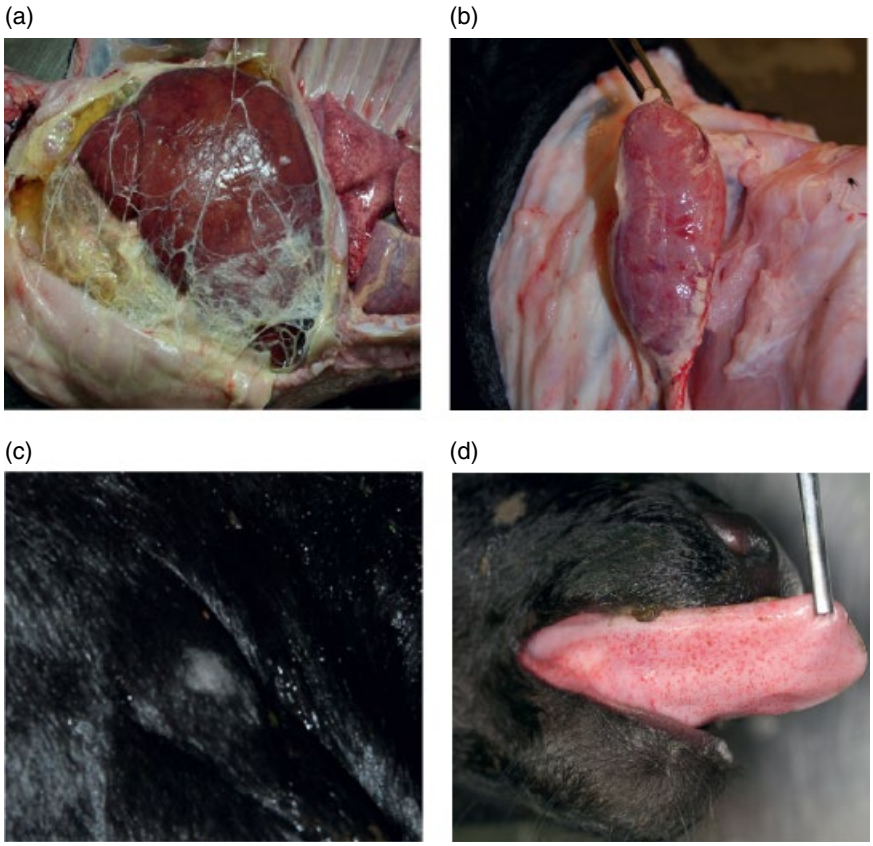

Figure 64.1 Gross changes in *P. abortibovis*-infected fetuses: (a) fibrinous peritoneal effusion and enlarged nodular liver; (b) enlarged prescapular lymph node; (c) skin lesion; (d) tongue with extensive petechiation of ventral lingual mucosa.

pathognomonic lesions occur in the thymus, characterized by depletion of cortical thymocytes and infiltration with macrophages [3] (Figure 64.2b).

Microbiological diagnosis of EBA continues to be hampered by an inability to culture the causative agent. While limited short-term replication of *P. abortibovis* has been observed in primary cultures of macrophages derived from fetal lymphoid necropsy tissues, substantive propagation of the bacterium in either primary or established cell lines has not been possible; all attempts to culture *P. abortibovis* on synthetic media have also failed [5]. Polymerase chain reaction (PCR) assays, both traditional and TaqMan-based, have been developed and target the 16S bacterial ribosomal gene [6, 7]. Both assays can be used to identify the presence of *P. abortibovis* in necropsy tissues of infected fetuses presenting with classical EBA pathology. The TaqMan is the assay of choice when identifying low levels of bacteria in necropsy tissues derived from fetuses suspected of being infected, such as fetuses presenting with equivocal or non-classical EBA pathology and weak calves that may or may not suckle. The TaqMan assay is also preferable for identifying *P. abortibovis* in the vector as only the occasional infected tick will have sufficient levels of bacteria detectable by a standard PCR [8, 9].

Routine bacterial histologic stains do not demonstrate *P. abortibovis* in fetal tissues, so a modified Steiner silver staining technique applied to the distantly related deltaproteobacterium *Lawsonia intracellularis* was used to microscopically visualize *P. abortibovis* in sections of formalin-fixed necropsy tissues. Steiner stain and immunohistochemistry applied to thin sections of formalin-fixed necropsy tissues (Figure 64.3a,b) and immunofluorescence applied to impression smears and/or homogenates of fresh tissue are the current methods of choice for microscopic diagnosis of EBA [10, 11].

A fluorescent antibody-based serologic assay has recently been validated for diagnosis of EBA [12]. Assay specificity is 100% with 95% sensitivity when cutoff criteria for a positive test were assigned at a titer of ≥1000. The assay has proven extremely useful in providing a timely diagnosis, especially in cases in which the majority of *P. abortibovis* has been eliminated by the fetal immune system. This serologic assay has also been useful in assisting veterinarians and their beef-producer clients in rural regions that do not have ready access to diagnostic laboratories as a means of diagnosing the disease by simply submitting a sample of body fluid such as blood or ascites in lieu of the entire fetus.

Pathogenesis

P. abortibovis apparently gains entrance to the developing fetus across the placenta from the infected dam. The dam, whether infected by tick bite or experimental inoculation, presents with no overt clinical signs. Reactions to experimental tick bites recorded in historical communications were most likely a response to contaminating microbes and/or tick saliva. The fetus has a "window" in development in which it is susceptible to an infection that will ultimately lead to fetal disease. This window is poorly defined but susceptibility is generally believed to be from conception through second trimester of gestation. Susceptibility early in gestation (<60 days) is not known. While the pathogen does not appear to impact conception, the possibility that it may induce early embryonic death in a small percentage of infected animals is under investigation. Infection of the fetus is a slow process, with definable lesions not becoming evident for two to three months [3]. The bacterium appears to replicate intracellularly in histiocytes as determined by immunohistochemistry (Figure 64.2); replication is extremely slow (approximately one day) when observed in short-term cultures of macrophages derived from fetal necropsy tissues. The intracellular nature of the infection, vascular orientation of lesions throughout the fetus, and slow and persistent development of disease would all be consistent with the hypothesis that lesions are immunologically mediated [3]. Slow growth of the bacteria is undoubtedly responsible for slow dissemination throughout the body and lesion development coinciding with development of immunologic maturation of the fetal immune system.

Pregnant sheep do not appear to be susceptible to foothill abortion; unpublished studies in which pregnant

ewes were infected in the first trimester resulted in the birth of healthy lambs. These latter studies would be consistent with the hypothesis that the bacteria replicate and disseminate slowly, and in the case of sheep the gestational period is too short to develop immunologically mediated lesions and abortion. Mule deer (*Odocoileus hemionus*) serve as an important host to the tick vector, but there is no evidence of EBA occurring in this species. Their gestation period is intermediate between sheep and cattle (six to seven months) and may be too short to allow for disease development. Alternatively, regular exposure to the organism through tick bites may confer immunity, and in those instances when abortions occur, fetuses would be rapidly scavenged, leaving no evidence. Multiple attempts to produce disease in immunocompetent laboratory animals, such as mice and rabbits, have failed.

Mice with severe combined immunodeficiency disease (SCID) are susceptible to infection with *P. abortibovis*. C3H-*scid* mice develop evidence of wasting at seven to eight weeks following infection and require euthanasia two to three weeks later [11]. The only obvious gross lesion is an enlarged spleen that harbors large numbers of infectious bacteria. Cryopreserved *P. abortibovis*-infected SCID mouse spleen cells are an excellent source of bacteria to predictably transmit infection to pregnant heifers. Unlike bacteria derived from the bovine fetus, recovered organisms are not opsonized and appear to have excellent viability. The absence of EBA-like lesions in immunodeficient infected mice would support the hypothesis that the fetal bovine lesions are immunologically mediated as suggested above [11].

Transmission

Observations that the distribution of the *Ornithodoros coriaceus* tick could be superimposed upon the distribution of foothill abortion precipitated studies to establish them as potential biological vectors [4, 8, 9]. This unusual soft-shelled tick (commonly called the Pajaroello tick) carries a colorful past as Native Americans in California feared its bite over that of a rattlesnake. They believed a second or third exposure to this tick bite would result in death. The tremendous pain and swelling of appendages that sometimes occurs following sequential Pajaroello tick bites is assumed to be an extreme allergic reaction to the tick saliva and/or associated contaminating microbes. An unusual and classical experiment was conducted in which naïve pregnant heifers were divided into two groups in an area considered endemic for the disease. One half of the heifers were maintained in tree houses with the tree bases tightly wrapped with metal to interfere with the potential ascent of crawling insects, and the other half were maintained on the ground below. All tree-housed heifers produced healthy calves, while foothill abortion occurred in the land-based animals. Studies were subsequently conducted in which wild-trapped ticks were experimentally fed on pregnant naïve heifers, further demonstrating disease transmission [4, 5]. The *O. coriaceus* tick has been collected in Mexico, California, Nevada, and Oregon (Figure 64.4), but foothill abortion has only been described in the above-mentioned three US states [8, 9, 13, 14]. Cattle ranching practices in Mexico may well be responsible for a lack of diagnosis of foothill abortion in this country; aborted fetuses can be rapidly scavenged in free-ranging cattle herds, making diagnosis unlikely.

Published studies have been directed at better understanding the vector–pathogen relationship using field-trapped ticks and PCR/TaqMan diagnostics to identify the presence of *P. abortibovis*. *O. coriaceus* can be readily collected in the field using dry-ice traps in the duff beneath brush and trees that have previously served as bedding areas for wildlife and/or livestock. These studies confirmed the extensive distribution of *O. coriaceus* in foothill regions of southern Oregon, central and western Nevada, and California [8, 9, 14]. Application of diagnostics to DNA extracted from ticks demonstrated a highly variable rate of infection with *P. abortibovis*. A positive result obtained by standard PCR was rare [9]. Data obtained using the more sensitive TaqMan suggest that infection rates are typically less than 20% but may exceed 50% (examples of high infection rates may be a mathematical artifact due to low tick numbers). The authors suggest that those ticks that are positive by TaqMan but not standard PCR may not be capable of biological transmission of the bacteria to cattle [9]. This would be supported by studies where experimental feeding of hundreds of ticks per heifer results in definitive disease transmission approximately 50% of the time [4, 5]. Efforts to better characterize the tick as a vector of *P. abortibovis* demonstrated that the bacterium was preferentially located to the salivary gland of field-collected ticks [9]. The source of this bacterium is currently unknown; possibilities being considered include soil or the presence of a mammalian/avian reservoir. A blood meal is required prior to each molt (progressive instar stages result in increased tick size) and maturation into either a male or female. The authors hypothesize that if ticks are infected while feeding, the multiple blood meals required during the process of maturation would increase the incidence of infection in larger (more mature) ticks. Studies suggest little difference in infection rate in nymphs, males, and females and therefore appear to contradict the concept of infection though a blood meal [9].

Figure 64.4 Published reports of trapped *O. coriaceus* (blue circles). Recent select collections of ticks were subjected to TaqMan-based detection of *P. abortibovis*; blue circles with red centers represent positive results. The majority of tick collection sites were sampled prior to the identification of *P. abortibovis* and associated PCR-based diagnostics. Tick collections in Mexico are based on historical literature and their locations roughly approximated. *Source:* © DeLorme. Topo North America™ 10.

Control

Control of foothill abortion has largely been limited to management practices. One approach is minimizing exposure of naïve pregnant cattle to tick-infested habitat during the window of gestation in which the fetus is susceptible to infection. Another approach is to intentionally expose naïve cattle to the tick prior to breeding such that immunity can be established; historically, EBA was not as prevalent prior to the current practice of breeding young heifers (less than two years of age). Such practices can sometimes modestly reduce losses; however, the reduction in foothill abortion is often offset by inefficient use of rangelands and increased costs associated with altered breeding and grazing strategies. An experimental vaccine has been extensively field-tested in excess of 60,000 heifers and the product became commercially available in September, 2020. Experimental and field testing of the vaccine have demonstrated the vaccine to be safe with apparently >95% efficacy. The vaccine is a cryopreserved live virulent bacteria derived from spleen cells of *P. abortibovis*-infected SCID mice; the vaccine cannot be safely administered to pregnant cattle. Extensive, though unpublished, data have demonstrated that the live bacteria have no adverse health effects, though animals clear the bacteria very slowly (30–40 days post vaccination). Naïve heifers vaccinated (infected) less than 30 days prior to conception can conceive but then can transfer *P. abortibovis* to the developing fetus, with a resulting fetal resorption/abortion three to four months later. Thus, vaccinated heifers should not be bred until 60 days post-vaccination. Limited experimental data have demonstrated solid immunity for a minimum of three years; this is consistent with field trial date that would suggest that administration of the vaccine to heifers in areas endemic with EBA will result in life-time immunity.

Infectious Agents: Neospora

Clare M. Scully

Department of Veterinary Clinical Sciences, Louisiana State University School of Veterinary Medicine, Baton Rouge, LA, USA

Introduction

Neosporosis is caused by the protozoan parasite *Neospora caninum*, an obligate intracellular parasite found in dogs and cattle as well as other species. True prevalence of infection is difficult to determine since published reports tend to be specific for a particular region. However, it is estimated that *Neospora* infects 10–20% of cattle and is responsible for 20% of abortions worldwide [1]. This parasite was first described in dogs having encephalomyelitis in Norway [2] in 1984 and was previously misidentified as *Toxoplasma gondii* until 1988, when the new species, *N. caninum*, was described [3]. The first report of bovine abortion associated with *Neospora* infection was from a New Mexico dairy in the USA in 1989 [4]. Both domesticated [5, 6] and wild [7–10] canids can serve as definitive hosts, while cattle [1], deer [11], and chickens [12] are intermediate hosts. However, there is some doubt that the red fox is truly a definitive host [13]. Although transmission can occur both horizontally [14] and vertically, vertical transmission is the primary source of infection in cattle [1]. The economic impact of *N. caninum* is the result of numerous factors including abortions, culling, decreased milk production, increased calving interval, and increased veterinary costs [15]. Global losses are estimated at USD $1.3 billion and in excess of $600 million in the USA annually [16].

Epidemiology

N. caninum has been identified worldwide and is considered a major cause of abortion in cattle [17]. Globally, 15–20% of dairy cattle and 10–20% of beef cattle have been found seropositive for *N. caninum* [1]. Surveys in California [17] the Netherlands [18], and New Zealand [19] indicate that approximately 20% of all aborted bovine fetuses submitted to diagnostic laboratories tested positive for this infection. The estimates of *Neospora* infection in US dairy cattle, based on serology, are variable but appear to be in the range 10–20% and ranges from 5 to 98% of cows in individual dairy herds. Many animal species test seropositive for *N. caninum* but do not exhibit clinical signs [1]. Due to the lack of one gold standard diagnostic test [20] numerous testing methods are utilized for identifying infection such as recognition of tissue cysts on histological examination, finding oocysts in feces [6], or identification of the parasite by immunohistochemical staining [21] or polymerase chain reaction (PCR) [22].

Life Cycle

The life cycle of *N. caninum* is depicted in Figure 65.1. *N. caninum* has a facultative heteroxenous life cycle, meaning that the organism may use more than one host during its life cycle [23, 24]. Unsporulated oocytes (10–14 μm) are shed in the feces of definitive hosts (i.e. dog or wild canid) [25]. The oocytes sporulate within 24 hours to the infective form. Each sporulated oocyte contains two sporocysts, and each sporocyst contains four sporozoites. When consumed by cattle or a wide range of other warm-blooded animals which can serve as intermediate hosts, eight sporozoites are released into the gastrointestinal tract for each oocyte consumed [1]. The sporozoites differentiate into tachyzoites (5–7 μm), which subsequently invade the epithelial cells of the gastrointestinal tract. The tachyzoites replicate rapidly via endodyogeny [26]. Endodyogeny is a form of asexual reproduction that involves an unusual process where two daughter cells are produced inside a mother cell, which is then consumed by the offspring prior to their separation [27]. Replication occurs rapidly within cells and tachyzoites may spread hematogenously within mononuclear phagocytes [28] to infect many cell types including neural cells, vascular endothelial cells,

myocytes, hepatocytes, renal cells, alveolar macrophages, and placental trophoblasts [29–31]. Tachyzoites differentiate into bradyzoites which are the slowly replicating encysted stage of the parasite. Each cyst may contain hundreds of bradyzoites [24]. In congenitally infected bovine fetuses and calves, tissue cysts are found in the brain and spinal cord [32]. A few thin-walled cysts have been found in skeletal muscle of two naturally infected two-day-old calves [33]. Bradyzoites are thought to persist for the duration of the host's life and be responsible for persistent infection, although tissue cysts have not been observed in histological sections of naturally infected cattle older than two months [24, 29]. Bradyzoites are believed to reactivate and differentiate back into tachyzoites, thereby establishing persistent infection [24]. Bradyzoites can be differentiated in tissue sections from tachyzoites by labeling with a specific antibody [34]. The cycle continues when tissue cysts shed by the intermediate host (cattle) are consumed by the definitive host (canids) [1].

Transmission

Neospora can be transmitted vertically or horizontally, with both routes being vital to long-term survival of the parasite [24]. Vertical transmission takes place when tachyzoites migrate transplacentally from dam to fetus during pregnancy [1, 25]. Among all known microbes in cattle, *N. caninum* is one of the most efficiently transmitted parasites transplacentally [1]. The terms "endogenous transplacental transmission" and "exogenous transplacental transmission" have been used to more precisely describe the origin and route of fetal infection (Figure 65.2) [23]. Endogenous transplacental transmission occurs in a persistently infected dam when the infection crosses the placenta and infects the fetus [23]. The endogenous form has a higher rate of associated abortion [35]. Exogenous transplacental transmission occurs when a previously non-infected dam ingests infective oocysts while pregnant and her fetus subsequently also becomes infected in utero.

Vertical transmission can result in abortion but in most cases the calf is congenitally infected but remains asymptomatic with no evidence of deleterious effects on subsequent calf health [36]. If the infection occurs during the second or third trimester when immunocompetence of the fetus is greater, the most likely outcome will be a live-born but persistently infected calf [24]. Once infected, cattle are presumed to be infected for life [37] and females can transmit the infection to successive generations [38, 39]. Although not every pregnancy results in transmission of the disease, it has been reported that the rate of transmission is as high

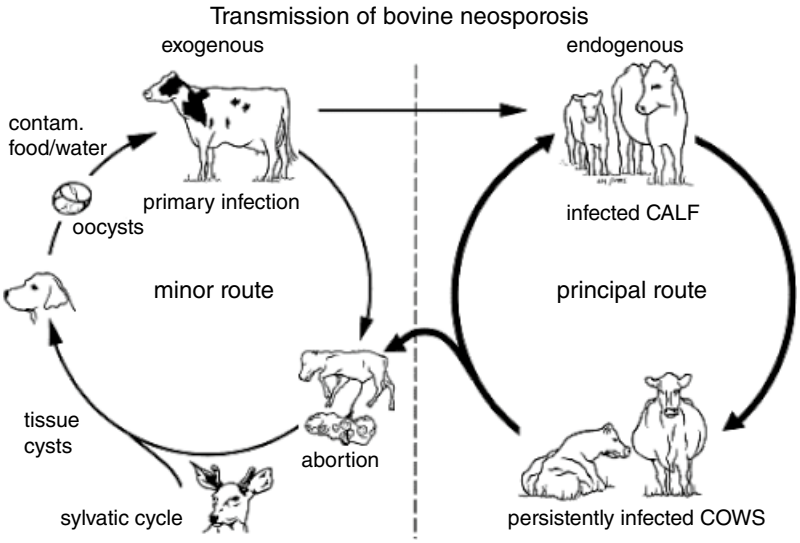

Figure 65.2 Transmission of bovine neosporosis. Oocysts are produced by the canine definitive host and their subsequent ingestion by a susceptible pregnant cow leads to infection of the fetus (exogenous transplacental transmission). Liveborn infected heifer calves would be expected to remain infected into adulthood when they, in turn, may pass infection to their fetus (endogenous transplacental transmission). Spread of *N. caninum* in this second way is the principal route whereby the parasite is propagated in a herd. *Source:* [26, 48, 49].

as 75–100% [16]. In the case of exogenous transplacental transmission, the number of oocysts ingested by the dam and stage of gestation influence pregnancy outcome [25, 40]. There is a report indicating that in persistently infected cattle, vertical transmission is more efficient in younger than older cows [41]. Also, transplacental infection may be more likely to occur in dams that were themselves prenatally infected compared with postnatally infected dams [42]. The risk of abortion was positively correlated with *N. caninum*-specific antibodies in individual animals [43] and severity of fetal *Neospora*-associated lesions also increased with higher maternal seropositivity [44]. Cows with high antibody titers (≥400) showed higher vertical transmission frequency (94.8%) than cows with low antibody titers of 25–200 (14.8%) [45]. Occasionally, a seronegative dam will give birth to a seropositive calf [46, 47]. This can occur when the dam has a long-standing infection with low antibody titer and she was wrongly diagnosed as uninfected [1].

Horizontal transmission is less common than vertical transmission [16]. The ingestion of sporulated oocysts from the environment is the only demonstrated natural mode of postnatal infection in cattle (Figure 65.2) [48, 49]. Both domestic and wild dogs are frequently implicated in horizontal transmission. This is attributed to canids consuming infected bovine placentas or fetuses and subsequently defecating in the environment where the oocytes are ingested by cattle [50]. There has been no horizontal cow-to-cow transmission reported at this time [38]. Experimentally, calves may become infected through ingestion of milk contaminated with tachyzoites [51, 52] and *N. caninum* DNA has been detected in colostrum of seropositive cows [53]. However, it remains doubtful that lactogenic transmission occurs naturally [50]. Since *N. caninum* DNA was reported in fresh and frozen semen from naturally infected bulls [54], the possibility of venereal transmission was investigated. Intrauterine inoculation of nine heifers with 107 *N. caninum* tachyzoites reacted with seroconversion and a specific interferon (IFN)-γ response. Also, *N. caninum* DNA was demonstrated in the blood and tissues of all nine heifers [55]. However, the numbers of tachyzoites used to test the venereal route of infection are higher than those previously found in semen of naturally infected bulls, which range from 1 to 10 organisms per milliliter associated with the cell fraction of semen [56, 57]. Therefore it seems unlikely that venereal transmission is significant under natural conditions.

Pathogenesis of Abortion

Neosporosis is primarily a disorder of the fetoplacental unit that occurs subsequent to maternal parasitemia resulting from either exogenous or endogenous infection [24]. In the case of exogenous infection, the ingested oocytes excyst in the small intestine and presumably release sporozoites which parasitize the maternal intestinal epithelium and transform into tachyzoites which, in turn, multiply in the mesenteric lymph nodes [24]. The tachyzoites are released into the blood and have been detected in the leukocyte fraction [28] of naturally infected cattle. The parasitemia results

in dissemination throughout the body including the gravid uterus. The endogenous (vertical) route of transmission is most common [38, 58]. It is suspected that latent infections are reactivated due to the immunosuppression associated with mid-gestation pregnancy [59]. It is also reported that endogenous transplacental transmission is more likely in cattle that were themselves infected in utero [60, 61].

The mechanism by which *N. caninum* actually causes abortion is a topic of ongoing investigation and multiple hypotheses have been proposed. First, since the parasite is able to establish itself in the caruncular septum before crossing to the fetal placental villi [62, 63] the resultant damage may result in fetal death due to placental insufficiency [24]. Placental insufficiency, because it causes fetal stress and release of adrenocorticotropin, could also cause premature delivery of either viable or compromised calves. Second, infection by *N. caninum* stimulates cell-mediated immune responses associated with cytokine release from the damaged placenta, resulting in fetal rejection by the maternal immune system culminating in fetal expulsion [24, 64, 65]. Finally, the placental damage may result in endometrial prostaglandin (PG)$F_{2\alpha}$ release causing luteolysis and abortion as has been demonstrated in goats with toxoplasmosis [66]. However, cows with high *Neospora* antibody titers have higher plasma progesterone levels throughout gestation than seronegative cows or cows with low antibody titers [67]; in a study in which exogenous progesterone was administered during the mid-gestation period, the risk of abortion increased dramatically in cows with high levels of antibodies against *N. caninum* [68]. It seems most likely that all three of the proposed mechanisms play a part in inducing *Neospora*-associated abortion in cattle.

The first-trimester fetus seems particularly susceptible to damage by invading *N. caninum* since it is not immunocompetent [69] and unlikely to survive infection. In the middle trimester the fetus may be able to mount an immune response to *N. caninum* challenge, although the response may not be robust enough to preclude fetal death [59, 70, 71]. By the third trimester the fetus is capable of mounting an immune response of sufficient magnitude that it is likely to survive *N. caninum* infection, leading to birth of clinically normal but infected calves. In beef cows experimentally infected with *N. caninum* at various times during gestation by either subcutaneous or intravenous routes, transplacental infection rate increased with gestational age and cows infected during later gestation generally delivered normal but infected calves [40].

In cows experimentally infected with *N. caninum* the most severe lesions are found in the placenta and the fetal brain [40, 70]. Lesions consist of a non-suppurative inflammatory response [63]. The associated inflammatory cells have been shown capable of producing INF-γ [59], which suggests fetal death may be more a consequence of the maternal immune response rather than direct effects of the parasite [59]. At the time of placental invasion the parasite also enters the fetal bloodstream, with a predilection for the central nervous system [63], where it is located perivascularly [30], and in younger fetuses causes widespread destruction of neuropil with a minimal inflammatory response [72]. When fetuses later in gestation become infected with *N. caninum* the tissue reaction is more moderate, with areas of necrosis restricted to small foci surrounded by intense inflammatory infiltrate in brain tissue [18, 73] and sometimes mild meningitis [74]. Fetal infection with *N. caninum* also causes characteristic lesions of inflammation and necrosis in tissues such as liver and heart [18].

Clinical Signs

N. caninum infection causes abortion in both beef and dairy cattle. Abortion may occur from three months of gestation to term but typically occurs at five to six months of gestation [4, 18, 75, 76]. Possible outcomes of infection include: fetal death followed by resorption [77]; mummification [78]; autolysis [79]; stillbirth [80]; live birth with clinical disease [79]; and clinically normal birth but persistently infected [36]. Fetuses dying in utero between three and eight months are usually expelled with evidence of moderate autolysis, while those dying before five months of gestation are more likely to mummify [24]. Experimental infection of pregnant cows at various points during gestation showed that parasitemia during the first 10 weeks resulted in fetopathy and resorption of the fetal tissue 3 weeks after infection. Infection at 30-weeks of gestation resulted in birth of asymptomatic congenitally infected calves [60]. The period in between appears as most likely for *N. caninum*-induced abortion.

In *Neospora*-infected calves clinical signs have been reported only in animals less than two months of age [81]. Infected calves may be born underweight, unable to rise, and with neurologic signs [81]. Hindlimbs and/or forelimbs may be flexed or hyperextended and the calf may be ataxic, have diminished patellar reflexes, and experience loss of conscious proprioception [81]. Exophthalmia has been observed in some cases [81].

Within herds, *Neospora*-associated abortions may be sporadic, enzootic, or endemic [4, 17, 30, 82]. In comparison with endemic abortion, epidemic abortion storms are less common [83]. It appears that most sporadic and endemic abortions in cattle due to neosporosis are the result of reactivation of chronic infections because *Neospora*-seropositive

cows are at twofold to threefold higher risk of abortion than are seronegative cows [76, 78]. Reactivation of a chronic *Neospora* infection may occur as a result of factors that cause immunosuppression. We have observed a *Neospora*-associated abortion storm in a dairy herd concomitant with an outbreak of coliform mastitis [46]. In herds with endemic *Neospora*-associated abortions there is often a positive correlation between serostatus of the dam and her daughters, indicating that the major route of transmission is vertical [84, 85].

Epidemic abortion outbreaks (abortion storms) have been defined as those in which over 10–15% of at-risk cows abort within a four to eight week period [78, 84, 86]. There is epidemiological evidence that epidemic *Neospora*-associated abortions may be caused by the postnatal infection of naive cattle via exposure to oocyst-contaminated feed or water, with up to 57% of pregnant dairy cows aborting over a few weeks to months [84, 87, 88]. However, in an epidemiological investigation of abortion storms in the Netherlands, the authors concluded that the abortion storms appeared to be induced by factors causing recrudescence of *N. caninum* infection in chronically infected animals rather than being the result of a recent introduction [86].

Diagnosis

Definitive diagnosis of neosporosis is challenging and relies on numerous diagnostic techniques. There are serologic assays available to test the maternal serum and fetal fluids (serum, fluid from body cavities) for *Neospora*-specific antibodies [89]. Serology of fetal fluids is useful after five months of gestation as the fetus becomes immunocompetent but sensitivities reported varied from 50 to 84% [90]. Immature fetal immunocompetence and a short interval between infection and death can all lead to a false-negative result [90]. The presence of antibodies does not definitively confirm *Neospora* as the cause of abortion since clinically normal calves may also have congenital antibodies [76].

Serology of the dam can aid in diagnosis of *Neospora*-associated abortion. Sera obtained within two weeks of abortion generally have the highest titers and then titers decline and may be undetectable 60 days after abortion [89, 91]. Seropositive cows do not display detectable clinical signs of infection and most deliver healthy congenitally infected calves. Therefore, seropositivity has a high predictive value for congenital infection in cows but not for abortion [92] (although there is a two to threefold increased probability of abortion of compared with seronegative cows [76]). High antibody levels persist for prolonged periods in some cows [91] or may increase again in subsequent gestations [90]. Seronegativity in a mother cow or heifer does not exclude *N. caninum*-associated abortions [93].

PCR has been utilized to detect parasite DNA [94], but it is not always found [29]. In a Swiss study, *N. caninum* was detected by PCR in the brain tissue of 21% of all aborted fetuses. Microscopic lesions indicative of cerebral protozoal infection were detected in 84% of PCR-positive fetal brains [93].

Histopathology of fetal tissues can be examined to identify characteristic lesions and parasites [95]. Multifocal inflammation and necrosis of the heart, brain, liver, and skeletal muscle are common and tachyzoites are found primarily in the brain [18, 90] Lesions can be found in the placenta but are not particularly valuable as diagnostic aids [90]. Even in grossly autolyzed or mummified fetuses it is possible to find suspect lesions, especially in the brain [90]. On necropsy, gross lesions are not frequently seen.

To positively identify parasites associated with lesions, immunohistochemistry is commonly employed [17, 32]. In one study, in which *N. caninum* tachyzoites were identified by immunohistochemistry performed on tissues taken from calves with confirmed neosporosis, 85% of the brains were positive, 14% of the hearts, and 26% of the livers [18]. Significant differences between epizootic and sporadic abortion cases with regard to positivity on immunohistochemical examination were found only in the liver, where tachyzoites were more frequently found and in higher numbers in epizootic cases than from sporadic cases [18]. One must bear in mind that positive results of any diagnostic tests without the presence of life threatening lesions are insufficient for a definitive diagnosis [29].

In investigations of herds in which multiple abortions occurred, a tentative diagnosis can be supported by cross-sectional or herd serology in which the *N. caninum* status of aborting and non-aborting cows is compared to determine if there is an association between serologic status and abortions [91, 96]. In the case of an abortion storm, a suggested protocol would be to immediately take blood samples from all animals at risk, then take post-abortion samples to determine if seroconversion occurred [90].

Control/Prevention

A number of approaches have been employed to control neosporosis in cattle herds. These include improving farm biosecurity, test and cull programs, test and exclude from breeding, and artificially inseminating with beef semen. Biosecurity may prove beneficial to avoid introducing the parasite into a closed herd not already infected with *Neospora* [97]. Farm management practices to reduce *N. caninum* infection can include: (i) minimizing fecal contamination of cattle feed

or water by canids [1]; (ii) prompt removal of aborted bovine fetuses and fetal membranes; and (iii) limiting the introduction of infected cattle into the herd and culling infected animals. If employing the test and cull method of control, every animal must be serologically tested and those that test positive removed from the herd. Animals that test negative should be periodically retested since titers tend to wax and wane and there is a possibility of horizontal transmission, resulting in new infections. This approach can be devastating depending on how many in the herd test positive. Notwithstanding the risk of horizontal transmission, a more economic approach would be to test each animal and exclude the daughters of seropositive cows from the replacement pool. If a cow is very valuable there is always the opportunity to preserve the genetics by embryo transfer into a seronegative dam [98].

It is possible to reduce the risk of *Neospora* abortions in dairy cattle by inseminating seropositive dams with beef breed semen. This is effective because crossbreed pregnancies have a more robust placentation with higher levels of peripartum pregnancy-associated glycoprotein, which may have protective value [99]. Beef breeds in general, and the Limousin breed in particular, are more resistant to *Neospora* infection than are dairy breeds [99]. Beef cow-calf herds that manage their cows on range for summer grazing have lower seroprevalence than those that do not, while increased seroprevalence is associated with higher winter stocking density [100].

These control methods might not be economically or practically feasible on dairies or beef cattle operations [101]. Buying replacements originating from seronegative herds can mitigate the risk of introducing infected replacements into a negative herd [102]. General management efforts to reduce stress from concurrent disease, environmental and social stress, and providing an adequate wholesome ration may reduce immunosuppression and hence abortion rates.

There is accumulating evidence that some *N. caninum* infected cows can develop a degree of protective immunity against abortion and/or congenital transmission, indicating that immunoprophylaxis to prevent abortion or congenital transmission is a feasible goal [66]. A commercial vaccine is not currently available. In the future, vaccine development is likely to depend on identification of specific *Neospora* genes that may enable the production of genetically engineered vaccines.

Treatment

Currently, there are no approved practical chemotherapeutic compounds useful for treatment of bovine neosporosis [16]. Various antimicrobial agents have been tested *in vitro* [103–105] or *in vivo* in mice [106], but there is no known drug that can be used to clear *N. caninum* infection in adult cattle. However, when toltrazuril was administered to congenitally infected newborn calves the infection was eliminated, suggesting that vertical transmission in subsequent generations may be reduced by treatment of calves soon after birth [107].

Infectious Agents: Mycotic Abortion

Frank W. Austin

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

Fungi are a diverse group of eukaryotes that includes yeasts, molds, mushrooms, rusts, smuts, and the recently reclassified microsporidia. They constitute one of the five kingdoms of life (Prokaryotae, Fungi, Protista, Plantae, and Animalia) in the current classification system. Like other eukaryotic organisms, fungi have membrane-bound nuclei, membrane-bound cytoplasmic organelles, and 80S ribosomes contained within a plasma membrane. Their membranes contain sterols, namely ergosterol, which determine cell membrane fluidity and act as boundary lipid. Fungi lack chloroplasts, found in plants and some protists, and have cell walls that contain chitin, unlike other eukaryotes. Many can reproduce both sexually (teleomorphic state) and asexually (anamorphic state).

There are several valid and recognized classification schemes for the kingdom Fungi. Recent phylogenetic analysis, based on ribosomal RNA and associated genes, divides the kingdom Fungi into one subkingdom, the Dikarya including the phyla Ascomycota and Basidiomycota, and five additional phyla composed of Chytridiomycota, Neocallimastigomycota, Blastocladiomycota, Glomeromycota, and the Microsporidia [1, 2]. Taxonomy based on molecular detection of genetic sequences has had little effect on the commonly known genus and species names of fungi, but did substantially change their higher taxonomic relationships. From a classical medical perspective, pathogenic fungi can also be classified into dermatophytes, yeasts, dimorphic fungi (having two anamorphic forms), hyaline hyphomycetes (e.g. *Aspergillis* spp.), dematiaceous hyphomycetes (a disparate group of melanin-pigmented fungi), coelomycetes (anamorphic fungi that form conidia in a cavity called pycnidia), zygomycetes (aseptate fungi), and basidiomycetes (a large group of fungi including puffballs, shelf fungi, rusts, smuts, and mushrooms that bear sexually produced spores on specialized cells called basidia) [3]. Additionally, based on morphology and reproductive features, fungi have been historically classified into the Ascomycota (sac fungi), Basidiomycota (club fungi), Zygomycota (conjugation fungi, aseptate), Deuteromycota (fungi imperfecti, with no known sexual state), and the Mycophycophyta (lichens and symbiotic fungi) [4].

At a very basic level, fungi are easily separated into two major morphologic categories: the filamentous or true fungi and yeasts. Most fungi are ubiquitous saprophytes in the environment, which feed on and recycle decaying organic matter. They prefer dark moist environments in which to grow. Filamentous saprophytic fungi, represented by hyaline hyphomycetes, dematiaceous hyphomycetes and zygomycetes, are by far the most commonly encountered agents producing bovine mycotic abortion.

Mycotic Agents

A wide variety of filamentous fungi and several yeasts have been reported to cause bovine abortion [5]. Mycotic abortion is a sporadic event. The incidence of mycotic abortion varies from 2 to 20% depending on the environment, location, and time of the year and generally less than 10% of the herd is affected [6]. The most common cause of bovine mycotic abortion is *Aspergillus* spp., responsible for approximately 84% of the cases reported. Of these, *Aspergillus fumigatus* was cited as the cause in 64% of 369 cases in which only one fungal isolate was obtained in culture (Table 66.1) [7]. In

Table 66.1 Fungi isolated in culture from 369 US cases in which a single isolate was obtained.

Fungus	Classification/features	Prevalence (%) in 369 cases
Filamentous fungi		
Aspergillus fumigatus	Ascomycota, hyaline hyphomycetes	64
Aspergillus terreus	Ascomycota, hyaline hyphomycetes	7.3
Aspergillus flavus	Ascomycota, hyaline hyphomycetes	2.7
Aspergillus nidulans	Ascomycota, hyaline hyphomycetes	3.8
Aspergillus rugulosus	Ascomycota, hyaline hyphomycetes	<1.0
Penicillium thermophilus	Ascomycota, hyaline hyphomycetes	<1.0
Penicillium vermiculatus	Ascomycota, hyaline hyphomycetes	<1.0
Penicillium flavus var. *flavus*	Ascomycota, hyaline hyphomycetes	<1.0
Scedosporium boydii	Ascomycota, hyaline hyphomycetes	2.4
Phialophora mutabilis	Ascomycota, dematiaceous hyphomycetes	<1.0
Curvularia geniculata	Ascomycota, dematiaceous hyphomycetes	<1.0
Exophilia jeanselmei	Ascomycota, dematiaceous hyphomycetes	<1.0
Scytalidium dimidiatum	Ascomycota, dematiaceous coelomycete	<1.0
Exophiala dermatitidis	Ascomycota, dematiaceous hyphomycetes	<1.0
Absidia corymbifera	Zygomycetes, aseptate	6.5
Rhizomucor pusillus	Zygomycetes, aseptate	3.0
Rhizopus arrhizus	Zygomycetes, aseptate	3.8
Rhizopus rhizopodoformis	Zygomycetes, aseptate	<1.0
Mortierella wolffi	Zygomycetes, aseptate	<1.0
Yeasts		<1.0
Candida krusei	Ascomycota, yeast	1.0
Candida pseudotropicalis	Ascomycota, yeast	<1.0
Candida tropicalis	Ascomycota, yeast	<1.0
Candida lusitaniae	Ascomycota, yeast	<1.0
Candida glabrata	Ascomycota, yeast	<1.0

Source: Adapted from [7].

mixed fungal infections, occurring in about 11% of the cases, *A. fumigatus* was found in association with other zygomycetes in 87% of cases examined. In approximately 14% of the 369 cases examined, zygomycetes were confirmed as the sole causal agents, constituting the second most common cause of bovine mycotic abortion. Zygomycetes were responsible for 21% of the abortions when considered with mixed infections. Dematiaceous ascomycetes as a group were associated with 7.5% of these cases. Yeasts of the genus *Candida* caused 2.4% of bovine abortions [7].

Pathogenesis and Pathology

The most likely routes for exposure to fungi causing mycotic placentitis and abortion are the respiratory and gastrointestinal tracts [8]. Intrauterine inoculation of *Aspergillus* conidia has been unsuccessful in experimental induction of mycotic abortion and ascending reproductive tract infections therefore seem unlikely [9]. Moreover, mycotic abortions have been experimentally induced by intravenous administration of *Aspergillus* microconidia and the hematogenous route is thought to be the path because lesions develop initially in the placentomes [8]. Fungi may enter the circulation through the alveolar septa or through gastrointestinal lesions resulting from penetration of mucosal barriers by rumen, reticular, or omasal infections or ulcers. Once the infection is established in the placentomes, it advances laterally to the intercotyledonary spaces. The placenta becomes grossly thickened, with a leather-like appearance of the intercotyledonary spaces. There is necrosis of the cotyledons and caruncular tissue and a thickening at the margins of the caruncle, imparting a concave or dished appearance. The placenta may have dry, thick, yellow

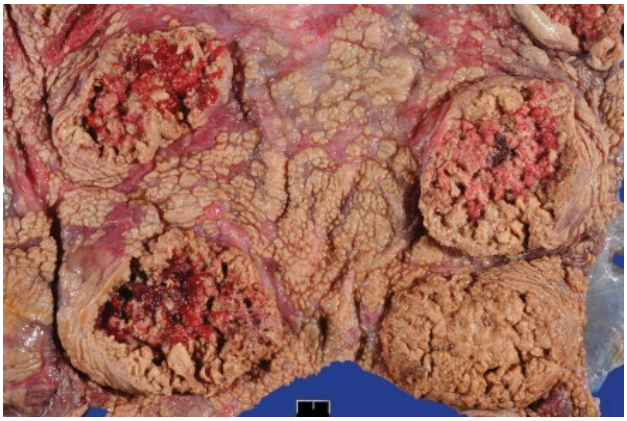

Figure 66.1 Bovine mycotic placentitis produced by *A. fumigatus*. Cotyledons are necrotic and there are thick yellow plaques covering intercotyledonary areas. *Source:* Photograph courtesy of Dr. J. Cooley.

plaques covering the intercotyledonary areas and most cotyledons when infected by *Aspergillus* spp. [10] (Figure 66.1).

A severe placental necrotizing vasculitis with thrombosis is a hallmark lesion associated with mycotic abortions. However, placental lesions with similar appearance can be produced by brucellosis and genital campylobacteriosis. Subsequently, fetal infection may occur involving the skin, lungs, brain, or liver. Fetal death is usually attributed to placental insufficiency. Skin lesions typically appear as dry, wrinkled, raised plaques with *Aspergillus* spp.; contrastingly, the fetus may appear wet and moist when infected by zygomycetes. The fetus is aborted soon after death, which occurs most commonly between six and eight months of gestation. Frequently the placenta is retained and the cotyledons remain firmly attached to the maternal caruncles, which may rupture at the peduncle. These latter events are most commonly observed with zygomycotic abortions and may lead to subsequent secondary infections [5]. Without severe uterine damage, most cows recover and have normal pregnancies later in life.

In approximately 25% of abortions caused by *Mortierella wolfii*, a zygomycete, severe post-abortion pneumonia is recognized to occur [7]. Following abortion, the caruncles and uterus can release large numbers of infective elements, resulting in an acute fungal embolic pneumonia. Cows usually die within 72 hours following the onset of clinical signs that include rapid shallow respiration with forced expiration [11]. In *M. wolfii* fetal infections, the liver and brain are commonly involved, unlike infections caused by other fungi [12].

Diagnosis

Diagnosis of mycotic abortion can be aided by gross, microscopic, histopathologic, or cultural methods of examination. Additionally, molecular detection of genetic sequences has been employed to identify specific fungal agents [13]. Definitive diagnosis is generally achieved through agreement of many of these methods. The visual demonstration of fungal hyphae and elements by microscopic methods in placental or fetal tissues and fluids combined with compatible gross lesions may confer a presumptive diagnosis. Histopathology combined with cultural or molecular methods allows for definitive confirmation of the etiologic agent responsible for abortion.

Specimens

Specimens for mycotic abortion can be used for gross examination, direct microscopic and histopathologic examination, fungal culture, and molecular detection. Specimens can include the placenta, fetus, fetal skin, fetal lung, and stomach fluid of the fetus. Because a definitive diagnosis of mycotic abortion frequently depends on agreement using multiple methods, the comprehensive specimen list presented in Table 66.1 is generally required. Specimens should be carefully selected and independently collected for each of the methods used. Extreme care should be taken to avoid contamination of specimens used for culture or molecular detection, which can easily lead to false-positive results.

The placenta is the most common and useful specimen for diagnosis of mycotic abortions. Because the lesions of mycotic placentitis may be focal and not involve some areas, the entire placenta should be submitted. The cotyledons with caruncular tissue contain the highest number of organisms and are considered to be the best specimen. The placenta will always be involved in mycotic abortion; however, the fetus or fetal tissues are not consistently affected.

Following abortion, the fetus can become easily contaminated by contact with the environment. In approximately 25% of mycotic abortions the fetal skin is infected and lesions appear as circumscribed, slightly raised, cutaneous, gray to yellow plaques. These lesions may coalesce into larger areas along the dorsum, the top of the head, and base of the tail. Although amniotic fluid is not commonly available following abortion, it will contain fungal elements when the skin is affected and transport them to other fetal areas and tissues that are not as easily contaminated [10, 14].

Stomach fluid is a commonly used specimen for culture and molecular detection when the fetus has been expelled and contaminated on its surface. Stomach fluid can also be used as an excellent specimen for direct microscopy. Likewise, the fetal lung is exposed to the amniotic fluid and commonly used to circumvent contamination of the fetal surface when diagnostic amplification techniques are employed.

Microscopic and Histopathologic Examination

Direct microscopic examination of the placenta, fetal skin, and abomasal fluid following digestion in 10–15% potassium hydroxide (KOH) can reveal fungal hyphae. Digestion of host debris is time and temperature dependent and can be quickened by the application of gentle heat. Direct visualization of fungal elements can be enhanced with the inclusion of calcofluor white in 10% KOH solution, which specifically binds cellulose and chitin of the fungal cell wall. Calcofluor white (or Uvitex B, Blankophor) fluoresces blue-white or apple-green when exposed to ultraviolet light [15–17]. Additionally, Parker permanent blue ink (10%) can be added to the KOH solution to impart contrast and aid visualization of hyaline hyphal elements. Lactophenol cotton blue dye can be used as a simple positive stain with stomach fluid specimens that do not necessarily need alkaline digestion.

The microscopic morphology and characteristics of the fungi can aid in identification and confirmation of the cultural isolate. The hyphae of zygomycetes are relatively broad (5–20 μm), thin-walled, and coenocytic (aseptate) [18]. Budding yeasts with narrow bases and broad pseudohyphae having constricted septa can indicate pathogenic *Candida* species [19]. The dematiaceous fungi causing abortions have brown to black intracellular pigment (melanin) that is easily seen. *Aspergillus* species have relatively narrow (2–6 μm) hyphae and frequent septae spanning parallel walls [10]. It is important to note that identification to the species level is not attainable through direct microscopic methods, but these methods can be quickly used to confirm a presumptive diagnosis of mycotic abortion, suggest a group of responsible fungi, and rule out other causes of abortion.

Adequate areas and portions of the placenta and fetal skin and lung should be collected into 10% buffered neutral formalin for histopathology if the whole fetus is not submitted to the laboratory. In routine hematoxylin/eosin-stained histopathology slide sections, hyaline fungal elements are poorly visualized. Therefore requests for special staining of slides using periodic acid–Schiff or Gomori's methenamine silver stain should be made if mycotic abortion is suspected.

Fungal Culture Methods and Molecular Identification

Because of the ubiquity of fungi in the natural environment, culture results should be interpreted with caution. Contamination of specimens from abortion cases is frequent. For this reason, specimens of the fetal lung and abomasal fluid or contents are commonly sought. The morphology and characteristics of the fungi recovered in culture should be in agreement with the results of direct microscopy and histopathology.

A common medium for the culture and isolation of fungi is Sabouraud's dextrose agar (SDA) with and without the addition of antibiotics. Antibiotics such as chloramphenicol and cycloheximide are commonly included in the media, such as Mycobiotic Agar (Difco), to suppress the growth of bacteria and saprophytic fungi, respectively. Care must be taken in choosing media as cycloheximide will inhibit zygomycetes. It can also partially inhibit some *Aspergillus* spp. and *Candida* spp. involved in mycotic abortions. For this reason, SDA with only chloramphenicol is recommended for the culture of fungal agents from mycotic abortions. Furthermore, zygomycetes can be difficult to culture as they do not remain viable in tissue for extended periods of time. Failure to recover these fungi when observed in direct microscopy or histopathology can be due to the toxic effects of placental or fetal autolysis [11]. Agar plates are incubated at 25–30 °C for several weeks prior to morphologic identification.

Following isolation and maturation of growth, filamentous fungi are classically identified on the basis of colonial and microscopic morphology (Figure 66.2). Speciation of the filamentous fungi can be problematic using these

Figure 66.2 Photomicrograph of a lactophenol cotton blue-stained slide of *A. fumigatus* from SDA plate culture. Note conidiophores with large terminal vesicles supporting numerous sterigmata that bear long chains of conidia. *Source:* Photomicrograph (20×) courtesy of Dr. F.W. Austin.

techniques and advanced molecular methods may be necessary. Yeasts are commonly identified on the basis of carbohydrate assimilation and biochemical testing using commercially available systems [19].

Molecular detection of specific genetic sequences obtained through polymerase chain reaction (PCR) methods is becoming commonly used in mycology reference laboratories for fungal identification. These methods can be applied to fresh tissues, tissues fixed for histopathology, or cultural isolates [13]. Identification of fungal species using unique genetic sequences can save considerable time and offer unparalleled specificity. However, because of the ubiquity of fungi in the environment and the extreme sensitivity of molecular methods, results should be used in conjunction with other methods to assure a conclusive diagnosis.

Prevention and Control

Since mycotic abortions occur sporadically and are produced by ubiquitous environmental fungi that are not contagious, the best means of control are preventative. Avoidance of moldy hay and feedstuffs and poor-quality silage can decrease the occurrence of mycotic abortion. Likewise, dark and moist environments with a high organic component favoring the growth of fungi should be eliminated. Decreasing environmental exposure to fungi by providing adequate ventilation, avoiding animal confinement, and decreasing herd density can further aid in preventing mycotic abortions. Therapy should be aimed at preventing uterine damage from retained placenta and associated secondary infections.

Compromised Pregnancy Success Caused by Heat Stress

Peter J. Hansen

Department of Animal Sciences, University of Florida, Gainesville, FL, USA

Introduction: Nature of the Problem

A useful term to describe the reproductive function of a herd of cows is 21-day pregnancy rate. Conceptually, this term measures the proportion of cows eligible to become pregnant in a 21-day period (i.e. those cycling) that actually become pregnant. The 21-day pregnancy rate is the product of the percentage of cows that are inseminated and the percentage of inseminated cows that become pregnant. In an ideal situation, all cycling cows will ovulate in a 21-day period, be inseminated at estrus, and establish pregnancy after insemination. In practice, the 21-day pregnancy rate is much lower. For US Holsteins using data from 2007 to 2016, the 21-day pregnancy rate averaged across regions and seasons was 15.7% [1] whereas median 21-day pregnancy rate in herds in Québec between 2001 and 2010 was 18% [2].

Heat stress is among the most consequential changes in the environment of the cow that can reduce 21-day pregnancy rate. Estrus detection rates as low as 20% during periods of heat stress have been reported [3] and pregnancy per artificial insemination (AI) can be 10% or even lower [4]. Management practices on many modern dairies have made the impact of heat stress, while significant, not as dire as could be the case. Results of a recent analysis of seasonal variation in reproductive function among Holsteins in the USA are shown in Figure 67.1. As compared to cows inseminated in winter, 21-day pregnancy rates for cows in summer declined by 5.3 percentage points in the southeastern states of the USA, 5.6% in the southern plain states, and by lesser amounts in less-warm regions of the country. Even in the northeastern USA, however, 21-day pregnancy rate declined in the summer.

Heat stress is defined here as the sum of forces external to a homeothermic animal (mammal or bird) that acts to reduce the animal's ability to regulate core body temperature. Consequences of heat stress on the physiology and productive potential of the cow depend on both physiological changes that an animal engages to regulate body temperature and the direct negative effects of elevated body temperature on cellular function. One of the causes of reduced milk yield during heat stress, for example, is lower feed intake by cows seeking to regulate body temperature through reduced metabolic heat production [5]. A cause of reduced fertility is the embryonic death caused by effects of elevated body temperature on embryonic viability [6–8]. In this chapter, the term heat shock will be used to describe actions of elevated temperature on cellular function.

Even a small increase in body temperature can compromise embryonic survival. In lactating dairy cows, conception rate declined 6.9–12.8% for each 0.5 °C increase in uterine temperature above the mean temperature of 38.3–38.6 °C [9]. In that study, rectal temperature was about 0.2 °C lower than uterine temperature, and therefore it can be inferred that fertility declines when rectal temperature reaches no more than about 39 °C. In an earlier study, also, fertility of lactating dairy cows declined at rectal temperatures of 39 °C and higher [10].

As shown in Figure 67.2, the problem of reproductive dysfunction caused by heat stress is greater for lactating dairy cows than for dairy heifers [11, 13–15]. What makes the lactating dairy cow more susceptible to heat stress is the difficulty in thermoregulation caused by the metabolic heat production of lactation. In Wisconsin, lactating Holsteins began experiencing rectal temperatures above 39 °C when the dry bulb temperature was 25 °C, whereas heifers first developed a rectal temperature above 39 °C when the dry bulb temperature was 33 °C [12]. Another consequence of the heat production required for milk

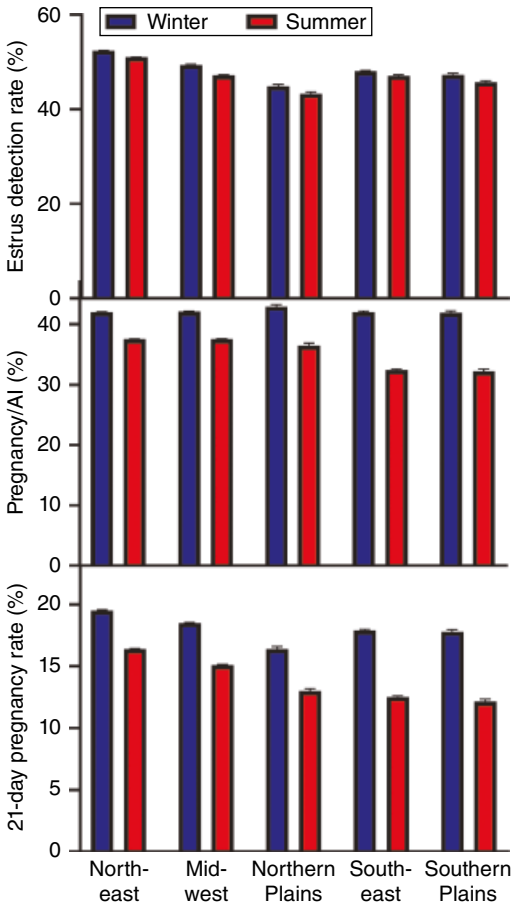

Figure 67.1 Differences in estrus detection rate, pregnancy/AI, and 21-day pregnancy rate between Holstein cows bred in summer (21 June to 21 September) and winter (21 December to 19 March) in the USA from 2007 to 2016. *Source:* Data are from [1]. Note that estrous detection rate includes cows inseminated using timed AI programs without estrus detection.

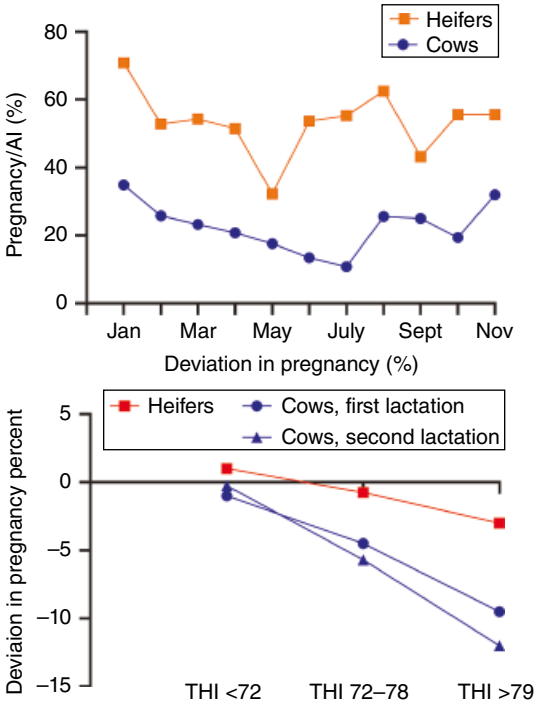

Figure 67.2 Differences between heifers and lactating cows in effects of heat stress on fertility. Data in the top panel represent the effect of month of insemination on pregnancy/AI of Holstein × Lai Sind crossbreds in Vietnam [11]. Data in the bottom panel are the deviation in pregnancy/AI percentage during July and August (pregnancy/AI minus average pregnancy/AI across the year) from Holsteins in Japan [12]. Heifers and cows were categorized based on the average temperature–humidity index (THI) during August.

synthesis is that higher-producing cows are more susceptible to infertility caused by heat stress than cows producing less milk [16–18].

Experimental heat stress of beef cattle can have large deleterious effects on pregnancy per insemination [19] and it is likely that the biology of heat stress is largely the same for all cattle. Nonetheless, heat stress is often not a large determinant of reproductive function in beef cattle. Metabolic rate is not as high as for lactating dairy cows, breeding seasons are typically not organized in the hottest time of year, and many cattle used for beef production in warm climates are genetically adapted for heat stress.

This chapter will focus on effects of heat stress on reproductive events important for establishment of pregnancy. There are also important effects of heat stress during late gestation that can affect placental function, fetal growth, and postnatal function [20] and on the fertility of the bull [21], but these aspects of heat stress are beyond the scope of the chapter. The first part of the chapter will describe what is known about the physiological and cellular mechanisms by which heat stress compromises reproductive function. The second part will address strategies for minimizing heat stress effects on reproduction.

Causes of Compromised Pregnancy Success

Estrous Behavior and Ovulation

Estrous behavior is reduced in cows exposed to heat stress (Figure 67.3). This conclusion is based on comparison of summer–winter differences in duration of estrus [22, 26], number of mounts per estrus [23], and the increase in pedometer activity during estrus [24]. Not surprisingly then, the ability of herdsmen to detect estrus is reduced during seasons associated with heat stress [1, 3, 27]. Reduced estrous behavior could be caused by reduced preovulatory concentrations of estradiol-17β in the blood [26]. It may also be that cows experience lethargy when heat

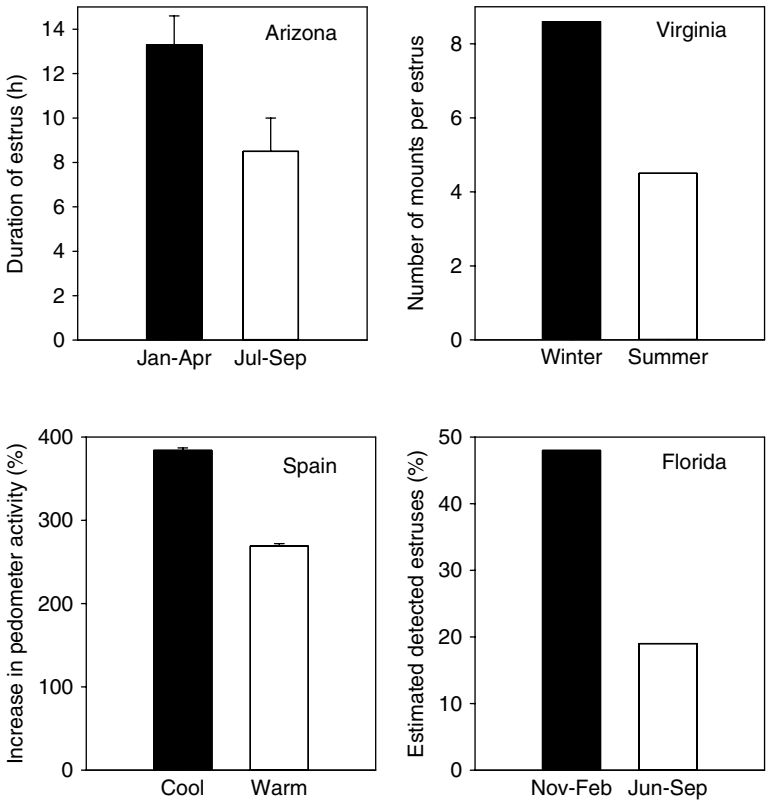

Figure 67.3 Seasonal changes in various characteristics of estrus in lactating cows including duration of estrus in Arizona [22], number of mounts per estrus in Virginia [23], increase in pedometer activity at estrus in Spain [24], and percentage of estrus periods estimated detected by herdsmen in Florida [3]. *Source:* [25].

stressed. Cows exposed to heat stress undergo several behavioral changes including increased time spent standing versus lying [28, 29] and there is evidence that prolonged periods of heat stress lead to reduced standing, possibly because of fatigue [29].

There is one report that ovulation failure can be increased during heat stress [30]. In particular, the percentage of cows that failed to ovulation after estrus was 12.4% in the warm period of the year and only 3.4% in the cool period. As will be discussed in the next section, heat stress can cause deviations in follicular development and such effects could compromise the ability of the follicle to undergo ovulation. In addition, the magnitude of the gonadotropin release caused by gonadotropin releasing hormone (GnRH) injection was reduced during periods of heat stress in a subpopulation of lactating cows (i.e. those with low circulating estradiol-17β concentrations) [31]. Thus, reduced pituitary responsiveness to GnRH could conceivably contribute to anovulation.

Compromised Function of the Oocyte

Heat stress can impinge on oocyte function during two distinct periods of oocyte development. The first is the period of follicular growth, when the oocyte experiences activation and then silencing of the genome, establishes communication with cumulus cells, and synthesizes cortical granules [9]. The second period is following ovulation when the oocyte undergoes nuclear and cytoplasmic maturation in preparation for fertilization and embryonic development.

Oocyte Damage During Follicular Growth

Damage to the oocyte during follicular growth has been demonstrated in experiments to evaluate seasonal variation in competence of oocytes to be fertilized *in vitro* and develop into blastocysts (Figure 67.4). In these experiments, which used lactating Holstein cows, the proportion of oocytes that became blastocysts after *in vitro* fertilization [32–34] or chemical activation [35] was lower in summer than winter. The seasonal effects on blastocyst formation largely represented decreased competence of cleaved embryos to develop rather than competence of the oocyte to cleave. One reason is that heat stress reduces accumulation of molecules in the oocyte important for early embryonic development and affects abundance of specific transcripts in the resultant embryo [36].

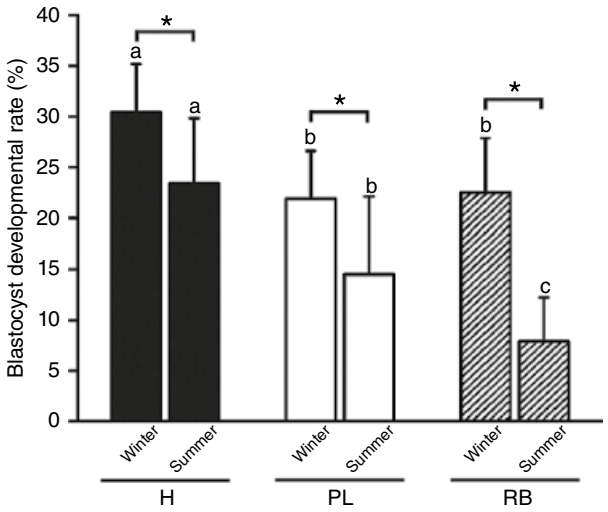

Figure 67.4 Seasonal variation in Brazil for oocyte competence for development in Holstein heifers (H), lactating cows at the peak of lactation (PL), and lactating cows classified as repeat breeders (RB). Oocytes were harvested by transvaginal aspiration and subjected to *in vitro* maturation and fertilization. Resultant embryos were cultured to the blastocyst stage. Asterisks represent differences within animal type between seasons. Letters above each bar represent differences between animal types within an individual season. *Source:* [32], © 2011, Elsevier.

Appropriate follicular development is critical to the ovulation of an oocyte competent to be fertilized and transform into an embryo capable of successful development [37, 38]. Heat stress can alter follicular dynamics by reducing growth of the dominant follicle and increasing the number of smaller-sized follicles [39–42]. Furthermore, heat stress can reduce follicular concentrations of estradiol-17β [43] and insulin-like growth factor-1 [42] while increasing follicular concentrations of androstenedione [43].

The mechanism by which heat stress alters follicular development is not well understood. Heat stress can reduce luteinizing hormone secretion [44, 45]. There may also be direct effects of elevated body temperature on steroid synthesis. Culture of cumulus cells at 40.5 °C reduced estradiol-17β production in the autumn but not in the summer or winter [43]. In the same study, incubation at 40.5 °C reduced forskolin-stimulated androstenedione production by thecal cells when cells were collected in winter but not when cells were collected in summer or autumn. Heat shock of 41 °C reduced basal and gonadotropin-stimulated synthesis of androstenedione and estradiol-17β by cultured follicular walls from the dominant follicle [46].

In some cases, heat stress can cause a reduction in circulating progesterone concentrations [47] and such a decline could conceivably contribute to a reduction in oocyte competence. This idea is based on the observation that fertility following ovulation of a first-wave dominant follicle, when circulating progesterone concentrations are low, is lower than fertility following ovulation of a second-wave dominant follicle, when progesterone concentrations are high [48, 49]. Moreover, supplementation with progesterone during the first follicular wave improved fertility [49].

Summer heat stress is followed by a gradual restoration of oocyte competence for fertility [16, 18] and oocyte competence for chemically activated development [50]. These observations are symptomatic that heat stress can affect follicular development early in the ~16-week period it takes for a primordial follicle to reach dominance [51]. Indeed, there is experimental evidence for delayed effects of heat stress on function of the follicle and oocyte. In one study [52], exposure of lactating Holsteins to heat stress affected follicular steroid production 20–26 days later. An experiment in Gir cattle (*Bos indicus*) indicated that carryover effects of heat stress can persist for up to 133 days after initiation of heat stress (i.e. 105 days after the end of heat stress) [39]. Cows were exposed to heat stress for 28 days and oocytes aspirated and subjected to *in vitro* maturation and fertilization at weekly intervals for up to 133 days after the beginning of heat stress. Heat stress did not affect follicular dynamics during the 28-day heat stress period but increased the diameter of the first and second largest follicles, as well as the number of follicles >9 mm, from days 28–49 after initiation of heat stress. Moreover, the percentage of oocytes that became a blastocyst was reduced by heat stress even at the end of the experiment at 133 days after initiation of heat stress (Figure 67.5).

Oocyte Maturation

The oocyte remains susceptible to disruption by heat stress during the process of nuclear and cytoplasmic maturation in the periovulatory period. Heat stress of superovulated heifers for a 10-hour period beginning at the onset of estrus and before insemination at 15–20 hours after the beginning of estrus decreased the proportion of embryos recovered at day 7 after estrus that were classified as normal [53]. There was no effect of heat stress on fertilization rate, so damage to the oocyte resulted in formation of an embryo with reduced competence for development.

Some of the effects of heat stress on oocyte function during maturation could be due to alterations in hormone secretion because, as mentioned previously, heat stress reduced the magnitude of the preovulatory surge in luteinizing hormone and estradiol-17β [26, 31]. In addition, exposure to elevated temperature can induce errors in oocyte maturation. Culture at elevated temperatures during maturation reduced the proportion of oocytes that completed nuclear maturation; increased the proportion with abnormal spindle formation, cortical granule distribution, depolarized

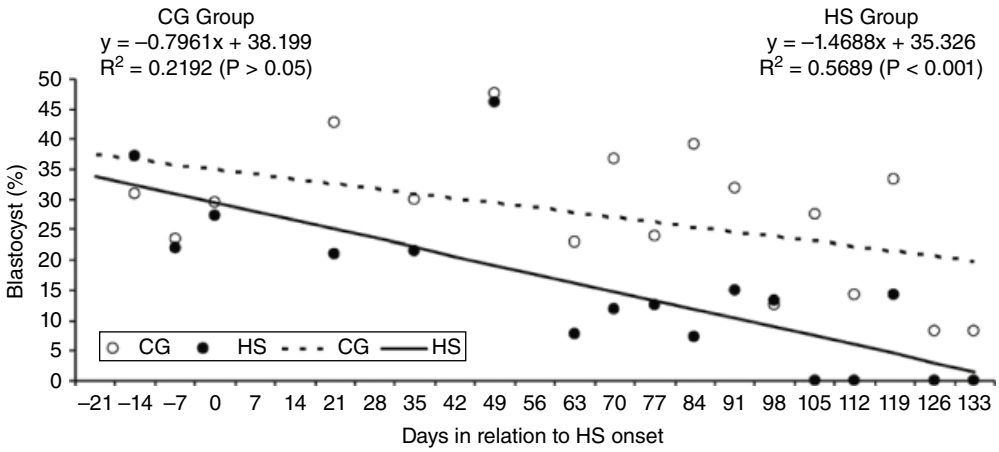

Figure 67.5 Changes in developmental competence of oocytes harvested from Gir cows that were either experimentally heat-stressed for 28 days (HS) or were maintained in a control environment (control group, CG). Oocytes were subjected to *in vitro* maturation and fertilization. Resultant embryos were cultured to the blastocyst stage. Note that competence of oocytes to become blastocysts remained lower for the HS group for up to 133 days after initiation of heat stress (i.e. 105 days after the end of heat stress). *Source:* [39] © 2008, Elsevier.

mitochondria, and apoptotic pronuclei; and decreased the proportion that cleaved and became blastocysts after insemination [54–59]. A recent experiment suggests heat shock alters histone methylation marks in the resultant four-cell and eight-cell embryo embryos [60].

Apoptosis has been implicated in disruption of oocyte function during maturation. Inhibition of apoptosis with a caspase inhibitor [55], sphingosine 1-phosphate [61], or inhibitor of ceramide synthesis [62] reduced effects of heat shock on developmental competence of the oocyte. Effects of heat shock on the oocyte also involve reactive oxygen species (ROS). Culture at elevated temperature increased oocyte production of ROS [63–65], and addition of the antioxidants cysteine [63], astaxanthin [64], melatonin [65], and retinol [66] protected the cultured oocyte from heat shock.

Effects of heat shock on the maturing oocyte, which are based on experiments conducted *in vitro* in artificial culture media, should be reevaluated in light of findings that follicular fluid contains molecules that can protect the oocyte from elevated temperature [67]. Specifically, addition of either follicular fluid or follicular fluid exosomes to oocytes undergoing maturation *in vitro* reduced the effects of culture at 41 °C on oocyte developmental competence. There are also reports that the ovary exists at a temperature about 1.1 °C less than rectal temperature [68]. If the ovary experiences local cooling, it would be unlikely to be compromised by direct effects of elevated temperature.

Fertilization Failure

Formation and maturation of spermatozoa in the male reproductive tract can be compromised by heat stress [69, 70] and there is evidence that embryos formed from sperm from heat-stressed bulls have reduced developmental competence [71]. Effects of thermal stress on the bull can be eliminated by AI. Fertilization in females inseminated artificially can still be compromised during periods of heat stress, as illustrated by results in Figure 67.6 comparing fertilization rates for lactating cows in summer and winter [12]. A major cause of reduced fertilization rate during heat stress is the result of actions of heat stress on the oocyte that were described in the section "Oocyte Maturation." The spermatozoa deposited in the reproductive tract may also be damaged by heat stress, however. Culture of spermatozoa at elevated temperatures as low as 40 °C reduced motility but not fertilizing capability [72]. At 41 °C, both motility and fertilizing ability were compromised [73, 74] through a mechanism involving mitogen-activated protein kinase 14 [74]. There may also be some long-term consequences for the embryo of being derived from a sperm cell exposed to heat shock in the female reproductive tract. There are reports in the rabbit that exposure of sperm to elevated temperature *in vitro* [75] or *in vivo* [76] resulted in abnormalities in development leading to a reduction in the number of implantation sites despite no effect on fertilization rate. More work is necessary to determine if damage to the spermatozoa by heat shock can lead to developmental abnormalities later in gestation in cattle.

Damage to the Preimplantation Embryo

When first formed, the preimplantation embryo is very susceptible to elevated temperature. A heat shock as low as 40 °C for 12 hours reduces development of zygote-stage embryos to the blastocyst stage [7]. Heat shock also reduces

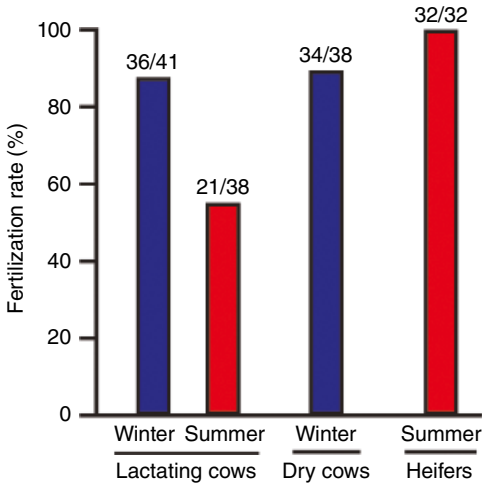

Figure 67.6 Seasonal changes in fertilization rate in Holsteins in Wisconsin. The reproductive tract of inseminated females was flushed 5 days after ovulation to recover oocytes and embryos. Fertilization rate was based on number of recovered embryos (>2-cell) divided by number of recovered oocytes and embryos (see numbers above each bar). For lactating cows there was a decrease in fertilization rate in summer compared to winter. For non-lactating animals, however, there was no difference in fertilization rate between seasons (compare dry cows in winter with heifers in summer). *Source:* Data are taken from [12].

developmental potential of embryos at the two-cell stage of development [6, 8], but thereafter the embryo becomes more resistant to heat shock. Development of four- to eight-cell embryos is compromised by heat shock but to a lesser extent than for two-cell embryos [6]. By the morula stage of development, the embryo is substantially resistant to deleterious effects of heat shock [6–8, 77]. The same phenomenon is observed *in vivo*. Exposure of superovulated cows to heat stress reduced blastocyst yield at day 8 after estrus when heat stress occurred at day 1 after estrus but not when it occurred at day 3, 5, or 7 after estrus [78].

Mechanism for Embryonic Mortality Caused by Heat Stress

The two-cell embryo exposed to 41 °C experiences alterations in ultrastructure characterized by swelling of mitochondria and movement of organelles toward the center of the blastomere [79] (Figure 67.7). Organellar movement is caused by disruption of the cytoskeleton [80]. Some of the damage caused by heat shock could be the result of increased production of ROS since, like for the oocyte, exposure of the preimplantation embryo to elevated temperature increases ROS production [8, 81]. In one experiment, effects of heat shock were greater in two-cell embryos cultured in a high oxygen atmosphere that facilitates oxidative stress [82]. In contrast, effects of heat shock were independent of oxygen tension in other studies [7, 83]. Similarly, the antioxidant dithiothreitol [82] and anthocyananin [84] have been reported to mitigate actions of heat shock, whereas other antioxidants including melatonin [81], vitamin E [85], and glutathione [86] were without embryoprotective properties.

Using Japanese Black cows, there is evidence for differences in the endometrial transcriptome between summer and winter at day 15 of the estrous cycle [87]. Accordingly, actions of heat stress on embryonic survival *in vivo* could involve effects on the reproductive tract as well as on the embryo directly. Heat stress can reduce the magnitude of the preovulatory surge in estradiol-17β during the preovulatory surge [45] and during the first follicular wave after ovulation [41] and these hormonal changes could conceivably change function of the oviduct or endometrium. So too could changes in circulating concentrations of progesterone but reported effects of heat stress are highly variable, with heat stress being associated with a decrease [88], increase [89], or no change [90] in blood progesterone. The direct effects of heat shock on oviductal or endometrial function have not been examined at temperatures characteristic of those experienced by heat-stressed cows. However, culture at 40.5 °C increased production of prostaglandin (PG)$F_{2\alpha}$ and E_2 from endometrial stromal cells [91] and PGE_2 from oviductal epithelial cells [92].

Developmental Acquisition of Thermotolerance by the Embryo

Several hypotheses have arisen to explain the process by which the embryo transitions from a state in which it is very susceptible to heat shock, at the one-cell to two-cell stage, to one, at about the 16-cell stage, where it has acquired resistance to heat shock. One possibility is that the early embryo is very susceptible to heat shock because processes required for embryonic genome activation are easily disrupted by heat shock. If this was the case, embryos exposed to heat shock at the two-cell or four-cell stage should block development at between the 8-cell and 16-cell stages; embryonic genome activation is required for development past this stage [93]. Such a preferential block at the 8- to 16-cell transition was seen in one experiment with two-cell embryos [83] but not in another where embryos were heat-shocked at the one-cell stage [7].

Another possibility is that the acquisition of capacity for transcription after the 8-cell to 16-cell stage allows the

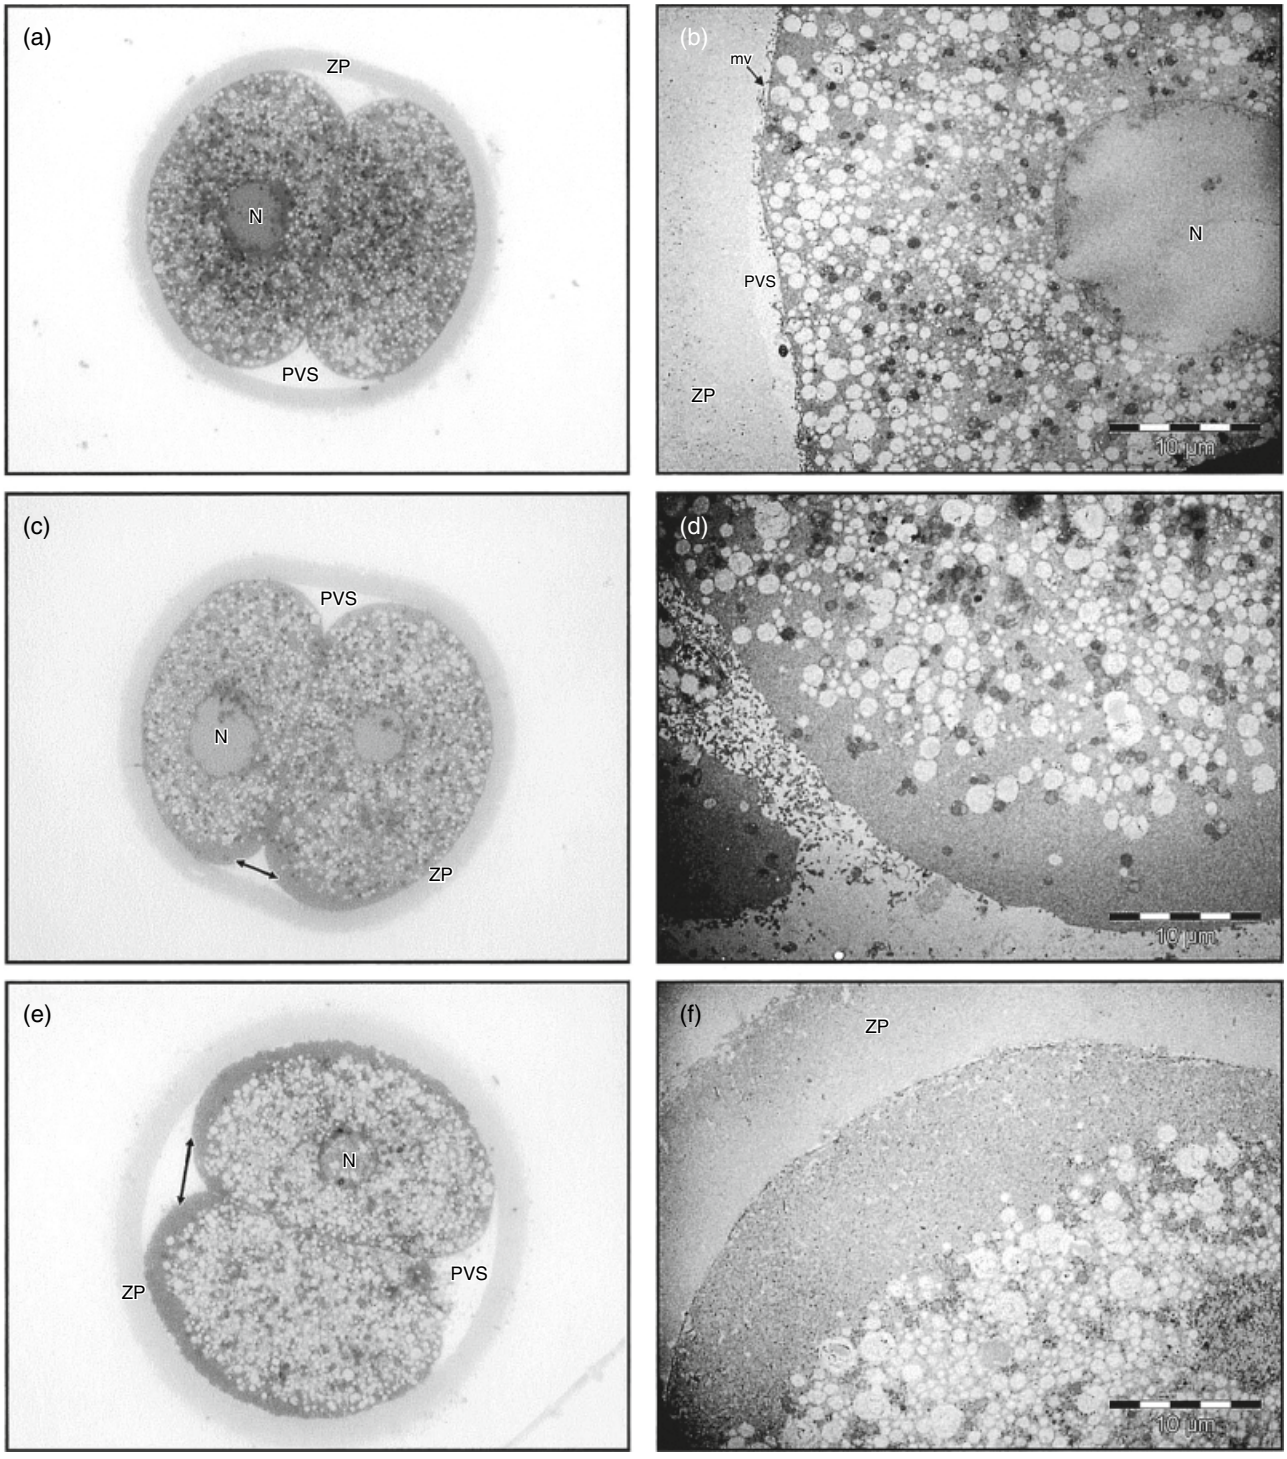

Figure 67.7 Effects of heat shock (41 °C for 6 hours) on the ultrastructure of two-cell bovine embryo produced *in vivo*. Panels (a) and (c) represent images taken using light microscopy after staining with toluidine blue O, while panels (b) and (d) represent images from transmission electron microscopy. Embryos cultured at 38.5 °C are shown in panels (a) and (b), while heat-shocked embryos are shown in panels (c) and (d). Arrows point to an area of the cytoplasm devoid of organelles. embryo to engage a wider range of stress responses to stabilize cellular function during heat shock. Prior to genomic activation, heat-shock-induced transcription of the heat shock protein gene, *HSPA1A*, is not possible [94], although steady-state amounts of mRNA for several stress proteins are higher in the one-cell or two-cell embryo than the morula, including *HSPA1A* [7, 93], probably because transcripts are inherited from the oocyte. Heat shock can also induce synthesis of heat shock protein 70 as early as the two-cell stage [95, 96], possibly through events regulated post-transcriptionally [94].

Other cell stress survival mechanisms may be developmentally regulated. There is, for example, a change in the balance between ROS generation and antioxidant protection as the embryo advances in development. Heat shock caused increased free radical production at day 0 and 2 of development but not at day 4 and 6 [8]. In addition, the cytoplasmic antioxidant glutathione is at its lowest during two- to eight-cell stages [97].

Another developmentally regulated mechanism that protects embryos from heat shock is the capacity for apoptosis. It is not until after embryonic genome activation that proapoptotic signals can activate the apoptosis response; the process is inhibited in two-cell embryos because of mitochondrial resistance to depolarization [98] and inaccessibility of caspase-activated DNAases to the intranucleosomal regions of DNA [99]. Exposure of the morula to 41 °C for nine hours results in about 10–25% of cells becoming apoptotic [100, 101]. Prevention of apoptosis exacerbates the deleterious effects of heat shock on development [100, 101], probably by eliminating those cells most damaged by heat shock.

Heat Stress and Pregnancy Loss

Results are conflicting as to whether late embryonic and fetal loss is affected by heat stress. A controlled experiment to test this hypothesis has not been carried out. Epidemiological analyses indicated an association between warm weather and increased pregnancy loss between day 35–45 and 90 of gestation for cows in Spain [102]. In another study from Spain, increased number of warm events from day 11–20 or 0–40 of gestation was associated with pregnancy loss between day 28–34 and 80–86 of gestation [103]. In contrast, there was no relationship between occurrence of heat stress before or after insemination and pregnancy loss between day 31 and 45 of pregnancy in California [104]. Similarly, there was an absence of seasonal variation in pregnancy loss between day 40–50 and 70–80 or between 70 and 80 and term among dairy cattle in Florida [105].

Physiological Approaches for Improving Pregnancy Success During Heat Stress

At least in high-producing dairy cows, alterations in animal housing to reduce the magnitude of heat stress are important for maximizing reproduction during warm periods of the year. The level of fertility in Israeli dairy farms in the summer, for example, is related to the magnitude of cooling that cows receive (Figure 67.8) [106]. Cooling cows can also increase detection of estrus [4, 108].

To be effective for improving fertility, cooling cannot be limited to a few critical days around ovulation because of the large window of time in which the oocyte is susceptible to heat stress [39]. Short-term cooling around the period of ovulation, fertilization, and early embryonic development causes only slight improvements in pregnancy/AI [4, 108].

Fertility can be depressed in the summer even when cows are housed in facilities with extensive cooling [106, 109]. Consequently, depending on the magnitude of heat stress and the effectiveness of cooling systems, achieving optimal fertility during warm weather depends upon regulating the physiology of the cow to overcome the effects of heat stress on estrous behavior and fertility. In this part of the chapter, some possible strategies for managing reproductive processes during heat stress will be outlined.

Timed Artificial Insemination

Introduction of hormonal protocols to program the timing of ovulation and allow for fixed-time insemination has meant that the effects of heat stress on estrus detection can

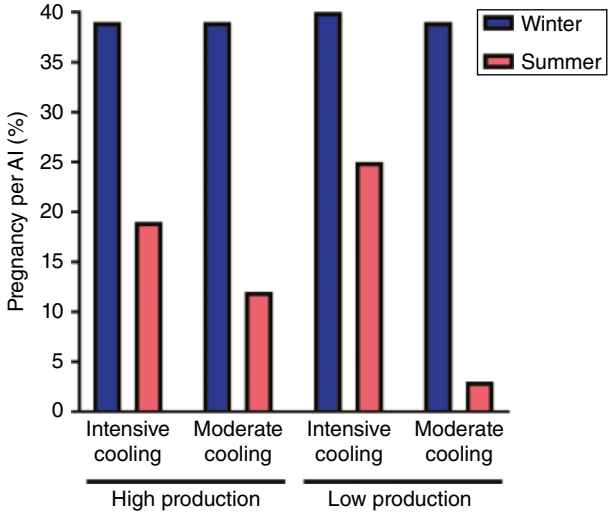

Figure 67.8 Effect of level of milk production (high vs low) and the degree of cooling that cows receive (intensive vs moderate) on fertility of dairy herds surveyed in Israel. *Source:* [107].

be eliminated. Accordingly, use of timed AI protocols during heat stress can increase the 21-day pregnancy rate compared to programs based on spontaneous [110] or prostaglandin-induced estrus [111, 112].

Effectiveness of timed AI protocols may be reduced somewhat during heat stress because there are indications that GnRH is less likely to induce ovulation during heat stress than at cool periods of the year [30]. This consequence of heat stress can be reduced by using more active analogs of GnRH such as dephereline [113]. In addition, effects of heat stress on the oocyte and embryo limit the expected improvement in 21-day pregnancy rate. In several studies, incorporation of timed AI caused no increase in pregnancy/AI [110, 111] or the increase was small [112].

However, new timed AI protocols are designed to increase fertility [114] and there is literature indicating that the relative differences in timed AI protocols for achieving high 21-day pregnancy rates are greater during heat stress. For example, a timed AI protocol involving estradiol cypionate one day before insemination improved pregnancy/AI compared to a protocol utilizing GnRH at insemination when cows experienced two or more days of hyperthermia (rectal temperature > 39.0 °C) but not when cows experienced zero or one day of hyperthermia [115]. In another experiment, the seasonal depression in pregnancy/AI after spontaneous estrus or a timed AI protocol involving insertion of a progesterone releasing intravaginal device (PRID) for nine days (followed by equine chorionic gonadotropin at device removal, GnRH 48 hours later, and AI 12 hours after GnRH) was not observed when the timed AI protocol was modified so that the PRID was inserted for five days only [116].

Embryo Transfer to Bypass Effects of Heat Stress on the Oocyte and Embryo

As illustrated in Figure 67.9, embryo transfer can eliminate much or all of the seasonal variation in fertility caused by heat stress [117–123]. The basis for its effectiveness is the circumvention of effects of heat stress on oocyte competence, fertilization failure, and embryonic death. By the blastocyst stage of development, when an embryo is typically transferred into a recipient female, the embryo has acquired substantial resistance to the adverse effects of elevated temperature [6–8, 77, 78]. Thus, the pregnancy success after embryo transfer during heat stress is much higher than following insemination. This is the case whether embryos were produced by superovulation [122–125] or *in vitro* production techniques [126–128]. The *in vitro* produced embryo can experience poor cryosurvival [129], so benefits of embryo transfer during heat stress are sometimes reduced [128] or eliminated [125] if cryopreserved embryos produced *in vitro* are transferred.

Embryo transfer can be used in conjunction with the same ovulation synchronization programs for timed AI [21, 126–128] so that actions of heat stress on detection of estrus can be eliminated for embryo transfer as well as for AI.

Progesterone Supplementation to Improve Embryo Survival

Hormonal treatments designed to increase circulating concentrations of progesterone after breeding can increase cow fertility [130]. This may also be the case during heat stress. Treatment of lactating dairy cows with human chorionic gonadotropin at day 5 or 6 after AI did not improve fertility in one experiment [131] but increased pregnancy/AI in cows regardless of parity [132] or for primiparous cows only [133]. Insertion of a progesterone-containing intravaginal device on day 5 ± 1 for 13 days increased pregnancy/AI when cows were in low body condition only [134]. Similarly, treatment with GnRH at AI or AI and day 12 after AI also increased pregnancy/AI [135].

Antioxidants

Exposure to elevated temperature increases ROS production by oocytes [63, 65] and embryos [8, 81]. Moreover, heat stress can increase markers of oxidative stress in the blood [136, 137]. Mixed results have been obtained from the few experiments evaluating whether provision of supplemental antioxidants can improve fertility during the summer. There was no improvement in fertility when cows were injected with vitamin E at insemination [4], given multiple injections of vitamin E and selenium before and after calving [85], or administered injections of β-carotene at −6, −3, and 0 days relative to insemination [138]. In contrast, feeding supplemental β-carotene for at least 90 days beginning at ~15 days after calving increased the proportion of cows that were pregnant at 120 days postpartum [110]. In addition, treatment of cows with melatonin implants in the summer reduced days open [139]. Interpretation of the melatonin study is difficult because melatonin has many biological actions, including as an antioxidant [65, 140] but also as an important mediator of photoperiodic regulation [141].

Follicle Removal to Eliminate Damaged Follicles After Heat Stress

Work in Israel has shown that inducing removal of follicles from the ovary in the autumn can hasten the restoration of fertility following heat stress. Beneficial effects on oocyte quality have been observed by turning over the follicular pool using follicular aspiration [50] or injection with either follicle stimulating hormone [142] or somatotropin [142].

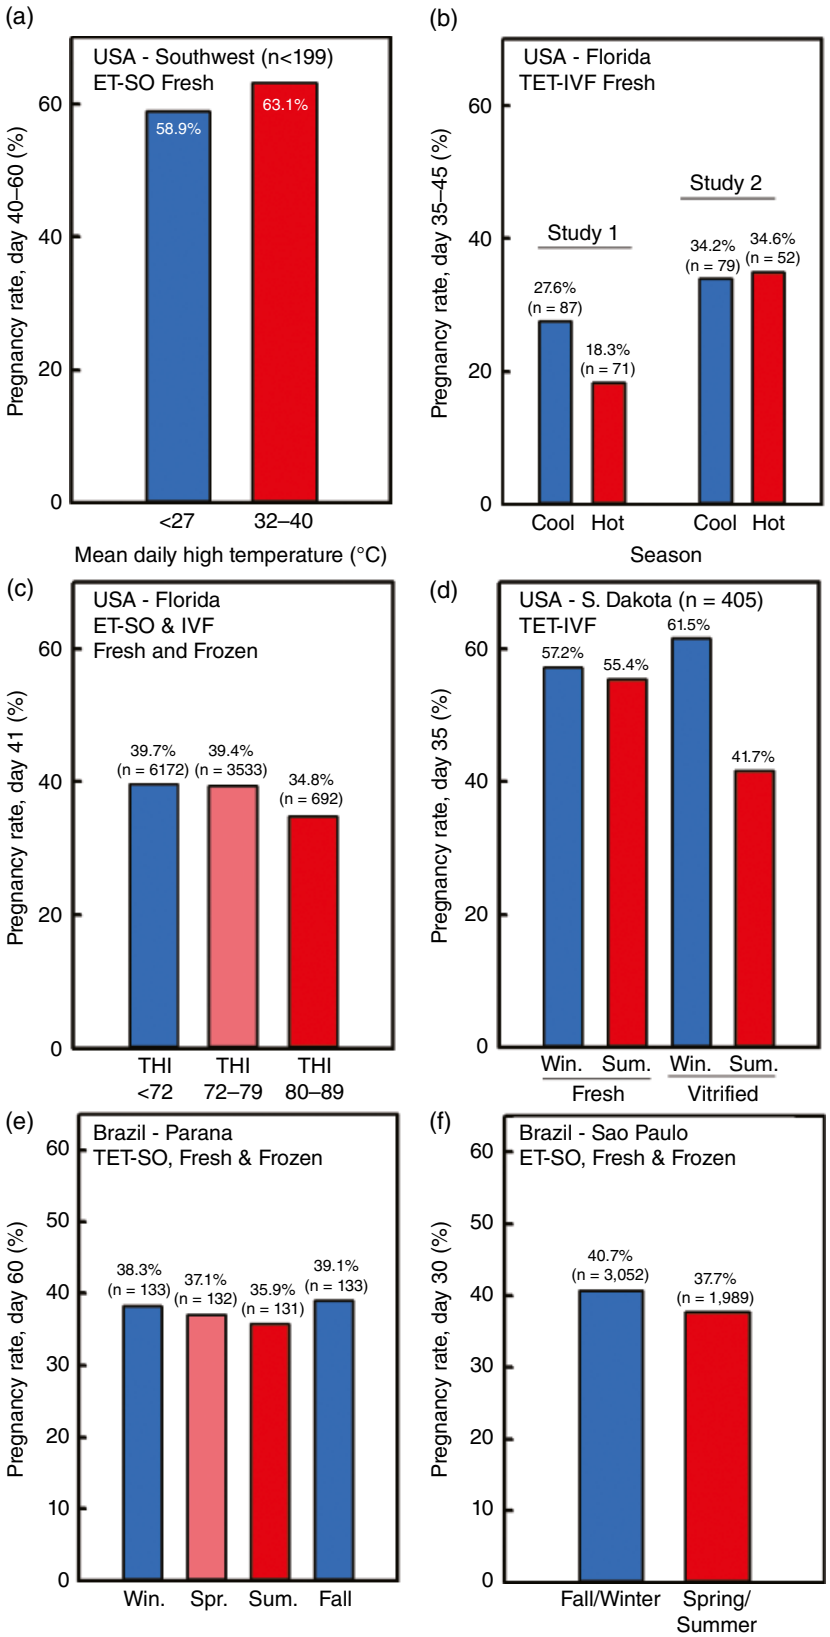

Figure 67.9 Pregnancy success after embryo transfer in cool and hot weather in lactating dairy cows. Note that in most studies there was little variation in percentage of females pregnant between cool and hot periods. ET, Embryo transfer; IVF, *in vitro* fertilized; S. Dakota, South Dakota; Spr., spring; SO, superovulation; Sum., summer; TET, timed embryo transfer; THI, temperature–humidity index; Win., winter. *Source:* [107].

Such treatments would not be expected to be effective in the summer because follicles emerging into the growing pool would also be damaged by heat stress. Consistent with this idea was the observation that treatment of lactating cows in the summer and autumn with three rounds of a GnRH and $PGF_{2\alpha}$ protocol to hasten removal of follicles did not improve pregnancy rate at first AI in multiparous cows, although it tended to improve pregnancy rate in primiparous cows [143]. Perhaps greater responses would have been seen if the study was limited to the late summer or autumn.

The Reproductive Tract Microbiome: Implications for Fetal and Neonatal Health

Riley D. Messman and Caleb O. Lemley

Department of Animal and Dairy Sciences, Mississippi State University, Starkville, MS, USA

Introduction

A new and expanding area of research in both human medicine and animal science is evaluating microbial diversity within different organ systems. In humans, the gut microbiome has been referred to as a supporting organ because of the numerous associations between the gut microbiome and overall host health [1, 2]. Additionally, negative impacts on host microbiomes throughout the body can have detrimental effects on overall health [3]. Therefore reproductive physiologists have begun investigating the roles that microorganisms could play in fertility and reproductive performance. Current research into the microbiome of the reproductive tract is promising but incomplete. The objective of this chapter is to highlight current impactful studies evaluating the microbiome of the female reproductive tract and provide direction for future research.

Microbiome Research Methodology

Bacteria, both pathogenic and commensal, that directly inhabit and co-exist in any environment are referred to as the bacterial microbiota of that environment's microbiome [4]. Researchers heavily agree that commensal bacteria are crucial for the maintenance of homeostasis in both human and livestock species [5, 6]. It has been determined that each body site harbors a unique microbial community that can differ completely from one site to another [7]. Therefore researchers have migrated from evaluating the entire microbiome of a host to instead evaluating specific microbiomes within the host's physiological systems [8]. Throughout the development of microbiology research, specific terminology, methodology, and data presentation have been adapted. Thus, before current literature can be discussed in depth, an overview of methods and data analyses unique to microbial research must be presented.

Firstly, obtaining a pure uncontaminated sample requires stringent methods dependent on the specific microbiota being sampled. The results of a study can be heavily impacted by sample collection methods. For example, the gut microbiota can easily be evaluated by collecting a stool sample, but sampling the microbiota of a specific organ would require sterile invasive procedures. Additionally, direct collection methods, such as stool collections, yield an extremely microbial dense sample with minimal contamination risk [7]. Conversely, utilizing swabs or lavages to collect samples proves more challenging to obtain samples without contamination and is less studied regarding protocol consistency and accuracy [9]. Typically, swabs are the least invasive but retrieve the smallest microbial biomass, whereas biopsies are more invasive but collect the most microbial biomass [7, 10]. Therefore, when determining how to sample, the researcher must consider sampling site, contamination risk, and how invasive their sampling procedure is.

After sample collection, the most common analysis used for evaluating microbiota composition is gene sequencing utilizing the 16S rRNA gene [11]. This method is not perfect but has been proven an objective, accurate, and reliable method for bacterial identification [12]. A highly conserved component of the transcription machinery of a microorganism's DNA is the 16S rRNA gene [13]. Therefore 16S rRNA is a great target gene for sequencing DNA in samples that contain thousands of different microbial species [13]. Additionally, the 16S rRNA gene is large enough (1500 base pairs) for information purposes, its function has not changed over time, and it is present in almost all bacteria and archaea, further attesting its use for studying microorganisms [14]. The 16S rRNA gene has both variable and conserved regions, and the variable regions differ between

specific microorganisms; this allows for differentiation between microbial species [15].

The methodology for the bioinformatic analysis of the microbiota is referred to as a pipeline. A pipeline utilizes bioinformatic software programs and laboratory kits which can change dependent on individual preference and the goal of the study, but the general steps taken within analysis are the same.

The first step within microbial analysis is DNA extraction from collected samples, the extracted DNA then undergoes quality/quantity check, next the universal 16S rRNA primers are used to amplify all bacterial DNA via polymerase chain reaction (PCR), then the 16S rRNA is sequenced from the bacterial DNA, and finally similar 16S gene sequences are clustered into operational taxonomic units (OTU) and identified [16]. OTU are groups of similar 16S rRNA reference sequences; typically, they are grouped at a certain percentage of similarity, such as 95 or 98% [17]. After clustering into OTU, a reference database, which has current information about what 16S gene sequences match specific bacterial taxonomy, is utilized to identify the species each OTU represents [18]. It is important to mention that not all sequences identified as an OTU will have a taxonomic match within the database. This occurs because that specific sequence has yet to be identified and assigned taxonomy. After the bacterial community has been characterized, statistical analysis for significant differences is the next step [16].

Most researchers present data analyzing the alpha and beta diversity of samples, as this is a quantitative analysis of comparable differences within and between samples, respectively. First, alpha diversity is the diversity within a sample that specifies species richness and evenness [19]. Alpha diversity is commonly measured via the Shannon diversity index, a statistical method that accounts for species abundance/richness and evenness within a sample [20]. Richness, or abundance, refers to the number of observed species within an individual sample. Evenness is the relative abundance of species within a sample [21]. Further explanation of alpha diversity is illustrated in Figure 68.1. Beta diversity is the extent of change in species composition in different samples [22]. The statistical methods to analyze differences in beta diversity are dependent on researchers, and commonly researchers utilize a non-permutational index (such as Bray-Curtis) accompanied with a permutational multivariate analysis of variance (PERMANOVA). Normally beta diversity is visualized using a principal component analysis which allows a visualization of the similarities between each sample [23]. This statistical graph allows readers to visualize the beta diversity between samples.

The aforementioned methods have provided insight about microbial composition throughout physiological systems in many species and the inner workings of microbial presence on overall health. Although many species and physiological systems have been analyzed, there is still much room for growth and the expanding of knowledge in microbiota research. A recent trend in microbiota research is to evaluate the microbiota of the reproductive tract and its impacts on fertility and reproductive performance.

The Microbiota of the Human Reproductive Tract

To date, the most in-depth research characterizing reproductive tract microbiotas, including the vagina, uterus, placenta, and amniotic fluid, has been performed in humans. Specifically, researchers are focusing on first determining if a microbiota exists, then characterizing the microbiotas located within the reproductive tract, and lastly, determining how the microbiota can affect fertility.

The vaginal microbiota and physiological environment of the vaginal tract was characterized by Ravel et al. [24]. In this study, the vaginal bacterial communities of reproductive age women (n = 396) were analyzed using the 16S rRNA gene. Subjects were of different ethnic and racial backgrounds (Caucasian, African-American, Hispanic, and Asian) and all were currently living in the USA. Results found that the majority of bacteria within the subjects' vaginal tracts had the common physiological ability to produce lactic acid. It was concluded that Caucasian and Asian women had different vaginal microbiotas than African-American and Hispanic women. Results also showed that the vaginal tracts of Caucasian and Asian women were primarily dominated by *Lactobacillus* species, but the vaginal tracts of African-American and Hispanic women had fewer *Lactobacillus* species. Previously, it was proposed that the production of lactic acid by *Lactobacillus* species in the women's vaginal microbiota was crucial for vaginal health [25]. However, Ravel et al. [24] dispute this claim and state that many factors including ethnicity and environment could contribute to the composition of the vaginal microbiota. Lastly, authors found that the pH of Caucasian and Asian women was significantly different from African-American and Hispanic women (4.2 compared to 5.0). Therefore the two groups clearly had different amounts of lactic acid production in the vagina.

Lactic acid facilitates an acidic vaginal environment, which can prevent the growth and attachment of potential pathogens [26]. Ronnqvist et al. [27] evaluated the role of *Lactobacilli* species in the vaginal tract and their relationship to other genital microbes and vaginal pH. In 191 women evaluated, the overall conclusion was that *Lactobacilli* species contribute to a low vaginal pH, which

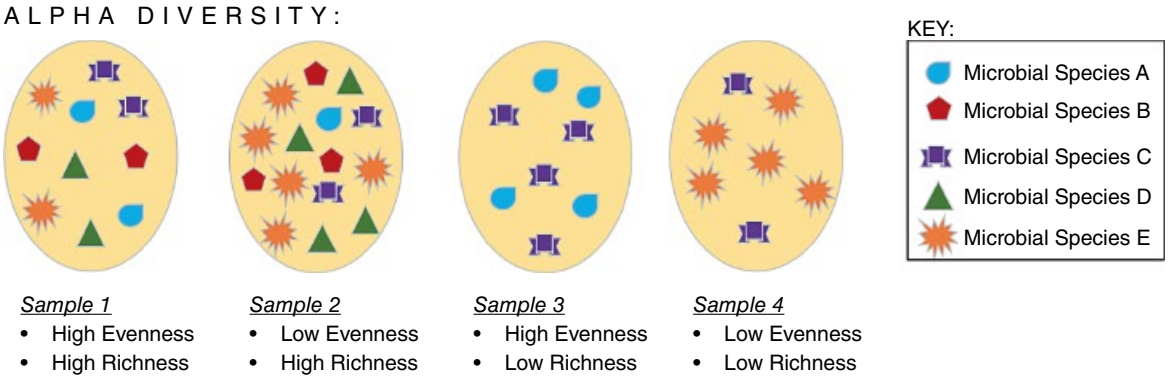

Figure 68.1 Alpha diversity is the microbial diversity within a sample. Alpha diversity is measured in evenness and richness. High evenness is when the population proportions are similar within the samples. For example, in samples 1 and 3 there are two of each microbial species and three of each microbial species, respectively. Therefore the microbial proportions are even within these samples. High richness is when there is a high number of microbial species within a sample. For example, in samples 1 and 2 all microbial species are represented, so these samples have high richness compared to samples 3 and 4 that only have two microbial species represented. See text for citations.

has a negative impact on the growth of Group B Streptococcus. Group B Streptococcus is associated with preterm birth, fetal injury, and neonatal mortality in newborns; recently, it was discovered that this pathogen also has the ability to infect fetuses in utero [28]. Therefore it can be inferred that an acidic vaginal environment is beneficial in women for preventing growth of pathogenic bacteria, but, as mentioned in Ravel et al. [24], the physiologically normal pH and bacteria that induce the acidic environment are different among ethnic groups. Therefore further characterization of the normal vaginal microbiota in different demographics of women is necessary.

After the original characterization studies, vaginal microbiota researchers shifted to determining if a microbiota is present within the uterus. Similar to animal species, obtaining sterile samples from the uterus in women is difficult due to anatomical barriers such as the vaginal tract and cervix. Data showing microbial populations in the uterus have been published and presented in the literature, but many researchers are still skeptical of the presence of a uterine microbiota and attribute current findings to contamination [29]. Additionally, if a microbiota exists, it is debatable if it has positive or negative effects on reproductive performance, fertility, or pregnancy establishment.

Within the uterus, the most abundant phyla reported include Firmicutes, Bacteroidetes, Proteobacteria, and Actinobacteria [30, 31]. This sampling pool included patients with both healthy and unhealthy reproductive tracts; therefore attributing microbial composition to uterine health appears difficult and unreliable at this time. Additionally, *Lactobacillus*, from the Firmicutes phyla, is the most abundant genus of the uterus in the aforementioned studies and others [32–34]. Recall that the colonization of the vaginal tract with *Lactobacillus* species led to decreased vaginal pH to prevent growth of pathogens, but within the uterus its role is up for debate.

Fang et al. [35] reported that women with endometrial polyps and chronic endometriosis had a higher relative abundance of *Lactobacillus* species in the uterus than healthy women, concluding that *Lactobacillus* has a negative effect on reproductive performance. However, Moreno et al. [36] reported that high levels of *Lactobacillus* species in the uterus increased success rates in women undergoing *in vitro;* fertility treatments and embryo implantation success. Interestingly, there are regular findings of *Lactobacillus* species within the uterine tract, but an obvious function or physiological role within the uterus is unknown. It is plausible that vaginal contamination of the sample occurred, and the research being reported is not actually to do with the uterine microbiota but a result of contamination. Therefore more in-depth research with multiple contamination checks needs to be implemented before a uterine microbiota can be confirmed.

Finally, researchers have analyzed tissue from the placenta and amniotic fluid during pregnancy to detect the presence of a microbial community. If a microbiota does exist, there could be major implications surrounding fetal microbial inoculation, fetal development, and fetal health both in utero and after birth [37].

Researchers studying the placenta and amnion in humans have found microbial populations present, but there is still much debate on whether it is colonization or contamination. In a study by Stinson et al. [38], amniotic fluid and fetal meconium were collected from women undergoing non-emergency cesarean sections (CSs) ($n = 50$). Each sample was characterized via 16S rRNA gene sequencing. They found that all meconium samples contained a high number of reads that matched *Pelomonas*

puraquae, and amniotic fluid samples had a low number of reads and microbial diversity with only skin commensals being present. Within their discussion, the authors acknowledged the possibility of contamination of meconium samples with *P. puraquae* within the laboratory, but largely concluded that the overall presence could not solely be due to external contaminants [38]. The authors attributed the presence of *P. puraquae* only in the meconium to the bacteria's ability to survive in the harsh environmental composition of meconium, whereas skin commensals were mostly found in the amniotic fluid because amniotic fluid typically contains high amounts of sloughed fetal skin cells [39].

Conversely, Lim et al. [40] found that all microbes present within the amniotic fluid were due to sample contamination either in the birthing suite, laboratory, or transport. This study was in agreement with previous literature regarding the low bacterial biomass in amniotic fluid samples [38, 40]. Due to the low bacterial biomass, current researchers in this field are still determining the best way to process and analyze these samples. Recent discrepancies with the materials and methods of Lim et al. [40] have been published in the literature [41]. Overall, concrete evidence supporting presence or absence of a microbiota in the amniotic fluid has yet to be presented in the literature.

Lastly, similar to the amniotic fluid, there is a debate in the literature of the existence of a placental microbiota. Aagaard et al. [42] found that the placenta contained a unique microbiota when sampling 320 women. The placenta was primarily inoculated with commensal bacteria. This study included samples from 320 women with both healthy and preterm births, and it was concluded that all placentas sampled had a low microbial biomass. Although interesting, the Aagaard et al. [42] study had some limitations that severely compromised the integrity of the paper in terms of validity; due to no contamination checks being reported or analyzed, there is no possible way to know if the microbial communities reported in this study were due to contamination or colonization.

The most impactful research evaluating the placental microbial population was done by Goffau et al. [43] which refutes claims from previous researchers that the placenta contains a microbiota. In this study, placentas (n = 537) from women that had vaginal deliveries, prelabor CS, and CS after labor onset were evaluated. Rigorous contamination evaluations were performed to determine if contamination occurred in either the delivery room or laboratory. Results showed that all microbiota present on the placenta samples were from contamination. However, native pathogens, specifically Group B Streptococcus, were discovered on the placenta samples. Therefore the authors concluded that while the placenta does not have a resident microbiota, it can harbor pathogens that can have fatal consequences to infant's post-partum.

Interestingly, through their evaluation of contamination, the authors also found that the placenta was naturally inoculated with vaginal microbiota during natural birth and CS after labor onset only. This suggests the ascension of vaginal microbiota through the cervix during labor to inoculate the placenta and fetus. Ultimately, if valid, the vaginal microbiota would be the first contact the fetus has with microorganisms, suggesting that the composition of the vaginal microbiota could be associated with the cause or prevention of neonatal diseases. While more research is needed to verify this study, it can be speculated that the vaginal microbiota is extremely important in the reproductive and overall health of women and their neonates.

Clearly, the research and evaluation of the role and presence of microbiota in the reproductive tract of humans is incomplete; however, previous research in humans can assist animal scientists in designing studies to evaluate the microbiota of the reproductive tract in livestock species.

The Microbiota of the Bovine Reproductive Tract

Literature covering the characterization and implication of the microbiota within the reproductive tract of bovids is scarce. Unfortunately, most of the literature in bovids and livestock species available regarding the reproductive tract microbiota has severe limitations, such as no contamination checks or fewer numbers of animals. Similar to humans, the colonization of the reproductive tract with microbiota could reveal linkages between microbial communities and fertility, reproductive tract health, and overall animal health. To date, the most researched microbiota of the reproductive tract is the vaginal microbiota and its role in reproductive performance.

Swartz et al. [44] found that the vaginal environment and microbial community composition of humans and bovids differ. This study utilized crossbred cows (n = 20) and compared the microbial data results to previous literature characterizing women's vaginal microbiota. These researchers found that bovids' vaginal tracts have low levels of *Lactobacilli* and near-neutral pH compared to humans. Due to the change in pH, it can be expected that the commensal vaginal bacteria within bovids produce less lactic acid and require a near-neutral pH for optimal growth. This was further demonstrated in the characterization of the bovine vaginal microbiota, with the three most abundant phyla being Bacteroidetes, Fusobacterium, and Proteobacteria [44]. Therefore previous literature associating the human vaginal

microbiota to fertility may not be directly applicable to bovids [45].

A study by Nascimento et al. [46] evaluated the vaginal microbiota in four subsets of bovids, each unique in their reproductive status. The Nelore cattle breed was utilized with pregnant cows (n = 5), non-pregnant cows (n = 5), pregnant heifers (n = 5), and non-pregnant heifers (n = 5) included in the study. In agreeance with Swartz et al. [44], the most abundant phyla in all animals were Firmicutes, Bacteroidetes, and Proteobacteria. Within this study, they found that great microbial variability exists among animals, and no statistical differences were found as a result. Additionally, this study was the first to mention the potential role of reproductive hormones influencing the composition of the vaginal microbiota, but no evidence was provided. Perhaps the most interesting finding from the study was the lack of obligate anaerobes in non-pregnant heifers' vaginal microbiotas. Typically, obligate anaerobes are the last bacterial community to colonize a specific environment [47]. Authors attributed this finding to the potential of an underdeveloped vaginal microbiota in heifers which could lead to decreased fertility in these animals [46].

Estrus synchronization protocols in cattle could potentially impact the vaginal microbiota, more specifically protocols that utilize vaginal inserts to deliver hormones. Moreno et al. [48] investigated the difference in vaginal microbial communities post-progesterone releasing intravaginal devices (PRID) in cows and heifers. Post-PRID removal the animals were classified as having either vaginitis or no vaginitis (healthy); this was determined by counting polymorphonuclear neutrophils in vaginal cytobrush samples. They found that cows and heifers with vaginitis had higher Proteobacteria, a more uniform microbiota, and an increased prevalence of opportunistic pathogens within their vaginal microbiota. Overall, vaginitis caused by the use of PRIDs could increase the prevalence of bacteria in the vaginal microbiota, which could act as uterine pathogens and negatively impact fertility.

In addition to maternal health and fertility, the vaginal microbiota could have impacts on the dam's offspring. Lima et al. [49] sampled the vaginal and fecal microbiota of Holstein cows (n = 81) and compared it to the fecal and upper respiratory tract (URT) microbiota of their calf (n = 81), at 3, 14, and 35 days old, to evaluate if the maternal microbiota could influence calf health. They found that the URT microbiota of calves and the dams' vaginal microbiota were highly similar (63% overlap with 253 shared OTU) regardless of days of life. *Mannheimia* and *Moraxella*, bacteria involved in bovine respiratory disease in calves, were some of the most prevalent shared between dam and calf, suggesting that the health of a calf could be affected by mother-to-offspring transmission during parturition.

Messman et al. [50] evaluated the role of estradiol and pregnancy status on bacterial community composition of the vaginal microbiota. Researchers sampled Brangus heifers (n = 78) at timed artificial insemination (TAI) to determine if there were differences in bacterial composition between pregnant and non-pregnant heifers or heifers with divergent estradiol concentrations. It was determined that the bacterial composition of the vaginal microbiota was not changed by estradiol concentrations at time of artificial insemination. Additionally, heifers that became pregnant versus non-pregnant heifers did not have a different vaginal microbiota at time of artificial insemination.

A study by Ault et al. [51] investigated the role of progesterone concentrations altering the vaginal and uterine microbiota and compared the vaginal and uterine microbiotas of pregnant and non-pregnant post-partum cows prior to TAI. Samples were collected from pregnant (n = 10) and non-pregnant (n = 10) cows at three time points (day 21, day 9, and day 2 prior to TAI) from the vagina and uterus via lavage; blood serum was also collected at the aforementioned time points for progesterone concentration analysis. The estrus synchronization protocol utilized in this study did not incorporate a vaginal insert (CIDR/PRID).

There were no differences in the alpha diversity of vaginal microbiota species abundance at any sample date prior to TAI, but the authors found that OTU significantly decreased in the uterus over time [51]. Ault et al. [51] utilized a principal coordinate analysis to visualize beta diversity within the samples. Results showed significant clustering at day 2 in the uterus ($P = 0.005$) and in the vagina at day 21 ($P = 0.002$) between pregnant and non-pregnant cows. The authors proposed the differences in the uterus at day 2 could be affecting pregnancy establishment in these animals. They also found that the composition of the uterine and vaginal microbiotas varied in beta diversity dependent on day of collection. Lastly, the authors found no direct relationship to progesterone concentrations and the vaginal and uterine microbiotas.

Overall, Ault et al. [51] agrees with previous literature stating that there is high variation and diversity within the microbiotas of the bovine reproductive tract [46, 44]. The authors suggested that close clustering of non-pregnant animals at day 2 prior to TAI is due to a group of closely related bacteria within the uterus that can prevent or decrease the likelihood of pregnancy establishment. Limitations from this study are the small sample size and lack of contamination checks.

The study by Ault et al. [51] is one of the few studies within bovids evaluating the uterine microbiota in live animals before parturition. Moore et al. [52] sampled the entire reproductive tract of virgin heifers and pregnant

cows. This study aimed to establish that the uteri of pregnant cows and virgin heifers possessed a resident microbiota. Researchers collected the endometrial samples of 10 virgin dairy heifers via biopsies, and collected amniotic fluid, placentomes, intercotyledonary placenta, cervical lumen, and vaginal tissue from five pregnant dairy cows after slaughter. All samples generated a microbiota, leading researchers to conclude that both pregnant and virgin uteri contained a resident microbiota. They found the three most abundant phyla in both the pregnant and virgin uteri were Firmicutes, Bacteroidetes, and Proteobacteria. These results led them to conclude that the uterine microbiota is established before females reach reproductive maturity. Therefore the uterus is not a sterile environment at the establishment of pregnancy and could potentially inoculate the calf in utero [52]. However, no contamination checks were mentioned in the publication and tracts of pregnant animals were collected on a processing floor where the possibility of contamination is extremely high.

The most literature evaluating bovine uterine bacterial communities has been studied in post-partum cows to evaluate the microbial abundance/composition and the risk of developing uterine disease, such as metritis. A study by Wang et al. [53] focused on characterizing the uterine microbiota of post-partum dairy cows with clinical (CE) and subclinical (SE) endometritis. Researchers collected uterine flush samples from 13 healthy, 5 SE, and 9 CE cows at 30 days post-partum. All cows had a similar microbiota with 293 of 445 shared OTUs. Clinical endometritis was characterized by an increased abundance of *Fusobacterium* and presence of *Trueperella* and *Peptoniphilus*. SE cows had no uterine pathogens but an increased abundance of *Lactococcus* and *Acinetobacter*. This study concluded that healthy, SE, and CE cows share a similar microbiota; however, the competitive and cooperative interactions within the microbiota still need to be established to determine how to combat uterine pathogens and promote a healthy uterine microbiota.

Santos et al. [54] found that the phylum Fusobacteria was affiliated with metritic post-partum cows, but in this study, no differences were found between healthy and metritic cows. Interestingly, Jeon et al. [55] evaluated the possibility of blood introducing pathogens into the uterus post-partum. They compared bacterial communities from blood, feces, and uterine samples at day 0 and day 2 post-partum and vaginal samples at seven days prior to calving. Results of the principal coordinate analysis showed distinct clustering of blood and fecal bacterial communities, but more scattered clustering of uterine and vaginal communities indicating greater variability [55]. Additionally, major uterine pathogens were detected in blood samples and there was a strong and significant interaction of uterine pathogens and the blood microbiota. The authors concluded that in addition to fecal and vaginal microbial contaminates, uterine bleeding post-partum can lead to the introduction of pathogens to the uterus.

Researchers who evaluate post-partum uterine microbiota generally assume that any microbial populations present are contaminates that contribute to decreased reproductive performance. This is in stark contrast to the Ault et al. [51] and Moore et al. [52] studies that proposed that the presence of a commensal uterine microbiota could facilitate pregnancy. Ultimately, further research will be needed to determine if a uterine microbiota exists in bovids; these studies need to implement contamination checks similar to human studies and be cognizant of contamination throughout the entire analytical process.

Implications of the Vaginal Microbiota in Compromised Pregnancy

Literature evaluating the role of the reproductive tract microbiota in bovine pregnancies that are compromised is sparse. The negative consequence of compromised pregnancy is intra-uterine growth restriction (IUGR) of the conceptus that has negative effects both in utero and after birth. There are many mechanisms that cause IUGR, but one of the most notable and prevalent in the beef cattle industry is nutrient restriction. Therefore researchers have spent decades studying nutrient restriction, IUGR pregnancies, and potential supplements to mediate the effects of both. Despite this breadth of knowledge, the implications of the vaginal microbiota in compromised pregnancies are unknown.

IUGR is defined as the retardation of growth and development of a mammalian conceptus during pregnancy [56]. The offspring of dams that experience nutrient restriction, especially during the third trimester when the majority of fetal growth occurs, are extremely susceptible to IUGR [57]. Primarily, IUGR is caused by the limitation of uterine capacity, translating to a decrease in nutrient flux to the fetoplacental–maternal unit [58]. This results in diminished nutrient availability to the fetus. The limited nutrients available to the fetus are shunted to primary organs, the brain, and necessary physiological systems that are critical for life [59]. As a result, IUGR calves characteristically have a smaller birth weight and larger head to body ratio, and are metabolically altered throughout their life [60]. Additionally, these calves tend to be weak, struggle earlier on in life, have a higher mortality rate, and can be an economic burden to producers [61]. Therefore researchers have begun to focus on mediating the effects of

nutrient restriction during pregnancy to counteract the negative effects of IUGR on calf performance.

Although several animal models have been developed to unravel the relationship between placental capacity and IUGR, there has been limited research evaluating how the reproductive tract microbiota is affected in IUGR pregnancies. In mice, pups experiencing IUGR had alterations of the intestinal microbiota [62]. In piglets experiencing IUGR, researchers found an unbalanced gut microbiota, impaired small intestine structure, and abnormal inflammatory and metabolic profiles 12 hours after birth [63]. A model for how microbial communities could influence IUGR pregnancies in women was described by Bardos et al. [64]. They postulated that dysbiosis throughout the maternal microbiota caused by pathogens can result in systemic inflammation, including inflammation of uterine and placental tissues [64]. The inflammatory response in these tissues could lead to decreased surface area for nutrient exchange, resulting in an IUGR fetus. Overall, these studies indicate that if the maternal microbiota is in a state of dysbiosis during pregnancy, systemic inflammation could result. Furthermore, during parturition the fetus is inoculated with the dam's microbiota; thus the newborn is exposed to a potentially pathogenic microbiota which results in alterations of fetal metabolic and inflammatory responses.

Houdijk et al. [65] found that during gestation metabolizable protein becomes scarce and nutrient partitioning will prioritize protein transport to the reproductive tract instead of the immune system. Thereby, an animal that is nutrient restricted will also be immunocompromised to a certain extent. This immunocompromised state, accompanied by the already immunosuppressive state of the reproductive tract during gestation [66], provides the perfect situation for the inoculation of the vaginal microbiota with potential pathogens. If the vaginal microbiota does become inoculated with pathogenic bacteria during gestation then localized inflammation in the reproductive tract will be present, the calf will be exposed to the pathogens during parturition, and the potential for a post-partum infection is severely increased. Therefore the implications of the vaginal microbiota in IUGR pregnancies is overwhelming, yet there is a paucity in the literature.

Summary

In conclusion, the study of the microbial communities of the reproductive tract is a new and emerging area of research. Most of the published literature, especially in bovids, has limitations which negatively impacts the validity of the research. However, these studies are important for characterization of the microbiota. More studies will be needed to characterize the reproductive tract microbiota throughout the estrous cycle, pregnancy, post-partum, and any other significant reproductive events. Once characterization is completed, comparison studies can occur and perhaps mechanisms of pathogenesis will be revealed. Ultimately, the long-term goal is to determine if a certain commensal bacteria community within the bovine vaginal tract facilitates the establishment of pregnancy or if the presence of pathogenic bacteria negatively impacts fertility, fetal development, or pregnancy establishment. More research will be needed to reveal the answers to such questions, but this field has promise for furthering knowledge in reproductive physiology and improving current production methods to increase pregnancy rates and economic profitability.

Bovine Abortifacient and Teratogenic Toxins

Brittany Baughman

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

A toxicant is a material that interferes with normal biological processes and causes adverse effects when it enters the body via ingestion, inhalation, dermal contact, or injection [1]. Reproductive toxicants are those capable of causing infertility, subfertility, early embryonic death, fetal developmental deformities (teratogens), fetal death, abortion, and stillbirths. Reproductive toxicants can cause deleterious effects by acting alone or by interacting with environmental, nutritional, or infectious stressors [2]. The effect of naturally occurring toxicants as well as anthropogenic compounds on reproduction in cattle while often sporadic can have considerable economic impacts [3].

Nitrate-/Nitrite-Accumulating Plants

Ruminants, particularly cattle, are at increased risk for developing acute nitrate/nitrite poisoning from the ingestion of excessive amounts of nitrate-accumulating forages, weeds, and crops. Plants attain nitrogen from the soil in the form of nitrate and nitrite. Excessive nitrogen accumulation may occur in a variety of grasses and weeds under specific environmental and artificial conditions including increased fertilization, drought, hail, frost, herbicide damage, decreased sunlight, increased soil acidity, and in soils deficient in sulfur, phosphorus, and molybdenum. Commonly incriminated nitrate-concentrating plants include cereal grains, forage crops, and common weeds [2, 4, 5]. Nitrate accumulates greatest in the roots and lower portions of the plant including the stalks and stems due to decreased photosynthesis-dependent nitrate reductase activity at these sites [2]. Cattle may also ingest excessive nitrite and nitrate compounds directly from nitrate-based fertilizers (storage of fertilizers in areas accessible to cattle) and from water contaminated with manure or fertilizer runoff [4, 6]. A few of the more commonly implicated nitrate-accumulating weeds are Johnson grass (*Sorghum halepense*), pigweed (*Amaranthus retroflexus*), jimsonweed (*Datura stramonium*), and lamb's quarters (*Chenopodium* spp.) [6, 7]. However, a variety of other plant species have also been implicated in nitrate poisoning [4] (Table 69.1).

Pathogenesis/Mechanism of Action

Normally dietary nitrate is converted to nitrite within the reticulorumen and is slowly metabolized to ammonia. However, when present in levels that overwhelm the microbial organisms' ability to reduce them, nitrate and nitrite are rapidly absorbed into the circulation. Once in the circulation nitrite ions readily interact with hemoglobin molecules of blood, promoting the oxidation of hemoglobin iron from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state and forming methemoglobin. The methemoglobin molecule is incapable of binding and transporting oxygen molecules. Once sufficient hemoglobin is oxidized to methemoglobin, clinical signs of hypoxia develop including exercise intolerance, dyspnea, muscle tremors, and cyanotic and occasionally brown-colored membranes and blood. Although maternal methemoglobin molecules are incapable of crossing the placenta, nitrite and nitrate readily cross and can induce fetal erythrocyte methemoglobinemia and anoxia. Typically, reproductive repercussions including abortions, stillbirths, and the birth of weak calves have been reported approximately three to seven days or more following maternal toxic exposure. In addition to the effects of methemoglobinemia, nitrite and nitrates act as potent vasoactive compounds resulting in vasodilation and hypotension [2, 8].

Diagnosis

In adult cattle nitrate/nitrite poisoning may be suspected based on clinical signs including brownish discoloration of the blood and mucous membranes and a history of exposure to possible nitrate-accumulating forages [2, 4]. However, the characteristic chocolate-colored mucous membranes and blood are not always present and can become less obvious as autolysis proceeds [9].

In cases of suspect nitrate toxicosis-induced abortion, a full necropsy should be performed on the fetus to rule out other potential causes. Ocular fluid from the fetus or cow can be collected for postmortem nitrate/nitrite analysis by ion chromatography with a conductivity detector. This test can be quite reliable when fluid is collected within hours of death and refrigerated. Standard nitrate dipsticks are also available and can be used to make a presumptive diagnosis of nitrate poisoning. Ideally, nitrate levels should approach 30 ppm or greater to be highly suggestive of nitrate/nitrite-associated abortion. However, a compatible history including maternal grazing on potential nitrate-accumulating forages, or some other form of excessive maternal ingestion of nitrates, is also needed [6]. Forage nitrate analysis should also be conducted for confirmation. Forages containing greater than 0.6–1.0% nitrates (6000–10 000 ppm on a dry-matter basis) have been associated with reproductive losses (abortion, stillbirths, and weak calves) [2].

Management and Treatment

Treatment of individual animals with intravenous methylene blue in a 1 or 2% aqueous solution at a rate of 1–2 mg/kg body weight with up to 10 mg/kg in severe cases can be performed. However, due to withdrawal times, cattle should not be sold for slaughter for up to 180 days [9]. Although methylene blue treatment can be effective in individual animals, it is likely cost prohibitive in herd outbreaks. When nitrate/nitrite poisoning is suspected cattle should be removed from pasture. *Propionibacterium acidipropionici* strain P5 (a bacterial feed additive) may be supplemented if exposure to high nitrate concentrations in feed or water is unavoidable. Water should be tested when nitrate contamination is suspected from manure or fertilizer runoff. Water nitrate concentrations should be below 440 mg/l, although acute toxicity is typically not appreciated until water nitrate levels exceed 1300 mg/l. [6]

Ponderosa Pine

Ponderosa pine or western yellow (*Pinus ponderosa*) are common large coniferous trees of the pine tree family (Pinacea) found in all US states west of the Great Plains and throughout western Canada. *P. ponderosa* is characterized by 18- to 28-cm-long, yellow-green needles with two to three needles per fascicle [4, 10]. Ponderosa pine contains a number of compounds that have been associated with toxicity including phytotoxins, mycotoxins, resins, and ligands [4]. Overt toxicosis and death in cattle have occasionally been reported; however, the primary toxicological effects of ponderosa pine needle ingestion in cattle are abortion, retained fetal membranes, and metritis. Open cows, steers, and bulls appear to be unaffected by pine needle

ingestion [11]. Isocupressic acid, a labdane resin acid, is the principal abortifacient compound found in pine needles and the bark of *P. ponderosa* [12]. Two related derivatives of isocupressic acid, acetylisocupressic acid and succinylisocupressic acid, have also been found to be abortifacient following hydrolytic conversion to isocupressic acid in the rumen [13]. Other potentially abortifacient acids present in lesser amounts in ponderosa pine needles include agathic acid, imbricatolic acid, and dihydroagathic acid [14].

Cattle most often ingest early green ponderosa pine needles as well as dry pine needles from the ground in the late fall, winter, and early spring when normal forages are scarce or when they are stressed [4, 10, 11]. Ponderosa pine needle toxicity can result in late-term abortion in cows when ingested primarily during the last trimester. However, abortions have been reported as early as three months of gestation. Cattle may undergo premature parturition anywhere from 2 to 21 days following ingestion of pine needles, although occasionally immediate abortions have been reported [4, 11]. Premature parturition has been induced in cattle fed pine needles 2.2–2.7 kg/day for a period of at least three days [4, 15]. Calves may be born stillborn or premature (small and weak) depending on the stage of the gestation at the time of ingestion [16]. Affected pregnant cows develop edematous swelling of the vulva and mucoid vaginal discharge followed by premature parturition or abortion [4]. Abortions are typically characterized by weak uterine contractions, uterine bleeding, incomplete cervical dilation, dystocia, birth of weak calves, agalactia, and retained placentas. The mechanism of action of isocupressic acid on pregnancy is not completely understood [16]. However, decreased blood flow to the uterus and increased caruncular arterial tone resulting in chronic vasoconstriction of the vascular bed with subsequent fetal parturition are reported. Histologic lesions of placental tissues may include necrosis and hemorrhage secondary to vasoconstriction [11, 16].

Management and Treatment

There are no methods to completely prevent pine needle-induced abortions, although the potential impacts may be minimized. Ideally, pregnant cows should be denied access to pine needles when they are most susceptible to the abortifacient effects of isocupressic acid (third trimester). Pregnant cows should be maintained in adequate body condition when grazing ranges with ponderosa pines to reduce consumption. Adequate food and shelter should be provided for cattle to minimize stress and consumption of pine needles. Calving schedules may be changed to late spring or fall when winter weather conditions are less likely to increase pine needle ingestion [10].

There is no effective treatment for pine needle toxicosis. Supportive care including antibiotic treatment and uterine infusion in cases of placental retention is recommended for cows that abort. Supplemental colostrum and milk may be required for live premature calves [11].

Abortions similar to those caused by ponderosa pine in cattle have been associated with accidental ingestion of Monterey cypress (*Cupressus macrocarpa*) in New Zealand. Monterey cypress is a native of California that has been widely planted throughout Europe and New Zealand. Analysis of *C. macrocarpa* in New Zealand detected elevated concentrations of isocupressic acid. Isocupressic acid is also the primary diterpene acid in *Pinus contorta* (lodgepole pine), *Juniperus communis* (common juniper), Korean pine (*Pinus koraiensis*), and California juniper (*Juniperus californica*), all of which have been associated with late-term abortions in cattle. Cattle abortions have also been attributed to the ingestion of bark from the Utah juniper (*Juniperus osteosperma*) and western juniper (*Juniperus occidentalis*), both of which contain increased concentrations of agathic acid but minimal isocupressic acid [13].

Ateleia glazioviana, *Tetrapterys acutifolia*, and *Tetrapterys multiglandulosa*

Abortions and neonatal mortality in cattle have been attributed to *Ateleia glazioviana*, *Tetrapterys acutifolia*, and *Tetrapterys multiglandulosa* poisoning in Brazil. *A. glazioviana* is a deciduous tree found in western Santa Catarina and northwestern Rio Grande do Sul. Cattle may browse the leaves of this tree when other forages are scarce due to overgrazing or drought. Ingestion of leaves can cause abortions at any time during pregnancy but most occur when green leaves are ingested during the fall and winter months.

T. acutifolia and *T. multiglandulosa* are toxic shrubs that can cause significant outbreaks of abortion and deliveries of weak calves. *A. glazioviana*, *T. acutifolia*, and *T. multiglandulosa* can cause similar clinical signs and lesions. Although abortions can occur at any stage of pregnancy, reports are most often described between six and nine months of gestation. Pregnant cows become lethargic one to three days prior to abortion and occasionally exhibit blindness. Fetal lesions are similar to those observed in adult intoxications. Aborted fetuses may demonstrate subcutaneous edema of the limbs, yellow clear thoracic and abdominal effusion, and myocardial pallor with increased thickness of the right ventricular wall and interventricular septum. The toxin or toxins responsible for abortions and clinical disease in these plants have not yet been identified [17].

Enterolobium spp. and *Stryphnodendron* spp.

Stryphnodendron spp. and *Enterolobium* spp. are trees in the family Fabaceae that produce pods that when ingested have been linked to gastrointestinal signs, photosensitization, and abortions in cattle and other ruminant species in Brazil [18]. *Stryphnodendron obovatum* trees grow in the central-western region of Brazil and are considered to be one of the most important causes of cattle abortions in this region. Cattle readily ingest the fallen pods during the dry season. Abortions may occur during all stages of gestation but are often observed during late pregnancy. The abortive effects of *S. obovatum* were experimentally reproduced by feeding mature pods to seven pregnant cows that were between three and seven months of gestation. Three of seven cows aborted between 20 and 30 days following the start of the study. A fourth expelled a mummified fetus seven months following the experiment. The underlying toxic properties of *S. obovatum* pods were not identified [19]. The abortive properties of *Enterolobium contortisiliquum* have been demonstrated experimentally in guinea pigs but not in cattle [18]. *E. contortisiliquum* and *Dimorphandra mollis* (also of the Fabaceae family) are commonly blamed for abortions in Brazil although this has not yet been proven experimentally [19].

Hairy Vetch (*Vicia villosa*)

Hairy vetch (*Vicia villosa* Roth) (Figure 69.1), originally introduced from Europe as a forage legume and cover crop, can be found throughout much of the USA and in many other countries including Argentina, Australia, and South Africa [4, 20, 21]. Hairy vetch poisoning in cattle is most often associated with the development of multiorgan, granulomatous, and eosinophilic perivascular inflammation most notably of the kidney, heart, adrenal gland, and skin. Clinical findings in affected cattle most often include pruritic dermatitis, conjunctivitis, weight loss, hematuria, and diarrhea. However, reports of sporadic abortion, neurologic dysfunction, subcutaneous swelling of the head, neck, and body, multifocal ulceration of the oral mucous membranes, purulent nasal discharge, rales, cough, and pulmonary congestion have also been reported [21].

Figure 69.1 Hairy vetch (*Vicia villosa*). USDA-NRCS PLANTS Database.

Diagnosis, Mechanism of Action, and Clinical Signs

Hairy vetch poisoning in cattle is most often a diagnosis of exclusion based on clinical signs, histologic findings, and grazing history [20]. Clinical manifestations of hairy vetch toxicity typically develop weeks following ingestion of the plant. The toxic principle of hairy vetch has not been definitively determined, but the pattern and composition of the inflammatory response is highly suggestive of a type IV hypersensitivity reaction. It has been postulated that the inflammatory reaction may be caused by one or more ingested plant constituents (absorbed as haptens or complete antigens) sensitizing antigen-specific lymphocytes that then become distributed throughout the body. Subsequent exposure to these antigens presumably evokes a type IV hypersensitivity response. Another proposed mechanism of toxicity is that vetch lectins bind directly to T-lymphocytes inducing T-lymphocyte activation, lymphokine production, cytotoxicity, and the classic granulomatous inflammatory response [21]. Once clinical signs develop recovery is not promising as there is no effective treatment. Cattle do not appear to be uniformly susceptible to hairy vetch poisoning. Cattle under the age of three years appear to be less prone to clinical disease. Vetch toxicosis has been reported in multiple breeds of cattle, although Holstein and Angus breeds appear to be more commonly affected [4].

Broom Snakeweed

Broom snakeweed (*Gutierrezia sarothrae*) (Figure 69.2) is an invasive, herbaceous, short-lived, woody perennial shrub native to the western rangelands of the USA. The plant can be found from Saskatchewan and Alberta, Canada, south through western Nebraska and Kansas into Texas and central Mexico, and extending to Washington,

Figure 69.2 Broom snakeweed (*Gutierrezia sarothrae*). *Source:* Photograph courtesy of Clarence A. Rechenthin, USDA-NRCS PLANTS Database.

Oregon, California, and Baja California. Heavy growth of broom snakeweed in rangelands is often indicative of poor range management (such as overgrazing) or may be seen in times of drought or following fires [4, 22]. There are two major species of broom snakeweed, *G. sarothrae* (turpentine weed, matchweed, perennial snakeweed) and *Gutierrezia microcephala* (threadleaf broomweed). *G. sarothrae* grows up to 70 cm tall and has a woody base and branching stems with alternate linear leaves and clusters of small yellow flowers. *G. microcephala* is similar in appearance to *G. sarothrae* but has smaller flowers [4].

Broom snakeweeds are toxic and abortifacient to cattle and other livestock species (sheep and goats) [11]. Potentially toxic and abortifacient compounds in broom snakeweed include saponins, furanoditerpene acids, terpenoids, steroids, and flavones [22]. Furanoditerpene acids and flavones found in the leaves of broom snakeweed are similar to isocupressic acid, the abortifacient compound in ponderosa pine. Saponin extracts from threadleaf snakeweed induced abortion in cattle at low concentrations and death in cattle at high concentrations [11]. Abortions caused by broom snakeweed occur mainly when cattle graze during the last trimester of pregnancy [23].

Reported clinical signs include anorexia, weight loss, poor hair coat, listlessness, mucopurulent nasal discharge, abortion, diarrhea, constipation, jaundice, rumen stasis, and death. Abortions can occur throughout gestation and are often accompanied by retained fetal membranes that may lead to uterine infection. Signs of abortion include weak uterine contractions, occasional incomplete cervical dilation, and excessive discharge of vaginal mucus. Low nutrition exacerbates fertility problems caused by broom snakeweed. Supplemental nutrition may enhance degradation and elimination of terpenes. Treatment of clinically affected animals is symptomatic and may include antibiotic use in cows with retained placentas to prevent infection [4, 11].

Snakeweed is typically not very palatable to cattle and is usually only grazed when there is significant grazing pressure due to depleted vegetation. The overall palatability of snakeweed is dependent on the concentrations of plant resins (including terpenes) which accumulate over the growing season. Higher resin concentrations decrease palatability [22]. Proper range management, including providing adequate nutrition for cattle by maintaining the range in good condition, decreases the likelihood of snakeweed toxicosis in cattle. In range regions where snakeweed dominates, management strategies to control the shrub may include the use of herbicides such as Tordon® 22 K (active ingredient: picloram) and Escort® XP (active ingredient: metsulfuron methyl) or prescribed burning. Low nutrition exacerbates fertility problems caused by broom snakeweed, whereas supplemental protein and energy may enhance degradation and elimination of terpenes [11].

Sumpweed (*Iva angustifolia*)

Marshelder, also known as narrowleaf sumpweed, is a native warm-season annual found throughout the south central USA and is a member of the sunflower family (Asteraceae). Reportedly, cattle consuming large amounts of the plant may display premature mammary development, premature milk let-down, and abortion. Sumpweed is seldom eaten by cattle; however, ingestion of young plants during the two- to eight-leaf stage of development has been associated with cattle abortions during four to eight months of gestation and premature calves. The toxic agent/compound is not known [24].

Moldy Sweet Clovers

White sweet clover (*Melilotus alba*) and yellow sweet clover (*Melilotus officinalis*) are biennial legumes (family Fabaceae) commonly grown as forages in the northwestern USA and western Canada. Both species have compound leaflets with serrated edges and pea-like flowers produced on axillary racemes [4]. Ingestion of hay or silage containing spoiled sweet clover (yellow or white) can induce toxicity. Sweet clover naturally contains coumarin which may be converted to the toxin dicoumarol, a potent vitamin K antagonist, by dimerization and oxidation through the actions of fungi such as *Aspergillus*, *Penicillium*, and *Mucor* [25, 26]. Dicoumarol interferes with synthesis of vitamin K-dependent coagulation factors II, VII, IX, and X. These factors are necessary for prothrombin conversion to

thrombin, which polymerizes fibrinogen to fibrin. Impaired fibrin production causes poor stabilization of platelet plugs, predisposing affected animals to hemorrhage [26].

Clinical signs of moldy sweet clover toxicity are often non-specific and vary from excessive hemorrhage following trauma to spontaneous hemorrhages including epistaxis, melena, hemarthrosis, hematuria, and anemia. Hemorrhages typically occur several days to weeks following ingestion of moldy sweet clover. Dicoumarol levels of 20–30 mg/kg in hay are usually required before clinical disease develops [27]. Dicoumarol can cross the placenta causing fetal hemorrhage and has been associated with sporadic abortions in cattle [4, 25, 28].

Clinical signs of dicoumarol toxicity secondary to moldy sweet clover ingestion are indistinguishable from anticoagulant rodenticide toxicosis. A diagnosis of moldy sweet clover poisoning should be suspected when cattle have a history of prolonged consumption of sweet clover combined with compatible clinical signs and prolonged blood clotting times. Dicoumarol analysis of blood from affected animals (live or dead) and analysis of silage or hay can confirm the diagnosis. In cases of clinical disease, affected silage or hay should be removed. Animals demonstrating clinical signs should receive an intramuscular or subcutaneous injection of vitamin K_1 (phytonadione) at a dose of 1.1–3.3 mg/kg body weight every 12 hours for 5 days or until prothrombin time and activated partial thromboplastin time return to normal [26]. In severe cases cattle may be treated with whole blood transfusions (2–4 l of blood per 450 kg) from a donor animal not being fed moldy clover [28]. Blood transfusions are typically indicated when packed cell volumes fall below 12% [26]. Other plants containing coumarin include sweet vernal grass (*Anthoxanthum odoratum*), *Lespedeza stipulacea*, many species of Umbelliferae, and other species of *Melilotus* (melilot) [4, 26]. Herd outbreaks of dicoumarol toxicity have also been reported in cattle ingesting moldy *A. odoratum* hay or silage [26].

Teratogenic Plants

Teratogens are compounds that are capable of inducing developmental malformations or birth defects via insult to a developing fetus. The vast majority of scientific research and investigation in the field of veterinary and human teratology has involved laboratory animals due to their short gestation periods compared with livestock and due to the significant differences in cost involved with project design and the care and maintenance of large-animal subjects [29]. Many factors are involved in the development of teratogen-induced congenital defects.

Teratogen susceptibility can vary greatly among genotypes within the same species which may result in variations in incidence and severity of malformations within the same herd. In order for a teratogenic compound to exert its effect on a fetus, it and/or its metabolites must first reach the conceptus by crossing the placenta. Teratogens, like many other toxins, are dose dependent. Sufficient amounts of the toxic compounds must be ingested by the dam, absorbed into the maternal circulation, and eventually pass through the placenta to the embryo or fetus. Teratogenic compounds in sufficient quantity may result in early fetal loss (abortion or resorption) rather than congenital malformation. In order for a teratogen to cause a specific defect, it must first exert its effect at the appropriate period of time during gestation. For example, for cyclopia to develop in a fetus exposed to *Veratrum californicum*, the toxic plant must be ingested on day 14 of gestation by sheep during the stage of primitive neural plate development [29].

Astragalus and *Oxytropis* (Locoweeds)

Locoweeds, or milk vetches (Figure 69.3), include several species of plants in the genera *Astragalus* and *Oxytropis* [23]. *Astragalus* and *Oxytropis* are members of the Fabaceae (Leguminosae) or pea family. These plants are characterized by their butterfly-like flowers displaying a single large banner petal, two side petals, and two lower fused petals forming a keel. *Astragalus* and *Oxytropis* species have a worldwide distribution. Collectively, locoweeds are considered to be the most detrimental poisonous plant of cattle in the western USA and are responsible for significant economic losses [4, 30].

Figure 69.3 Milk vetch (*Astragalus* spp.). USDA-NRCS PLANTS Database.

Clinical signs of locoweed poisoning are caused by the toxic effects of the indolizidine alkaloid swainsonine found in multiple species of *Astragalus* and *Oxytropis*. Swainsonine is produced by the fungal endophyte *Undifilum oxytropis* (formerly *Embellisia oxytropis*) which can be found in the parenchymal layers of the infected plant seeds [11]. Locoweed poisoning is the chronic condition that develops in ruminants after weeks of ingesting swainsonine-containing plants. Common clinical signs of locoism include depression, incoordination, tremors, weight loss, emaciation, ataxia (staggering), altered mentation, belligerence, aggression, proprioceptive deficits, and eventually death. Reproductive failure, embryo loss, abortion, and occasional birth defects can be associated with locoweed poisoning and are often seen prior to more severe clinical signs in the cow [31].

Mechanism of Action

Swainsonine inhibits the lysosomal enzyme α-mannosidase, which is required for normal hydrolysis of mannose-rich oligosaccharides. In the absence of hydrolysis incompletely processed oligosaccharides accumulate within the cells of multiple organs and tissues resulting in a loss of cellular function and cell death [30, 31]. α-Mannosidosis is the most important acquired lysosomal storage disease in grazing livestock [32]. Microscopic lesions of locoism can be found in many organs and tissues throughout the body; however, cellular vacuolation due to accumulated oligosaccharides is reportedly most pronounced within the brain, liver, kidney, pancreas, and thyroid gland [31].

Teratogenic Effects

Sporadic outbreaks of abortion and congenital limb deformity have been reported in a number of pregnant domestic animal species including cattle, sheep, goats, and horses grazing on species of *Astragalus* and *Oxytropis*. Fetal malformations may include brachygnathia, contracture or overextension of joints, limb rotations, osteoporosis, and bone fragility. The toxic agent responsible for the fetal malformations has not been determined but is likely unrelated to those responsible for the development of lysosomal storage disease [33].

Management and Treatment

Because of the transient nature of locoism, adult animals may recover if they are promptly removed from the swainsonine-containing plants early in the course of their intoxication. Swainsonine is readily cleared from the body, making recovery rapid unless significant tissue damage is present. Although many locoweeds are not highly palatable to cattle, once forced to graze it (usually due to extreme grazing conditions) cattle may develop a preference for the plant that can lead to intoxication [11].

Other Swainsonine-Containing Plants

A number of other swainsonine-containing plant species cause livestock poisonings similar to locoweed poisoning. Some of these include *Ipomea* spp. in Brazil and Africa, *Swainsona* spp. in Australia (swainsonine was first identified in *Swainsona canescens*), and toxic species of *Ipomea*, *Sida*, *Solanum*, *Physalis*, and *Convolvulus* [11, 31]. Swainsonine-containing plants in Brazil include *Sida carpinifolia*, *Ipomea carnea* subsp. *fistulosa*, and *Turbinata cordata*. Fetal malformations and abortions with these plants are similar to those seen with swainsonine-containing locoweed [17, 32].

Other Toxic Effects of *Astragalus* spp.

Over 260 US species of *Astragalus* have been identified as nitrogen accumulators. Nitrogen-containing *Astragalus* spp. can cause both an acute form and a chronic form of nitrate poisoning in cattle. In the acute form cattle develop methemoglobinemia and respiratory distress. Chronic intoxication manifests as generalized weakness, incoordination, and other central nervous system (CNS) signs (knuckling of the fetlocks, goose-stepping, heel-clicking paralysis) and death. Methylene blue treatment can reverse methemoglobinemia in affected cattle but does not prevent mortality, indicating that the cause of death is likely attributed to other factors. Over 20 *Astragalus* species have also been identified as selenium accumulators and may induce selenium toxicosis ("alkali disease") with prolonged grazing [11].

Lupines

Lupines (*Lupinus* spp.), commonly known as blue bonnet, belong to the Fabaceae (legume) family (Figure 69.4). These perennial herbaceous plants are indigenous to North America and range throughout much of the USA. Over 100 species of lupines have been identified. Plants grow up to 1 m high. Leaves are alternate and palmately divided with 5–17 leaflets, which can be smooth or hairy depending on the species. Flowers of *Lupinus* spp. are bonnet-shaped and are present on racemes that are located on a single central stalk. Poisonous varieties of lupine responsible for cattle toxicosis in the USA are predominantly found in the Rocky Mountain region and in states located to the west of the

Figure 69.4 Silver lupine (*Lupinus albifrons* Benth). *Source:* Photograph by Pete Veilleux, East Bay Wilds.

Rockies. Lupines are typically not very palatable to cattle and are most often grazed only when other forages are not readily available [4, 11].

Three specific syndromes in livestock have been attributed to lupine toxicosis in the USA: (i) "crooked calf disease," a teratogenic condition caused by pregnant cows grazing lupines; (ii) acute fatal neurologic disease in adult cattle; and (iii) lupinosis. Lupinosis is not an alkaloid-induced toxicity but is instead caused by cattle grazing lupines infected with the fungus *Phomopsis leptostromiformis* that produces the mycotoxin phomopsin. Clinical signs of phomopsin poisoning may include severe hepatic, renal, and muscle disease in cattle and sheep [4]. Clinical signs of the neurologic syndrome in adult cattle include muscle weakness, agitation, frequent urination and defecation, depression, frothing at the mouth, relaxation of the third eyelid, muscle fasciculations, ataxia, lethargy, collapse, and sternal recumbency followed by lateral recumbency, respiratory failure, and death [11].

Maternal ingestion of toxic lupines during days 40–70 of gestation results in significant fetal malformations depending on the concentration of teratogenic compounds present in the plant [29]. Alkaloids responsible for fetal teratogenic effects (crooked calf syndrome) include anagyrine, ammodendrine, and *N*-methyl-ammodendrine [11].

The most commonly observed lupine-induced fetal malformation is arthrogryposis of the forelimbs (Figure 69.5), which may be accompanied by scoliosis, torticollis, lordosis, kyphosis, or palatoschisis (cleft palate) [11, 34]. Muscles from affected limbs are often hypoplastic or atrophied. Muscle atrophy is attributed to disuse of the affected limb(s) in utero [34]. The mechanism of action for teratogenic fetal effects is an alkaloid-induced decrease in fetal movement secondary to desensitization of skeletal muscle-type nicotinic acetylcholine receptors. Decreased or inhibited fetal movement results in skeletal malformations including skeletal muscle contractions and cleft palate formation [11].

Figure 69.5 Arthrogryposis of hindlimbs (crooked calf).

Management and Treatment

Prevention and management of lupine poisoning can be achieved by coordinating grazing periods of susceptible pregnant cows with growth stages of the plant, ensuring that susceptible pregnant cows do not graze during the flower and pod stages of growth when anagyrine concentrations are at their highest. Other effective measures may include changing the calving periods from spring to fall and by instituting intermittent grazing between lupine-free pasture and lupine-infested pasture to break the cycle of lupine ingestion. Broadleaf herbicides such as 2,4-D can also be utilized to reduce lupine numbers in heavily infested pastures, although lupine populations commonly reestablish due to the presence of resident seeds within the soil.

Treatment of clinically ill cattle involves supportive and symptomatic care. Animals displaying signs of intoxication should not be stressed and should be allowed to rest. Because the toxic alkaloids are rapidly excreted in the urine, affected adult animals will often make a full recovery within 24 hours. No treatment is available for severe fetal malformations. However, calves with mild contracture defects, of the forelimbs primarily, may recover if the elbow joint can be locked into place within one week of birth [11].

Poison Hemlock (*Conium maculatum*)

Poison hemlock, also known as European hemlock, spotted hemlock, and California fern, is a biennial perennial member of the parsley/carrot (Apiaceae, formerly Umbelliferae)

Figure 69.6 Poison hemlock (*Conium maculatum*). USDA-NRCS PLANTS Database.

family found all across the USA (Figure 69.6). *Conium maculatum* is one of the most toxic members of the plant kingdom [35]. It was originally introduced to North America from Europe as an ornamental plant and is also native to Asia but can be found throughout North and South America, North Africa, Australia, and New Zealand. Poison hemlock is a tall branched plant with distinctive purple spots along its stems, multiple small white five-petaled flowers, a single taproot, and a distinctive mousy odor [4, 31, 36].

Poison hemlock contains eight known piperidine alkaloids [36]. The two major toxic alkaloids are γ-coniceine found in immature growing plants and coniine found in mature plants and seeds [4, 31, 36]. However, all vegetative organs, flowers, and fruits contain alkaloids [35]. Alkaloid levels vary based on environmental factors (such as temperature and moisture), stage of growth, and geographic location. Fresh drying the plant in the sun for seven days results in significantly decreased levels of the toxic piperidine alkaloids [31].

Poison hemlock is highly toxic to cattle and in acute poisoning cases clinical signs may develop rapidly following ingestion (30 minutes to 1 hour). Reported clinical manifestations include depression, abdominal pain, mydriasis (dilated pupils), frequent urination and defecation, increased salivation (ptyalism), lacrimation, muscle tremors and fasciculations, incoordination and ataxia, respiratory distress, recumbency, collapse, and death. Animals surviving acute poisoning usually recover but abortions may result. The teratogenic effects of *C. maculatum* are most often appreciated in cases of chronic ingestion by pregnant cattle. However, fetal malformations have also been described in piglets and lambs [36]. Ingestion of the plant between days 40 and 70 of gestation can result in a wide array of skeletal malformations in the neonate [4]. Reported teratogenic malformations are indistinguishable from those caused by lupines and tobacco species. Fetal malformations may include torticollis (twisted neck), scoliosis (vertebral column curvature), palatoschisis (cleft palate), arthrogryposis (multiple joint contractures), and excessive flexure of the carpal joints (crooked calf disease) [35, 36].

Mechanism of Toxicity in Acute Poisoning

Conium alkaloids, specifically γ-coniceine, coniine, and *N*-methylconiine, act as non-depolarizing blockers (akin to curare) resulting in paralysis of motor nerves through their action on the medulla. It has been proposed that these alkaloids initially stimulate the skeletal muscles and produce subsequent neuromuscular blockade through their action on nicotinic receptors [4, 35, 36]. Death occurs when the phrenic nerve is affected and respiratory muscles become paralyzed [36].

Mechanism of Teratogenicity

Poison hemlock-related fetal malformations, such as joint contractures, are believed to result from fetal immobility induced by neuromuscular blockade of nerves. Palatoschisis in calves may be secondary to the loss of fetal mandibular and tongue movements, which are both required for palatal shelves to become closer in the developing fetus. In the absence of jaw and tongue movements, the tongue permanently occupies the site where palatal shelves should fuse [36, 37].

Management and Treatment

Treatment of poison hemlock toxicosis relies largely on supportive care. In cases of acute toxicity, gastric lavage and activated charcoal treatment may be performed on individual animals. Control of the weed can be managed through the use of broadleaf herbicides, although populations will reestablish via seed reserves in the soil [11].

Tobacco Poisoning

Nicotiana glauca (tree tobacco), *Nicotiana tabacum* (cultivated tobacco), *Nicotiana trigonophylla* (wild or desert tobacco), and *Nicotiana attenuata* (wild or coyote tobacco) are members of the nightshade (Solanaceae) family. Wild tobacco varieties are indigenous to the southwestern USA while cultivated tobacco grown in the USA is predominantly raised in the southeastern states. Tobacco is an

herbaceous branching annual that grows between 0.3 and 1.2 m in height, with hairy stems and leaves and fragrant tubular flowers with five parts. Tree tobacco (*N. glauca*) is an evergreen shrub or small tree growing 2–6 m tall with alternate bluish-green hairless leaves. Flowers are 5 cm long, tubular, and produced on the leafless branches [4].

Tobacco contains numerous alkaloids (over 40), most of which are neurotoxic pyridine alkaloids including nicotine. Animals may become intoxicated by grazing the plant or ingesting cut stalks [38]. In adult cattle clinical signs of acute toxicity may include excitation, followed by depression, respiratory failure, and death in severe cases. Treatment of affected animals is symptomatic. The principal toxins responsible for tobacco toxicosis in cattle are nicotine and anabasine. *N. glauca* produces the piperidine alkaloid anabasine, a potent nicotinic acetylcholine receptor agonist. Anabasine is acutely toxic as well as teratogenic [38]. Ruminants are relatively more tolerant of the neurotoxic alkaloid effects of nicotine. However, the teratogenic anabasine can induce fetal skeletal malformations including arthrogryposis, palatoschisis, torticollis, lordosis, and kyphosis. Fetal defects resulting from tobacco intoxication occur when cattle ingest the plant between days 30 and 60 of gestation.

The fetal malformations caused by tobacco toxicosis are indistinguishable from those induced by poison hemlock, locoweeds, and lupine poisoning. This similarity of teratogenic fetal malformations is attributed to the analogous molecular structures of anabasine and coniine (principal toxin of *C. maculatum* and lupines) and its analogs [4].

At low doses anabasine stimulates depolarization of postsynaptic membranes of ganglia and at high does causes neuromuscular blockade. Like poison hemlock and lupine toxicosis, the mechanism of teratogenicity is believed to be caused by the neuromuscular blockade of nerves and subsequent decrease in intrauterine fetal movement resulting in the development of joint contractures, palatoschisis formation, and other skeletal malformations [39, 40]. In acute toxicosis, cattle should be removed from contaminated fields or pastures. In severe cases, supportive and symptomatic treatment is recommended for affected animals and may include gastric lavage [28].

Veratrum californicum (False Hellebore)

V. californicum grows in dense, sharply defined stands in high moist meadows or hills [29]. Individual plants grow approximately 2–3 m tall and have short rootstalks and alternate smooth, broad, parallel-veined oval leaves that are present in three ranks. Numerous toxic alkaloids have been identified in *V. californicum*; however, the jervine alkaloids including cyclopamine, jervine, and cycloposine are associated with the plant's teratogenic effects [4, 39]. Among the toxic alkaloids, cyclopamine is present at the highest levels and is the principal teratogenic alkaloid [29].

Teratogenic effects are predominantly seen in sheep but fetal malformations have also been reported in goats and cattle [33]. The teratogenic alkaloids exert their effects by interfering with the sonic hedgehog (SHH) signal transduction pathway, by inhibition of neuroepithelial cell mitosis and migration, and by decreasing chondrocyte proliferation. In pregnant ewes, ingestion of *V. californicum* on days 12–14 of gestation (most notably day 14) results in cyclopia and prolonged gestation. Embryo death can result from maternal exposure on days 19–21. Cleft palate results from maternal exposure on gestational days 24–30 and metacarpal and metatarsal defects occur when ewes are exposed on days 28–31 of gestation [39].

Ingestion of *V. californicum* in pregnant cows between days 12 and 30 of gestation may cause fetal malformations, including cleft palate, harelip, brachygnathia, hypermobility of the hocks, syndactyly, and decreased numbers of coccygeal vertebrae. When pregnant cows ingest the plant in later stages of pregnancy (days 30–36), teratogenic alkaloids inhibit growth in length of metacarpal and metatarsal bones [33].

There is no specific treatment for *V. californicum*-induced fetal malformations. However, malformations can be prevented by removing pregnant animals from *V. californicum*-infested pastures and ranges during the first trimester of pregnancy [4].

Mimosa spp.

Mimosa tenuiflora and *Mimosa ophthalmocentra* are perennial trees or small shrubs native to Brazil. *M. tenuiflora* and possibly *M. ophthalmocentra* (Fabaceae, Mimosoideae) can induce fetal malformations and embryonic death in goats, sheep, and less frequently cattle. Affected calves, lambs, and kids may be born with an array of malformations, which can include arthrogryposis, micrognathia, cheiloschisis (harelip), palatoschisis, kyphosis, lordosis, torticollis, blindness, microphthalmia, corneal opacity, ocular dermoids, acephaly, bicephaly, hydranencephaly, glossal hypoplasia, meningocele, and syringocele. The toxic principle of *M. tenuiflora* is unknown, but tryptamine-derived alkaloids have been isolated from the leaves and seeds [17].

Mycotoxins

Mycotoxins are naturally occurring compounds or secondary metabolites produced by fungi that cause deleterious effects (mycotoxicoses) when ingested or when susceptible animal species are exposed to them. Mycotoxisosis in livestock occurs when animals graze on infected grasses or crops or are fed infected grains. Chemical analysis via thin-layer chromatography, gas and high performance liquid chromatography, and mass spectrometry can accurately detect the concentrations of various mycotoxins in properly collected and prepared samples [41, 42].

Ergot Alkaloids

Ergot alkaloids include more than 80 indole compounds and are associated with two mycotoxicoses in livestock species: fescue toxicosis and ergotism [2]. Both conditions may share similar clinical manifestations and in many cases may be indistinguishable from one another [43]. Ergot alkaloids are produced by the mold *Claviceps purpurea* on wheat, rye, and other cereal grains and by the endophyte *Neotyphodium coenophialum* growing on tall fescue (*Lolium arundinaceum* [Shreb]). Ergot alkaloids have similar molecular structures to the biogenic amines norepinephrine, serotonin, and dopamine and act as agonists at various serotonin receptors [44, 45]. This agonistic effect is thought to be responsible for clinical manifestations of ergot alkaloid toxicosis. In both fescue toxicosis and ergotism the principal ergot alkaloid believed to be most responsible for clinical disease is ergovaline. Ergovaline is a potent α_2-adrenergic agonist on arterioles and other blood vessels causing vasoconstriction [42].

Tall Fescue

Fescue toxicosis is a costly grass-related intoxication of livestock in the USA and throughout many other countries. Fescue toxicosis is a descriptive term used for several clinical syndromes (summer slump, fescue foot, and fat necrosis) attributed to ingestion of endophyte-infected tall fescue [42].

Tall fescue (*L. arundinaceum* [Shreb]) is a cool-season perennial grass grown in temperate climates and is one of the most abundant forage crops in the continental USA [46]. In cases of fescue toxicosis, livestock ingest the fungal endophyte *N. coenophialum* (formerly *Acremonium coenophialum* and *Epichloe typhina*) that grows within the intercellular spaces of the leaf sheaths, stems, and seeds of tall fescue grass [2]. Tall fescue and its endophyte *N. coenophialum* share a mutually beneficial relationship. The endophyte produces toxins (ergot alkaloids, loline alkaloids, and peramine) that are distributed throughout the plant, making it more resistant to drought, parasitism, and fungal infection [42]. The endophyte of tall fescue produces an array of ergot alkaloids but ergovaline is the primary ergopeptine alkaloid believed to be responsible for inducing toxicosis. Ergot alkaloids are highly concentrated within the seeds of tall fescue and levels are greatest in the summer and early fall when seed heads are present [46]. Drought and rainy conditions as well as fertilization with nitrogen- and phosphorus-based fertilizers tend to increase ergovaline concentrations [42].

Several syndromes including summer slump, fescue foot (Figure 69.7), and fat necrosis (lipomatosis) are associated with fescue toxicosis in cattle. The most costly of the three is summer slump. As the name implies, clinical manifestations of this condition are most often appreciated in summer months when the ambient temperature is above 31 °C [42]. Affected cattle typically have a rough hair coat, unthrifty appearance, reduced feed intake, decreased milk production with lower weaning weights of calves, reduced conception rates, agitation/nervousness, ptyalism, and increased respiratory rates [42, 47].

Mechanism of Action

Ergot alkaloids are dopamine D_2 receptor agonists and mimic the endogenous tonic inhibition of pituitary lactotropes by dopamine, thereby inhibiting prolactin secretion from the anterior pituitary gland [42]. Decreased serum prolactin is a relatively consistent finding in livestock feeding studies involving ergot alkaloid-infected forage. Therefore serum prolactin concentrations may be utilized as a diagnostic indicator of endophyte toxicosis [48].

Reproductive Effects

The hormone prolactin plays an important role in mammary gland growth, milk production, corpus luteal function, gonadotropin secretion, lipogenesis, copper homeostasis, and immune modulation. Decreased prolactin production caused by the D_2 dopaminergic effects of ergovaline and other ergot alkaloids can cause agalactia at parturition, most notably in horses. Cattle and other ruminants produce a placental lactogen that can overcome the initial lack of prolactin stimulation at the time of parturition. However, lower concentrations of prolactin coupled with decreased feed intake can cause decreased milk production in these species [42]. Prolactin also plays an important role in gonadotropin secretion and corpus luteal function and development. Decreased concentrations of luteinizing hormone and prostaglandins have been documented in animals exposed to ergot alkaloids [48]. Ingestion of endophyte-positive fescue and ergopeptide exposure has been associated with low progesterone production in cattle and horses. Decreased progesterone, as well as other imbalances in reproductive hormones, can result in difficulty maintaining early pregnancy in cattle and in late pregnancy problems in mares [42].

In addition to their dopaminergic effects, ergot alkaloids act as potent serotonergic agonists and α_2-adrenergic agonists on blood vessels, particularly arterioles. Peripheral vasoconstriction of vessels is believed to contribute to the hyperthermia exhibited in some cases of summer slump in the warm summer months along with dysregulation of the hypothalamic thermoregulatory center due to decreased prolactin secretion. In winter months, toxicosis may result in fescue foot, a condition caused by peripheral vasoconstriction of vessels of the distal limbs secondary to the combined effects of ergovaline and cold environmental temperatures. The tail switch and ear tips as well as the distal limbs (most often the hindlimbs between the coronary band and fetlock) may also be affected [42].

Management and Treatment

Cattle experiencing clinical signs of summer slump should be removed from endophyte-contaminated pasture or their diet should be diluted by feeding supplemental grain or nonfescue forages [42]. Cattle with gangrenous dermatitis (fescue foot) can be treated with antibiotics to prevent secondary infections. Shelter or wind breaks may be beneficial in minimizing the effects of cold weather. Domperidone, a D_2 dopamine antagonist, is used to treat fescue toxicosis in mares with agalactia and prolonged gestation. Experimentally, domperidone has been shown to ameliorate some clinical signs of fescue toxicosis in heifers, including reversal of decreased weight gain and increased circulating concentrations of progesterone. These results suggest that treatment of cattle with fescue toxicosis may have clinical and economic merit [49].

Ergotism

Ergot is a general term referring to a group of parasitic fungi belonging to the genus *Claviceps*, most notably *C. purpurea*, that infect rye, barley, wheat, oats, and other cereal grains [44]. Infection of grains with *C. purpurea* results in colonization of the grain ovary wall or base with fungal mycelia. The mycelia produce a sticky exudate called honeydew containing conidia (asexually produced spores). Following germination within the hardened honeydew (sclerotia), conidia can be transferred to and infect other seeds by insect vectors or direct contact [44, 45]. Signs of ergotism – the various toxic effect(s) of ergot alkaloids produced by *Claviceps* spp. – develop secondary to the ingestion of toxic levels of ergot-infected grains [44].

Clinical signs of ergotism are primarily caused by the ergopeptine class of ergot alkaloids, which include ergotamine, ergocristine, ergosine, ergocornine, ergocryptine, and ergovaline. Ergot alkaloids act as serotonin receptor agonists due to the similarities of their molecular structures with the biogenic amines dopamine, serotonin, and histamine [44, 45]. Vasoconstriction results from the agonistic activity of ergot alkaloids. Other potential effects include uterine stimulation and dopaminergic activity at D_2 receptors resulting in decreased prolactin secretion [45]. Documented cases of ergotism in the USA are uncommon because milling and cleaning processes are successful in removing ergot-infected grains [41].

Ergot alkaloid toxicity is known to cause four distinct disease forms in livestock: (i) cutaneous and gangrenous lesions on the tail and extremities, (ii) hyperthermia and production loss, (iii) reproductive failure, and (iv) the less common and frequently debated neurologic form [2, 45]. The gangrenous form of ergot poisoning represents the chronic form of intoxication by ergot-producing fungi. Clinical signs of gangrenous ergotism include acute lameness with swelling and hyperemia. Lesions present most often in the rear limbs, although all four limbs may be affected in some cases; however, necrosis is usually restricted to below the fetlock but occasionally extends to the metatarsals [20]. Vasoconstriction of small arteries and arterioles due to the potent α_2-adrenergic agonistic effects of ergovaline causes ischemia and necrosis of the distal limbs, ear tips, and the distal third of the tail. This gangrenous form is most often associated with winter months due to exacerbation of the vasoconstrictive effects by cold

weather [45]. The hyperthermic form of the disease is the most commonly reported form of ergotism and is seen most often in summer months when the weather is warm [44]. The neurologic form of ergotism appears to be rare and may be associated with acute intoxication with large doses of ergot alkaloids [45].

Management and Treatment

When ergotism is suspected, infected grains should be removed. No effective treatment is available for ergotism in cattle, although animals with the hyperthermic form should recover given time [45].

Aflatoxins

Aflatoxins (B_1, B_2, G_1, and G_2, named for their respective blue or green fluorescence under ultraviolet light) are a group of structurally related difuranocoumarin compounds produced primarily by *Aspergillus flavus* and *Apergillus parasiticus*. Aflatoxins can be found throughout the world and can commonly contaminate animal feed and crops in warm subtropical and tropical climates under appropriate conditions [40, 41, 43]. Grains stored under high moisture (>14%), at warm temperatures (>20 °C), or those improperly dried are at risk of becoming contaminated [50]. *A. flavus* strains invade damaged plant tissue and predominantly produce aflatoxin B_1 which is considered to be the most toxic and carcinogenic aflatoxin [43].

All animals are susceptible to the toxic effects of aflatoxins, although differences in species sensitivities do exist. Susceptibility can vary with breed, age, dose, nutritional status, and length of exposure [50]. Cattle and other ruminants are considered to be relatively resistant in comparison with monogastric species. However, young calves are at greater risk of developing clinical toxicosis compared with adult animals [43].

Aflatoxins are primarily hepatotoxic but can also have immunosuppressive, carcinogenic, mutagenic, and teratogenic effects [43]. Some aflatoxins have been shown to cross the placenta in laboratory animals and humans. Decreased male fertility via decreased spermatozoa production, embryo loss, fetal death, and possible teratogenic effects have been reported with aflatoxicosis, most notably with aflatoxin B_1 and G_1 in animals [51]. Abortions in cattle are uncommonly reported with aflatoxicosis, but sporadic herd outbreaks have been attributed to ingestion of feeds contaminated with aflatoxin B_1, B_2, G_1, and G_2 [43]. However, the negative reproductive impacts do not appear to be due to any direct activity of aflatoxins in the oocyte or embryo but instead are attributed to altered maternal homeostasis [41].

Treatment

There is no specific treatment for aflatoxicosis. Instead treatment of affected cattle involves supportive and symptomatic care. Contaminated feed should be removed and replaced with aflatoxin-free feeds [51].

Zearalenone

Zearalenone is a potent estrogenic mycotoxin produced by the fungus *Fusarium graminearum* and multiple other species of *Fusarium*. Zearalenone contaminates cereal grains including corn and to a lesser extent wheat, barley, sorghum, millet, rice, and oats under specific environmental and storage conditions [39]. Zearalenone can have profound effects on reproductive function due to its estrogenic actions. Clinical signs attributed to zearalenone toxicity are most often reported in swine, although signs may also be observed in ruminant species as well. Clinical signs of zearalenone toxicity mimic those of estrogenic stimulation and can include decreased fertility, abnormal estrous cycles, vulvar swelling, vaginitis, reduced milk production, and mammary gland enlargement. Heifers appear to be more susceptible to the effects of zearalenone than adult cows [41, 52]. However, in pregnant cows the potential for abnormal embryonic or fetal development with possible fetal death, abortion, and dystocia exists [2].

Zearalenone and its derivatives (α- and β-zearalenol) are believed to exert their toxic effects by competitively binding to specific estrogen receptors and by modification of steroid metabolites. Zearalenone and α- and β-zearalenol have chemical structures closely resembling naturally occurring estrogen [53]. Zearalenone and its metabolites can directly bind with cytoplasmic estradiol-17β receptors and translocate receptor sites to the nucleus where stimulation of RNA leads to protein synthesis and clinical signs of estrogenism [52]. β-Zearalenol appears to be the predominant zearalenone metabolite in cattle as opposed to α-zearalenol which predominates in most other species including swine [2].

Treatment

Treatment of zearalenone intoxication relies on removal of contaminated feedstuff and replacement with high-quality clean feeds. Clinical signs will typically resolve within three to seven weeks. Prevention of *Fusarium* spp. growth and subsequent zearalenone production can be achieved by maintaining low moisture concentrations (15–16%) [52].

Phytoestrogens

Phytoestrogens are biologically active non-steroidal plant compounds that are similar in structure or function to mammalian estrogen and can compete for estrogen receptors on cells [4, 54]. Plant estrogens can have broad effects on both human and animal populations. Phytoestrogens are found in a number of legumes including alfalfa (*Medicago sativa*), soybeans (*Glycine max* L.), red clover (*Trifolium pratense*), subterranean clover (*Trifolium subterraneum*), white clover (*Trifolium repens*), aslike clover (*Trifolium hybridium*), and burr medic (*Medicago* spp.) among others [4, 39, 55].

Concentrations of phytoestrogens in plant material can vary significantly. Estrogenic compounds are often produced in response to environmental or physiologic plant stressors such as fungal infection, insect infestation, and animal predation. Phytoestrogen concentrations have also been shown to increase in cool wet conditions [54].

Over 100 phytoestrogen molecules have been identified. Phytoestrogens are subdivided into broad categories based on their chemical structure. Categories of phytoestrogens include isoflavones, flavones, coumestans, stilbenes, and lignans [54, 56]. Isoflavone compounds can be found in high concentrations in soybean, red clover, and white clover. Coumestrol (potent estrogenic phytoestrogen) can be found in alfalfa as well as white clover and soybean sprouts [54]. Stilbenes are found in cocoa- and grape-containing products and lignans are prevalent in flax seed [56, 57].

Once ingested, phytoestrogens are absorbed in the rumen by resident microbial activity. Because of structural similarity with endogenous hormones, phytoestrogens can bind to nuclear receptors [56]. Although phytoestrogens may mimic estradiol-17β (E2), their effects may not always be similar [58]. The affinity phytoestrogens have with ERα receptors and ERβ receptors is relatively weak in comparison with endogenous E2 [56]. However, phytoestrogens can be present in much higher concentrations in the body (as much as 100-fold higher) than endogenous estrogens, allowing for potentially profound effects. Phytoestrogens may exert agonistic, partial agonistic, or antagonistic effects depending on the concentration of E2 [56, 57].

The toxic effects of phytoestrogens are dependent on dose, route of exposure, duration of exposure, and timing of exposure [57]. Organ systems in young animals appear to be more sensitive to phytoestrogens than adults. Cattle infertility has been reported in herds fed red clover silage containing isoflavones and alfalfa-containing coumestans [58]. However, cattle appear to be less sensitive than sheep to the phytoestrogenic effects of clover forages [54]. The effects of high concentrations of phytoestrogens may include clinical signs of hyperestrogenemia (nymphomania, cystic ovaries, swollen genitalia, infertility, impaired pregnancy maintenance) or antiestrogenic effects such as gonadal hypoplasia and signs of anestrus, depending on the action of the phytoestrogen on estrogenic receptors.

Uterine endometrial release of prostaglandin (PG)$F_{2\alpha}$ is regulated by oxytocin, progesterone, and estradiol (E2) in ruminants and induces luteolysis and corpus luteum regression. In a study conducted by Mlynarczuk et al. [55] the phytoestrogens coumestrol, daidzein, and genistein were shown to stimulate the genes responsible for synthesis of oxytocin precursors (neurophysin-I/oxytocin) and post-translational synthesis of oxytocin, PGA (peptidyl-glycine-α-amidating monooxygenase) in granulosa cells, and luteal cells in cattle. These phytoestrogens stimulated oxytocin secretion from the ovarian follicle and corpus luteum. It is speculated that phytotoxin-induced oxytocin release during early pregnancy or implantation may result in early luteolysis, formation of persistent corpus luteum, and subsequent impaired pregnancy maintenance and early embryonic death [54, 55].

Management and Treatment

In order to prevent or minimize potential reproductive problems, forages can be analyzed for isoflavones and coumestrol concentrations and feeds containing low or no levels can be substituted for high phytoestrogen-containing forages. Once phytoestrogen-affected forages have been eliminated from cattle rations, animals will typically resume normal reproductive cycling within a period of four to six weeks [54].

Trace Minerals and Heavy Metals

Heavy metals and trace minerals are common environmental contaminants and when present in sufficient levels can cause significant health and reproductive impacts in domestic livestock. Heavy metals include elements that under appropriate conditions play a necessary role for normal body function, such as iron, copper, zinc, and chromium, as well as toxic elements that have no biological functions. Many minerals are crucial for animal health, survival, and production due to the essential roles they play in the physiological, structural, and regulatory functions of the body. However, ingestion of excessive amounts of minerals may lead to acute poisoning or chronic poisoning, when animals ingest lower concentrations over prolonged periods of time [59].

Potentially toxic heavy metals include lead, mercury, cadmium, chromium, arsenic, and nickel. Environmental

pollution with trace elements, toxic metals, and metalloids is often attributed to mining, industrial wastes, urbanization, and intensification of farming practices (pesticide and herbicide activity). Transfer of heavy metals from contaminated soils into plants and successive levels of the food chain can be a significant health risk in both animals and humans. Clinical manifestations of trace mineral and heavy metal intoxication can vary depending on the element involved, health of the animal, and degree of exposure. Several heavy metals have been identified as potentially teratogenic and abortifacient in animals [60]. However, in cattle the most commonly reported heavy metal toxicities involve lead and arsenic.

Arsenic

Arsenic (As) is a ubiquitous metalloid element present in multiple forms, the most common oxidative states being the As^{3+} and As^{5+} valence forms [61]. Arsenic can be found in both organic and inorganic forms, although inorganic arsenite is the most toxic form of the element.

Arsenic is predominantly used in the manufacture of pesticides, wood preservatives, glass, alloys, semiconductors, and pharmaceuticals. Environmental contamination of arsenic has been attributed to smelting of lead, copper, and nickel, combustion of fossil fuels, manufacturing of arsenic-containing compounds, and overuse or improper storage of arsenic-containing herbicides and insecticides [62].

Peracute exposure to large doses of inorganic arsenic is often fatal and may result in death within minutes to hours depending on dose. Clinical signs of acute toxicosis may be profound and include colic, bloody diarrhea, neurologic signs such as ataxia and incoordination, weakness, and collapse followed by death. Gross postmortem lesions in cattle may include abomasal hyperemia, increased intraluminal intestinal fluid, edema of the rumen, omasum, reticulum, and abomasum, ruminal mucosal necrosis, and gastrointestinal hemorrhage [61].

Mechanism of Action

Absorption of arsenic compounds depends on the particle size and its aqueous solubility. Soluble forms of arsenic are readily absorbed via both passive and active means [61, 62]. In pregnant animals, inorganic arsenic crosses the placenta and accumulates in the neuroepithelium of the developing fetus. Organic arsenic accumulates in the placenta but does not appear to cross the membrane. Laboratory animal studies have demonstrated the embryotoxic effects of high doses of inorganic arsenic, with development of teratogenic defects such as cleft palate, encephalocele, microphthalmia in hamsters and failure of limb bud development, prosencephalon hypoplasia, and somite abnormalities in rats and mice exposed during early gestation. Arsenic at lower concentrations can also have significant placental and fetal toxic effects [40, 62]. However, reports of abortion in cattle with subclinical or chronic arsenic toxicosis are sporadic.

Diagnosis, Treatment, and Prevention

A presumptive diagnosis of arsenic toxicosis is often based on an appropriate clinical history of exposure and suspicious clinical signs. Necropsy lesions can also be suggestive. However, definitive diagnosis requires demonstration of elevated liver and kidney arsenic concentrations. Arsenic levels of approximately 8–10 ppm in fresh liver and kidney and 2–4 ppm in liver and kidney from autolyzed carcasses (several days old) are diagnostic.

Early recognition and medical intervention is imperative for successful treatment of arsenic intoxication cases. In cattle not showing clinical signs, gastric lavage with a saline purgative and 20–30 g sodium thiosulfate administered orally or intravenously in a 10–20% solution may be effective. Injection of dimercaprol 1.5–5 mg/kg intramuscularly (IM) two to four times daily for 10 consecutive days should also be administered if over four hours have elapsed since time of exposure. Additional treatment with sodium thiosulfate 30–40 mg/kg intravenously (IV) two to four times daily until recovery (typically two to four days) is also recommended [61].

Cadmium

Cadmium (Cd) is a divalent transition metal with chemical properties similar to those of zinc [63]. Unlike many minerals, cadmium has no essential physiologic or biochemical function in the body and is highly toxic to animals and humans [59]. Cadmium compounds are widely utilized in industrial applications. They are used in iron and steel plating and can be found in batteries, semiconductors, solders, plastic stabilizers, and solar cells. Environmental contamination of water and soil is often secondary to industrial pollution. Cadmium may enter the environment from steel and iron production, zinc refining and smelting, mine wastes, coal combustion, improper battery disposal, and the use of sewage sludge and rock phosphate as fertilizers [63]. Batteries are considered to be one of the most common sources of cadmium intoxications in cattle in the USA. However, phosphate fertilizers and sewage sludge are also important sources of cadmium toxicosis in cattle [64].

Some plants readily accumulate cadmium from contaminated soil, making it available for consumption by grazing animals [59, 63].

Cadmium, once ingested, is primarily absorbed through the respiratory system and digestive tract and accumulates mainly within the liver and kidneys. Gastrointestinal absorption of cadmium is much less than other divalent cations (zinc and iron). However, intestinal absorption can be increased in animals with iron deficiency. Following absorption, the metal circulates either in red blood cells or bound to albumin in the plasma. Cadmium interacts with the metabolism of essential minerals such as calcium, zinc, iron, copper, and selenium. Cadmium ions can displace divalent metals such as zinc from their binding sites on metallothionein (major metal-binding protein) [63, 64]. Metallothionein functions in cadmium detoxification through high-affinity binding with the mineral that results in a toxicologically inert compound [59, 64]. Cadmium along with other heavy metals (Cu, Zn, and toxic mercury) induces metallothionein synthesis in multiple organs including the liver and kidneys. However, because metallothionein's action is limited, excessive amounts of cadmium ingested acutely or over time can exceed metallothionein's ability to bind it and significant multiorgan damage can develop [59]. In the liver, cadmium toxicity results in hepatocellular apoptosis and necrosis [63]. High levels of dietary cadmium can cause decreased feed intake, poor weight gain, anemia, decreased bone absorption, and abortions [64]. There is no specific treatment for cadmium poisoning in livestock and therefore exposure should be minimized or prevented in the environment and in feeds [63].

Lead

Lead poisoning in cattle often results from environmental contamination. Cattle may become acutely intoxicated from the ingestion of large quantities of lead-containing materials, licking old storage batteries, licking or ingesting lead-containing paint chips on outbuildings or from discarded paint cans, eating lead-containing lubricants, and drinking water from lead-containing water pipes [6]. Chronic exposure most often occurs from ingesting forages grown on polluted pastures in the vicinity of mines or industrial sites.

Only about 2–10% of ingested lead is absorbed by the digestive tract and distributed throughout the body [6]. Absorbed lead is slowly excreted in bile, milk, and urine and is deposited in tissues, predominantly in the kidney, liver, brain, and bone.

Lead induces toxic effects via multiple mechanisms including combining with calcium- and zinc-binding proteins, random hydrolysis of nucleic acids, and by inducing RNA catalysis via activation of ribosomal 5S RNA [65]. Lead interferes with protein/hemoprotein biosynthesis, inhibits mitochondrial and membrane enzymes, and causes deficits in cholinergic, dopaminergic, and glutamatergic functions [40]. Lead disrupts calcium homeostasis, causing the accumulation of calcium in lead-exposed cells and mitochondrial release of calcium inducing apoptotic cell death.

In adult cattle acute toxicity typically causes death within 12–24 hours. When poisoning is less acute animals may survive four to five days. Clinical signs may include cortical blindness, delayed menace response, delayed withdrawal reflex, decreased glossal tone, ptyalism, frothing at the mouth, champing of the jaws, respiratory difficulty, tachycardia, ataxia, head pressing, convulsions, circling, and recumbency. Signs of subacute poisoning may include depression, anorexia, bruxism, colic, diarrhea, ruminal atony, CNS signs, and abortion [40, 65].

Lead readily crosses the placenta and can pass through the immature blood–brain barrier of developing fetuses where it concentrates in the CNS [6, 40, 65]. Lead can also accumulate in the placenta during times of fetal stress. The toxicity of lead is primarily attributed to its ability to mimic and substitute calcium. Effects of lead on the developing fetus have been demonstrated in laboratory animals and may include growth retardation, reduced fertility, neural tube defects, brain defects, urogenital defects, and tail defects [39, 65].

Diagnosis

Antemortem diagnosis of acute lead poisoning should be based on a history of exposure, clinical signs, and blood lead concentrations greater than 0.35 μg/ml. Hematologic abnormalities may also be indicative of lead toxicity and may include anemia, anisocytosis, poikilocytosis, polychromasia, basophilic stippling, metarubricytes, and hypochromia. Postmortem gross and histologic lesions in cattle are non-specific and therefore definitive diagnosis relies on the clinical history and liver and kidney lead concentrations [2]. Acid-fast positive lead inclusion bodies within nuclei of proximal renal tubular epithelial cells may be observed in some cases, although the presence of these inclusions is variable. Brain lesions are usually absent, but mild to moderate brain swelling may be appreciated along with vascular congestion. In select cases of subacute lead poisoning laminar cortical necrosis may be observed [66].

Treatment

In cattle, chelation with calcium disodium edetate (Ca-EDTA) is the preferred option. It may be administered

intravenously or subcutaneously at a dose of 110 mg/kg daily divided into two doses for two to three days and then repeated two days later. Thiamine may also be utilized as an adjunct to Ca-EDTA treatment in ruminants; in adult cattle a dose of 250–2500 mg/day is recommended and for calves 2 mg/kg daily. Cathartics such as magnesium sulfate (400 mg/kg per os [p.o.]) may be administered or a rumenotomy may be performed to remove larger ingested lead sources but is rarely successful in cases of particulate lead ingestion. Convulsions may be controlled by barbiturates or tranquilizers. Withdrawal times in cattle may be greater than one year and can be estimated by periodically monitoring blood lead concentrations [28].

Selenium Toxicosis

Selenium poisoning is most commonly attributed to (i) ingestion of selenium-concentrating plants grown in soils high in selenium content; (ii) accidental overdoses of selenium from ingestion of improperly mixed rations or injections; and (iii) environmental contamination due to either plant accumulation or water contamination [67]. Selenium is a non-metallic element that is an important antioxidant but can be toxic in excessive amounts. Naturally occurring selenium toxicosis is most often a regional problem in the western USA between the Rocky Mountains and the Mississippi River. Grains and forages grown in high-selenium regions may passively accumulate toxic levels of selenium, causing chronic toxicosis in herbivores [68]. The toxic dose of selenium in ruminants is unclear. References range from 2.2 to greater than 20 mg/kg body weight across species [67]. Table 69.2 lists common obligate selenium-accumulating plants and potential secondary selenium- accumulating plants.

Table 69.2 Selenium-accumulating plants of the USA.

Obligate selenium-accumulating plants
Milk vetches (*Astragalus* spp.)
Golden weeds (*Conopsis* spp.)
Woody aster (*Xylorhiza* spp.)
Princes plume (*Stanleya pinnata*)
Secondary selenium-accumulating plants
Acacia (*Acacia* spp.)
Sages (*Artemisia* spp.)
Asters (*Aster* spp.)
Saltbrush (*Atriplex* spp.)
Paintbrush (*Castilleja* spp.)
Bear tongue (*Penstemon* spp.)
Gumweed (*Grindelia* spp.)

Source: Adapted from [4].

In adult cattle clinical signs of acute selenium toxicosis may include respiratory distress, lethargy, restlessness, anorexia, watery diarrhea, pyrexia, teeth grinding, ptyalism, stilted gait, tetanic spasms, and death. Signs have been reported as early as 8–10 hours following exposure or as late as 36 hours. In cases of chronic selenium toxicosis ("alkali disease") resulting from long-term ingestion of seleniferous forages, clinical signs including depression, weakness, anorexia, weight loss, emaciation, diarrhea, anemia, hair loss, hoof deformities, and lameness may be observed [67, 68]. Reproductive abnormalities secondary to clinical and subclinical selenium toxicosis have been reported in multiple domestic species including cattle. However, a clear association between selenium toxicosis and abortion is not well documented. Reproductive abnormalities including decreased conception rates and increased fetal resorption rates were documented in cattle, sheep, and horses fed diets containing 20–50 mg selenium/kg [67].

Selenium is efficiently transferred across the placenta into fetal tissues, most notably the liver, during gestation. Excessive selenium concentration in the fetus may be teratogenic and abortifacient. Selenium levels in the fetal liver have been reported to reach as high as eight times that of the dam. Normal fetal hepatic selenium concentrations are reported to be 0.3–1.2 ppm. In a study conducted by Yaeger et al. [68] high fetal liver levels (3.47–5.25 ppm) were present in clinically healthy calves, so concentrations above 3.0 ppm are not necessarily indicative of toxicosis. Subclinical selenium may influence the immune system and pregnancy outcome [68].

Management and Treatment

Avoidance of excessive selenium exposure or ingestion is recommended for prevention of clinical disease. Once diagnosed, sources of excess selenium (forages, rations) should be removed. Effective selenium chelators are not available and therefore medical treatment relies largely on supportive care, which can be lengthy especially in cases of hoof lesions [67].

Vitamin A

Vitamin A is essential for vision, growth differentiation and proliferation of epithelial tissues, bone growth, reproduction, and fetal and embryonic development. Deficiencies in pregnant animals can result in abnormal development including disrupted organogenesis, failure of embryo growth, and resorption. Conversely, excessive vitamin A, through oversupplementation (or injection), has

been linked to reproductive failure in cattle. Though uncommon, hypervitaminosis A has been associated with fetal malformations, including neurologic and craniofacial defects with preimplantation exposure [69]. Teratogenicity appears to be increased by protein or protein-energy malnutrition [33]. Hypervitaminosis A may disrupt the retinoic acid receptor, impairing normal homeobox gene expression. Alterations in specific homeobox genes have been associated with retinoic acid-induced teratogenesis [70]. In laboratory studies using the rat as the animal model, anomalies were stage and dose dependent. When exposure occurred early following implantation, limb and genitourinary abnormalities developed [69].

Endocrine-Disrupting Compounds

Endocrine-disrupting compounds are a diverse group of compounds, natural and synthetic, that can potentially modulate or disrupt hormone homeostasis [71, 72]. Common synthetic endocrine disrupters include pesticides (DDT and organophosphorus pesticides), herbicides, fungicides, plasticizers, polystyrenes, polybrominated biphenyls and polychlorinated biphenyls (PBBs and PCBs), polychlorinated dibenzodioxins, and alkylphenolic compounds [71, 73]. These compounds are typically present in the environment at low concentrations but are persistent and have the potential to exert adverse effects on humans and animals. Exposure to endocrine disrupters may in some cases contribute to, or directly cause, infertility, pregnancy loss, intrauterine fetal death, and fetal teratogenic effects. The effects of endocrine-disrupting compounds can have impacts on developing fetuses and postnatal offspring by affecting different biochemical pathways [71]. Synthetic endocrine disrupters are suspected to have potential reproductive effects in a number of animal species, but clinical studies are limited.

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAHs) are a family of organic compounds with two or more fused aromatic rings. PAHs are formed from incomplete combustion of organic materials and are produced from industrial and automobile emissions, forest fires and wildfires, coal burning, volcanic eruptions, and hazardous waste sites [74, 75]. Livestock are exposed to PAHs through contaminated water, air, soil, and forages. PAH compounds are ubiquitous in the environment and are of significant concern due to their carcinogenic and other detrimental health effects demonstrated in laboratory animals and their suspected health effects in humans and domestic animals. The reproductive and developmental impacts of PAHs in domestic animals have not been thoroughly studied. PAH compounds have a steric resemblance to steroid molecules. In studies using the rat as a model, the PAH benzo(a)pyrene affected serum concentrations of progesterone, androgens, estrogens, prolactin, and, indirectly, luteinizing hormone. PAHs have also been shown to have toxic effects on rodent fetal development, resulting in fetal death, absorption, and teratogenic effects. The effect of these compounds on the reproductive health of cattle has not yet been clearly elucidated [74].

Polychlorinated Biphenyls

PCBs are chlorinated hydrocarbons that have been extensively utilized in industry in hydraulic fluids, transformer oils, plastic material, and lubricants. PCBs were widely synthesized from the 1920s to the 1970s in the USA and are still being produced in many developing countries. The chemical stability of PCBs allows these chemicals to accumulate in the environment and their lipophilic nature permits them to concentrate in fatty tissues [76]. Huge concentrations of PCBs have been found in sewage sludge from industrial and agricultural origins that is utilized as pasture and forage fertilizer. Cattle may become exposed from ingesting contaminated water and food. Although studies in large animals are scarce, PCBs have been shown to be embryotoxic in a number of species. PCBs either alone or in combination can impair normal oocyte maturation [71]. PCBs act as synthetic endocrine disrupters that affect steroid synthesis by increasing the activity of cytochrome P450 via their high affinity for estradiol and/or arylhydrocarbon receptors. Select PCBs have been shown to increase the secretion of oxytocin from the bovine ovary and $PGF_{2\alpha}$ from uterine endometrial cells. Alterations in progesterone and oxytocin induced by PCBs and other endocrine disrupters can impair normal ovulation via either luteal regression or prolonging the lifespan of the corpus luteum, but also potentially impair blastocyst implantation and recognition of pregnancy due to disturbed ratios of $PGF_{2\alpha}$ to PGE_2 [77]. In a study using the rabbit as an animal model, direct exposure of the pregnant uterus to PCBs resulted in high embryo PCB concentrations and in some cases induced embryo toxicity and pregnancy loss [76].

Organochlorine Insecticides

Organochlorine insecticides encompass a wide array of compounds that can be divided into three distinct groups including the dichlorodiphenylethanes (e.g. DDT, dicofol,

perthane, methocychlor), the hexachlorocyclohexanes (e.g. benzene hexachloride, chlordane), and the chlorinated cyclodienes (e.g. aldrin, endrin, dieldrin) [40]. The most infamous organochlorine insecticide is dichlorodiphenyltrichloroethane or DDT.

DDT is a chlorinated hydrocarbon that was widely used in the USA as an insecticide following the Second World War until it was banned in 1972 due to potential human and animal health hazards and environmental impacts. DDT is highly resistant to degradation and thereby is able to persist in the environment for long periods. DDT and other organochlorines can be absorbed orally or topically. In some developing countries persistent chlorinated hydrocarbons such as DDT, aldrin, and dieldrin (all of which are banned in the USA and Europe) are still used for insect control and can potentially contaminate cattle pastures and forages, leading to intoxication. Organochlorine insecticides exert their effects on the peripheral nerves and CNS by slowing Na^+ influx and inhibiting K^+ efflux, which causes partial depolarization of the neuron and thereby decreases the threshold for another action potential, resulting in premature depolarization of the neuron. DDT can also induce necrosis of the zona fasciculata and the zona reticularis layers of the adrenal gland, resulting in mineralocorticoid and glucocorticoid deficiency. The aryl hydrocarbons and cyclodienes decrease action potentials and also inhibit postsynaptic binding of γ-aminobutyric acid (GABA) [78].

In laboratory animal studies, organochlorines such as DDT have demonstrated estrogenic-like effects resulting in impaired fertility and pregnancy losses [40]. In a study by Mlynarczuk et al. [77] DDT along with hexachlorocyclohexanes and PCBs appeared to stimulate oxytocin synthesis in the corpus luteum of pregnant cows, decreasing the ratio of progesterone to oxytocin which presumably affected the force of myometrial contractions and increased the risk of abortions.

Clinical signs in cases of acute toxicosis in large animals may include apprehension, hypersensitivity, belligerence, muscle fasciculations of the face, neck, and limbs, and convulsions. There is no specific antidote for organochlorine poisoning; instead treatment is symptomatic. In cases of dermal exposure the animal should be washed with soap and water. Activated charcoal may be administered in cases of acute toxicity [78].

Organophosphate and Carbamate Insecticides

Livestock intoxication with most insecticides is often accidental and due to topical or oral dosage miscalculations for parasite control and formulation errors. However, intoxication may also result from the improper storage of insecticides that allows cattle access to the chemicals [79].

Organophosphates and carbamates both inhibit the activity of acetylcholinesterase by binding the enzyme and preventing it from hydrolyzing acetylcholine [80]. Inhibition of acetylcholinesterase results in the accumulation of acetylcholine, which causes overstimulation of muscarinic and nicotinic acetylcholine receptors. Toxicity is typically acute in nature with rapid onset of clinical signs (15 minutes to 1 hour). Common clinical signs in animals may include ptyalism, lacrimation, respiratory distress, muscle fasciculations and tremors, agitation, ataxia, and death [80]. Anticholinesterase compounds are potentially embryotoxic, fetotoxic, and placentotoxic due to the high concentration of acetylcholinesterase in these placental and fetal tissues. Organophosphates and carbamates readily cross the placenta and act on cholinergic and non-cholinergic components of the developing nervous system and other organs [40]. Diagnosis of suspected organophosphate or carbamate poisoning relies on quantifying the levels of acetylcholinesterase inhibition in the blood from live animals and in brain tissue (cerebral cortex preferably) from deceased animals. Inhibition of more than 70% acetylcholinesterase is considered positive for intoxication [80].

Treatment

In cases of cattle intoxication secondary to topical exposure the animal should be bathed with soap and water to remove any residual insecticide. Medical treatment is restricted to the use of atropine, activated charcoal, and supportive care. Atropine competitively inhibits acetylcholine at muscarinic receptors thereby reducing muscarinic effects. The recommended dose of atropine is 0.25–0.5 mg/kg body weight. One-fourth of the initial dose may be given intravenously and the rest subcutaneously or intramuscularly. The dose may be repeated if clinical signs recur. Dosages of activated charcoal range from 0.45 to 0.9 kg in adult cattle orally [80].

Exogenous Hormones

Therapeutic Use

Birth in the cow is triggered by an abrupt rise in fetal plasma cortisol, which induces increased synthesis of estrogens and prostaglandins. The elevation of estrogens and prostaglandins leads to regression of the corpus luteum and the rapid decline of maternal progesterone levels. The prepartum withdrawal of progesterone resulting from luteolysis appears to be essential in the calving process. Induction and

manipulation of bovine parturition via the use of exogenous (synthetic) hormones is often instituted as a management tool. Exogenous hormones, including prostaglandins, glucocorticoids, estrogens, and oxytocin, are commonly utilized to induce abortion or parturition according to the stage of pregnancy [81]. Potential reasons for termination of pregnancy or early parturition in cattle may include advancing the calving date in late-conceiving cows, synchronizing the beginning of lactation, terminating prolonged gestations, controlling fetal development in cases of oversized fetuses, treating conditions such as uterine hydrops, or where termination is necessary for the health of the cow [82].

Table 69.3 Potentially harmful xenobiotics in pregnancy.

Xenobiotic	Potential fetal effects
Acepromazine	Phenothiazines should be avoided near term due to fetal CNS depression
Albendazole	Associated with decreased conception rate (i.e. embryolethality) at a dose of 25 mg/kg in cows at 7 and/or 14 days of gestation
Aminoacetonitrile	Associated with skeletal defects in cattle
Aminoglycosides (amikacin, gentamicin)	Cross placenta. In rare cases amikacin has been associated with eighth cranial nerve toxicity or nephrotoxicity in the fetus
Atropine	May produce fetal tachycardia
Barbituates (pentobarbital, thiamylal, thiopental)	Cross placenta and induce respiratory depression; pentobarbital possibly increases neonatal mortality
Carbon monoxide	Associated with abortions and stillbirths secondary to hypoxia
Chloramphenicol	Synthetic bacteriostatic antibiotic that may decrease protein synthesis in the fetus particularly in bone marrow
Corticosteroids (cortisol, dexamethasone, prednisone, prednisolone)	Associated with fetal and neonatal articular cartilage defects Associated with increased incidence of congenital defects including cleft palate Induces parturition in cattle during late gestation
Diazepam	Associated with congenital defects in humans, rats, and mice in first trimester
Dimethylsulfoxide (DMSO)	Teratogenic in laboratory animals, not advised for use in pregnant animals
Diethylstilbestrol (DES) and estradiol	Contraindicated during pregnancy, cause fetal malformations of genitourinary system, possible fetal bone marrow depression
Griseofulvin	Teratogenic in cats and rats
Lidocaine	Probably safe but may induce fetal bradycardia
Metronidazole	Teratogenic in laboratory animals
Parbendazole	Anthelmintic associated with vertebral column and other skeletal defects in cattle
Phenothiazine	Anthelmintic associated with primary photosensitivity in cattle and a suspected cause of abortion
Prostaglandin($PGF_{2\alpha}$) cloprostenol, misoprostol)	Used for abortifacient or parturition induction in cattle
Quinolones (ciprofloxacin, enrofloxacin)	Associated with fetal cartilage defects
Sulfonamides (trimethoprim sulfa, sulfadimethoxine)	Cross the placenta, and have caused congenital defects in rats and mice but defects not reported in other species. Avoid long-acting sulfonamides due to risk of folate antagonism and bone marrow depression
Testosterone	Masculinization of female fetus
Tetracyclines (doxycycline, oxytetracycline, tetracycline)	Can induce bone and teeth malformations and dental staining in the fetus; may cause toxicity in mother
Urea and high protein diets	Associated with abortions and embryonic death in cattle
Warfarin	Causes embryotoxicity and congenital malformations (neural tube defects in laboratory animals)
Xylazine	Contraindicated in pregnant cattle due to increased tendency of premature parturition (Gilbert R)

Sources: Adapted from [3, 39, 87].

Accidental or Inappropriate Use

$PGF_{2\alpha}$ and its analogs (cloprostenol and fluprostenol) are powerful luteolytic agents that induce rapid corpus luteum regression and cessation of its secretory activity, uterine smooth muscle contraction, and cervical relaxation [83]. In cases where induced abortion is desired, $PGF_{2\alpha}$ and its analogs may be administered. Administration of $PGF_{2\alpha}$ 5–7 days following ovulation and up to 150 days of gestation is typically effective for termination of pregnancy. Estrogens administered within 72 hours of ovulation can impair oviductal embryo transit, thereby preventing embryo implantation. After this period, estrogens induce luteolysis, thereby inducing abortion.

A combination of $PGF_{2\alpha}$ and dexamethasone/flumethasone is commonly used to induce abortion between 150 and 180 days (5–8 months) of gestation but is also effective in all stages of gestation. The combination of these two hormones allows the elimination of both ovarian corpus luteum progesterone and placental progesterone production. Following administration, abortions will usually occur within five days. During the last month of gestation dexamethasone or prostaglandins may be used alone to induce parturition [84].

Oxytocin is a nonapeptide hormone produced by neurons in the paraventricular or supraoptic nucleus of the hypothalamus and stored in the pars nervosa of the pituitary gland [85]. During parturition and lactation, and in response to osmotic challenge, oxytocin is released into the systemic circulation from axon terminals in the neurohypophysis and acts directly on the smooth muscle of the uterus to induce rhythmic contractions. Exogenous oxytocin is often used as a uterine contractor to precipitate and accelerate normal parturition and postpartum evacuation of retained placentas or uterine debris. It also stimulates contraction of smooth muscle cells of the mammary gland for milk let-down and is used in cases of agalactia [83].The responsiveness of uterine musculature to oxytocin varies significantly with the stage of the reproductive cycle. Oxytocin can result in luteolysis in the cycling cow or heifer by inducing the release of $PGF_{2\alpha}$ from endometrial cells. During early phases of pregnancy, the uterus is thought to be relatively insensitive to the effects of oxytocin, while in the late phases the sensitivity is markedly increased. However, in a study by Yildiz and Erisir [86] oxytocin administration to pregnant cows four to seven days following insemination resulted in a higher risk of pregnancy loss and early embryonic mortality.

Pharmaceuticals

The administration of certain pharmaceuticals to pregnant animals can pose a significant risk to the developing embryo and/or fetus. Before any medication is administered to a pregnant animal, the drug label should be closely reviewed to ensure that the product is safe for prenatal use. Table 69.3 lists some contraindicated xenobiotics along with their potential fetal effects. However, it should be noted that many of the effects have been documented only in laboratory animals.

Introduction

Heritable congenital defects are being recognized at an increasing rate, but only a few are unequivocally propagated as a result of specific but unrelated trait selection. In some cattle populations, inherited defects have become a frequent and economically important source of pregnancy loss. Veterinarians, animal scientists, and cattle breeders should be aware of heritable defects and prepared to investigate and report animals exhibiting abnormal phenotypes.

Genetic testing has changed cattle production, not only in terms of traits beneficial to production, but also in the ability to identify and manage harmful genetic defects. As selection practices amplify the genetic impact of certain individuals, the potential for observation of heritable defects increases concordant with increases in the frequency of deleterious alleles. The surveillance of such disorders has become a part of bovine health programs.

Congenital abnormalities are very often discounted as randomly occurring "accidents of gestation;" the defects may not be deemed reportable and appropriate samples may not be collected. Failure of identification or delay in detection of heritable defects may allow further distribution of the causative alleles. Obvious defects such as skeletal malformations, extensive soft tissue abnormalities, severe neurological disorders, and diseases of the skin are more likely to be recognized, whereas defects involving internal organs or abortions and stillbirths may be less obvious and more easily missed. Surveillance may be further compromised by the reluctance to report potentially heritable disorders. The major cattle breed associations of the USA and Europe have staff assigned to receive reports of suspect inherited deficits and often coordinate or otherwise facilitate investigations.

Several reviews on inherited disorders in cattle have been published [1–3], and a regularly updated electronic database, Online Mendelian Inheritance in Animals (OMIA), is available at www.omia.org [4].

This chapter describes the fundamentals of report investigations, and morphologic characteristics, mode of inheritance, breeds affected, and availability of specific tests or anatomic hallmarks for select heritable bovine fetal abnormalities. A comprehensive summary of all known heritable congenital abnormalities is beyond the scope of this chapter. The purpose of this review is to emphasize heritable bovine fetal abnormalities frequently encountered, recently described, active in current cattle populations, and those for which the mutation has been identified and a test is available.

Event Investigation

The etiologies of congenital defects in cattle can be divided into heritable, toxic, nutritional, and infectious categories; distinguishing among different causes is essential in the management of the disease but may be challenging. Reports of congenital defects by cattle breeders require at least a cursory epidemiologic investigation when the animal's phenotype does not immediately identify to a known characterized defect. Given the economics and speed with which genome sequencing can be done, the opportunities to advance knowledge and provide new tools to assist breeders have never been more feasible. Samples for possible DNA extraction must be preserved at the start of investigation and can be frozen (tissue) or chilled (whole blood) until the need to process has been determined.

Generally, it is advisable to collect samples from an affected calf for DNA, and from the presumed sire and dam if easily available and before they are removed from the herd. Samples related to affected calves resulting from artificial insemination can be obtained later from stored semen and may already have some genomic data on file.

The minimum database must include examination of the affected animal(s) with a good characterization of the phenotype (ideally a necropsy performed by a pathologist) and a thorough clinical history. It is seldom possible on the basis of clinical features alone to be confident of the etiology, but information such as the pedigree details, knowledge of the number of animals affected, and maternal diet during pregnancy may provide useful clues. Additionally, infection of dams with teratogenic viruses during pregnancy may result in congenital abnormalities. As a result, knowledge of individual and herd immunization and incidence of relevant viral infections must be determined. In some cases, teratogenic or nutritional causes of congenital abnormalities may appear very similar to genetic causes. Therefore assessment of historical data is essential in any attempt to distinguish genetic and acquired causes of congenital defects. Not only a current clinical history but also a record of environments and movement of animals and contemporaries throughout gestation is needed, as many teratogenic effects are initiated long before parturition.

When the pedigree of the sire and dam are known the corresponding breed association is an excellent resource. Breed associations have access to extended pedigrees available on the internet (usually under expected progeny differences [EPD]) where you can look for ancestral relationships expected in recessive traits. The pedigrees also often list the genotyping that has been done regarding carrier status of well-characterized defects. When the parents are registered there may be support for investigating the defect as part of the breed's improvement or quality assurance program.

For further guidance, a comprehensive and thorough review of the approach to investigate congenital skeletal diseases in farm animals, with emphasis placed on investigating genetic causes, is available [5].

Arthrogryposis Multiplex

Arthrogryposis multiplex (AM) is a lethal autosomal recessive genetic defect that originated in Angus cattle. Beginning in 2008, researchers in collaboration with the American Angus Association (AAA) investigated abnormal calves believed to fit the description of what was then called AM and commonly referred to as "curly calf syndrome" in Angus cattle. Within two months, researchers obtained samples and pedigrees from affected calves and their parents, the mutation was identified, the DNA test was developed and validated, and the status of over 700 AI bulls was determined [6].

Calves with AM are born dead or die shortly after birth. They are small for their gestational age and have markedly diminished muscle mass, but dystocia is common as a result of the congenital arthrogryposis, scoliosis, and torticollis. It appears that in AM an essential protein that allows communication between nerves and muscle tissue is absent, so the calf (which fails to move in utero) is born with the joints of all four limbs fixed and the legs twisted. There are several characteristics of AM, including arthrogryposis, kyphoscoliosis, and decreased muscling [7] (Figure 70.1).

The mutation is a deletion that involves three genes; one of these genes is involved in the development of nerve and muscle. Affected calves are missing about 23 kb. These missing base pairs result in complete loss of function of all three genes in homozygous calves [6].

Bovine Dwarfism

Dwarfism as a heritable condition has been reported in many mammals, including multiple breeds of cattle [1, 8–14]. Several types of inherited chondrodysplasia have been reported in the bovine. Although the phenotypic expression is variable, all are characterized by systemic skeletal disorders, including shortness and deformity of limbs, head, and vertebrae. Dwarfism has been recognized in the Angus, Brown Swiss, Danish Red, Dexter, Hereford, Holstein, Japanese Brown, and Shorthorn breeds [15]. No single gene or mutation

Figure 70.1 AM in an Angus calf that was born dead. Note generalized muscle hypoplasia, contracted forelimbs, and fixed hindlimbs. *Source:* Image courtesy of Dr. David Steffen, University of Nebraska.

is responsible for all reported cases of bovine dwarfism. Here we describe two unique forms of bovine dwarfism.

Dexter bulldog dwarfism has been a major problem for the Dexter breed since its description in the early nineteenth century [16]. Homozygosity for the Dexter dwarf mutation is lethal and fetuses are generally aborted at approximately seven months of gestation. Clinically, the defective fetuses are characterized by an extreme disproportionate dwarfism, a short vertebral column, marked micromelia, large abdominal hernia, and relatively large head with a retruded muzzle, cleft palate, and protruding tongue [17].

Bulldog dwarfism of Dexter cattle is caused by two discrete mutations in the aggrecan (*ACAN*) gene, and DNA testing is available for the mutation [17]. When defined strictly on the lethal bulldog phenotype, the inheritance pattern of Dexter dwarfism is described as autosomal recessive (i.e. the bulldog dwarf is homozygous for the genetic mutation). However, because heterozygotes have an intermediate dwarf phenotype, the trait can also be described as having an incomplete dominance mode of inheritance (8% expression of *ACAN* in heterozygotes compared with homozygous normal) [17]. This has presented a major problem for Dexter breeders, because the favored Dexter phenotype, featuring short legs (a mild form of disproportionate dwarfism), tends to be heterozygous for the bulldog mutation. Selecting for the favored Dexter phenotype maintains a lethal allele at a high frequency [17].

Dwarfism in Aberdeen Angus calves was described in 1951 and determined to be autosomal recessive [10]. The AAA handled the issue by the virtual annihilation of all animals associated with the primary source herd [18]. Following the efforts of the breed association to eliminate dwarfism, there were no certified reports to the AAA of dwarfism in registered Angus cattle from the 1970s until 2002. At the start of the twenty-first century, abnormal Angus calves were reported in several herds in the western USA. Unlike the previous form of dwarfism, these calves appeared normal at birth, but failed to grow and after several months appeared to have abnormally short legs and thick bodies. Gross and histopathological examination of these calves indicated evidence for diminished endochondral ossification and other features consistent with dwarfism, including the protrusion of the alar wing of the basisphenoid bone into the cranial cavity, abnormalities of the ventral vertebral bodies, and curving of the transverse vertebral processes ("long-nosed" dwarfism) [19]. The genetic defect of the long-nosed Angus dwarf is not the same as the defect in Dexter (mutations in *ACAN*) or Japanese brown cattle (*LIMBIN* mutations). A non-sense mutation of cGMP-dependent type II protein kinase (*PRKG2*) leading to a premature stop codon and 85 C-terminal amino acids being truncated, including a large portion of the kinase domain, is the causative mutation for Angus dwarfism. Growth plate organization is regulated, in part, by PRKG2 regulation of sex-determining region Y box 9 (SOX9) phosphorylation. Phosphorylation of SOX9 is required for proper transition of chondrocytes from a proliferative to hypertrophic growth phase. Therefore dysfunction within the growth plate chondrocytes results in abnormal long bone growth and dwarfism in Angus cattle [19, 20].

Brachyspina Syndrome

Brachyspina syndrome is a lethal malformation in the Holstein breed [21–23]. The syndrome is characterized by calves born dead following a slightly prolonged gestation. The gross morphology of brachyspina syndrome shares many features with short spinal lethal syndrome in cattle, first described in Old Norwegian Mountain calves born in 1930 [24]. Brachyspina calves are growth retarded, with severe shortening of the entire vertebral column and limbs. Most vertebral segments have some lack of organization, with irregular ossification separated by cores of cartilage that prevent identification of individual vertebra. Multiple defects of the internal organs, including renal dysplasia and intestinal atresia, are consistently present, whereas brachygnathism and caudal dislocation and compression of the brain are inconsistently present. The appendicular skeleton may or may not be affected.

Although variation in morphology caused by a common syndrome is not unusual, six reported cases of brachyspina syndrome may have had more than one etiology, since they were morphologically diverse. In two reports of brachyspina syndrome, genealogical examination showed that the cases occurred in familial patterns [22, 23], a common ancestor to all parents was found, and the occurrence of the abnormal calves could potentially be explained by transmission of recessive alleles. Although these observations supported the hypothesis of a genetic basis of brachyspina syndrome, association does not prove causation. Widely used sires may occur as common ancestors in the pedigree of malformed calves without that individual being a carrier, or without the defect having an inherited etiology. If brachyspina syndrome is inherited as an autosomal recessive anomaly, it may be an emerging worldwide disease in the Holstein breed.

Complex Vertebral Malformation

Complex vertebral malformation (CVM) syndrome is a recessively inherited lethal disorder in the Holstein breed that increases embryonic death, abortion, and perinatal

death. CVM fetuses have a composite of phenotypic abnormalities, including axial skeletal deformities (e.g. hemishaped and misshaped vertebra, ankylosis of mainly the cervicothoracic vertebra, and scoliosis), symmetric arthrogryposis of the lower limbs, craniofacial dysmorphism, and cardiac anomalies [15, 25, 26]. Clinical heterogeneity among affected calves may make it difficult to make a diagnosis of CVM; however, a presumptive diagnosis can be made at necropsy (if pedigree information is available).

Genealogical research identified Carlin-M Ivanhoe Bell (registration number 1667366), an elite Holstein-Friesian bull born in 1974, to be the main ancestor of cattle carrying this mutation [15]. Because of the superior lactation performance of his daughters, Ivanhoe Bell was extensively used for two decades. Carriers of the CVM mutation exist in Holstein cattle populations worldwide and the frequency of CVM carriers among Holstein sires has reached an alarming level [25, 27–30].

By comparing DNA sequences of unaffected and affected calves, research [31] has uncovered a point mutation in the form of a transversion (G→T) in the *SLC35A3* gene, causing a valine at position 180 to be replaced with phenylalanine. The *SLC35A3* gene product is a Golgi-resident transporter critical for the formation of glycoproteins and, ultimately, axial skeleton development. A screening test (DNA) for CVM is now available and has been widely performed on Holstein sires. Pedigree information now includes the designation "TV" for tested animals free from CVM and "CV" for carriers of CVM.

Congenital Contractural Arachnodactyly

Congenital contractural arachnodactyly (CA), or "fawn calf syndrome," is a non-lethal autosomal recessive genetic defect of Angus cattle. CA calves are normally born alive and most can walk, suckle, and survive. The birthweight of CA calves is "normal." The phenotype is subtle, so that CA may not initially be recognized as a defect. CA is a developmental defect involving reduced elasticity of the connective tissue of muscles first identified in Victoria, Australia in 1998 but now reported in many countries [32]. Although CA is a less severe disease than lethal genetic defects of Angus calves, without human intervention up to 20% of CA calves die soon after birth because they are unable to stand and suckle [32]. CA manifests in newborn calves as elongated limbs, congenital proximal limb contracture, congenital distal limb hyperextension, and congenital kyphosis, with significant postnatal improvement in these clinical signs as the calf grows and matures [32].

Researchers have identified the gene that causes CA and have characterized the specific mutation responsible for CA as a deletion of at least 54 kb, severely compromising function [33]. A diagnostic assay has been routinely used since 2011; however, the assay should not be used within Gelbvieh cattle due to the known presence of false positives. The false positives are due to a yet uncharacterized allele within specific Gelbvieh pedigrees.

Developmental Duplication

In 2012, a rising incidence of notomelia (polymelia where the extra limb is rooted along or near the midline of the back; Figure 70.2) and other forms of polymelia was noted in cattle of the Angus breed in Australia and the USA [34]. In 2013, a single base pair substitution was identified in the *NHLRC2* gene of these bovine polymelia cases. The mutation causes valine-to-alanine substitutions at residue 311 (V311A) of the NHLRC2 protein [35]. The recessive syndrome of diverse congenital malformation phenotype in cattle caused by *NHLRC2* mutation is called "developmental duplications (DDs)" [34].

Homozygosity of the *NHLRC2* mutation in these calves is associated with several different forms of polymelia (cephalomelia, notomelia, and pygomelia [accessory hind limbs]) producing both accessory forelimbs and accessory hindlimbs as well as conjoined twinning (Figure 70.3) (including parasitic rachipagus [fusion of the back] and caudal duplication syndrome). In a 2013 survey of Angus cattle, calves were identified with neural tube defect-related lesions that included but were not limited to Chiari malformation, dermal cyst, encephalocele, meningocele, spina bifida, polymelia and conjoined twinning. Although the allele prevalence of this V311A *NHLRC2* mutation in the registered Angus population was approximately 16% at

Figure 70.2 Developmental duplication in an Angus calf. Note the notomelia. *Source:* Image courtesy of Dr. Brian Whitlock, University of Tennessee.

the time, 11 of 13 consecutive cases with neural tube defect-related lesions were homozygous for the *NHLRC2* mutation, demonstrating a causal association [36].

Polymelia is, however, rare, even in Angus calves that are homozygous for this *NHLRC2* mutation. Population genotype ratios have shown that almost half of the expected number of *NHLRC2* mutant homozygotes is present in the Angus population as phenotypically normal individuals and the other half is missing from the population, apparently due to various phenotypes, testing of those animals, and possibly a high rate of early embryonic death (J. Beever, personal communication) [37]. The incidence of newborn calves with the various malformations associated with homozygosity of this *NHLRC2* mutation, including polymelia, is not sufficient to explain the number of homozygotes missing from the population. The incomplete penetrance of developmental defects in bovine conceptuses homozygous for the *NHLRC2* mutation suggests that there are additional genetic or environmental determinants of the resulting phenotype and that the newborn calves with polymelia and other neural tube defect-related lesions observed in this DD syndrome are rare survivors of what are normally lethal embryonic malformations caused by *NHLRC2* mutation.

Hypotrichosis

Congenital hypotrichosis is partial to complete lack of hair that is obvious at birth or within the first weeks of life. Affected calves are often born with very short, fine, kinky hair that may fall out, leaving bare spots. As a result, affected calves may suffer from cold stress, leading to death or failure to thrive. Congenital hypotrichosis can have a non-genetic or genetic etiology. In cattle, non-genetic hypotrichosis can be caused by iodine deficiency, adenohypophyseal hypoplasia, maternal ingestion of European white hellebore (*Veratrum album*), intrauterine infection with bovine viral diarrhea virus, or autoimmunity.

Various forms of genetic hypotrichosis have been described in serval cattle breeds including Hereford, where it is inherited as an autosomal recessive trait [38]. More recently, congenital hypotrichosis has been reported in Belted Galloway cattle [39]. The inherited hairless phenotype can vary in severity and is frequently observed on the legs and head, with affected calves generally being identified at birth or shortly thereafter. The inherited condition may vary in expression as affected animals mature and may be less noticeable in older animals, with the hair coat color sometime appearing "frosted" and the tail switch may be underdeveloped. Some affected animals may also have reduced growth rates. Both single locus and haplotype whole genome association analysis determined that single-nucleotide polymorphisms (SNPs) located on bovine chromosome 29 were significantly associated with congenital hypotrichosis phenotype in cattle. Homozygosity analysis revealed a critical region spanning approximately 770 kb at the top of bovine chromosome 29. Possible candidate genes were sequenced to determine the causative mutation. Sequence analysis revealed an A1684T substitution in exon 9 of hephaestin-like 1 resulting in a premature stop codon. Subsequent genotyping showed all affected calves were homozygous for the point mutation. Hephaestin-like 1 is responsible for copper ion transport. Copper deficiency has been shown to cause anemia, poor

immune function, slower growth rates, and discolored or poor hair coats in cattle. More than 300 animals have been tested, with no phenotypically normal animals exhibiting the homozygous mutant genotype [39].

A small deletion mutation was found in the bovine *KRT71* gene that is associated with the congenital hypotrichosis phenotype in Hereford cattle. The K71 protein is a hair follicle-specific protein that is thought to participate in the formation of structurally important keratin intermediate filaments within the inner root sheath of the hair follicle. The mutation is predicted to result in a premature stop codon that will produce either an mRNA transcript that is degraded or a truncated protein that is unable to participate in proper heterodimer formation in the inner root sheath of the hair follicle. It is expected that formation of the keratin intermediate filaments, necessary for structural support, and hair shaft molding do not occur. Homozygosity for a loss-of-function mutation in bovine KRT71 is associated with abnormal hair development, corresponding to congenital hypotrichosis in Hereford cattle (J. Beever, personal communication).

Inherited Congenital Myoclonus

Inherited congenital myoclonus (ICM), also known as idiopathic epilepsy, is a seizure disorder observed in Hereford cattle and their crosses caused by an autosomal recessive genetic defect incompatible with life. ICM is characterized by spontaneous and stimulus-responsive myoclonic spasms that are prenatal and prevent calves from rising at birth. Affected calves have a "normal" phenotype when they are not experiencing seizures. Environmental stressors (heat, cold, weaning) can trigger the seizures, and the seizures can last from minutes to more than one hour. Bovine ICM has been attributed to a severe disturbance of glycine-mediated neurotransmission in the spinal cord [40, 41]. The observed phenotype is due to a non-sense mutation in codon 24 of the glycine receptor polypeptide, which results in truncation of the α_1-subunit and subsequent loss of cell-surface expression [42].

Junctional Epidermolysis Bullosa

Hereditary junctional epidermolysis bullosa (JEB) is a recessive inherited blistering disorder of the skin and mucous membrane in which tissue separation occurs within the lamina lucida (i.e. under the basal plasma membrane of the basal keratinocytes and above the basement membrane) of the basement membrane zone at the dermal–epidermal junction. Congenital JEB has been sporadically observed in Charolais cattle, but the causative mutation had not been identified until recently. Four cases that were born in the same French herd from consanguineous matings were recently reported [43]. Analysis of the pedigree data revealed that all JEB-affected animals traced back, on both maternal and paternal sides, to a single founder bull born in the UK in 1986, which suggested an autosomal recessive mode of inheritance as the most parsimonious model.

At birth, acral clinical lesions were observed with dysungulation of the four hooves and erosion and ulcers on the skin from the carpal and tarsal joints, fetlocks, ears, eyes, and muzzle, and in the oral cavity, most cases having ear deformities (atrophied pinna and closed ears) as well [43]. For humane reasons, as a result of anorexia, apathy, emaciation, and obvious pain, affected calves were euthanized not long after being born. Because of the rare occurrence of JEB in Charolais cattle and the rapid euthanasia of affected animals, only one case was available for DNA sampling, thus preventing the use of a classical autozygosity mapping approach. As a consequence, whole genome sequencing of this animal was completed. Ultimately, a 2831-bp deletion encompassing exons 17–23 of the integrin beta 4 (*ITGB4*) gene, a gene previously associated with the same condition in humans [44], was identified as the cause for JEB in this herd of Charolais cattle. ITGB4 encodes the beta subunit of the alpha 6 beta 4 integrin heterodimer. This transmembrane receptor is a key component of the hemidesmosome anchoring complex which connects basal keratinocytes to the basement membrane. Genotyping a second case and six parents of affected calves revealed a perfect association between this mutation and the assumed genotypes of the individuals. Analysis of genotyping data from 6870 Charolais cattle detected only 44 heterozygous animals for a 5.6-Mb haplotype around ITGB4 that was shared with the carriers of the mutation. Genotyping of 16 of these 44 animals revealed that none was a carrier of the deletion, suggesting a rather recent origin for this mutation in the Charolais breed [43]. At about the same time a similar report was madFe regarding a Charolais calf from Germany [45]. Genetic analysis revealed an *ITGB4* loss-of-function mutation where the affected calf was homozygous for a 4.4-kb deletion involving exons 17–22. Along with the dam, some Charolais cattle belonging to the affected herd carried a single copy of the deletion [45].

Maple Syrup Urine Disease

Maple syrup urine disease (MSUD) is an autosomal recessive disease of branched-chain amino acid metabolism that is caused by mutations in one or more of the four subunits of the branched-chain α-ketoacid dehydrogenase (BCKDH)

complex. In cattle, MSUD was first observed in Australia affecting both Hereford [46] and Shorthorn calves [47]. MSUD was subsequently detected in Canadian Hereford cattle in 1987 [48]. Two different mutations in the E1α subunit (branched-chain ketoacid dehydrogenase E1, alpha polypeptide [BCKDHA]) of the enzyme were later identified [49, 50]. In Herefords, a transition mutation within exon 2 (c.154C > T) of the BCKDHA gene results in a nonsense substitution (p.Q52X) causing the complete absence of E1α protein [49]. A missense substitution (p.P372L) caused by a transition in exon 9 (c.1372C > T) is responsible for MSUD in Shorthorns [50].

Although MSUD was recognized in the mid-1980s, there were very few calves reported due to negative selection based on pedigree and the implementation of molecular diagnostic testing, particularly within Australian Herefords. However, more recently several affected calves have been reported in both Herefords [51] and Black Herefords in the USA. The Hereford c. 154C > T mutation was shown to be responsible in reported cases (J. Beever, personal communication) [51]. In Black Herefords further investigation revealed a carrier frequency of approximately 13% among 287 animals tested. Furthermore, it was determined the founding sire within the Black Hereford registry was an MSUD carrier, as was his registered Hereford sire. Examination of more than 33 000 Hereford animals that had been genotyped for the c. 154C > T mutation demonstrated an allele frequency of 0.04%. However, three prominent modern AI sires were also shown to be carriers, increasing the risk of observing MSUD-affected calves over the next several calving seasons.

MSUD-affected calves are frequently born asymptomatic but rapidly develop significant neurologic symptoms within 12–24 hours following birth [46, 48, 52]. Calves appear lethargic and are unable to rise by themselves. Calves are often found laterally recumbent with occasional limb paddling or tremors followed by periodic opisthotonus. Euthanasia is often required within 48–72 hours. Field diagnosis can be made by the presence of darkish-brown urine having a burnt maple syrup-like odor. Clinical diagnosis can be made by significantly elevated serum branched chain amino acid (BCAA) levels.

Neuropathic Hydrocephalus

Neuropathic hydrocephalus ("water head") is a lethal autosomal recessive genetic defect of Angus cattle. At the same time that AM calves were being submitted, calves with hydrocephalus were also submitted. These calves were similar in description and pedigree to calves described by Dr. Denholm in Australia.

Figure 70.4 Neuropathic hydrocephalus in an Angus calf that was born dead. Note the markedly enlarged cranium. *Source:* Image courtesy of Dr. Kristie Steuer, Animal Health Center, Laramie, Wyoming.

Affected calves are born near term and weigh 10–20 kg at birth. The head is markedly enlarged (Figure 70.4). The bones of the skull are malformed and appear as loosely organized bony plates that fall apart when the head is opened. The cranium is filled with fluid and no recognizable brain tissue is evident. The spinal canal is also dilated and no observable spinal tissue is found [53]. Because of the hydrocephalic cranial enlargement, dystocia is almost invariable. Delivery per vagina can normally be achieved by incising the cephalic vesicle of the domed cranium to drain the fluid. Manually removing the skull bones from the collapsed vesicle before applying traction may be necessary.

The genetic mutation leads to the abnormal function of a protein involved in the development and maintenance of the central nervous system and results in neuropathic hydrocephalus [53]. Nearly 10% of AI sires representing a broad cross-section of registered Angus genetics were found to be carriers of this syndrome [54]. Given the number of calves reported, this frequency is higher than expected. This phenomenon could be explained by a relatively high percentage (50–70%) of pregnancy wastage in embryos and/or fetuses. This is consistent with what is known about mutations in this gene for other species (i.e. complete disruption of this gene in mice results in 100% fetal mortality before the halfway point of gestation) [55].

Oculocutaneous Hypopigmentation

From 2012 to 2014, the American Simmental Association (ASA) received reports of cattle with "white-colored" eyes and a diluted hair coat (Figure 70.5). Tissue samples

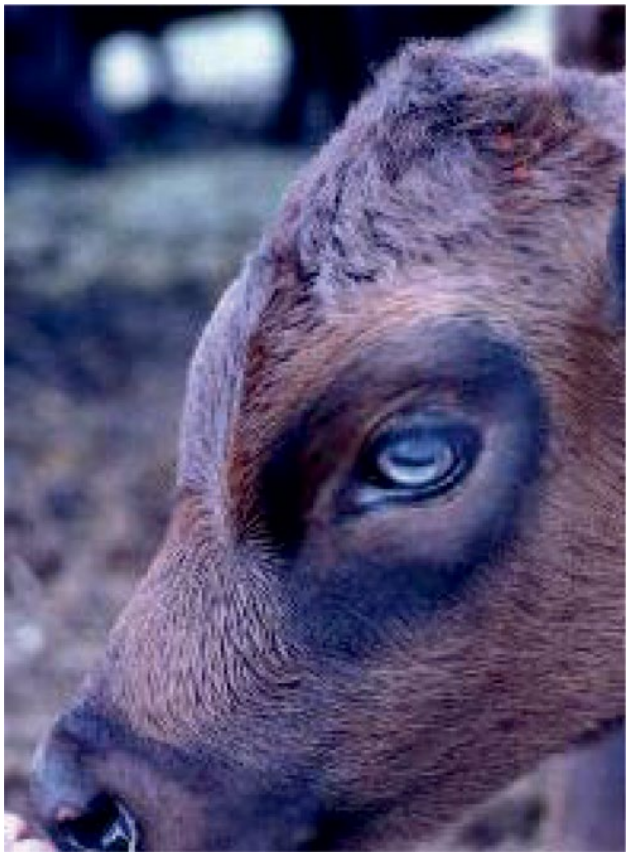

Figure 70.5 Oculocutaneous hypopigmentation in an Angus calf. Note the pale blue iris and diluted hair coat color. *Source:* Image courtesy of the American Angus Association, St. Joseph, Missouri.

collected from four affected calves were genotyped. The resulting genotypes were analyzed in contrast to the genotypes of ~80 Simmental sires. This analysis provided clear evidence that the condition was inherited as a recessive trait. Based on these results, the DNA sequence for several genes was analyzed in each of the affected calves. Within one of these genes, a mutation was identified that is predicted to impair the function of the encoded protein. An amino acid exchange in the Ras-related protein Rab-38 gene was identified as the disease causing mutation (J. Beever, personal communication) [56]. In mice, mutations within the same gene cause a very similar condition that is referred to as "chocolate," where black mice have a diluted coat color and beige-colored irises [57]. Information contained in reports and literature from the 1970s and 1980s, and in these current Simmental cases, indicate that this abnormal phenotype has little or no effect on the viability or performance of affected individuals.

Further investigation indicated the mutation was present at a relatively low frequency in the Simmental population, consistent with the very low frequency of affected calves reported over the three-year period. Examination of carrier pedigrees revealed a single Simmental bull as the most popular recent ancestor with DNA available for testing. However, several of the genotyped carriers did not have this sire in their pedigrees, indicating the mutation could have been introduced to the Simmental population much earlier. Considering this information and the prior description of similar traits in other breeds, namely heterochromia irides (HI) in Angus cattle, the possible origin of this mutation was investigated by obtaining samples from known HI carriers. Although there are very few DNA samples available from these older animals, a sample was obtained for one of the relevant Angus sires and he was found to be a carrier of this newly identified mutation in Simmental cattle. Therefore it is most likely that the mutation was introduced into the Simmental population by the use of Angus cattle during the development of black purebreds. The subsequent screening of more than 1200 Angus sires indicates the mutation has most likely been eliminated from the current Angus population via pedigree selection in the early 1980s (J. Beever, personal communication) [56].

Osteopetrosis

Osteopetrosis ("marble bone") is a lethal autosomal recessive genetic defect previously identified in humans and animal species. Cattle breeds known to be affected are Black and Red Angus, Hereford, Simmental, and Holstein. The defect was most recently reported in the Red Angus breed [58]. Calves affected with osteopetrosis are born 10–30 days early. They usually have head abnormalities that consist of brachygnathia inferior, impacted molars, and a protruding tongue. The long bones are shorter than normal, and the marrow cavities are filled with unresorbed bone (primary spongiosa) but are very fragile and can be easily broken [58].

The disease is caused by a deletion of *SLC4A2*, a gene necessary for bone remodeling during development. *SLC4A2* encodes an anion exchanger protein necessary for proper osteoclast function. Loss of *SLC4A2* function appears to induce premature cell death and results in cytoplasmic alkalization of osteoclasts, which in turn may disrupt acidification of resorption lacunae. Histological examination of affected tissues reveals scarce, morphologically abnormal osteoclasts displaying evidence of apoptosis [59].

Pulmonary Hypoplasia with Anasarca

Pulmonary hypoplasia with anasarca (PHA) is a lethal autosomal recessive disorder of a single missense mutation characterized most notably by dystocia, profound anasarca,

death of the calf, and not uncommonly death or morbidity of the cow [54, 59]. Originally, PHA calves were identified as Maine-Anjou, Shorthorn, or their crosses (composite cattle); however, cases are also reported in Australian Dexter, Hereford, and belted Galloway cattle [3, 54, 60].

Breeding of two PHA carriers would theoretically produce 25% affected fetuses. However, there appears to be a high percentage of pregnancy wastage from approximately 90–200 days of gestation. Homozygosity for the PHA mutation is lethal and fetuses are generally aborted at approximately seven months of gestation. When PHA fetuses survive to near term, they invariably result in dystocia. It appears that PHA calves thought to be "bred to the AI date" are usually premature births of calves conceived due to natural service following an AI program.

The most obvious external characteristic of PHA calves is marked anasarca, resulting in large calves (Figure 70.6), frequently requiring cesarean section. Furthermore, PHA is characterized by the absence or near absence of lung tissue (pulmonary hypoplasia; Figure 70.7), lymphatic agenesis (absence of lymph duct and nodes), and athymia [60, 61].

Heterozygous PHA carriers have a "normal" phenotype and can be identified only by genetic testing. Following identification of the gene in late 2006, over 40 popular Maine-Anjou, Shorthorn, and "club calf" sires were identified as PHA carriers. Interestingly, several of the most popular Shorthorn bulls are carriers for both tibial hemimelia and PHA. A syndrome similar to PHA was identified in Dexter cattle in 2006 when Windsor et al. [54] reported three cases of PHA in the Dexter breed. The cows were related and inheritance was felt to be autosomal recessive. Although the mutation in the Dexter breed involves the same gene as the condition seen in Maine cattle, it is not identical. The Maine-Anjou mutation was a simple point mutation, whereas the Dexter mutation was an 84-bp deletion involving the same exon as the Maine mutation (J. Beever, personal communication).

Recessive Defects Discovered from the Absence of Homozygous Haplotypes

Lethal recessive defects were often discovered in the past from reports of abnormal calves and subsequent breeding trials to confirm the inheritance. Defects that affect embryo loss were sometimes discovered from occasional abnormal calves that reached late gestation or parturition [21, 25] or from physiological differences between normal and heterozygous phenotypes [62]. Instead of relying on breeder reports of abnormalities, embryonic defects may more easily be discovered using fertility traits and genotypes stored in national or international databases [63].

Genotypes and haplotypes for large numbers of individuals provide a new tool for identifying lethal recessive genes. Defects that cause embryo loss are difficult to detect without genomic data, even with very large sets of phenotypic and pedigree data, because of insufficient observations per estimated interaction [64]. With genomic data, lethal recessives may be discovered from haplotypes that are common in the population but are never homozygous in live animals. This method requires genotypes only from apparently normal individuals and not from affected embryos and therefore is the opposite of most previous strategies [65]. The new approach can discover lethal defects without phenotypic data. If the number of genotyped individuals is large, the expected number of homozygous haplotypes is sufficiently large so that their complete absence is unlikely to be attributed to chance.

Five new recessive defects have been discovered in Holstein, Jersey, and Brown Swiss breeds by examining

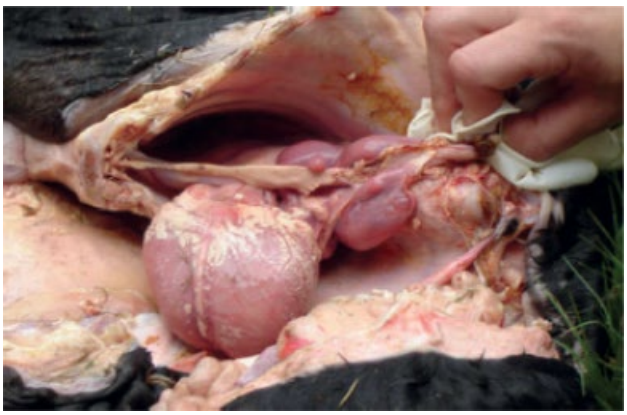

Figure 70.7 Thorax of a calf with pulmonary hypoplasia with anasarca syndrome. While the lungs of a "normal" bovine fetus at a similar stage of gestation are proportionate to those of a neonate, note the severe pulmonary hypoplasia (severely hypoplastic lungs are to the right of the heart). *Source:* Image courtesy of Dr. Brian Whitlock, University of Tennessee.

haplotypes that had high population frequency but which were never homozygous. Genotypes from the BovineSNP50 BeadChip (Illumina, San Diego, CA) were examined for 58 453 Holsteins, 5288 Jerseys, and 1991 Brown Swiss apparently normal individuals with genotypes in the US database. Phenotypic effects were confirmed using records for conception rate in a smaller population of cows from the affected breeds. Estimated effects on conception rate ranged from −3.0 to −3.7 percentage points, which was slightly larger than estimated effects for previously known lethal alleles of −2.5 percentage points for brachyspina and −2.9 percentage points for CVM [66]. Estimated effect of carrier interaction for stillbirth rate was small (≤1.8 percentage points) but comparable to the effect of CVM (1.4 percentage points) [66]. For each of the five new defects, 2.7–20.7% of elite animals in the current population are carriers. However, selection against carriers would improve fertility only slightly. For example, conception rates would increase by <1 percentage point if any of the haplotypes were eliminated from the population [66].

Tibial Hemimelia

The tibial hemimelia (TH) syndrome was first described in 1951 in Scotland in the Galloway breed of cattle [67]. This lethal condition is characterized by multiple congenital skeletal deformities, most notably shortened or absent tibia, abdominal hernia, cryptorchidism, failed paramesonephric duct development, hirsutism, and improper neural tube closure resulting in meningocele. Calves are born dead or die shortly after birth. The Scottish Galloway Association used test breeding and pregnancy termination to identify carriers and eliminate the autosomal recessive defect from Galloway breeding stock [68].

The syndrome was first described in the USA in 1974 [69], and subsequently in a case report of a female Simmental calf with arthrogryposis, ventral abdominal hernia, TH, and non-union of the paramesonephric ducts, with the suggestion that it might be a genetic disorder [70]. A decade later, TH was identified in six genetically related registered Shorthorn calves, three from the USA and three from Canada [71]. Although the skeletal abnormalities varied, the combination of TH, abdominal hernia, and meningocele was felt to be strikingly similar to the condition previously described and determined to be inherited as an autosomal recessive trait in Galloway cattle. Pedigree analysis of the Shorthorn calves suggested that homozygosity of an autosomal recessive allele was responsible for the defect.

Identification of the defective gene mutation causing TH was made in 2005 [72]. The defective gene has been shown to be aristaless-like homeobox 4 (*ALX4*), a major regulator of hindlimb formation (J. Beever, personal communication). The deletion removes approximately one-third of the *ALX4* gene, including the upstream regulatory sequence, and involves approximately 46 kb. After identification of the initial deletion, it was noted that although the parentage of some TH calves was DNA-verified, some parents did not test positive for this deletion. Additional studies revealed that other TH carriers possess a larger deletion of 450 kb that overlaps the previous/smaller deletion, and removes four genes including *ALX4*. The later and larger identified deletion is rare and affected calves sired by carriers of that deletion are compound heterozygotes (heterozygous with the smaller mutation on one chromosome and the larger mutation on the other). Although "heterozygous," these calves are affected like those homozygous for the smaller deletion. The frequency of the larger mutation is so low, and the magnitude of the deletion so much larger, that it is unlikely that there have been any TH calves homozygous for the larger deletion. In Galloway cattle TH is most likely caused by a duplication of 20 bp in exon 2 of *ALX4*, resulting in a frameshift and substantially altered secondary and tertiary structure of the homeodomain, which supports the explanation for a loss of function [73].

Vertebral and Spinal Dysplasia

In 2010, early data emerged regarding newborn calves in Germany with short, crooked tails in the Holstein cattle breed [74]. Forty-one animals, all offspring of a single sire, showed pathognomonic tail malformations, providing highly significant evidence for a congenital inherited defect, which was subsequently termed vertebral and spinal dysplasia (VSD). The defect is characterized by vertebral (specifically tail) deformities and neurological dysfunctions with gait abnormalities of the hindlimbs. The deformities and neurological dysfunctions varied from very mild (only tail deformities) to severe (paraparesis). The malformations and dysfunctions associated with VSD, as well as the mode of inheritance and the genotyping of the suspected carrier sire, indicated that VSD is a defect previously not described in cattle. VSD is inherited in a dominant mode but shows incomplete penetrance of the phenotype. Genome-wide mapping, haplotype tracking within a large pedigree, resequencing of target genome regions, and bioinformatics analyses unambiguously confirmed the mutant c.196G allele as causal for this previously unknown defect. The non-synonymous VSD mutation is located within the highly conserved T box of the *T* gene, which plays a fundamental role in eukaryotic species body organization and vertebral development [74].

Summary

In recent years, several heritable defects have been identified that have had significant impact on specific cattle populations. Molecular geneticists, veterinary pathologists, breeders, and breed associations have cooperatively identified genetic disorders, characterized the pathology, determined the genetic mutations responsible, and developed tests to identify carriers. It is likely that the genetic mutations in other heritable congenital defects of cattle will be identified through similar collaborative efforts.

Although the investigation of heritable bovine fetal anomalies has often been left to those in academia (specifically, animal scientists and veterinary pathologists), many of the currently recognized inherited disorders of cattle would have gone undiscovered without the assistance of private practitioners and producers. For any surveillance program to be successful, recognition of a potentially heritable defect is the first step. The anomaly must be reported, appropriate samples collected and preserved, and pedigree information made available. Veterinarians in the field can play a pivotal role in discovery and surveillance by recognizing and reporting inherited defects of cattle.

Introduction

Large offspring syndrome (LOS) refers to an overgrowth phenotype sometimes observed in cattle fetuses and newborns produced by the use of assisted reproductive technologies (ART) [1–4]. Enlarged body and limb size are the most commonly identified phenotypes [5]. However, LOS is not always characterized by overgrowth [3]; other phenotypes include abnormal organ growth, large tongue, muscle and skeleton malformations, umbilical hernias, abnormal placental vasculature, hydroallantois, and increased abortions throughout gestation [2–15]. These characteristics have prompted the use of a different designation for this syndrome, namely abnormal offspring syndrome (AOS) [3, 6, 14], a nomenclature that we will use throughout this chapter.

In this chapter we will discuss the current knowledge on ART-induced AOS. Even though AOS also manifests in cloned (somatic cell nuclear transfer [SCNT]) offspring [16, 17], and we present some data to that effect, most of the work presented here will focus on AOS resulting from common, non-invasive ART procedures. The reason for this is that AOS is an epigenetic syndrome (explained in detail in subsequent sections) and adding the confounding of somatic cell reprogramming (or lack thereof) complicates interpretation of results. When relevant, we will discuss findings from sheep as AOS has also been documented in this species, and from Beckwith–Wiedemann syndrome (BWS), a human congenital overgrowth condition which phenocopies AOS. In addition, we present evidence of spontaneous AOS in cattle [11] and provide two examples of financial loss incurred by the cattle industry as a result of this syndrome.

Assisted Reproductive Technologies (ART) in Cattle

In vitro production of embryos (IVP or ART) encompasses a series of laboratory procedures in which oocytes are collected from the ovaries either from live cows, often after superovulation [18], or from ovaries harvested at an abattoir [19]. If using live animals, superovulation may be followed by artificial insemination (AI) and embryo collection by uterine lavage with an embryo-compatible solution (i.e. flushing). Embryos may be transferred immediately (i.e. fresh) or frozen for future use. This procedure is referred to as multiple ovulation embryo transfer (MOET). Alternatively, oocytes may be harvested from ovaries *ex vivo* and cultured *in vitro* to promote their nuclear and cytoplasmic maturation [20, 21]. Then, the oocytes are incubated with spermatozoa, a procedure referred to as *in vitro* fertilization (IVF), and the putative zygotes are cultured in a medium designed to promote their development to the blastocyst stage. Variations on this basic procedure are many and depend on the laboratory, the technician, and the final purpose and have included the use of somatic cell coculture, serum supplementation, or a combination. Many media possess components that are undefined, such as serum or bovine serum albumin (BSA) (refer to section on "Serum Supplementation"). The use of defined media is favored by some [22], while others turn to the "physiological basics" by the use of reproductive fluids to supplement the culture medium in order to achieve an environment in which embryos are exposed to components found *in vivo* [23].

ART are commonly used in cattle for experimentation purposes [24] and are the method of choice when trying to improve genetic merit of the offspring in a shortened

length of time when compared to natural reproduction [25]. Genetic merit is defined as the rank of an animal for its ability to produce superior offspring relative to other selection candidates [26]. In addition, ART can be used to produce genetically manipulated animals with improved production traits [27]. The first IVF-culture-transfer calf (bull calf born 9 June 1981) was reported by Brackett and colleagues in 1982 [28], and currently ~1.1 million transferable bovine embryos are produced each year (Figure 71.1).

Although widely used, these technologies are not without complications for the offspring. The observation that ART can induce the birth of abnormally large calves was first documented in the 1990s [9]. In that report [9] the authors noted: "At present, little information is available to identify the factors or possible mechanisms influencing excessive fetal growth." Even though this adverse outcome of IVP has been recognized and extensively studied since the early 1990s [2–4, 6, 13–15, 29–33], we are not yet able to predict which embryos are molecularly programmed to suffer AOS, as the etiology and the incidence of the syndrome are unknown. Increase in weight and size lead to dystocia in some instances and cesarean section is needed for delivery [34]. Of note is that overgrowth of the fetus is sometimes independent of gestation length [5]. A main hurdle to the understanding and perhaps elimination of AOS is that there is a lack of peer-reviewed data describing the status of AOS in the industry [7]. As a result, many believe this issue has been resolved, yet AOS continues to have detrimental effects on some ART-conceived offspring and its dam, which can result in financial loss to cattle producers and the embryo transfer industry (see examples in section "Economic Loss to the Industry as a Result of AOS").

Abnormal Offspring Syndrome – An Overgrowth Syndrome in Ruminants that Recapitulates the Human Syndrome Beckwith–Wiedemann (BWS)

Overgrowth syndromes refer to a group of conditions in humans with the common features of excessive growth which includes body weight, height, and organ size, and a higher risk of tumorigenesis [35]. One of the best characterized overgrowth syndromes, namely BWS (OMIM #130650), was first reported in the 1960s by Hans-Rudolf Wiedemann [36] and J. Bruce Beckwith [37], and was initially called EMG syndrome after its major symptoms (i.e. exomphalos, macroglossia, and gigantism) [38, 39]. The incidence of BWS is ~1 : 10 340 natural births [40]. Therefore it can be estimated that of the 3.7 million babies born that were conceived naturally in the USA in 2019 [41] ~357 were afflicted with BWS. This number may, however, still be an underestimation since individuals without obvious phenotypes may not ever be diagnosed. Common phenotypes observed in BWS are macroglossia (large tongue), macrosomia (large body size), lateralized overgrowth, ear malformations, abdominal wall defects (exomphalos/hernia), and hyperinsulinism [42, 43]. In addition, children with this

condition have an increased risk of embryonal tumors during early childhood [44]. Types of tumors observed include neuroblastoma, rhabdomyosarcoma, unilateral Wilms tumor, hepatoblastoma, adrenocortical carcinoma, and phaeochromocytoma, with Wilm's tumor of the kidney being a cardinal feature of this syndrome [43, 45]. Further, children conceived by ART have a higher likelihood of BWS than the naturally conceived population [46].

BWS is a heterogeneous molecular condition, as various epigenetic and genetic defects have been reported [43]. The first genetic linkage reported for BWS was with the insulin-like growth factor 2 (*IGF2*) gene [47], an imprinted gene found on chromosome 11p15 in humans. Subsequently, studies found genetic and/or epigenetic mutations on human chromosome 11p15 in BWS [48–50]. The syndrome is not limited to epigenetic alterations at 11p15 [51], and as such has been termed a multilocus imprinting disturbance. The main molecular defects of BWS can be categorized into three groups: (i) DNA methylation defects, (ii) changes of chromosomal contents, and (iii) gene mutations at chromosome 11p15. Among BWS cases with positive molecular diagnosis, the majority (65–73%) have DNA methylation defects, while the remaining cases may have some genetic abnormality (i.e. 16–33% have changes of chromosomal contents and 1–8% show gene mutations) which can ultimately affect imprinted gene expression (i.e. resulting in a secondary epimutation [52]) [53–63].

Shared phenotypes observed between AOS and BWS are large tongues, large body size, abnormal organ growth, abdominal wall defects, hypoglycemia, and abnormal placental development [3, 15, 43]. As the causes of BWS at the molecular level have been largely attributed to epigenetic defects, which include alterations of DNA methylation and loss-of-imprinting (LOI) [43], we will discuss these epigenetic modifications/mechanisms in the next section.

Epigenetics, DNA Methylation, and Genomic Imprinting

Epigenetics is the study of chromatin behavior and all the modifications, mechanisms, and molecules that orchestrate gene expression, gene silencing, and genome integrity. DNA methylation refers to the addition of a methyl group (CH_3) to the fifth carbon of cytosines (in most cases at CpG dinucleotides) by the DNA methyltransferases (DNMTs). The "p" stands for phosphodiester bond and this nomenclature is used to indicate that a guanine follows a cytosine in the DNA sequence. This epigenetic modification is inherited through cell division and is critical for embryonic and fetal development and reprogramming of the germ cell lineage [64]. In addition, DNA methylation has roles in gene expression by regulating binding accessibility of proteins to DNA [65], is involved in the control of genomic imprinting [66], retrotransposons repression [67], and dosage compensation (i.e. X-chromosome inactivation) [68]. Further, an inverse correlation exists between DNA methylation at the promoter, transcription start site, and first exons of genes, and transcript levels [69]. Methylated cytosines promote a silent state of genes by attracting methyl-CpG-binding domain protein which interferes with the binding of transcriptional regulators and forms complexes with enzymes which can promote a silent state of chromatin [70, 71]. Other epigenetic modifications/factors that are involved in the regulation of chromatin, although not discussed in detail here, include histone post-translational modifications [72], histone variants [73], long and short non-coding (nc) RNAs [74, 75], and the epigenetic writers, readers, and erasers of histone proteins and DNA [76]. The epigenome is responsive to endogenous and exogenous environments and, as such, is labile [77]. Of relevance to this review is that artificial environments associated with ART have been shown to have profound effects on the epigenome of gametes and embryos [78–80].

Genomic imprinting is a series of precisely regulated epigenetic processes that lead to parental-allele-specific expression (Figure 71.2) of a subset of genes in mammals [81–83]. Since the discovery of the first three imprinted genes in mouse, namely, *Igf2*, *Igf2r*, and *H19* in 1991 [84–86], more than 100 genes (the number will depend on the species) have been identified to be imprinted in mammals [87, 88]. Most of the identified imprinted genes are located in clusters containing two or more genes subject to genomic imprinting. Within each cluster, a discrete region of DNA, termed as the imprinting control region (ICR), regulates the proper allele-specific expression of imprinted

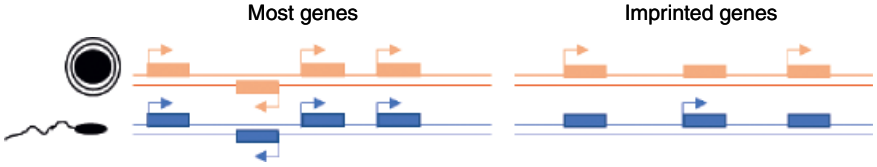

Figure 71.2 Gene expression in mammals. Shown is a pictorial representation of the expression of most genes which are expressed in a biallelic manner and imprinted genes which are expressed in an allele-specific (monoallelic) non-random manner.

genes. ICRs are marked with parental-allele-specific DNA methylation, which distinguishes the parental alleles in the same nucleus. The allele-specific DNA methylation at ICRs is established in the germline in a sex-specific manner [89]. In mice, male germline methylated ICRs are established before birth, while acquisition of the maternal-specific DNA methylation occurs postnatally during oocyte growth. These gametic DNA methylation imprints escape the wave of global DNA demethylation that occurs after fertilization and are maintained in somatic cells throughout development. Further, as part of the global DNA demethylation that occurs in primordial germ cells, methylation imprints are erased in order to get reestablished in a sex-specific manner [90].

The importance of genomic imprinting in mammalian development was first demonstrated by pronuclear transplantation experiments, in which androgenetic and gynogenetic mouse embryos resulted in embryonic lethality [91, 92]. Conceptuses derived from zygotes which contained two maternal genomes were smaller than the biparental fetuses and had an undeveloped placenta, while those containing two paternal genomes had a severely retarded fetus but a well-developed placenta [91, 92]. Therefore genomic imprinting may be regarded as the block to parthenogenesis in mammals [93]. Investigations of imprinted gene function also demonstrated the significance of genomic imprinting in mammalian development. For example, mice with maternal transmission of the non-functional allele of *Igf2*, a paternally expressed fetal growth factor, showed normal growth, but paternal transmission of this mutant allele had deficient growth that was similar to *Igf2* null mice [85]. Although less effort has been put forth in determining the function of imprinted gene products than in understanding the mechanism of imprinting, these genes emerge as important players in numerous biological processes including fetal growth, placental development, neural development, metabolism, and behavior [94, 95].

Abnormal Offspring Syndrome

The first cases of fetal overgrowth and developmental abnormalities in cattle were reported by Willadsen et al. [17]. In that study, 8–64 cell-stage embryos from beef and dairy breeds were collected by flushing superovulated cattle and embryos split into individual blastomeres for cloning experiments. Interestingly, those authors report in their discussion that when the manuscript was being written (i.e. 1 October 1990) some calves from the study had already calved themselves, a point that indicates that these studies were performed in the mid-1980s and that AOS was already being observed at that time – information we have also learned through personal communications from individuals working with SCNT at the time. In the Willadsen study, 8/11 cases of abnormal offspring observed had twins that were of normal appearance. This is reminiscent of the situation in humans in which monozygotic twins can be discordant for BWS [96], pointing at the epigenetic nature of the syndrome. Overall, AOS is associated with decreased pregnancy rates, higher loss of embryos, increase in fetal or neonatal weights, increased organ size, abnormal limb and spinal cord formation, increased incidence of hydroallantois, prolonged gestation, and ultimately poor outcome of the offspring, in part due to dystocia [2, 6, 9, 17, 97–99].

Treatments Associated with AOS

Serum Supplementation

For many years, the field has recognized that augmentation of embryo culture media with serum may induce an overgrowth phenotype (Table 71.1) [31, 33, 110]. For example, in one study, 25% of ovine embryos cultured *in vitro* with serum supplementation developed as large offspring [32]. In addition, the presence of serum in the culture medium has been associated with increased body weight and gestation length in sheep, which, similar to cattle, suffer ART-induced AOS [97]. Serum can also result in increased organ size (a phenotype of AOS [31]).

Supplementation with serum during *in vitro* embryo culture has been historically used to stimulate blastocyst formation (see Figure 71.3 for an example from our laboratory) [123, 124]. However, while supplementing the culture medium with fetal calf serum and BSA was found to improve and accelerate blastocyst yield by day 6, serum can also decrease embryo survival rate [100, 101]. Different culture conditions and supplementation with serum have been reported to cause transcript abundance changes of several developmentally important genes involved in cell–cell junctions, transport, RNA processing, and stress in bovine embryos [102, 103]. In addition, alterations of imprinted- and non-imprinted gene expression as a result of *in vitro* embryo production have been reported in numerous studies [88, 102–108, 111, 112, 125–128]. For example, a twofold increase of *IGF2* (a paternally expressed fetal growth factor) transcript was detected in liver of day 70 bovine fetuses that were cultured in medium containing estrus cow serum when compared with the serum-restricted group [29]. These fetuses presented loss of methylation (LOM) at the insulin-like growth factor 2 receptor (*IGF2R*) ICR, which was correlated with reduction of the *IGF2R* transcript and protein levels. IGF2R is a maternally expressed [15, 109] scavenger receptor of the paternally expressed fetal growth factor IGF2.

AOS has been observed in offspring that were not exposed to serum supplementation during embryo culture; however, serum is still often used to supplement the maturation medium in some of those cases (personal communication). A question that remains unanswered is why/how is serum promoting AOS. This is a very complicated question to address as the exact nature of the molecule(s) that can affect the epigenome and/or gene expression is not known and could be diverse. For example, studies in which the composition of bovine serum was determined showed that it is composed of sundry hormones, vitamins, growth factors, lipids, carbohydrates, and transport proteins, among other unidentified biomolecules [129–131]. In addition, these components may change between batches as shown for fetal calf serum [131], a fact that could be attributed to differences in maternal diet, breed, gestational age, and seasonal environmental factors, among others.

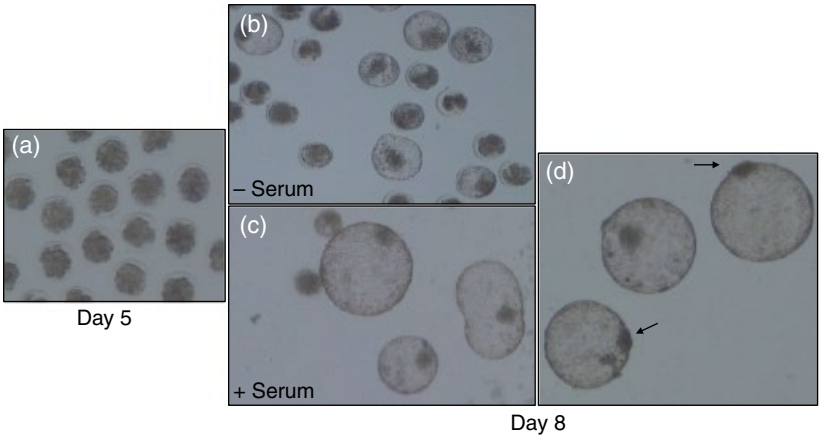

Figure 71.3 Why add serum to the culture medium? Shown are day 5 (left; a) and day 8 (right; b, c) bovine blastocysts which were processed together (*in vitro* maturation, IVF, and embryo culture) by us until day 5 (a), at which time they were separated into two groups. One group received 10% estrus cow serum (c) whereas the other group was not supplemented (b). Embryos in the serum group were more advanced in stage (note that they have hatched from the zona pellucida) and there were more at the blastocyst stage when compared to the control group. In addition, some of the hatched blastocysts in the serum group had a protruded embryonic mass (arrows; d). Pictures are to scale except (d) which is magnified to show protruding embryonic mass. *Source:* Pictures are courtesy of Rocío Rivera.

Coculture with Somatic Cells

Coculture of embryos with various types of cells has also been used to increase blastocyst yield (Table 71.1) [113, 116, 122]. Similar to what has been found with serum supplementation, overgrowth [30, 115] and increased gestation length [115] have been reported for ovine embryos that were cocultured with granulosa or oviduct epithelial cells. In addition, the size of the primary muscle fibers (which form during the first wave of myogenesis) and the ratio of secondary to primary fibers of the cocultured fetuses were greater than the controls, which indicates that hypertrophy of the primary fibers and hyperplasia of the secondary fibers are associated with the increased body weight observed in these fetuses [114]. A confounding element of some of the studies in which AOS was observed is that the culture medium was also supplemented with serum [2, 99].

Maternal Diet

Another factor associated with AOS is maternal diet (Table 71.1). For example, substantial increase in embryo mortality and one case of fetal overgrowth were found in ewes fed excess amounts of urea (excess rumen-degradable nitrogen) from 21 days before mating to day 63 of gestation when compared to controls [117]. The average weight at birth for controls was 7.16 kg and the weight of the single lamb (male) of the high urea group was 10.1 kg. The cause behind the overgrowth is not clear but may be due to the higher systemic urea concentration, including the uterooviductal microenvironment [117], and/or postprandial daily elevations in plasma ammonia observed in the ewes. In addition, in that study, embryos collected on day four and cultured to the late blastocyst stage were observed to be more developmentally advanced and have increased metabolism than their control counterparts. Of note is that in the study, embryos were cocultured with oviductal cells in the presence of 10% fetal serum. Nonetheless, these authors still observed an increased rate of metabolism and development of preimplantation embryos, suggesting that ammonia buildup in the culture medium may be in part responsible for the observation, and noted that in their previous study [132] they observed that serum supplementation of medium increased the levels of ammonia *in vitro,* similar to the levels found in the urea-fed ewes. They go further and propose ammonia as a causal agent for the result on embryonic development, which may be compared to the situation in mouse in which high levels of ammonium during embryo culture resulted in fetal abnormalities [133].

Asynchrony of Maternal Environment

Asynchrony between embryo age and maternal environment has also been reported in sheep to result in larger than normal offspring [118] or to have altered myogenesis (Table 71.1) [114]. In one study, day 3 embryos were placed in a day-6 uterus for a period of three days and then transferred into another recipient synchronous with the embryo (i.e. day-6 uterus and day-6 embryo) [118]. In the asynchronous fetuses, abnormal increase in the weight of the offspring was observed when compared to the completely synchronous double embryo transfer group. The cause for this observation may be that an advanced uterine

environment provided one or more secretory signals or hormones earlier than required by the embryo. To this effect, increased fetal growth was observed in pregnant sheep primed with progesterone (controlled internal drug release [CIDR]) for three days after ovulation when compared to control [119]. The lambs were heavier (weight in grams = 220.8 ± 3.2 and 247.6 ± 4.1 for control and progesterone group, respectively) and longer (crown–rump length in millimeters = 204.0 ± 1.1 and 212.1 ± 1.4, respectively) at birth, which they proposed may be due to the advanced maternal environment experienced by the embryos during preimplantation development. In another study the authors found that while muscle weight was not altered in the asynchronous group when compared to the control, the ratio of secondary to primary fibers in sections of plantaris muscle was increased, as well as the number of muscle fibers, a phenomenon they hypothesized may involve hyperplastic growth in the secondary fibers [120]. The latter hypothesis is interesting as the study by Wilmut and Sales [118] showed that in the asynchronous transfer group, embryos were larger, more had hatched from the zona pellucida, and one had a clear embryonic disk reminiscent of a day-10 sheep embryo, also suggesting hyperplasia as a result of factors present in the advanced uterine environment. We also observed that the embryonic mass was protruding from some of the hatched blastocysts cultured in serum (Figure 71.3d). It should be noted, however, that increased fetal weight has not always been observed in studies of similar design [121].

Molecular Alterations Associated with AOS

It has been more than 20 years since the hypothesis that epigenetic factors play a role in AOS was first pointed out [5] and almost 30 years since the first indication of AOS being an epigenetic syndrome was shown [17]. In the past two decades, many researchers have demonstrated correlations between abnormal phenotypes and epigenetic aberration in AOS [32, 134–141]. The onset of these aberrations has been proposed to be the results of incorrect reprogramming of epigenome in early embryos during critical stages of the preimplantation period [3]. Genome-wide reprogramming of the epigenome during early embryo development is a conserved mechanism in ruminants [142, 143]. The reprogramming will not affect some genomic sequences such as imprinted methylation and histone modifications retained in the paternal genome which are inherited by the zygotes [144–146]. Changes in environmental factors, including chemicals, oxygen level, and temperature, may affect the success of the reprogramming procedure. Studies have shown that level of non-esterified fatty acids in the culture medium affects global DNA methylation in embryos [147]. Supplementing vitamin C in the culture medium has been shown to improve the reprogramming of DNA methylation at loci initially being aberrant in SCNT-derived embryos [148]. Level of oxygen exposure affects the expression of the demethylase *TET* family, de novo methyltransferase *DNMT3A*, and its cofactor *HELLS* in bovine embryos, which may further alter the DNA methylation [149]. Studies have also shown that active DNA demethylation followed by de novo methylation in paternal pronuclei of zygotes can be perturbed by heat-stress spermatozoa [150]. Since DNMTs are directly responsible for de novo methylation and maintenance, it is highly possible that their expression and function are disrupted in AOS. One study on SCNT-derived fetuses showed alteration of DNA methylation at the potential promoter regions of *DNMT3a* and *DNMT3b* [151].

DNA methylation affects the accessibility of DNA and therefore can regulate gene expression. Like humans, the global DNA methylation pattern in bovines is high in gene body and low in promoter regions [111, 134]. Although this pattern remains the same, the level of DNA methylation across the gene body and intergenic regions can be different in AOS. A metagene analysis revealed that DNA methylation level of gene region (defined as gene body ± 2 kb) in cotyledon of deceased SCNT-derived calves is lower than naturally conceived calves [134]. Another study of IVP derived bovine AOS fetuses demonstrated global aberration of the DNA methylome in these fetuses, and the majority of changes occur within gene body [111]. However, only a small percentage of differentially expressed genes can be directly correlated to adjacent (<20 kb) DNA methylation changes, indicating the involvement of other mechanisms [111]. Other groups have reported large changes in intragenic DNA methylation level [140]. The impact of *in vitro* culture of the embryo on the methylome has been shown in a stage-specific manner [152]. Higher ratio of hypomethylated versus hypermethylated regions within intronic, exonic, promoter, and proximal promoter regions was found in embryos transferred as zygotes, the reverse was found in embryos transferred at 4-cell and 16-cell stage, and about equal amount of hypermethylated and hypomethylated regions were found for embryos transferred as blastocysts [152].

Histone modifications, including methylation, phosphorylation, acetylation, ubiquitylation, and sumoylation, play important roles in replication, transcription, heterochromatin formation, chromatin compaction, and DNA damage repair [153]. Studies have shown genome-wide elevation of histone H3 lysine 9 dimethylation and acetylation in SCNT derived embryos [154]. Increased histone H4 acetylation has been reported for imprinted genes, including *IGF2* in deceased SCNT derived fetuses [135].

Increased permissive mark histone H3 lysine 4 dimethylation and decreased repressive mark histone H3 lysine 9 dimethylation were associated with increased expression of *PHLDA2* in placenta of SCNT derived fetuses [139]. It is important to note that some studies have also shown that during SCNT some original somatic histone modifications can escape reprogramming and be inherited by the embryos [141]. This aberration of histone modification can further affect gene expression and genomic imprinting [141].

Non-coding RNAs, especially long non-coding RNAs (lncRNAs) and microRNAs (miRNAs), also play important roles in epigenetics and have been shown to be involved in AOS. lncRNAs have function in regulation of gene transcription, working as a precursor or sponge for small RNAs and remodeling broad chromatin domains [155]. Misregulation of lncRNAs in AOS, for example *KCNQ1OT1*, has been reported in many studies [15, 138, 156]. In addition, alteration in expression level of hundreds of miRNAs has been shown in mid-gestation IVP derived bovine AOS fetuses [136]. These affected miRNAs show clustering tendency in the genome, especially from the DLK1-DIO3 genomic imprinted cluster, also shared by BWS [136], and some are associated with adjacent DNA methylation changes. In consideration of miRNAs' most important function, namely inhibiting translation, these misregulated miRNAs could lead to expression changes of hundreds to thousands of genes at the protein level while having no or little effects on mRNA level.

Genomic imprinting regulates parental origin-specific expression of imprinted genes. We have reported that AOS is a global LOI condition [138]. Disruption of normal DNA methylation pattern at ICRs of imprinted genes and the corresponding LOI and change in expression level have been widely reported in overgrowth syndrome in bovines and humans. For example, there is a gain of methylation at H19/IGF2 ICR in BWS, as well as *H19* downregulation and *IGF2* overexpression [29, 111, 134, 137, 157–159], LOM at KvDMR1 and *CDKN1C* downregulation [15, 156], XIST DMR LOM and *XIST* upregulation [137, 157, 160], IGF2R ICR LOM and *IGF2R* upregulation [32, 137, 138, 157, 158, 161, 162], and misregulation or LOI of other imprinted genes [138, 147, 159, 163–165]. These imprinted genes have critical roles during early embryo development, and the effect of their dysfunction will be aggravated by downstream signaling pathways and can finally result in global gene misregulation. Conversely, upstream misregulated genes and epigenetic signatures can result in LOI. When LOM at DMRs occurs in early embryonic stages due to *in vitro* culture or SCNT, the methylation may be regained in a later stage partially or completely, suggesting the existence of repairing mechanisms [159], although ICR methylation is only deposited during gametogenesis and once lost cannot be regained.

IGF2 is a paternally expressed gene and functions in promotion of growth and development of the conceptus [166]. Similar to human and rodent models, the mRNA of *IGF2* can be transcribed from multiple promoters in a tissue- and developmental stage-specific way in bovines [167–169]. The dramatic influence of *Igf2* on body weight has been widely studied through null mutation or overexpression experiments in rodents [170–172]. *IGF2R* is maternally expressed and its protein binds to IGF2 with high affinity and results in degradation of excess IGF2 [173]. In addition to body weight changes, *Igf2r* null mutation or overexpression studies in rodents have shown similar abnormal phenotypes observed in AOS, including omphalocele, visceromegaly, and placentomegaly [174, 175]. *CDKN1C* is maternally expressed and encodes an inhibitor of cyclin-dependent kinase. Knockdown of *CDKN1C* in bovine zygotes significantly reduced the development rate to blastocysts [176]. *Cdkn1c* is required for normal embryo development and rodents with null mutations on this gene exhibit similar abnormal phenotypes found in AOS, including umbilical hernia, omphalocele, macroglossia, and placentomegaly [177–179].

As mentioned, very few correlations were found between altered gene expression and DNA methylation status at promoter/body of the gene regions (i.e. short range interactions) in these fetuses [111, 136]. This is not surprising, however, as several reports show that DNA methylation at remote regulatory regions (i.e. enhancers) is more explanatory of altered gene expression [180, 181]. For example, methylation of DNA can cause changes in binding efficiency of transcription factors (activators and repressors) and architectural proteins to DNA, which affect enhancer/silencer activity and chromosomal conformation, respectively [180, 181]. Together, these alterations can affect gene expression at megabase or interchromosomal levels [180–183] – a question we are currently addressing in the laboratory.

Effects of *In vitro* Maturation of Bovine Oocytes: Association to the Epigenome

A question that remains is "how early are gametes and/or embryos programmed to suffer AOS?" A study performed to analyze the effect of *in vivo* versus two different *in vitro* maturation media showed that *in vitro* matured oocytes had significant upregulation of *H19*, *IGF2R*, and *PEG3* mRNA levels [184], genes that are known to be paternally *(H19, IGF2R)* and maternally *(PEG3)* imprinted. Moreover, *DNMT1a*, *DNMT3a*, and *DNMT3b* mRNA were upregulated in both *in vitro* maturation groups, suggesting that

DNA methylation factors (proteins) could have been altered. However, the researchers did not find any differences in methylation levels of aforementioned genes in the maturation treatments [184]. The fact is that each maturation medium will have its specific effects on gene expression in the oocyte. For example, maturation of oocytes in medium containing non-esterified fatty acids had altered transcript levels of *DNMT3a* and *IGF2R* [185]. This may be associated with a global effect on the epigenome [186] which results in global misregulation of transcripts, including those involved in gene expression, transcription initiation, and energy metabolism [187]. As noted, the epigenome is responsive to environment, including internal physiologic state and external stimuli [186–188], and as such can be altered. To that effect, *in vitro* matured bovine oocytes showed loss of immunoreactive acetylation of lysine 12 in histone 4 (H4K12ac) following germinal vesicle breakdown, suggesting an activation of gene expression for the oocyte to resume to meiosis [186]. In addition, a DNA methylome study demonstrated differential methylation between those oocytes that were matured *in vitro* when compared to *in vivo* controls [189]. Altogether, these findings suggest that *in vitro* maturation of bovine oocytes does not completely mimic the *in vivo* model and may induce aberrations in DNA methylation and/or gene expression that could affect long-term embryonic or fetal development, which ultimately could lead to AOS.

Spontaneous AOS

Congenital abnormality has been observed from time to time in the field, either presenting as abortion or present at term birth. In addition, perinatal mortality, death occurring prior to, during, or within 48 hours of calving, is a recognized problem in the cattle industry [190]. In developed countries, 25–46% of perinatal deaths in cattle are the result of dystocia, and in the USA, 32% of perinatal deaths are due to unknown causes [190]. Dystocia is defined as an abnormal or difficult birth at any stage of labor. Dystocia has a direct negative impact on calves [190, 191], dam survival, reproduction performance [192], and milk production [193]. Replacement of stillborn calves is a substantial cost to the cattle industry and can amount to more than USD $125.3 million per year in the dairy industry [194]. One of the main causes of dystocia is fetal–maternal size mismatch [195], such as with abnormally large fetuses.

AOS manifest as large for gestational age calves have long been recognized [196]. With the advent of ART, AOS became almost exclusively associated with calves derived from these techniques [4]. However, it appears that AOS occurs spontaneously in non-ART calves as well, a phenomenon that we have coined as spontaneous LOS (SLOS) (Figure 71.4) [11]. Differentiating between AOS and other etiologies of fetal oversize can be challenging. When determining the cause of these conditions it is best to categorize them by gestational length – prolonged versus appropriate.

There is no established definition for post-term or prolonged gestation in cattle. In humans, births more than two weeks over the expected delivery date are considered post term and are independently associated with reduced neonatal outcomes [197]. Most cattle do not exceed a gestation of 290 days, and therefore a gestation length exceeding 300 days can be considered prolonged [198]. Gestation length, even when in the normal range, directly correlates to birth weight (i.e. longer gestation results in greater birth

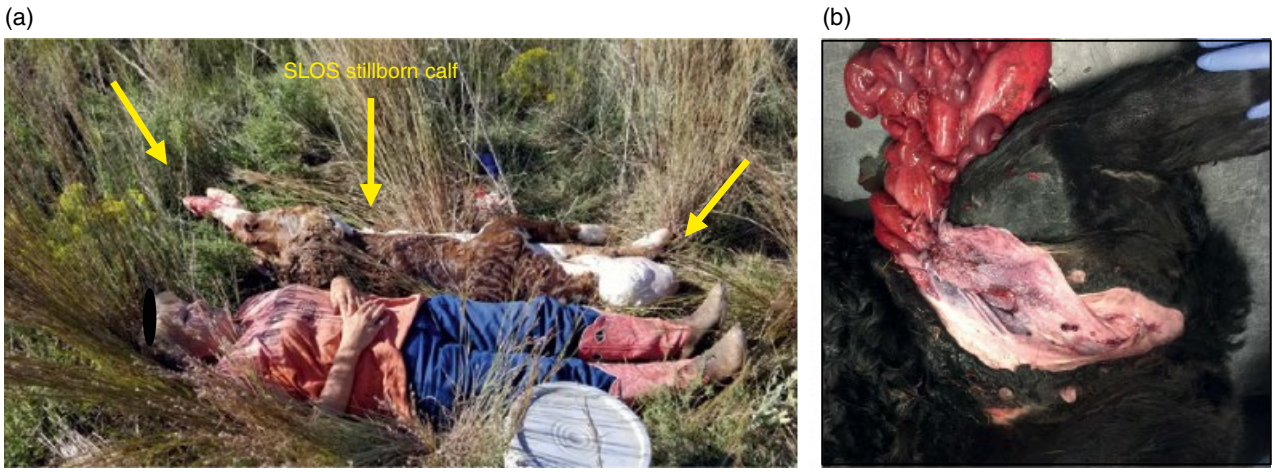

Figure 71.4 Examples of spontaneous AOS. (a) Dead SLOS calf at birth (yellow arrows are pointing to the calf). Next to the calf, a woman lying down for size comparison. (b) A newborn Angus SLOS calf. The calf was euthanized at birth and diagnosed with cloacal exstrophy, omphalocele (exomphalos), and diastasis recti (abdominal separation). *Source:* Pictures are courtesy of Rocío Rivera.

weight) [199]. As such, calves from prolonged gestation are almost invariably large (rare exceptions reported), and in general have poor survival outcomes. These calves may also have long hair-coats, overerupted teeth, and overgrown hoof capsules and have been reported to weigh from 59 to 98 kg. Once identified, these calves require delivery by cesarean section in order to salvage the dam.

Prolonged gestation and failure to initiate parturition have been documented in Ayrshire, Holstein-Friesian, Guernsey, Jersey, Swedish Red and White, and Belgian Blue breeds [200–204]. Prolonged gestation in these cases is secondary to adenohypophyseal hypoplasia/aplasia, cerebellar hypoplasia, and adrenal hypoplasia of the fetus, collectively referred to as "pituitary giants." Dysfunctional fetal hypothalamic–pituitary–adrenal (HPA) axes results in a failure to initiate parturition, and consequently fetal oversize. A hereditary component has been suspected in many of these cases; however, putative genetic variants have not yet been identified. Infectious and toxic agents such as Akabane virus, bluetongue virus, bovine viral diarrhea virus, and *Veratum californicum* may also prolong gestation through impairment of the fetal HPA axis and should be considered in these cases [205].

Fetal giants have been rarely recognized in calves that are born at normal gestation length. No specific descriptions of these calves have been made, with calves over 59 kg (130 lb) at birth considered to be fetal giants [196]. Using this weight as a threshold is likely to remove the effect of breed on inclusion as a fetal giant, as this weight is very large regardless of breed. In humans a neonate is considered large for gestational age if their weight exceeds the 97th percentile for a given gestational age (approximately 10 lb at term), regardless of race [206]. What is considered large for gestational age and a fetal giant in cattle is still yet to be fully agreed; however, we have defined it as a calf that is 75% bigger than expected (approximately 55 kg for Angus and 68 kg for Holstein).

SLOS calves have been observed in both Holstein and Brown Swiss, with calves of both male and female sex. These calves were all extremely large (63–86 kg) and required delivery by cesarean section. Calves affected by this condition may have a variety of other clinical features including macroglosia (enlarged tongue), ompaholocele (umbilical hernia), linear folding of the ears, and flexural and angular limb deformities. The survival of these calves is poor, with the majority dying within the first few days of life. We analyzed the muscle of one of these SLOS for LOM at KvDMR1 and observed that as in ART, SLOS appears to have an epigenetic association (Figure 71.5).

There are currently no estimates for the number of SLOS calves born each year. If we assume that ART-associated AOS occurs at a similar rate to non-ART-related BWS in humans (1/10 340 live births [207]), it is estimated that approximately 5000–10 000 calves are born each year in the USA with SLOS [208]. While the absolute number is unknown, the potential economic impact of these calves is

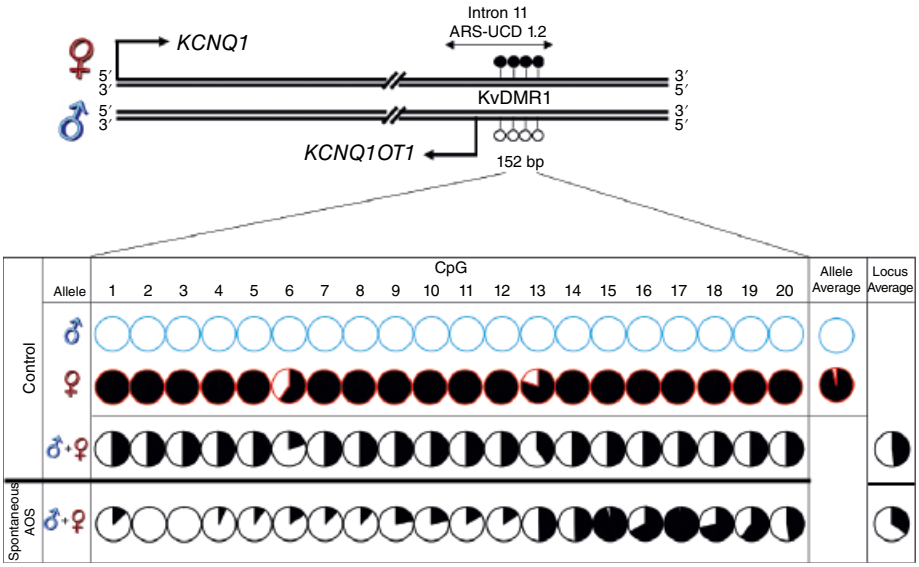

Figure 71.5 Loss of methylation at KvDMR1 in SLOS. Each circle represents a CpG dinucleotide in 5′ to 3′ direction with the 152-bp amplicon. Open circles = unmethylated CpG; filled circles = methylated CpGs. NCBI Reference Sequence: NC_037356.1. ARS-UCD1.2 Chromosome -29: 48908288–48908439. Primers used to amplify the bisulfite converted DNA were: forward: GTG AGG AGT ATG GTA TTG AGG, and reverse: TCA ACC CTC TCA ACC AAT AAC. Product size = 385 bp (only 152 bp are shown). Annealing temperature = 59 °C and number of CpG = 38. The sample used for control is the tongue of fetus C010 ([15]) and the muscle is of a SLOS (53-kg Holstein calf which was collected at birth and deemed "abnormally big" by the veterinarians at UC Davis).

likely to be significant. As these calves invariably result in dystocia requiring resolution by cesarean section, it is estimated that AOS costs cattle producers $3–5 million per year [209]. This does not, however, account for more mildly affected individuals. Milder case presentation has hampered the estimation of incidence of similar conditions in humans, as they are rarely investigated, and therefore the true incidence is likely to be much higher [210]. Given the potential for mildly affected individuals to exist in bovine populations, this condition may be more pervasive. There is strong evidence that calf mortality is increasing and we propose that this may be in part due to mild SLOS. Calf birth weight has a large bearing on neonatal calf outcomes, with increasing birth weight positively associated with increased risk of calf mortality [211]. This has an economic impact, but also a welfare implication for affected calves. These calves are not only at greater risk of mortality, but also will be more likely to have failure of passive transfer of immunity, require more medical interventions, and have indicators of physiologic stress [212]. Large for gestational age calves are likely to be encountered by most bovine practitioners. SLOS should be considered when evaluating these cases and when counseling clients.

Economic Loss to the Industry as a Result of AOS

There are no published data on the economic loss experienced by the industry as a result of AOS. A main phenotype of the AOS is increased bodyweight and size of the calves which can lead to dystocia requiring surgical fetal extraction [34]. LOS calves can also have an enlarged tongue at birth, which can lead to difficulty breathing and suckling, resulting in lower neonatal viability. Furthermore, the cost of veterinary services can bring economic burden to the farmer. Given the lack of information on economic loss to producers, we asked an embryo transfer technician and a farmer who each experienced AOS to provide actual and projected economic loss as a result of SLOS. Below we provide the information given and summarize their losses in Figure 71.6.

Example 1 (Oklahoma, 2019)

> Six continental breed composite embryos. Conventionally derived embryos from the same flush that were transferred fresh not frozen. First recipient goes into partial paralysis due to oversized calf's head pinching nerve in birth canal. I induced the calf 16 days prior to due date. This first calf weighed 124 lb at time of calving and did not survive. With an estimated growth of 1.5 lb/day, conservatively, in the last month of gestation it can be assumed the calf would have weighed roughly 148 lb. This encouraged me to palpate the remaining five recipients to estimate size of fetus. Two days after the first, I induced the remainder of the recipients. At 14 days premature I had 5 calves all requiring either an episiotomy or cesarean to deliver. Of these 5, only 2 calves survived. The 2 surviving

Example 1. Continental breed composite

Total loss	$28,832.37
Cow related loss	$5000 (4 x $1250 to replace with open 6 y/o cows)
Calf related loss	$7200 (4 x $1800 for embryo calves)
Medical related loss	$1782.37
Future loss	$14,850 (4 cows x 4 more calves per cow x 450 lbs x $1.65)

Example 2. Charolais

Total Loss	$29,200
Cow related loss (Current + Predicted)	$14,500 (dam valued at $2600, sold for salvage $500 + value of next four calves as yearlings were expected –$12,400)
Calf related loss (170 lbs = 77 kg)	$2,600 (Average selling price of their yearling bulls)
Sire related loss	$11,000 (sire cost – had to sell to market after SLOS son)
Medical related loss	$1,100

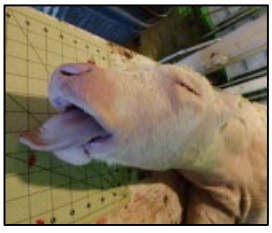

Figure 71.6 Examples of calf death, adverse outcomes to the dams, and financial loss to producers as a result of LOS.
Source: Pictures are courtesy of Rocío Rivera.

calves consisted of a 113-lb heifer and a 122-lb bull. The 3 deceased calves consisted of a 118-lb heifer, a 127-lb bull, and one bull that weighed 142 lb that lived for roughly 24 hours before passing. Four of the recipients also perished in the event.

Example 2 (Missouri, 2019)

Probably the largest financial impact was to the herd reputation. I gave $11 000 for the herd sire and since the birth of this calf have had to send him to market, no one wants to buy a bull from a sire that sired a 171-lb calf. Also, 60% of my female herd are daughters of this sire – is the worth of these animals now in question? I have noticed less local buyer traffic for my purebred seed stock cattle since the word of our farm having a 171-lb dead calf. This total impact is very high but difficult to place a figure on at this time.

Summary

The observation that ART can induce the birth of abnormally large calves was first documented in the 1990s [9]. However, we are not yet able to predict which embryos are molecularly programmed to suffer LOS as the etiology and the incidence of the syndrome are unknown. A main hurdle to the understanding and perhaps elimination of LOS is that *there is a lack of peer-reviewed published data describing the current status of LOS problems in the commercial embroy transfer–IVP industry* [7]. Overgrowth syndrome occurs naturally in ruminants and humans [11, 40] and both have been shown to increase in incidence in offspring conceived by ART [46, 132]. This fact speaks to the epigenetic nature of this condition. AOS can cause financial burden to genetic improvement and embryo transfer companies as well as cattle producers. Often both, the dam and the calf die as a result of dystocia. Early identification of AOS would allow early elective termination of the pregnancy in order to prevent the aforementioned monetary losses and animal welfare concerns associated with AOS.

Management to Decrease Neonatal Calf Loss in Beef Herds

David R. Smith

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

Calving is a highly anticipated event for the beef cow-calf producer. The first few weeks of each calf's life are critical to its future health and productivity, and collectively the health and productivity of the herd, as well as the financial success of the enterprise. Successful calving seasons are planned in advance, with much consideration to minimizing the likelihood and costs of the known hazards of this phase of cattle production. Important hazards during the calving season are birthing problems, dangers from the environment, and sickness or death from disease. Understanding these hazards allows the cattle producer to make long-term and near-term plans to minimize risk. Veterinarians can help beef cattle producers take appropriate actions to prevent neonatal calf losses by conducting a herd-specific risk assessment.

Risk assessment is a process of:

1) evaluating the likelihood and costs (or benefits) of potential hazards (or opportunities), termed risk analysis;
2) determining what actions, at what relative cost, can be taken to mitigate those hazards, termed risk management; and
3) sharing the action plan with all members of the team, as well as keeping records to show what was done and whether the actions were successful, termed risk communication.

The process of risk assessment can be iterative to provide a continuum of actions toward ongoing improvement [1]. A risk assessment may be completed formally or informally, and the process may be qualitative or quantitative [2, 3]. As part of the risk analysis phase it may be necessary, or at least useful, to supplement published evidence with herd-specific data from health records [4], outbreak investigation [5], or clinical trials [6]. It is possible to recognize important hazards and estimate their costs without quantitative data during the risk analysis stage, but it is more difficult to evaluate progress or compliance in the risk management stage without using records.

Unfortunately, few cow-calf operations collect animal health data in a format that is easily analyzed [7]. The lack of a simple record-keeping system on many farms hinders the process of recognizing important hazards and their costs, and makes it difficult to document that risk management actions were implemented or to evaluate if those actions were effective. If records exist at all, they may be on paper (e.g. in pocket-sized health record books) or in a computerized digital format (e.g. spreadsheets or databases) with free text fields, none of which allow the veterinarian or the producer to quickly and easily discover animal health relationships [7]. Some proprietary database systems capture health information and may present information in standardized graphs or summaries, but do not always allow easy querying of other health relationships. Free text fields are difficult or impossible to analyze because of misspelled words, multiple names or descriptors for the same disease (e.g. diarrhea, scours, loose, enteric), and multiple pieces of information in the same field. Often it is too costly to wade through inefficient record systems to get the needed information from which a risk assessment can be performed. Therefore it may be beneficial for the veterinarian to help the cattle producer establish a system for capturing and analyzing health and performance data.

A desirable system for evaluating calf health and performance captures data on all calves at risk, not just treated calves. Useful information includes the calf's identification, identification of the dam, age of the dam, calf's birth

date, date of onset of health concerns, and information describing variables of interest (e.g. birth and weaning weights, risk factors for disease, economic data).

A risk assessment evaluates the reasons for the occurrence of hazards, the likelihood of the hazard, and its cost. In the absence of farm-specific information, risk assessments are often based on published information and expert opinion. For example, based on a national survey of beef cattle herds completed in 2007–2008 [7], 2.9% of calves were born dead and another 3.5% died or were lost prior to weaning. These rates were similar, regardless of the herd size. In this survey, the reasons for beef calves to die in the first three weeks of life, in order of frequency, were (i) birth related (25.7% of deaths); (ii) weather related (25.6%); (iii) unknown causes (18.6%); (iv) digestive system related (14%); (v) respiratory disease (8.2%); and (vi) predation or injury (6.2%). Note that these are population averages and not every beef herd experiences losses according to this distribution. However, in the absence of herd-specific information, these data inform us that, on average, the important hazards to the survival of neonatal calves are problems occurring during calving, dangers from the environment, and contagious diseases.

Managing risks requires greater understanding of the factors associated with those hazards, how to mitigate those factors, and the associated costs [1]. Economics should not be the sole basis for making decisions about the care of animals. However, the cost of healthcare remains an important financial constraint to most cattle producers and is therefore an important consideration. The relative costs of disease prevention and control practices are relevant to risk management decisions. Comparing the relative costs of different approaches to managing risk can help inform animal care decisions.

The cost of even highly effective risk management practices should not be overlooked. As a simplified example, assume that a vaccine is 75% effective and costs $10 per head to administer (e.g. for product, labor, and supplies). If the disease occurs at an annual incidence of 40 cases per 10 000 head, then vaccination would reduce the incidence to 10 cases per 10 000 head per year. The annual cost to prevent 30 cases in a population of 10 000 would be $100 000, or $3333 to prevent each case. In this scenario, use of the vaccine might only be economically justified to prevent extremely costly diseases (e.g. causing high mortality in herds of high value). If the annual incidence of disease were 400 cases per 10 000, the cost of preventing each case would be $333. In this scenario, if the cost of the disease (e.g. costs for labor to treat, medications, lost performance, and deaths) averaged $100 per case, then use of the vaccine would not be economically justified unless the expected incidence in the absence of vaccine was 1333 cases per 10 000.

Factors other than direct monetary costs or benefits play into a farmer's decision to use a preventive intervention. It might be more useful to consider units of utility rather than units of money in the calculation of risk management costs and benefits [1]. For example, in addition to the animals' monetary value, a particular farmer's unit of utility might also include their concern for the health and welfare of their cattle or pride of owning healthy and productive cattle. Also, average or expected values do not consider the impact of extreme events. For example, the occurrence of infectious diseases may cluster in time and place as an outbreak. Therefore, just as with many insurance plans, the decisions to use vaccines or to take other preventive actions may be based on minimizing the risk of a catastrophic outbreak, even if the average cost of the prevention is greater than the average cost of the disease. Finally, the relative level of risk aversion of the individual producer may affect the utility breakpoint at which a risk management practice is adopted [1].

What follows are qualitative risk assessments with generalized approaches to managing the risk of the most common hazards of the neonatal period in beef herds. The veterinary practitioner may be able to provide a more tailored approach to managing health risks within specific cattle herds using specific herd data. The emphasis of this chapter is on disease and injury prevention; however, timely and effective treatment is also important in managing the overall cost of disease or injury.

Risk Assessment of Calving Hazards

Successful calving occurs when a live calf is born without complications to the calf or the dam. Problems with the birthing process are called dystocia. Dystocia may be due to factors of the calf or factors of the dam [8].

Calf Factors of Dystocia

The factors of dystocia related to the calf are size, posture, and presentation. Large calves are more likely to experience dystocia because they have difficulty fitting through the dam's pelvis. Posture refers to the position of the calf's head and legs as the calf enters the birth canal. Presentation refers to the calf's orientation relative to the dam. The most normal presentation and posture at birth is the calf upright, facing toward the rear of the cow, with the head between extended front legs. A breech birth is an example of both abnormal posture and presentation; the calf is backwards with the rear legs folded under the body. Of these factors, calf size is the most common problem and most preventable, through genetic selection [8].

The consequences of dystocia to the calf are metabolic or physical injury that may result in death during or following the birthing process. Lack of oxygen in the blood causes injury to cells and results in acidosis and low blood sugar. Physical injuries include congestion and swelling of the head and tongue which may prevent nursing, or broken bones due to excessive force during calving assistance.

Dam Factors of Dystocia

Factors of dystocia attributable to the dam are age, pelvic size, and metabolic health [8]. Dystocia is more common among heifers and also cows with small pelvic dimensions. Common metabolic problems at calving are from muscle weakness due to protein–energy malnutrition, exhaustion during prolonged muscular contractions, and low blood levels of calcium or magnesium. The dam may experience metabolic or physical injury during or following the birthing process. The most common problems for the dam are exhaustion from muscular contractions, pressure injury to leg muscles while being recumbent, and bruises or tears to the uterus and vagina. The consequences of these problems include failure of the dam to get up after calving, prolapse of the uterus, excessive bleeding, or infection of the reproductive tract. Each may ultimately be fatal.

Managing the Risk of Dystocia

There are long-term and near-term strategies for preventing problems associated with dystocia [9]. Long-term strategies include genetic selection for calving ease and pelvic size, and implementing sound heifer breeding and development programs. Near-term strategies include providing exercise and balanced nutrition to heifers and cows prior to and after calving, frequent monitoring of calving progress, early and appropriate calving assistance, ready access to the appropriate tools for calving assistance, copious use of lubricants, and attention to sanitation (e.g. use of soap and water) during birthing assistance. Describing methods for calving assistance are beyond the scope of this chapter; however, an important aspect of managing dystocia risk is helping producers know when veterinary assistance should be sought. Cattle producers should seek veterinary assistance when they:

- do not know what is wrong;
- know what is wrong, but either do not know what to do or recognize it is beyond their abilities; or
- know what is wrong and what to do about it, but have been unsuccessful after 30 minutes of trying [10].

Risk Assessment of Environmental Hazards

The environmental conditions in the neonatal period are important to the health and well-being of the dam and her calf.

Environmental Hazards to the Calf

Common environmental factors that present a hazard to the neonatal calf are weather extremes, crowding, predators, and physical sources of injury. At birth, the calf is limited in its ability to regulate its body temperature, so extremely warm or cold environmental conditions present a risk for hyperthermia or hypothermia, respectively, especially when accompanied by wet and muddy or dry and dusty conditions. Crowded herd conditions increase the chance for injury from being stepped on, butted, or otherwise injured by others in the herd, and increase opportunities for pathogen exposure and transmission. Predators present the greatest hazard to calves recently born or calves weakened by illness or injury. Calves may be injured from a variety of physical hazards in the calving environment including protruding nails, broken posts, loose wire, holes, steep embankments, standing water, various sources of electricity, and toxins (e.g. from lead batteries or chemical containers).

Environmental Hazards to the Dam

Cows are less susceptible to weather stressors compared to their calves, but dystocia or metabolic disease increases their risk for hypothermia or hyperthermia. During the periparturient period, cows may be more likely to slip and fall, and the likelihood further increases when the floor surface has a steep slope or is slippery due to snow, ice, or mud. Cows calving near ditches and streams or other low spots are at risk to fall or not be able to rise after lying down. As with calves, cows may be injured by a variety of physical hazards that may be present in the calving environment.

Risk Management of Environmental Hazards

The risk of injury to cow or calf can be minimized by providing favorable environmental conditions. Long-term strategies include breeding in a time frame such that calving occurs during favorable weather conditions and designing and using calving facilities with minimal physical hazards. Near-term strategies for environmental safety include a precalving survey of the environment and facilities for potential sources of injury, and frequent surveillance of the herd during the calving season.

Risk Assessment of Neonatal Calf Diarrhea

Neonatal calf diarrhea, commonly called scours, is one of the most likely reasons for morbidity or mortality of beef calves [7]. Neonatal calf diarrhea is a detriment to calf health and well-being, and the disease is costly to cattle producers due to reduced calf growth performance, death loss, and the expense of labor and medicines to treat sick calves [11, 12]. Also, restraint and treatment of calves puts veterinarians, herd owners, and their employees at risk for injury or zoonotic infection. Finally, it is disheartening to most cattle producers to see young calves sicken or eventually die following often valiant, but futile, treatment attempts.

Neonatal calf diarrhea is a complex disease [13–16], with many interrelated component causes. Component causes are the factors that in combination are sufficient to cause signs of disease [17]. The component causes of neonatal diarrhea in calves include more than the etiologic agent. In fact, it may be rare that knowledge of the presence of an agent by itself leads to a solution to outbreaks of neonatal calf diarrhea. Agent, host, and environmental factors collectively explain the occurrence of clinical signs of diarrhea, and these factors interact dynamically over the course of time [18]. To make effective risk management decisions, cattle producers and their veterinarians must understand the dynamic relationships occurring between agent, host, and environmental factors within the context of the specific production system [19]. For example, even if the etiologic agent(s) involved are known, understanding the various sources of the agent and routes of transmission on the farm might be useful for prevention and control.

Agent Factors of Neonatal Calf Diarrhea

Numerous pathogens have been recovered from cases of neonatal calf diarrhea, including bacteria such as *Escherichia coli* and *Salmonella* spp., viruses such as rotavirus and coronavirus, and protozoa such as cryptosporidia [13, 14, 19–26]. The adult cow-herd commonly serves as the source of pathogens from one year to the next [27–32]. The usual pathogens associated with neonatal calf diarrhea can commonly be recovered from calves in most cattle herds, including calves in herds of cattle not experiencing calf diarrhea [19]. Recovering a pathogen from a calf with diarrhea might help to explain the immediate cause of the calf's morbidity or mortality. However, that knowledge alone rarely explains the reason for the outbreak, nor does it necessarily provide a complete approach to treatment, control, or prevention of cases [16]. Multiple agents can often be recovered from calves in herds experiencing outbreaks of calf diarrhea, suggesting that, even during outbreaks, more than one agent may be involved.

Host Factors of Neonatal Calf Diarrhea

After absorbing antibodies from colostrum or colostrum supplements in the first 24 hours of life, calves may obtain passively acquired maternal immunity against diarrhea-causing pathogens common to the herd [33–35]. The quantity of antibodies absorbed is determined by the quality and quantity of colostrum the calf ingests, how soon after birth it is ingested, and the calf's physiologic state [34, 36]. The presence of antibodies in colostrum requires prior exposure of the dam to the wild-type agent or vaccine antigens. Vaccines are sometimes used to immunize the dam against specific agents so that the calf will receive passive antibody protection from colostrum [16, 37]. Also, some commercially available colostrum supplements and replacers contain antibodies directed against specific calf diarrhea pathogens [38, 39]. Unfortunately, the use of vaccines or colostrum supplements has not always prevented outbreaks of calf diarrhea in beef cattle herds.

Calves become ill or die from neonatal diarrhea within a narrow range of age, typically one to three weeks of age [13, 20, 22, 40]. The narrow range of age within which calf diarrhea occurs cannot be explained by the incubation period of the agents because diarrhea is observed within a few days of experimental pathogen challenge in colostrum-deprived or gnotobiotic calves, regardless of age [41–43]. It may be that calves experience an age-specific susceptibility to diarrhea agents that occurs as maternal immunity is waning and before the calf is primed for an effective immune response [37]. Therefore the first 7–21 days of age typically define the age of susceptibility, as well as the age calves are most likely to initially shed diarrhea-causing pathogens in their feces, becoming infective to other calves in the herd [44–48]. In some calving systems, the relative number of susceptible and infective calves can change dynamically with time [18]. Exposure to pathogens of a dose-load or duration sufficient to cause disease is called an effective contact. At times, particularly late in the calving season, the number of infective calves may greatly outnumber the number of susceptible calves, resulting in widespread opportunities for effective contacts.

The dam's age also contributes to a neonatal calf's risk for diarrhea. Calves born to heifers often have a higher risk for diarrhea and have lower maternal antibody levels than calves born to older cows [49]. Calves born to heifers are probably more susceptible to disease in the neonatal period because heifers produce a lower volume and quality of colostrum, may have poor mothering skills, and are more likely to experience calving difficulty [50, 51].

Environmental Factors of Neonatal Calf Diarrhea

Environmental conditions may contribute to both the level of pathogen exposure and the ability of the calf to resist disease. Exposure to pathogens may occur through direct contact with other cattle or via contact with contaminated environmental surfaces. Keeping the environment clean has long been recognized as important for preventing calf diarrhea [52, 53], but it may not be possible to do so effectively. Crowded conditions increase opportunities for effective contacts with infected animals or contaminated surfaces. Ambient environmental temperature (e.g. excessive heat or cold) and moisture (e.g. mud or snow) are important stressors to the neonatal calf, may impair the calf's resistance to disease, and also affect pathogen concentration in the environment, opportunity for exposure to pathogens, and dose-load of ingestion.

Temporal Factors of Neonatal Calf Diarrhea

Host susceptibility, pathogen exposure load, and pathogen transmission occur dynamically over time within the calving season [19]. Although the adult cow-herd likely serves as the source of most calf scour pathogens from year to year [27–32], the average dose-load of pathogen exposure to calves is likely to increase over time within a calving season because calves infected earlier serve as pathogen multipliers and become the primary source of exposure to younger susceptible calves. This multiplier effect can result in high prevalence of infective calves and widespread environmental contamination with pathogens [54]. Each calf serves as growth media for pathogen production, growing the number of pathogens to even greater numbers [43–45]. Therefore calves born later in the calving season may receive larger dose-loads of pathogens and, in turn, may become relatively more infective by growing even greater numbers of agents. Eventually the dose-load of pathogens overwhelms the calf's ability to resist disease. These factors alone or in combination may explain observations that calves born later in the calving season are at greater risk for disease or death [18].

Risk Management of Neonatal Calf Diarrhea

Biosecurity is the sum of actions taken to prevent the introduction of a disease-causing agent into a population (e.g. pen, herd, or region) and biocontainment describes the actions taken to control a pathogen already present in the population [55]. In theory there are three approaches to preventing outbreaks of neonatal calf diarrhea: (i) eliminate the pathogens from the population; (ii) increase calf immunity against the pathogens; or (iii) alter the production system to reduce opportunities for pathogen exposure and transmission [56]. However, the endemic nature of the common pathogens of calf diarrhea makes it difficult or impossible to make cattle populations biosecure from these agents. Colostral immunity is critical to protect neonatal calves from disease [37]. However, passive immunity against diarrhea pathogens decreases with time [37], and managers of beef cattle herds have limited ability to improve calf ingestion and absorption of colostral antibodies beyond not interfering with maternal bonding. Unfortunately, vaccines are not available against all pathogens associated with calf diarrhea, vaccines may not provide sufficient cross-protection against all pathogen strains [48], and pathogens may evade the protection afforded by vaccination by evolving away from the vaccine strains [57]. For these reasons, a biocontainment approach for controlling calf diarrhea, primarily by reducing effective contacts, may be a useful risk management strategy in many cattle production systems [56].

Effective contacts can be prevented by physically separating animals, reducing the dose-level of exposure (e.g. through the use of sanitation or dilution over space), or minimizing contact time [56]. For example, these principles have been successfully used to prevent neonatal illnesses in dairy calves by using calf hutch systems [58]. Various biocontainment systems for beef herds have been developed to prevent calf diarrhea [59–62]. Each of these strategies is designed to manage cattle in a system that prevents calves from having effective contacts with pathogens by reducing opportunities for exposure and minimizing dose-load.

One example of a beef cattle biocontainment system for controlling neonatal calf diarrhea is the Sandhills Calving System [62, 63]. The management actions defined as the Sandhills Calving System prevent effective contacts among beef calves by segregating calves in calving pastures by week of age. This is achieved through scheduled weekly movement of pregnant cows to clean calving pastures. The objective of the system is to recreate, during each subsequent week of the season, the more ideal conditions that exist at the start of the calving season, where cows are calving on ground that has been previously unoccupied by cattle (for at least some months) in the absence of older, infective calves.

The Sandhills Calving System prevents effective contacts by using clean calving pastures, preventing direct contact between younger calves and older infective calves, and preventing later-born calves from being exposed to an accumulation of pathogens in the environment. The specific actions to implement the system may differ between herds in order to meet the specific needs of each production system. Key components of the systems are age segregation of calves, the frequent movement of pregnant cows to clean calving pas-

tures, and opportunity for maternal bonding and colostrum ingestion with little management interruption. Age segregation prevents the serial passage of pathogens from older calves to younger calves. The routine movement of pregnant cows to new calving pastures prevents the build-up of pathogens in the calving environment over the course of the calving season and helps to prevent exposure of the latest-born calves to an overwhelming dose-load of pathogens.

Ranchers using the Sandhills Calving System have observed meaningful and sustained reductions in morbidity and mortality from neonatal calf diarrhea, and greatly reduced use of medications [63]; however, there may be additional costs associated with this production system compared with other methods of calving management. For example, there may be changes in land usage that require fencing or placement of water sources. Time and labor devoted to checking cows and delivering feed may increase. Cattle calving in extensive pastures may have greater health risks due to inclement weather or unobserved dystocia. Development of a ranch specific plan for implementing the Sandhills Calving System or other biocontainment system must take place well in advance of the calving season. Available pastures must be identified and their use coordinated with the calving schedule. Water, feed, shelter, and anticipated weather conditions must be considered. The size of the pastures should be matched to the number of calves expected to be born in a given week so as not to be damaging to later grazing.

The costs of implementing the Sandhills Calving System may be offset by benefits to labor management. For example, there may be some efficiency because cattle movement could be scheduled once a week as labor is available. Moving cows without calves to a new pasture is often easier than sorting and moving individual cow-calf pairs. Also, the workload is partitioned between pasture groups such that cows at risk for dystocia are together in one pasture while calves at risk for diarrhea are in another.

Risk Assessment of Pneumonia in Calves Prior to Weaning

Pneumonia is the leading cause of death in calves from three weeks of age to weaning [64]. This is perplexing considering that, before weaning, calves typically live in conditions with little stress and relative isolation from external sources of pathogens. And yet, preweaning pneumonia affects approximately 20% of beef cow-calf herds [65, 66]. Pneumonia in calves prior to weaning may affect up to 10% of US beef calves [67], resulting in death of 0.6–1.4% of all calves [68–70]. Calves affected with preweaning pneumonia may weigh 17–37 pounds less at weaning compared to unaffected calves [70, 71]. Pneumonia in calves prior to weaning is typically seen as one of two syndromes [72]. The first is intermittent, low incidence pneumonia in calves less than one month of age; the other is as a rapidly occurring outbreak of pneumonia in a large portion of calves in the herd when calves are three to five months of age. This latter syndrome is paradoxically associated with characteristics of highly managed herds, including having a larger herd size, using rotational grazing, and practicing estrus synchronization [65, 66]. It is likely that these characteristics are associated with greater opportunities for effective contact between calves. The annual cost of pneumonia in beef calves prior to weaning to the US beef industry is approximately $165 million [73]. The cost of labor to treat pneumonia in beef calves often exceeds the cost of medication [74].

Agent Factors for Preweaning Pneumonia

The common bacterial pathogens of pneumonia, *Mannheimia haemolytica*, *Pastuerella multocida*, and *Histophilus somni*, are found in the upper respiratory tract of most cattle. The inciting damage is often due to viral infections that may not be present in all cattle herds all the time. The most commonly recognized viral pathogens are bovine herpes virus 1, bovine viral diarrhea virus, and bovine respiratory syncytial virus, but many others are likely to be involved, including bovine coronavirus [75, 76]. Invasion of the lower respiratory tract with a pathogen may be a necessary condition of pneumonia, but exposure to these pathogens is not causally sufficient because it is difficult to create pneumonia through experimental challenge with bacteria or viruses alone [77].

Host Factors for Preweaning Pneumonia

Passively acquired maternal antibodies, important for protecting young calves against respiratory pathogens, wane with time. The serum half-life of passively acquired immunoglobulin G (IgG) is approximately 16–20 days, so that by the time a calf is 90–120 days of age, less than 2% of the antibodies it absorbed from ingested colostrum remain. The immune system is functional but unprimed at birth and acquired immunity is weaker, slower, and more easily overcome prior to five to eight months of age [78]. Therefore calves that are three to five months of age may be particularly susceptible to pneumonia even in the absence of additional stressors.

Environmental Factors for Preweaning Pneumonia

Although the setting for cow-calf production is often extensive and pasture-based, the opportunities for pathogen transmission from calf to calf may be relatively high because, regardless of the size of the pasture, cattle are gregarious and

will congregate closely around water sources and feedbunks, in shade, and when bothered by flies. Some management practices such as pasture moves and gathering for sorting also result in temporary periods of high animal density and greater opportunity for pathogen transmission.

Temporal Factors for Preweaning Pneumonia

Intermittent pneumonia in very young calves is likely due to calves with failed transfer of passive immunity [72]. On the other hand, it is the age-related loss of maternal immunity that may explain sudden outbreaks of preweaning pneumonia in herds with managed breeding seasons [72]. Herd immunity is the protection afforded to susceptible individuals because most of the individuals in the population are immune [79]. In herds with a narrow window of calving, most calves are relatively similar in age and herd immunity may be lost over a relatively short span of time as the majority of calves in the herd approach 90–120 days of age. Other temporal factors, such as weaning, commingling of groups, and severe weather can be important stressors and further reduce a calf's ability to resist disease.

Risk Management of Preweaning Pneumonia

Actions that increase the opportunity for calves to obtain colostrum in the first few hours after birth reduce the risk for failed transfer of passive immunity and may reduce the risk for pneumonia in young calves. It seems prudent to take actions to reduce the rate of effective contacts in herds that regularly experience outbreaks of pneumonia in calves three to five months of age. Also, vaccination of calves against bovine respiratory disease prior to three months of age seems prudent and has been anecdotally effective, although logistically challenging. However, the optimum set of protocols to prevent pneumonia in calves of this age remains an important subject of investigation.

Summary

Beef cattle producers can anticipate the most likely and most costly hazards to their cows and calves at calving time and can use this knowledge to plan for their prevention. Minimizing the risk of these hazards requires long-range and near-term planning. Calving problems may occur because of factors of the calf or the dam. Planning ahead for calving problems and close monitoring of the herd during calving can minimize the likelihood and/or cost of dystocia. Environmental conditions such as weather or physical hazards in the calving area are also important sources of injury to cows and calves. Planning to calve during favorable weather seasons and monitoring the environment for dangerous conditions minimizes the risk of these hazards.

A common cause of sickness or death of calves in the first three weeks of life is diarrhea. Understanding the complex interactions that cause calf diarrhea is the basis for developing strategies for disease control and prevention. The common pathogens of calf diarrhea are common to most cattle herds and it is unlikely that cattle could be made biosecure from these agents. Managers of beef cattle herds have few opportunities to improve rates of colostrum uptake and absorption, and vaccines are not always protective. Colostral immunity wanes, making calves age-susceptible and age-infective. Each calf serves as growth media for pathogen production, amplifying the dose-load of pathogen it receives and resulting in high calf infectivity and widespread environmental contamination over time in a calving season. For these reasons it is logical to apply biocontainment strategies to prevent effective transmission of the pathogens causing diarrhea. Cattle management systems based on an understanding of infectious disease dynamics have successfully reduced sickness and death due to calf diarrhea.

The most common cause of death in calves from three weeks of age until weaning is pneumonia. As with neonatal calf diarrhea, loss of maternal immunity may play a role in outbreaks of pneumonia, especially in calves three to five months of age. Outbreaks of pneumonia in beef calves have, paradoxically, been associated with characteristics of highly managed herds that create more opportunities for effective contacts. Strategies to prevent or control outbreaks of pneumonia in calves prior to weaning are still a subject of investigation.

Management to Decrease Neonatal Calf Loss in Dairy Herds

Ricardo M. Stockler

Auburn University College of Veterinary Medicine, Auburn, AL, USA

Introduction

The neonatal life, between birth and 30 days of age, is known among dairy producers and veterinarian practitioners to be determinant and most challenging for the calf as it is the time period when the greatest mortality occurs. The ultimate objective of all dairy farmers is to raise healthy and productive replacement dairy heifers. This chapter emphasizes practical approaches for decreasing morbidity and mortality of dairy heifers from birth to weaning, focusing on topics such as the pregnant dam, the calving period, neonatal dietary requirements, husbandry, and health maintenance of the newborn dairy heifer calf.

From Birth to Weaning

Neonatal morbidity and mortality not only can be influenced by the nutritional and physiological status of the dam but also may be directly associated with genetic traits [1]. Calf sire and breed [2], dam breed, trait heritability, feed efficiency, milk yield, carcass composition, and gestation length [3–5] are some examples of genetic variabilities that will in some degree influence neonatal death [1]. Calving season, calving environment, dry cow nutrition, dam vaccination history, and other specific risk factors associated with dystocia [6] such as age at first calving [2], gender and birth weight [3, 7], stress and uterine inertia, as well as infectious and non-infectious causes following eutocia such as congenital defects [8], twinning [7, 9], prematurity or dysmaturity, and abnormal placentation or premature placenta separation [10] are some non-heritable traits that may lead, as one factor or multifactorial reasons, to the demise of the calf during or shortly after calving.

The producer with the help of the veterinarian practitioner should always explore and analyze the situation by becoming aware of the risk factors for the individual or more importantly the cohort of animals where the problem has occurred. Proper animal identification and knowledge of the reproductive status of the dam are imperative for a successful disease investigation.

European researchers [11] published in 2016 a review on the influence of epigenetics and fetal programming on certain traits of production animals. They detailed the impact of the in utero environment and its influence on the ruminant progeny's overall health and welfare. It is suggested in the literature that fetal programming in the neonate during pregnancy may occur by epigenetic changes that are controlled by gene expression in the placenta and fetus (see Chapter 27, "Fetal Programming").

The maternity area or pen should have good lighting, with minimum human and farm equipment traffic, and be separate from the rest of the herd; also producers should avoid multiple-use areas as these can serve as focal points to spread infectious agents and transfer diseases between newborns and adults. A well-designed facility does not replace good management, and thus close observation is essential so that the cattle spend the minimum necessary amount of time in the calving area. It is imperative to note that if cows are to be calved in a designated pen or stall, providing a well-bedded dry enclosure with good air quality is essential. Larger dairies may opt to use calving paddocks or pastures, which allows close observation and therefore prompt movement of cows close to calving (two to three weeks prior to calving) and fresh cows.

The economics associated with raising a dairy heifer are positively related to the price of feed (milk, milk replacer, waste milk and pasteurization, concentrate), type of housing, death losses, culling rate, and other fixed variable

costs [12, 13]. Zwald et al. [13] reported that the average cost of raising a replacement heifer in the northern USA was about $4.28 per day from birth to moving the heifers out of hutches into group pens. A more recent report published by Iowa State University Extension and Outreach in 2019 [14] suggested an increase over the past years of roughly $1.00–1.25 per calf per day from birth to weaning. This means an estimate for a typical 56-day birth to weaning period is now a little over $300 in total cost per calf. The same publication notes that a good rule of thumb to remember is that overall cost until breeding age, in 2019, was approximately $2.33 per head per day for a 700-pound heifer. Further, to get the heifer to two years of age, the report indicated that after accounting for the extra costs associated with reproduction and labor, a typical $2.67 per head per day would be realistic considering the region and current economy as a whole.

Colostrum

Colostrum management is critical: for neonates to achieve successful transfer of maternal immunoglobulin (Ig), a sufficient amount of immunoglobulin must be present in the colostrum, combined with a low bacterial count [measured in colony-forming units (cfu)], and be consumed by the calf shortly after birth while the large immunoglobulin molecules are still able to be absorbed through the intestinal mucosa. Colostrum management is discussed in Chapter 75.

High-quality colostrum contains immunoglobulin at a concentration in excess of 50 g/l with a bacterial count of less than 100 000 cfu/ml [15]. Every neonate should be ingesting a minimum of 150–200 g of immunoglobulin within the first four hours of life [16]. As far as the volume to be offered, the rule of thumb is 3–4 l of good-quality (>50–75 g/l of IgG) colostrum; however, one must also consider the 10–12% of body weight rule [17] such that overfeeding should be avoided in some lighter calves, such as Jerseys and low-birthweight Holsteins, and some of the dual-purpose breeds (e.g. Milking Shorthorn, German Fleckvieh). It is important to note that genetics, production levels, and dry period length [18] positively impact the quality of colostrum.

For optimum health, calves less than one week old that received sufficient good-quality colostrum should manifest minimum serum IgG_1 concentrations of 1 g/dl [19]. High coliform-type bacterial count may bind free Ig in the intestinal lumen and/or directly block uptake and absorption of the Ig molecules by the epithelial cells, thus interfering with passive transfer. Recent work by Elizondo-Salazar and Heinrichs [20] showed that the best method to reduce bacterial counts in colostrum is to batch pasteurize at 60 °C for 60 minutes, known as the 60/60 rule. This treatment has been proven to reduce the concentration of pathogenic bacteria while preserving the nutrient value and provide a superior-quality Ig to the neonate. The shelf-life with refrigeration is 8–10 days [17].

Nutrition from Birth to Weaning

Drackley [21] published a comprehensive report on calf nutrition in 2008. To summarize, a 45-kg calf requires 1.75 Mcal/day for maintenance in a thermoneutral environment. This is equivalent to 325 g of milk solids or 2.5 l of whole milk or 3 l of milk replacer, as the latter is lower in fat content compared with whole milk. As a guideline, producers should be feeding calves a milk diet from birth to weaning at a measured quantity of 10% of body weight per day, divided into two feedings; this amount may be adjusted up to 12% during the winter months [22]. Increasing the frequency of feeding (three or four times a day), increasing volume (15% of body weight a day), and increasing the solid contents are some techniques producers may use to increase weight gain. Obviously there are disadvantages associated with those decisions, as increasing volume and frequency may decrease starter grain intake and cause digestive upset and diarrhea and the total solids in milk replacer should not exceed 15%.

Another factor to take into consideration is the type of milk replacer and the fat/protein concentration. Typically, 20 : 20 is most commonly found; however, one must consider the season, as winter months require more energy, cost, and overall health performance (e.g. due to presence of diseases, weight loss vs gain). Traditional versus accelerated feeding programs of dairy calves are some strategies often used by the dairyman. The traditional program uses 20% protein and 20% fat, as mentioned above. Often energy intake and growth are limited due to the levels fed. Higher intake may give calves enough nutrition for growth, but the higher protein will limit gain. The accelerated method uses milk replacers with higher protein (up to 28%) and lower fat (~15%) content. This feeding scheme tends to be more costly, and the producer must look at the season, as lower fat during the winter is not desirable.

Often it is more economical to feed whole milk (out of the bulk tank) instead of replacer; if that is the case, pasteurization is highly recommended to decrease bacterial count and cow–calf disease transmission (e.g. paratuberculosis, salmonellosis).

Calf starter, commonly called calf manna, provides another source of energy for calves and it can be offered as early as 1.5–2 weeks of age along with milk. An amount of

1.5% of body weight for the first week after birth increasing to 2% until weaning (10–12 weeks old) is recommended. It is also important to note that a calf should not be weaned off milk completely until it is regularly consuming 1 kg of starter feed daily [21]. The dairyman should always consult with the veterinarian of record and the nutritionist to determine an appropriate feeding scheme and type of milk replacer program.

Calf Housing

It is commonly understood among dairy producers, staff, and veterinarian practitioners that all calves must be kept dry, free from drafts, and separate from each other (no nose-to-nose contact) until weaning. The health advantages associated with this type of husbandry are well described in the literature [22–24].

Calf hutches or individual pens have been standard in the dairy industry [25] for many years. A standard minimum dimension of 3 m^2 is recommended and about an extra 10–15% open area between calves must be available to allow for cleaning and disinfection [20]. Different calf hutches/pens are available on the market and their use will vary depending on the region of the USA. Calf barns are very popular in the northern region, whereas outdoor hutches are commonly found in other areas of the USA. Hutches are usually not bedded (slatted wood floors, California-style hutches), or bedded with sand, straw, shavings, or other suitable material. The author recommends the use of sand as bedding due to its inorganic characteristics which facilitates disease prevention by offering the best when it comes to drainage of urine and feces. The calf hutch should face south in the winter and north in the summer [22], and be located in a prepared, sloped area to allow water drainage away from the hutch. Dirt, gravel, concrete, or slatted wood may be used as flooring material. A rack to hold water and feed buckets and/or nipple bottle should be placed outside the hutch, as this significantly reduces bedding maintenance. Common biosecurity practices must be practiced daily. Nipple bottles and water and feed bucks must be properly disinfected and rinsed, and must not be swapped between calves.

Weaning

Although age (10–12 weeks), weight (90–100 kg), and health condition must be considered, a calf should be weaned off milk and moved into a group pen only when consuming at least 1 kg of solids for three consecutive days [21, 22]. It is advisable to keep the calf in the hutch up to 10 days with starter feed ad libitum after complete removal of the milk diet; this practice allows the calf to lose its urge to nurse, as well as encouraging the consumption of dry feed on a regular basis, adapting and promoting rumen growth. Vaccination against the most common respiratory diseases may be considered before moving into the group pens. The author's experience suggests the use of a commercial intranasal product used according to the label and with the veterinarian on record's consent.

Health Maintenance

As discussed previously, good-quality colostrum delivered to the neonate within the first four to six hours after birth is essential for successful passive transfer of maternal immunoglobulins. It is recommended practice to remove the calf to a clean and dry area, protected from severe weather conditions, where basic calf care can be done. Close examination for any obvious gross abnormalities, such as cleft palate or other birth defects, followed by inspection and disinfection of the umbilicus are critical. Proper identification using tags and the placement of an official United States Department of Agriculture (USDA) identification, radio frequency identification tags (RFIDs), and maintenance of accurate records are also important (livestock owners should follow their state rules). The use of a "calf card" with information such as date of birth, sex, dam number, colostrum feeding (amount and quality), calving ease, and general comments is recommended. This information can be easily transferred to the dairy management software for easy access at a later date.

A comprehensive review article summarized the role of vaccines and of the neonatal immune system, as well as its impact on vaccine response [26]. The authors concluded that, first and foremost, one must assess the disease risks at the production site, consider the dam's immunity (i.e. colostrum quality), and the age of the calf in order to determine the vaccination protocol. Despite new research being done to avoid vaccine interference with maternal antibodies, one must never undervalue the importance of delivering good-quality colostrum, nor support the extra-label drug use of vaccines [27]. Vaccination schedules are farm specific and vary according to dairy practices; however, an example of a classic timetable is summarized in Table 73.1.

The most recent National Animal Health Monitoring (NAHMS) Beef 2017 Cow-Calf Study [28] reports 7.8% of beef cattle in the USA are horned, improved from 27.8% horned in 1997 and 12.4% in the 2007–2008 survey; conversely, NAHMS Dairy 2014 [25] reported that roughly 95% of dairy operations dehorned or disbudded heifer calves

Table 73.1 Typical vaccination protocol. Variation and inclusion of other pathogens (rotavirus, coronavirus, *Moraxella bovis* and *bovoculi*, etc.) may vary among farms.

Pathogen	Route	Age at first dose	Booster (follow label)	Comments
IBR	sc or in	6–8 weeks	3–4 weeks later	Revaccinate at breeding age (10–12 months old), then yearly
PI3	sc or in	6–8 weeks	3–4 weeks later	Revaccinate at breeding age (10–12 months old), then yearly
BRSV	sc or in	6–8 weeks	3–4 weeks later	Revaccinate at breeding age (10–12 months old), then yearly
BVD (types 1 and 2)	sc or in	6–8 weeks	3–4 weeks later	Revaccinate at breeding age (10–12 months old), then yearly
Clostridium spp.	sc	6–8 weeks	3–4 weeks later	Revaccinate at breeding age (10–12 months old), then yearly. Inactivated toxoid, local reaction may occur
Leptospirosis (five-way)	sc	6–8 weeks	3–4 weeks later	Revaccinate at breeding age (10–12 months old), then yearly. May consider including hardjo-bovis strain

Must follow label directions and the veterinarian on record recommendations.
Follow the vaccine label with respect to indication, dose, route, frequency, and meat withdrawal.
IBR, Infectious bovine rhinotracheitis; PI3, parainfluenza 3; BRSV, bovine respiratory syncytial virus; BVD, bovine viral diarrhea; in, Iintranasalntranasal; sc, subcutaneous.

and more than half of those procedures were accomplished by the producers and not by a veterinarian.

In November 2019, guidelines regarding dehorning of calves were published by the American Association of Bovine Practitioners [29] to help veterinarians and producers standardize this common livestock procedure to enhance overall knowledge of what and how this procedure is performed, subsequently enhancing animal welfare. It is widely known that by having non-horned cattle, the risk of injuries to herd mates and farm personnel is greatly reduced, as well as affording easier use of milking facilities, animal handling areas, and feed and water trough areas. A variety of methods are available and choice commonly differs by age of the calf at time of the procedure.

Chemical caustic paste, Barnes or scoop-type instrument, electric or gas-filled iron, or a combination of Barnes and dehorning iron are the options available [30]. The author suggests this procedure is done as early as possible in life. Removing the horn bud (while the bud is not yet attached to the skull, usually by eight weeks of age) is a lot easier and less traumatic to the patient.

The application of caustic paste is advantageous if applied correctly over the horn buds and in calves that are less than two days old, housed individually, and protected from a wet environment [31]. The use of an electric or butane gas-filled dehorning iron at one to four weeks of age is the quickest and most efficacious method for removal of the horn bud [22, 31, 32]. The procedure is simple but requires precise restraint of the head with the help of a cattle halter. An injectable sedative (xylazine 0.025–0.05 mg/kg i.v.) may be used, although it is often not necessary. Federal law restricts sedatives to use by or on the order of a licensed veterinarian. The author strongly recommends the use of local anesthesia to numb the cornual nerve bilaterally with the goal to mitigate the immediate pain associated with this practice. Administering 3–5 ml of 2% lidocaine using an 18- or 20-gauge 2.5-cm needle on each side should provide adequate anesthesia of the area within three to five minutes and last for up to five hours [26, 29, 31].

Furthermore, it is imperative to mention that one should step back and consider practices that include genetic selection by utilizing polled sires, as genomics and selection make this a viable option for the future with many dairy breeds.

Common livestock procedures such as dehorning/disbudding bring up a point related to the use of antiflammatory and pain control type medications. Analgesics/anesthetics were used by 28% percent of dairy operations that disbudded/dehorned heifer calves according to the most recent NAHMS survey [25].

A recent study published in 2017 [33] looked into the effects of flunixin meglumine transdermally on pain biomarkers at the time of dehorning. Although easy to use, the group concluded that transdermal flunixin meglumine given at the time of dehorning did not provide substantial analgesia based on the pain biomarkers investigated. Differently, meloxicam orally (1 mg/kg) has been shown to

decrease pain for up to 24 hours after a single dose of the drug [33]; however, it is vital to note that there are currently no approved drugs in the USA for use in cattle with an indication to provide pain control. The Animal Medicinal Drug Use Clarification Act of 1994 (AMDUCA) allows extra-label drug use provided a valid veterinarian–client–patient relationship exists, and the drug selection process, records and withholding times outlined in the AMDUCA and current research must be followed.

According to the USDA survey in 2014, 56% of deaths of preweaned replacement heifers were due to diarrhea or other digestive disease and 24% due to respiratory disease [25]. In contrast, after weaning, respiratory disease is responsible for almost 59% of deaths. Deaths of young calves due to respiratory disease usually occur around 12 weeks of age when replacement heifers are moved from hutches into a group pen. Strict colostrum management and vaccination protocols are known to be the top key factors that must be followed in order to minimize high mortality and morbidity at this young age.

It is imperative to recognize that the use of drugs and/or nutraceuticals do not replace a competent immune system. Colostrum management, good nutrition, and solid husbandry practices are often what are needed to raise healthy calves during the first weeks of life. Heller and Chigerwe published a review that summarizes the treatment and diagnosis of the most common infectious causes of diarrhea in the neonate bovine [34]. A herd investigation of diarrheic calves is primarily accomplished by understanding the age of onset, mortality, and morbidity, as well as the prevalence and incidence of the problem [34, 35]. The age of onset is crucial to rule out the likely etiology. Table 73.2 reviews the age and etiology of calf diarrhea. However, it should be noted that the majority of enteric diseases in calves are caused by mixed infections [36], and definitive diagnosis is valuable when the incidence of diarrhea is increased within a population with the goal of addressing potential medical, biosecurity (zoonosis), husbandry, and dietary problems, whereas diagnosing individual sporadic cases is known to be of little value. Frequently, clinical signs and age of the neonate dictate the likely cause of the diarrhea and supportive care is usually the treatment option, as the majority of etiologies have no specific therapy. As suggested in a review by Constable, the main goal when treating an individual is to prevent septicemia or bacteremia, decrease the bacterial load (mainly *Escherichia coli*) in the small intestine and abomasum, prevent negative energy balance, and reduce stress by providing analgesia [37].

In general, utilizing a combination of Gram-negative spectrum antimicrobials and a non-steroidal anti-inflammatory drug, while decreasing the volume and increasing the frequency of the milk diet, are the current recommendations [37, 38]. There is a plethora of antimicrobials available to treat bacterial enteritis in diarrheic calves [38], so it is important to consider the prudent use of these drugs when it comes to following the manufacturer's label; AMDUCA guidelines by discretionary use of extra-label drugs and, most importantly, a protocol should be in place that addresses the appropriate dosing, route, and frequency that reaches and maintains an effective therapeutic concentration at the site of infection [38].

Oral electrolytes are considered the hallmark of routine treatment to achieve rehydration. Smith [38] states that these products must supply a sufficient amount of sodium to normalize extracellular fluid, provide agents that facilitate the absorption of sodium and water from the intestines into the circulatory system, correct the metabolic acidosis, and provide energy. It is extremely important to understand that oral electrolytes do not replace the milk diet and vice versa; milk must not be mixed with the oral electrolytes, nor should it be fed concomitantly. The producer must always follow label directions when it comes to mixing the electrolyte solution, as improper mixing will interfere with the osmolality of the fluid in question and diarrhea, and further severe metabolic imbalance may occur.

Table 73.2 The most common infectious causes of calf diarrhea and age of occurrence.

Etiology	Age of onset
Clostridium perfringens type C	<2 days old
Clostridium perfringens (others)	Varies with type, typically secondary
Enterotoxigenic *E. coli* (ETEC)	0–7 days old
Enterohemorragic *E. coli* (EHEC)	2–30 days old
Rotavirus	5–14 days old
Coronavirus	5–30 days old
Cryptosporidium parvum	5–30 days old
Salmonella	>5–14 days old and anytime
Nutritional	Until weaned
Giardia	2 weeks to 2 months, typically secondary
Eimeria sp.	>25 days old
Parasites (HOTC complex)	After 3 weeks old
BVDV	PI3 calves – anytime

HOTC, *Haemonchus contortus*, *Ostertagia ostertegi*, *Trichostrongyles axei*, and *Cooperia* sp; BVDV, bovine viral diarrhea virus; PI3, parainfluenza 3.

Critical Care Management of the Neonate

Manuel F. Chamorro and Thomas Passler

Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

Neonatal calf morbidity and mortality are a major economic concern for beef and dairy cattle producers worldwide. Perinatal calf mortality in the first 48 hours of life has been estimated to be between 3 and 10.3% [1, 2]. A recent study determined that 6% (greater than 500 000 calves) of the total dairy calf mortality per year in the USA occurs at birth or shortly after [2]. Previous reports indicate that between 69 and 75% of perinatal beef and dairy calf mortality in the USA occur within the first 96 hours of life [3]. Therefore it is imperative to provide immediate evaluation and care of newborn calves to ensure calf survival and health and prevent economic losses associated with perinatal mortality. Several factors including dystocia, a fetus derived from cloning or *in vitro* fertilization, prematurity, dysmaturity, congenital defects, and neonatal infection (septicemia) represent risk for calf mortality during the perinatal period and should be addressed accordingly to prevent losses.

Pathophysiology of Extrauterine Neonatal Adaptation

Physiological changes in the cardiovascular and respiratory systems of the fetus are critical for normal adaptation of the calf to the extrauterine environment and survival. During stage 2 labor, the rupture of fetal membranes and umbilical cord initiates hypoxia in the calf [4]. Reduction of oxygen and accumulation of carbon dioxide in the calf's blood induce gasping reflexes, initiation of breathing, and inflation of the lungs [5]. Reduced alveolar pressure by the action of surfactant production allows air to remain in the lungs after initiation of regular breathing [6]. As oxygenation improves, pulmonary blood flow pressure decreases and peripheral vascular resistance increases, leading to the closure of the foramen ovale and ductus arteriosus, ceasing fetal circulation [5]. The normal progression of the fetal adaptation process can be altered by dystocia or other complications during calving such as meconium aspiration, prematurity, dysmaturity, and the presence of congenital abnormalities. Metabolic acidosis in the newborn calf due to hypoxemia and hypercapnia is a common consequence of dystocia and other complications during calving [7]. Persistent hypoxemia can lead to neonatal asphyxia, hypoxic encephalopathy, persistent foramen ovale and ductus arteriosus (right to left shunting), failure of adaptation, reversion to fetal circulation, and, ultimately, death.

Initial Assessment and Management of the Newborn Calf

Physiological adaptation needs to occur in the fetus to ensure viability of the calf after birth. Calves born after gestation of normal/physiological duration and by normal (unassisted) parturition usually have minimal problems adapting to the extrauterine environment. However, calves born by dystocia or assisted parturition carry a higher risk of adaptation failure and have an increased risk of morbidity and mortality [7–9]. Common disorders observed in compromised newborn calves are hypoxemia, respiratory and metabolic acidosis, hypothermia, and failure in the transfer of passive immunity [10, 11]. Early and vigilant monitoring should be performed in calves born following dystocia or assisted calving. Under normal circumstances, calves should attain sternal recumbency during the first 2–3 minutes and should attempt to stand within 15 minutes of birth. Hypoxic and acidotic neonates

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.
© 2021 John Wiley & Sons, Inc. Published 2021 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/hopper/bovine

usually have difficulty maintaining sternal recumbency, have a weak or absent suckle reflex, and require more time to stand [12]. Results from one study demonstrated a probability of 84% for mortality in calves that took greater than 15 minutes to achieve sternal recumbency [13]. Other clinical signs, such as failure to initiate respiration, tachypnea (<10 rpm), bradycardia (<40 bpm), pale or cyanotic mucous membranes, and the presence of a swollen tongue strongly suggest hypoxemia or inadequate neonatal adaptation and need to be addressed immediately [8, 14]. Recent studies evaluating newborn beef calves reported a significant association between abnormal mucous membrane color (white, red, or blue), inability to completely withdraw the tongue when pinched, and weak suckle reflex with decreased blood pH, increased blood lactate, and failure in the transfer of passive immunity [8, 14]. In human infants, a scoring system (Apgar score) that is based on five criteria (Appearance, Pulse, Grimace, Activity, and Respiration) is used to quickly assess neonatal well-being. While modifications of the Apgar scoring system have been used to identify compromised calves early after birth, inconsistency and lack of practicality has reduced their use among veterinarians and producers [14]. Critical points in the initial management of hypoxic/acidotic calves include establishing a patent airway, stimulating respiration, maintaining adequate body temperature, and ensuring adequate transfer of passive immunity [8, 15].

Establishing a Patent Airway

The calf is placed in sternal recumbency to favor oxygen and carbon dioxide exchange. Fluid removal from the upper respiratory tract by hand or suction is important when promoting airway patency. Suction can be used to remove fluid from the upper respiratory tract; however, it should be used with caution. Suction time should not exceed 5–10-seconds per bout in order to prevent reflex vagal bradycardia [16]. Alternatively, manual suction with a bulb syringe can be used to remove excess fluid. In the opinion of the authors, newborn calves should never be suspended by the hind limbs in an attempt to clear fluid from the respiratory tract. This action can interfere with normal respiratory adaptation by increasing thoracic (pulmonary) pressure because of the abdominal viscera pressing on the diaphragm [15]. (Editor's note: Brief suspension, for a duration of less than 90 seconds, has been shown to be beneficial following delivery by C-section specifically due to a positive functional impact on postnatal pulmonary mechanics and gas exchange.) Signs of inability of the calf to start spontaneous respiration should prompt stimulatory action.

Stimulation of Respiration

Spontaneous respiration should occur within 30 seconds of birth. Assistance should be provided if the calf fails to start breathing on its own during the first one to three minutes after birth. Several non-invasive methods to stimulate respiration have been described in newborn calves including vigorous towel-rubbing of the thorax and limbs, placing a finger or a piece of straw in the calf's nostrils, and pouring cold water over the calf's head and ears [5, 17, 18]. Results from one study demonstrated that newborn calves that had 5 l of cold water (5° C, 40° F) poured on their heads immediately after birth had increased respiratory rates, increased tidal volumes, and improved pulmonary function compared with control calves with no water poured on the head [15]. The authors of another study suggested that the insertion of a 20-gauge 1-inch needle in the nasal planum could stimulate the phrenic nerve and respiration [19]. If the calf does not respond to non-invasive stimulatory methods, pharmacological stimulants and/or endotracheal intubation and mechanical positive pressure ventilation (PPV) are necessary to preserve the calf's life. In this case, PPV is aimed at initiating respiration instead of treating hypoxia [20]. Specific treatment of persistent hypoxia will be discussed in the section "Specific Perinatal Conditions of Newborn Calves".

Treatment with pharmacological respiratory stimulants such as caffeine, aminophylline, or doxapram hydrochloride has been advocated for compromised neonates and can decrease the need of PPV in field situations [10, 11]. These drugs directly stimulate the respiratory center in the medulla and can improve diaphragmatic contractility. Caffeine and aminophylline dosages are mostly adopted from human and equine medicine [11]. In contrast, results from some studies have demonstrated beneficial effects of doxapram on respiratory function and survivability of ruminant neonates [21–23]. Caffeine can be administered orally or per rectum at a loading dose of 10 mg/kg and continued with 2.5–3 mg/kg SID (once daily) as maintenance dose. Aminophylline can be used at 4–10 mg/kg intravenously (IV) BID (twice daily) or TID (three times daily) or as a CRI (constant rate infusion) at 10–30 mg/kg/day. Doxapram hydrochloride can be used at 0.5 mg/kg IV SID or, in cases of emergency resuscitation and anoxia, at 5–10 mg/kg injected at the base of the tongue [11]. Reports on the effectiveness of these medications to stimulate and improve respiratory function in neonates are varied and inconclusive. Additional controlled clinical trials are needed to make judicious recommendations on the use of respiratory stimulants in compromised neonatal calves [10].

If mechanical ventilation is needed, a 6- to 10-mm endotracheal tube is usually effective. If a rebreathing bag is going to

Figure 74.1 One-day-old calf with hypoxemia and hypercapnia.

be used, it should be equipped with a safety valve to prevent excessively high pressures and alveolar damage. The ventilation rate should be around 15–25 respirations per minute. If 100% oxygen supply is available, a flow rate of 150–200 l/min with a 50-psi line and a maximum pressure of 39 mmHg through the endotracheal tube is recommended [5, 20]. The endotracheal tube should be removed once the calf starts fighting it. When mechanical ventilation with oxygen is unavailable, intranasal humidified oxygen should be administered in combination with pharmacologic respiratory stimulants. Intranasal oxygen can be administered at a rate of 2–10 l/min through soft intranasal cannulas inserted into nasal passages and advanced at the level of the medial canthus. The exterior portion of the cannulas is sutured or stapled to the skin (Figure 74.1). Red rubber catheters (10–12 mm in diameter) can be used as soft intranasal cannulas for humidified oxygen administration in calves [6].

Cardiac Stimulation

While cardiac resuscitation is unrewarding in calves born without a heartbeat, it should be attempted immediately in bradycardic newborn calves [heart rate (HR) < 40 bpm] or those that develop asystole. Cardiac stimulation should be performed in conjunction with respiratory stimulation because severely bradycardic or asystolic calves are usually not breathing on their own. The chances of successful revival are much greater when cardiac stimulation starts before nonperfusing rhythm or asystole [10]. Epinephrine is the drug of choice for cardiac stimulation in calves. Epinephrine can be used at doses that range from 0.1–0.2 ml/kg of the 1:10000 concentration to 1 ml/45 kg of the 1:1000 concentration. It can be given IV or intratracheally every three to five minutes [24]. Cardiac compressions to assist circulation can be initiated at the same time. A cardiac compression rate of 100 per minute with 8–10 respirations per minute has been described as reasonable for newborn calves [10]. If response to epinephrine is poor and severe bradycardia or asystole continue, vasopressin at 0.4 IU/kg IV can be administered. Vasopressin is a peripheral vasoconstrictor that has resulted in positive outcomes when used during cardiopulmonary resuscitation in humans [25]. In general, rapid initiation of cardiac compressions (before asystole), establishing an appropriate compression rate (100 per minute), and establishing an airway (endotracheal intubation) are considered the most important steps of cardiopulmonary resuscitation of calves [10].

Maintaining Adequate Body Temperature

The thermostatic mechanisms that regulate body temperature after birth usually fail in calves born following a prolonged calving process or severe dystocia [26]. This is especially true during times of the year when environmental temperatures shift dramatically during the day. Rapid thermoregulation after birth is critical for the calf's adaptation and survival. Hypothermic calves (rectal temperature <98 °F or 36.5 °C) should be assisted with the use of heating devices such as electric heating pads, circulating water heating pads, or infrared heaters. One study demonstrated that exposure of newborn calves to an infrared heater for 24 hours immediately after birth resulted in improved rectal temperature, increased arterial hemoglobin oxygen saturation, increased tidal volume, increased dynamic lung compliance, and increased respiratory rates compared with calves not exposed to the heaters [15]. Caution and close monitoring are important when using electric heating devices (heating pads, lamps) as burning is possible. Once the rectal temperature of the calf is >98 °F (36.5 °C), the heating device should be removed.

Ensuring Adequate Transfer of Passive Immunity and Nutrition

High-quality maternal colostrum or a colostrum replacement product should be given to newborn calves during the first four hours of life to achieve adequate transfer of

passive immunity. The correlation between inadequate transfer of passive immunity and calf morbidity and mortality before weaning is well documented in the literature [27–31]. Recently, adequate transfer of passive immunity in dairy calves has been suggested as shown by immunoglobulin G (IgG) levels in serum at 24 hours of life >21 g/l [28]. In beef calves, adequate transfer of passive immunity is defined as serum IgG levels at 24 hours of life >24 g/l [27]. The total mass intake of IgG required to achieve these goals varies between 200 and 300 g. In beef cattle, 200–300 g of IgG can be found in a volume of 1.5–2 l of maternal colostrum. Under normal conditions, a beef calf is expected to nurse this amount from its dam. In contrast, in dairy cattle a volume of 4–6 l of good quality maternal colostrum (>50 g of IgG/l) is required to achieve 200–300 g of total IgG for the calf. In hypoxic newborns, smaller volumes of colostrum at greater frequencies (30 minutes–1 hour) should be fed by bottle or esophageal tube to achieve complete intake. In addition to passive immunity, maternal colostrum provides newborn calves with nutrition, vitamins, and growth factors essential for calf survival during the first hours to days of life. In cases of confirmed failure of transfer of passive immunity in calves older than one day, fresh or frozen plasma (30 ml/kg IV) from their dam or a healthy donor from the same farm should be given. After colostrum feeding, nursing from the dam should be encouraged and monitored in beef calves. Alternatively, pasteurized whole milk or milk replacer at 12–20% of body weight per day should be fed at smaller volumes every three to four hours. In calves with poor or absent suckle reflex that tolerate tube-feeding, repeated tube feedings may be necessary. In calves that do not tolerate tube feeding (e.g. bloating, regurgitation) parenteral nutrition should be considered [32].

Clinical Pathology

To evaluate respiratory function and ventilatory capabilities of newborn calves, arterial blood gas measurement is considered the gold standard. Arterial PaO_2, $PaCO_2$, bicarbonate (HCO_3) concentration, SaO_2, and blood pH values should be evaluated. Reference values for newborn calves from birth to 24 hours of life are shown in Table 74.1 [33]. Although venous blood could be used for measurement of blood pH, HCO_3 concentration, and base excess, arterial blood is required for measurement of PaO_2 and $PaCO_2$ because of the poor correlation between arterial values with venous blood values [4, 34]. The caudal auricular artery (medial intermediate branch) and the brachial artery are commonly used by practitioners to obtain arterial blood samples. After properly identifying the arteries in their respective anatomic locations, blood can be collected using either a commercially available arterial blood gas sampling kit or a heparinized tuberculin syringe and a 25-gauge needle. After sample collection, the air from the syringe should be evacuated and the needle capped with a rubber stopper until analyzed. Samples should be sealed and submitted for analysis as soon as possible; however, if sealed correctly and placed on ice, samples can provide reliable results up to four hours after collection. Blood gas analysis is usually performed routinely in referral centers, but it can also be performed in field conditions with a commercial blood gas analyzer (i-Stat Corporation, East Windsor, NJ). Newborn calves that fail to adapt to the extrauterine environment commonly develop persistent hypoxemia, hypercapnia, and combined respiratory and metabolic acidosis [11].

Pulse oximetry is another non-invasive and immediate technique that has adequate accuracy to measure oxygen saturation of hemoglobin (SaO_2) in newborn calves. However, the reliability of this technique is lesser in cases

Table 74.1 Mean and (SD) values of blood gas analyses of arterial blood in 57 neonatal calves from birth to 24 hours of age.

Variable	At birth	0.5 h	4 h	12 h	24 h	P^a	P^b

of low oxygen saturation (<70%), carboxihemoglobinemia, methemoglobinemia, hypotension, anemia (Hb < 3 g/dl), or dark-pigmented skin [24]. The oximeter sensor can be placed on non-pigmented skin or mucosa such as the vulva, the prepuce, or the lip. Oximetry values <90% represent desaturation and oxygenation disturbance in most species. In addition to blood gas analysis, blood glucose, complete serum chemistry profile, and a complete blood count (CBC) can provide insight on the energy and electrolyte balance, liver and renal function, and probability of neonatal infection. The presence of hypoglycemia and metabolic and electrolyte abnormalities should be corrected with appropriate IV fluid therapy. Neonatal infection carries a more guarded prognosis and management includes IV fluids, plasma, systemic antibiotics, and non-steroidal anti-inflammatory drugs [35, 36].

Specific Perinatal Conditions of Newborn Calves

Persistent Hypoxemia

Dystocia can result in severe respiratory and metabolic acidosis in the fetus due to excessive accumulation of carbon dioxide in the blood. Healthy newborn calves born following dystocia can usually self-correct hypercapnia within a few hours after birth as respiration continues and oxygenation improves [7]. However, under certain circumstances, such as prolonged dystocia, premature calf, low concentration of inspired oxygen, bacterial or viral pneumonia, and congenital respiratory or cardiovascular abnormalities, hypoxemia persists and becomes life threatening [24]. Clinical signs are observed immediately after birth and tend to worsen over time. Signs such as inability to maintain sternal recumbency, inability to stand or difficulty in standing, weak or absent suckle reflex, hypothermia (rectal temperature <98 °F or 36.5 °C), low or infrequent breathing, and bradycardia (<80 bpm) are usually observed [12]. Other clinical signs may be present depending on the initial cause of adaptation failure and should be identified quickly through a thorough physical examination. Neurological signs such as severe depression, unresponsiveness, and seizure activity suggest hypoxic encephalopathy.

Diagnosis of persistent hypoxemia is based on history, clinical signs, and arterial blood gas analysis. Hypoxemia (PaO_2 < 45 mmHg), hypercapnia ($PaCO_2$ > 57 mmHg), and acidemia (blood pH <7.3) are common abnormalities found in these calves [7, 11, 12]. Treatment of persistent hypoxemia/hypercapnia in field conditions can be challenging. Affected calves should be started on intranasal humidified oxygen at 2–10 l/min. Respiratory stimulants such as doxapram hydrochloride, aminophylline, and caffeine at the doses described in the section "Initial Assessment and Management of the Newborn Calf" can be used to improve respiratory function. Sodium bicarbonate ($NaHCO_3$) therapy to combat metabolic acidosis is not recommended in hypoxic calves with abnormal ventilation as it could intensify hypercapnia and lead to cerebral acidosis [6]. In cases of hypoxic encephalopathy, treatment with furosemide (1 mg/kg IV BID), mannitol (0–0.5–1 g/kg IV as a 20% solution), and dimethyl sulfoxide (DMSO) (0.5–1 g/kg IV as a 10% solution) could aid in the treatment of cerebral edema; however, this therapeutic regime is rarely effective [24]. Ideally, repeated blood gas measurements indicate response to therapy. Calves with poor response after 12 hours of intranasal oxygen have a poor prognosis and may require mechanical ventilation.

Persistent Pulmonary Hypertension

This syndrome occurs in neonatal calves that undergo a delayed transition from fetal pulmonary hypertension to low resistance pulmonary circulation. Vasoconstriction of pulmonary vessels in response to persistent hypoxemia and reversion to fetal circulating patterns (right to left shunting) are the major contributing factors to pulmonary hypertension. This condition has been described in human infants and foals, and more recently in cloned calves [37–39]. Factors such as failure of the neonate's cardiopulmonary circulation to transition from the fetal state, meconium aspiration, high altitude, and pneumonia have been associated with its presentation in calves [38]. Clinical signs are observed immediately after birth and are similar to those described for calves with persistent hypoxia. Diagnosis is based on history, clinical signs, blood gas analysis, diagnostic imaging, and increased pulmonary arterial pressure. Repeated arterial blood gas analyses demonstrate persistent or progressive hypoxemia (PaO_2 <80 mmHg). Thoracic radiographs and computed tomography (CT) scan usually demonstrate atelectasis with decreased vascular patterns in the lungs. Cardiac catheterization demonstrates increased pressures in the pulmonary artery, right ventricle, and right atrium [11, 24]. Treatment of this condition consists of intranasal oxygen supplementation and mechanical ventilation if hypoxemia and hypercapnia persist. In calves unresponsive to mechanical ventilation, nitric oxide at 5–40 ppm in the ventilator gas can be attempted to promote peripheral vasodilation [24]. Additionally, endothelin-1 (ET-1) receptor antagonists such as sildenafil administered orally or as a suppository have been used as alternative vasodilators in humans [40]. The prognosis of persistent pulmonary hypertension depends on the initial cause of the disease. Non-response to oxygen therapy is also associated with a poor prognosis.

Respiratory Distress Syndrome

Disorders caused by incomplete organ development are usually seen in premature calves. In the case of the lungs, this can be life threatening, as affected calves can present with progressive respiratory difficulty, tachypnea, increased inspiratory and expiratory effort, hypoxemia, and ultimately death [41]. This is known as respiratory distress syndrome (RDS) and has been associated with inadequate surfactant production in prematurely born calves [42]. The surfactant system in the lungs is completely developed in the fetus at around 270 days of gestation. Calves born before 270 days of gestation have an increased risk of developing RDS due to lack of adequate amounts of surfactant production [43]. Surfactant is essential to prevent pulmonary collapse during breathing by reducing alveolar tension and maintaining alveolar stability. Insufficient surfactant production results in end-expiratory collapse and reduced gas exchange surface in the lungs. As the need for oxygen increases, the calf's inability to maintain adequate ventilation leads to progressive hypoxemia. Aspiration of meconium also impairs surfactant function and can promote RDS. Meconium causes an inflammatory reaction in the lungs, affecting function of type 2 pneumocytes and decreasing surfactant production [44]. Calves affected by RDS are usually premature as evidenced by the following physical characteristics: rounded heads, small body size, silky short hair, short umbilical hair, and incomplete or absent eruption of incisors. Clinical signs of progressive respiratory difficulty including tachypnea, inspiratory and expiratory dyspnea, apnea, severe lethargy, and pale or cyanotic mucous membranes are commonly observed 15–60 minutes after birth in calves with RDS [41].

Diagnosis of RDS is based on history, clinical signs, and the presence of severe hypoxemia (PaO_2 <45 mmHg), hypercapnia ($PaCO_2$ >58 mmHg), and acidemia (blood pH <7.2). In one study, the mean PaO_2, $PaCO_2$, and blood pH of 20 premature calves with RDS was 29.6 mmHg, 67.7 mmHg, and 7.1, respectively [41]. Radiographs of the lungs 24–48 hours after birth can aid in the diagnosis of RDS by demonstrating the degree of atelectasis, lung volume, and lung density in affected calves [38]. Treatment of calves with RDS consists of intranasal oxygen and mechanical ventilation in cases of persistent hypoxemia and hypercapnia. Results from one study demonstrated an increase of PaO_2 from 38.4 to 58.7 mmHg in calves with RDS within three hours of intranasal oxygen therapy (5–6 l/min) with no additional treatments [45]. Crude bovine surfactant collected from freshly slaughtered healthy cattle has been advocated in the treatment of RDS in calves. Intratracheal administration (via endotracheal tube) of a single dose of bovine surfactant (100 mg/kg) to calves with RDS resulted in a reduction of mortality by 60% in the treatment group compared with the control group [41]. Unfortunately, the cost of surfactant therapy at the reported dosage and with commercially available surfactant products is cost prohibitive for most producers (USD $12 000–16 000 for a single dose). Glucocorticosteroid therapy is a common and widespread practice for treatment of RDS among producers and veterinarians. Dexamethasone treatment appears to improve and favor lung maturation and surfactant production in the newborn calf [42, 46]; however, evidence of the efficacy of dexamethasone in the treatment of RDS in calves is lacking in the literature.

Prevention of Perinatal Mortality

Prevention of dystocia and reduction in the risk of premature calving should be the basis for prevention of perinatal mortality. All calves born before 270 days of gestation have an increased risk of developing RDS. Therefore avoidance of stressful management situations that can result in premature calving is a key factor in prevention. After 270 days of gestation, pregnant cows should not be transported, hoof trimmed (tilt table/chute), sedated with α2 agonists, or exposed to heat for long periods. High-risk pregnancies (cloned calves) or pregnancies carrying embryos of high genetic value need to be monitored through ultrasonography during the last trimester of gestation (every two weeks) for evaluation of the fetomaternal junction and early detection of edema hydrallantois, or other problems [47]. These findings decrease fetal viability, and decisions on induction of parturition or elective cesarean section should be made. A combination of dexamethasone and dinoprost (PGF2α) to induce parturition in cattle after 260 days of gestation reduces the risk of RDS in calves by accelerating type 2 pneumocyte maturation and surfactant production [42, 46]. Induction of parturition in cows under 260 days of gestation (230–260 days) to prevent RDS in the calf is possible with a modified seven-day induction regime [48]. Dexamethasone (5 mg) is given intramuscularly (IM) BID for four days. On day 5, 10 mg of dexamethasone is given IM BID. On day 6, 40 mg of dexamethasone and 25 mg of dinoprost are given IM once. Parturition usually occurs after day 6 [48].

Colostrum: A Review

Jenna Stockler and Manuel F. Chamorro

Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

Maternal colostrum contains immunological and nutritional components that are essential for the calf's survival and health during the first months of life. Immunoglobulins (Ig) and leukocytes present in colostrum provide the newborn with specific immunity against common infectious pathogens. Additionally, nutritional components of colostrum such as complex carbohydrates, fat, protein, and minerals provide energy and modulate activation of cell metabolism to guarantee the calf's survival during the first 24 hours of life. The association between overall dairy- and beef-calf health and adequate colostrum intake has been previously documented in the literature [1–4]. Adequate colostrum intake is related to the ingestion of an acceptable quantity of high quality colostrum in a timely manner and usually results in adequate transfer of passive immunity (API) to the calf. In contrast, a lack of adequate colostrum intake usually results in failure in the transfer of passive immunity (FTPI). FTPI is a condition associated with inadequate levels of colostrum derived Ig and other immune factors in the calf's serum at 24 hours of age. Calves that develop FTPI have greater morbidity and mortality rates before weaning compared with calves with API [4–6]. To prevent FTPI, newborn calves should receive an adequate amount of high quality maternal colostrum or a commercial colostrum replacement product within the first six hours of life. Monitoring the transfer of passive immunity in newborn calves at the individual-calf and herd levels is a key management strategy to reduce economic losses associated with calf morbidity and mortality. Evaluation of the level of absorption of passive immunity is usually performed through several on-farm and laboratory tests. This allows producers and veterinarians to make corrective decisions on overall colostrum management.

The Cow

Placenta

Placentation in the ruminant is described as synepitheliochorial and thus in utero passage of Ig from the dam to the fetus is prevented. This type of placentation forms a syncytium between the maternal endometrium and the fetal trophectoderm, separating the maternal and fetal blood supplies [7]. As a result, calves are born agammaglobulinemic and dependent on the absorption of Ig, leukocytes, and other immune factors present in maternal colostrum to achieve API.

Colostrogenesis and Components of Colostrum

Colostrum contains not only Ig but also other factors that help with establishment of the calf's immune system and prevention of disease. Colostrogenesis occurs several weeks prior to parturition and ceases abruptly immediately prior to parturition [8]. Physiologic changes, specifically endocrine control, coincide with the absorption of Ig across the mammary epithelium. Endocrine changes that have been shown in the weeks leading up to parturition include increased estrogen levels; increased serum corticosteroid, growth hormone, and prolactin; and a severe decrease in progesterone. Previous research has demonstrated that estrogen, alone or with progesterone, initiates the IgG1 Fc-receptor of the neonate (FcRn) within the mammary gland [8, 9]. These receptors are specific to the Fc portion of Ig [10]. The FcRn contains subunits and the expression of these, along with intracellular proteins, is upregulated by both estrogen and progesterone, which in turn increases transport of Ig across the mammary epithelium. Transport and release of Ig across the mammary epithelium and into the alveolar lumen occurs by transcytosis [7, 10]. Bovine colostrum is a mixture of lacteal derived secretions, proteins, leukocytes, growth factors, hormones,

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

vitamins, minerals, non-specific antimicrobial factors (lactoferrin), and other nutrients. Microelements, such as zinc and selenium, are shown to have increased concentrations in bovine colostrum [11]. Variability of the components of colostrum is likely but not limited to factors such as nutrition, breed, season, and age [12]. A review recently published expands on these effects in dairy cattle [13].

Absorption of Ig is crucial for the prevention of FTPI and disease. The predominant Ig found in bovine colostrum is IgG, specifically IgG1, accounting for 75–90% of the total IgG. IgA and IgM account for approximately 5 and 7% of the total Ig in colostrum, respectively. While IgG is transported through the alveolar epithelium by a receptor-mediated mechanism, IgM and IgA are locally produced in the mammary gland by plasmacytes [13, 14]. Varying concentrations of Ig are found in subsequent lactations and also when comparing cows to heifers [15]. The role of Ig in colostrum was described in 1969 [16]. IgG1 from maternal colostrum is the most important component of passive immunity in the calf. IgG1 is the only Ig capable of being resecreted to the enteric and respiratory tract mucosa to provide specific immunity and protection against common infectious diseases. IgG antibodies can activate complement and sensitize bovine skin [16]. IgM is important in opsonization, neutralization of viruses, and complement activation [17, 18]. IgA is found in the majority of mucosal secretions and prevents infection by agglutination of infectious agents. Additionally, IgA contributes to colonization of commensal bacteria within the gut, respiratory tract, and ocular mucosa [10, 18–20].

Another important component of colostrum is maternal leukocytes. The cell populations present in descending order include macrophages, neutrophils, and lymphocytes. Research has demonstrated that maternal leukocytes from colostrum enhance the development of the neonatal immune system [21]. The leukocytes that are present in colostrum and then absorbed into neonatal circulation are immunocompetent and can facilitate antibody production by enhancing activation of the calf's naïve T lymphocytes [22, 23]. The process of heat treatment, freezing, and thawing results in depletion of maternal leukocytes from colostrum [13, 24]. The role of maternal leukocytes present in colostrum on cell-mediated immune responses of the calf has been studied [13, 22, 25–29]. Results from one study demonstrated early (one week) cell-mediated immune responses in calves fed whole colostrum compared with late (two to three weeks) cell-mediated immune responses observed in calves fed acellular colostrum [28]. Another study evaluated neonatal calves that were fed fresh, frozen, or acellular colostrum, and their peripheral blood mononuclear cells (PBMC) response against bovine viral diarrhea virus (BVDV) and mycobacterial protein derivatives was assessed [27]. In this study, the cows from which the colostrum was harvested had all been vaccinated against BVDV. At 24 hours of life, PBMC responses were detected only in calves receiving fresh colostrum, not in calves receiving frozen or acellular colostrum. Similarly, another study evaluated fecal shedding of *Escherichia coli* after calves were fed whole colostrum versus acellular colostrum. The calves were inoculated with *E. coli* three hours after birth and then fed colostrum treatments. Calves that received whole colostrum shed less *E. coli* in their feces and had higher levels of both IgA and IgM [26]. Immune responses to naturally occurring respiratory and enteric disease were not different in calves fed cellular vs acellular colostrum [13, 30, 31].

Other components of colostrum that are essential for the calf in early life include proteins different from Ig, fat, cytokines, nutrients, antimicrobial factors, hormones, and growth factors. As stated by McGrath et al., "in general, colostrum contains less lactose and more fat, protein, peptides, non-protein nitrogen, ash, vitamins and minerals, hormones, growth factors, cytokines, and nucleotides than mature milk" [32]. Many of these factors are essential for the development of the gastrointestinal tract, protection of the Ig, endogenous glucose production, and thermoregulation [13, 32–34]. One example of these factors is trypsin inhibitor enzymes, which protect the Ig from proteolytic degradation in the calf's intestine [13, 32]. The energy that colostrum supplies as the first milk is essential for thermoregulation and calf survival during the first 24 hours of life, especially for calves born in the winter and during extreme cold conditions [35]. The major growth factors in colostrum include insulin-like growth factor (IGF) and transforming growth factor beta-2 (TGFβ-2) [33, 36]. IGF is essential for early intestinal transport, metabolism of glucose, synthesis of proteins, DNA, RNA, regulation of cell proliferation, and inhibition of apoptosis. Also, IGF has been shown to increase the villus size of enteric cells which allows for increased absorption of nutrients within the intestine [13, 36–38]. Other components of colostrum are vitamins. Colostrum intake is important for normal plasma concentrations of β-carotene, vitamin A, and vitamin E. Lack of adequate vitamin levels due to delayed colostrum intake (>12 hours) can result in decreased fatty acid synthesis and failure of the cell membrane protein pumps. This does not hold true for water-soluble vitamins. Many of these aforementioned components have been and still are being studied to understand how important they are in the protection of the calf and API.

Colostrum Intake

Beef and dairy calves are not the same in regards to how they are raised and how colostrum is provided. The most recent National Animal Health Monitoring System (NAHMS) dairy

study (2014) indicated that on dairy farms with greater than 30 cows, 95.4% of owners hand-fed colostrum to at least some calves [39]. On the very small operations (<30 cows), 16.8% of calves suckled from the dam [39]. Overall, 53.2% of dairy calves were hand-fed colostrum. On the beef-calf side, usually the calf naturally suckles the dam and therefore there are still a lot of uncertainties because consumption and assessment of colostrum are difficult to quantify. One survey of beef cow-calf producers in the USA demonstrated that 86.1% of producers intervened with colostrum consumption because they subjectively deemed the calf did not suckle enough [40]. The type of colostrum administered varied with each calf but the majority was from the calf's dam [40]. Studies evaluating beef cow colostrum and appropriate quantities needed are lacking.

Absorption of large proteins across the intestinal wall is a very non-selective process. During the first 24 hours, Ig and other molecules are absorbed through the small intestine by endocytosis. The large molecules are transported to the intestinal cell membrane where they are exocytosed into the lymphatics or portal circulation and thus gain entry into the systemic circulation [7, 13, 41]. The non-selectivity of Ig absorption has been proven with elevated concentrations of other proteins and enzymes, such as γ-glutamyl transferase (GGT) and even bacteria such as *E. coli*. Bacterial contamination of colostrum is common during suboptimal hygienic conditions of colostrum harvesting and can result in exposure of the calf to infectious pathogens during colostrum feeding. Colonization of the intestine and absorption of *E. coli* can result in neonatal infection, including septicemia and enteric disease [41, 42]. One explanation for this is that bacteria compete with the same sites that Ig will use for uptake across the intestinal cells. It is also possible that disruption of microvilli induced by bacteria prevents absorption of other large molecules including Ig [41]. Although bacterial contamination of colostrum is more common on dairy farms where colostrum is artificially fed to calves, beef calves are just as susceptible to enteric disease in the early neonatal period if colostrum contamination with environmental pathogens occurs.

Intestinal absorption of Ig from colostrum ends when activation of lysosomes within enterocytes starts to break down protein, including Ig. This process is commonly known as "gut closure." The ability of the intestine in the neonatal calf to absorb Ig past 24 hours is minimal. Ig concentration in colostrum begins to decline once parturition has occurred. This is of particular importance in the dairy cow in relation to milking. Studies have shown that there is a decrease in the Ig concentration of colostrum over time and with subsequent milkings in dairy cattle [43–45]. One study showed that for every hour post calving there was a 3.7% decrease in colostral IgG [13, 46]. Certainly, this concept would also be relative to the beef cow and the importance of the calf suckling within the first hours after birth. Apparent efficiency of absorption (percentage AEA) of colostral Ig by the intestine has a sustained increase within the first six hours, followed by a steady decline. Ideally, the IgG AEA from colostrum should be between 30 and 35% (Figure 75.1). In contrast, serum Ig in the calf demonstrates a steady increase after six hours of life following adequate colostrum intake [7, 47, 52]. Results from one study demonstrated that in Holstein male calves, absorption of Ig similarly decreased approximately 16% at 6 and 12 hours of life [47]. Goals for colostrum intake, to avoid FTPI, and for maximum absorption should be to supply the calf with adequate, good quality colostrum within the first six hours after birth [7, 13, 52, 53].

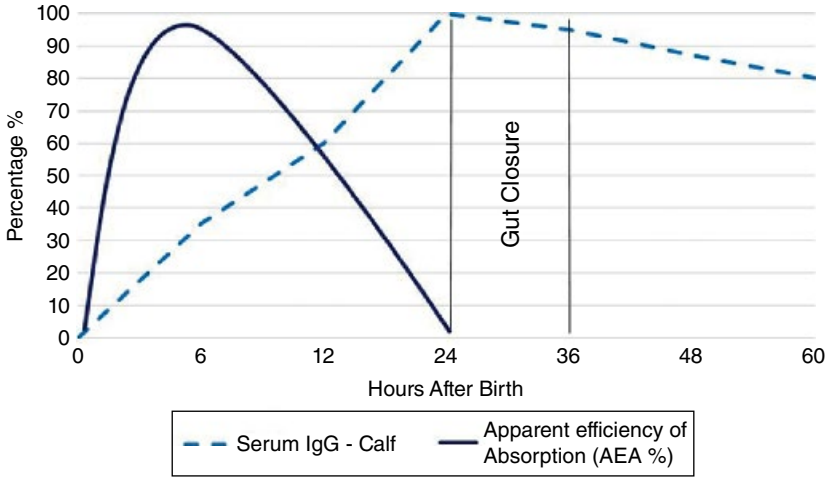

Figure 75.1 Relationship between colostrum absorption and serum Ig of the calf. *Sources:* [3, 47–51, 66].

Colostral intake, time after birth, and Ig concentration of colostrum are important to reach API in calves. Results from studies in beef and dairy calves have demonstrated that a lower serum IgG level at 24 hours of life as a result of inadequate colostrum intake is the "most important factor affecting pre-weaning health and survival" [2, 4, 6, 52, 54, 55].

Many of the guidelines for colostrum administration and feeding are based on dairy studies. This concept is not surprising, simply because of how dairy animals are raised and the ease of sampling; however, beef calf colostrum intake, administration, and supplementation are increasingly being studied. Recommendations throughout time have been that dairy calves should receive approximately 10% of their body weight (BW) in colostrum [12, 56]. One study evaluating different volumes of colostrum based on BW (7, 8.5, 10% BW) found that dairy calves fed at 8.5% BW had greater serum IgG concentrations than the other two percentages within the first two days of life [57]. The amount of colostrum supplemented to beef calves that failed to suckle adequately is normally between 0.5 and 1.25 l in most studies or a volume equal to 10% of the calf's BW [3, 52, 58, 59]. It has been shown that beef calves fed 5% of their BW within one hour of birth, followed by either suckling the dam or being tube-fed six to eight hours after, had API [60]. Differing amounts of colostrum needed are known to be due to the concentration of IgG in colostrum [61]. Beef cows have a higher grams per liter Ig concentration than dairy cows [62, 63]. Likely this is due to the volume of colostrum produced at the first milking, genetic factors, and management [12, 63, 64].A study showed that when comparing dairy to beef cow colostrum, beef cow colostrum was two times more concentrated with IgG than was dairy (65.5 g/l for dairy vs 143.2 g/l for beef) [63]. Other studies have found on average IgG concentrations of 95.9 g/l in beef cow colostrum and 64–65 g/l in dairy cow colostrum [61, 63, 65]. Further, when comparing beef and dairy calves in regards to colostrum supplementation, size of calf, quality of colostrum, and time of feeding are very important.

Colostral Volume and Time of Consumption

Consumption of colostrum can occur naturally by suckling directly from the dam or through artificial human intervention with a nipple bottle or an esophageal feeder. As a general rule that can be extrapolated from current literature, the average dairy and beef calf should receive between 280 and 300 g of total IgG mass from colostrum during the first six hours of life [6]. In dairy operations, this could be achieved with the administration of 4–6 l of good quality maternal colostrum (>50 g IgG/l). In beef calves, this could be achieved by suckling 2–3 l of maternal colostrum. Results from a study demonstrated that the mean colostral IgG concentrations in Holsteins was 74.4 g/l and over three-quarters of the samples had >50 g/l. [66] Therefore feeding protocols in colostrum management programs on dairies should be based on assessing colostrum quality and measuring colostrum IgG concentrations.

Removal of the dairy calf from the dam after birth is imperative. The dairy calf does not consistently suckle the appropriate quantity of colostrum required, and there is increased risk of exposure to pathogens when left with the dam [13]. Administration of colostrum to the dairy calf should be achieved with either a nipple system or use of an esophageal tube-feeding device. Early studies questioned the efficacy of tube feeding and IgG absorption once administered [67]. Tube feeding resulted in adequate API in those calves fed sufficient volumes of colostrum (3 l or greater). One of the main concerns with feeding colostrum using an esophageal tube is that the fluid will remain in the reticulorumen for an extended period, negatively affecting absorption of IgG (AEA). Outflow of colostrum from the rumen to the abomasum and small intestine takes approximately three hours, so as long as sufficient quantity of good quality colostrum is administered, API should be achieved [13, 68]. There was also no difference in serum IgG levels in calves fed the bottle versus tube feeding in this study [68]. A proceedings abstract evaluated beef calves suckling from the dam, bottle feeding, and two different esophageal tube-feeding times (immediately or four hours after birth). The group found that calves suckling from the dam achieved the highest IgG concentration; however, the levels did not differ significantly in those calves fed with the tube [69]. Beef calves (unassisted delivery) should be standing and suckling within one and four hours after birth, respectively [52, 59]. Results from one study demonstrated that beef calves not consuming colostrum within four hours of birth were 6.4 times less likely to reach API [52]. Colostral supplementation is likely required in the beef calf that experiences a prolonged or assisted delivery. In a study evaluating subclinical trauma during calving and transfer of passive immunity, beef calves experiencing a difficult delivery or a C-section had greater risk of FTPI [58]. If supplementation of a beef calf is required, placing the dam in a chute and allowing the calf to suckle for approximately 15–20 minutes is preferred. If the calf does not have an adequate suckle reflex, the cow should be milked and colostrum provided to the calf. Results from studies evaluating suckle reflex responses in beef calves demonstrated that calves with poor or weak suckle reflex responses had 41.6 times greater odds of failing to consume colostrum within four hours and developing FTPI [52, 58].

Colostrum Source

Sources of colostrum include the following: maternal (pooled versus non-pooled), colostrum replacers (CRs) (lacteal, serum, plasma, or whey) [70], and colostrum supplements. Maternally derived colostrum is considered the gold standard for both dairy and beef calves [7, 13]. As already stated, beef calves are expected to suckle from the dam and if there are any complications (dystocia or delayed suckle response) then intervention should occur and colostrum must be provided to reach API. Beef producers should keep a stockpile of colostrum products, including frozen colostrum from cows on the farm, high quality dairy cow colostrum, or ideally a colostrum-based CR [71]. While beef cows are not considered to make a large volume of colostrum, when possible collection and freezing of colostrum should be performed on the farm. Beef cow colostrum could be collected from cases of dystocia with a dead fetus or from high-producing beef cows. Maternal colostrum collected immediately after calving contains the highest IgG concentration. As time passes and collection of colostrum is delayed, other mammary gland secretions dilute IgG and colostrum quality drops. Results from one study demonstrated that delayed colostrum collection by 6, 10, and 14 hours after calving resulted in a reduction of colostrum IgG concentrations by 17, 27, and 33%, respectively [45]. Once collected, fresh colostrum should be refrigerated or frozen within one hour of collection. Refrigerated colostrum can be used up to 12 hours after collection but not more. Frozen colostrum stored at −20 °C can be stored and used up until one year and still be effective. Proper collection and storage of maternal colostrum is a key management strategy to prevent bacterial contamination and FTPI.

Dairy farms usually have access to a large amount of colostrum and should be able to utilize it appropriately. Pooled versus non-pooled colostrum has been evaluated extensively within the dairy industry [48, 53, 72, 73]. Pooled colostrum has mainly been used to improve the quality of fair quality colostrum and potentially maintain an adequate supply in times of enhanced need [53]. Additionally, pooling of colostrum increases the risk of transmission of colostrum-borne pathogens such as *Mycobacterium avium* subsp. *paratuberculosis*, *Mycoplasma bovis*, *Salmonella* spp., and bovine leukemia virus (BLV) to newborn calves [12, 53, 74–78]. One report indicated that the use of pooled colostrum still occurs on all-sized dairy farms but is more common on medium (100–499 cows) and large (>500) operations compared to small farms (30–99) [39]. The same report indicated that 55.1% of heifer calves on all operations were fed unpasteurized individual-cow colostrum and the remainder were either fed pooled colostrum, a CR, or other product [39]. Results from another study demonstrated that 70% of calves fed pooled maternal colostrum developed FTPI compared with only 11% of calves fed a CR product [79]. Another report indicated that when feeding calves single-cow maternal colostrum compared to a CR, the proportion of calves with FTPI was 28 and 93%, respectively [80, 81]. Feeding pooled and non-pooled maternal colostrum (dam or different dam) to dairy calves resulted in API in all calves, and no significant differences in colostral IgG were demonstrated in another report [82]. Bacterial contamination of maternal colostrum reduces absorption of IgG in the intestine and increases the risk of FTPI and neonatal infection. One study demonstrated that feeding calves with colostrum containing high bacterial counts (>1 000 000 colony forming units [cfu]/ml) resulted in reduced efficiency of IgG absorption and lower serum IgG at 24 hours after birth [83, 84]. Properly harvested maternal colostrum (beef or dairy) should contain <100 000 cfu/ml [13, 56]. The intensity of colostrum management (testing, collection, pasteurization, storage) and colostrum pooling strategies can influence success or failure in the prevention of FTPI in dairy calves; however, colostrum pooling strategies have not been studied in beef cattle.

An alternative source of colostrum when high quality maternal colostrum is unavailable or prevention of colostrum-borne pathogens is warranted on the farm is the use of commercial CR or colostrum supplement products. Other reasons such as convenience and consistency can make these products appealing to producers and veterinarians [13, 85]. CRs can be utilized on dairy farms that do not collect, store, or feed maternal colostrum, or that have abnormal health events at calving, or when cows leak colostrum before collection [86]. Replacers can also be utilized in the face of a maternal colostrum shortage. This could occur in times of calving clustering, discarding colostrum from cows that test positive for transmissible diseases (Johne's disease, *Salmonella* spp., *M. bovis*, BLV, BVDV, etc.), or on farms that do not practice colostrum pasteurization and storage. CRs are designed to be a "true substitute" for maternal colostrum and are mainly colostrum or plasma derived [80]. Replacers also contain vitamins, minerals, fat, and protein that are important for the early life of the neonatal calf. Colostrum derived CRs (lacteal) are a product of fresh frozen bovine colostrum collected from Grade A dairies. The colostrum is processed at a manufacturing plant where it is pooled and undergoes heat treatment or irradiation, spray drying, IgG testing and standardization, and packaging [87, 88]. Blood, from US Department of Agriculture (USDA) inspected abattoirs, is collected to make plasma/serum derived CRs [87]. Blood is centrifuged for separation of serum/plasma and red blood cells. The

plasma fraction is spray dried and then powdered to achieve a final Ig concentration of approximately 20 and 75% crude protein [89]. Plasma derived CRs are deficient in fats, vitamins, and minerals and thus additives are supplemented to these type of colostrum products. While colostrum derived CRs contain >90% of IgG1, plasma derived CRs contain IgG1 and IgG2 in similar concentrations and distribution. The only Ig capable of being retransferred to the respiratory and enteric mucosa after colostrum absorption in the calf is IgG1. Results of one study demonstrated that the level of neutralizing BRSV-IgG1 present in nasal secretions at 24 hours of age was significantly higher in neonatal dairy calves fed a colostrum-based CR product compared with calves fed a plasma-based product [71]. This suggests that colostrum-based products not only provide additional nutritional value but also provide specific immunity where the calf needs it the most. A licensed CR product should contain ≥100 g of IgG per packet. Not all CRs in the USA are licensed by the Center for Veterinary Biologics (CVB) and thus variability of products on the market exists especially in regard to the amount of IgG provided. Colostral products licensed by the USDA CVB and with the claim "to aid in the treatment of failure of passive transfer" must go through testing to ensure efficacy, potency, and safety [13, 90]. Other countries require all colostrum products to be licensed by their respective agencies.

Colostrum supplements are *not* intended to replace maternal colostrum. Also, colostrum supplements and CRs should never be used interchangeably as they do not provide the same benefit to the calf. Colostrum supplements are designed to do what their name implies – provide a supplement to a poor quality colostrum or a low volume of colostrum. Supplements provide between 25 and 60 g of IgG per package [87]. Colostrum supplements will not provide API and should not be used as such. Studies evaluating the use of colostrum supplements have demonstrated that if fed alone, calves will develop FTPI [91]. No added benefit of using a colostrum supplement has been reported on farms where a good colostrum program is in place [13, 92]. An appeal of colostrum supplements is their price. The cost of these products is approximately 50% of that of a CR (~USD $13 vs $26, respectively).

The validity of CRs and supplements has been thoroughly studied and evaluation of API investigated in the last 30 years [53, 79, 80, 85, 91, 93, 94]. Mixed results in regards to transfer of passive immunity have been reported in these studies. These studies have compared CRs to maternal colostrum, colostrum supplements, and lacteal or serum derived replacers. Results of one study demonstrated that only calves fed 4 l of pooled maternal colostrum containing 100 g of IgG acquired API compared to calves fed 4 l of colostrum supplements of different origin and with different IgG concentrations (100, 50, 60, and 90 g of Ig in each product). The serum IgG concentrations at 24 hours were 12.1, 6.8, 3.5, and 2.2 g of IgG/l in study calves fed pooled maternal colostrum, a serum based colostrum supplement, and two different milk based colostrum supplements, respectively [94]. Another study comparing maternal colostrum, serum derived CRs, and colostrum supplements found that the total mass of IgG fed and processing method were critical to ensure API [89]. This group also found that maternal colostrum conveyed API, whereas the replacer and supplement did not (18.8 g/l vs 8.35 g/l and 6.62 g/l, respectively). The main explanation for this was the amount of IgG present in maternal colostrum. Calves that were fed a plasma derived CR exhibited lower serum IgG and total protein concentrations between one and eight days of age compared with calves fed maternal colostrum in one study. Interestingly, in this study although there was a trend, the number of calves treated for illness was not significantly different between the two groups [80]. Serum IgG at 24 hours of age was significantly lower in calves fed a single dose (100 g of IgG) of a CR product when compared with calves fed two doses (200 g of IgG) of the same CR or 3.8 l of maternal colostrum containing 55–502.2 g of IgG in another study [95]. Additionally, these calves that received the two doses of CR had evidence of API. Similar to previous reports, the timely administration of an adequate total mass of IgG was essential to achieve API.

In one study, 100% of calves fed 150 g of IgG of a CR product developed FTPI compared with only 11% of calves fed 450 g of IgG of the same CR product [96]. In another study, serum IgG at 24 hours of age was evaluated in four groups of calves. The calves were fed either 3.79 l of maternal colostrum containing 106 g/l IgG, 3.79 l of low-quality maternal colostrum supplemented with 40 g of IgG (41 g/l IgG), a single dose of a CR containing 110 g of IgG, or a single dose of a CR containing 150 g of IgG. Calves fed maternal colostrum or low quality maternal colostrum supplemented with 40 g of IgG had a higher mean serum IgG concentration compared with calves fed the CRs (27.04, 22.33 g/l vs 12.79, 16.90 g/l, respectively) [70]. Additionally, 20% of calves fed a single dose of CR containing 110 g of IgG developed FTPI. In a report, feeding dairy heifer calves 300 g (three packages of 100 g each) of a colostrum derived commercially available licensed CR within the first 6 hours of life resulted in a mean 24-hour serum IgG of 26.9 g/l and a mean serum total protein (STP) of 6.2 g/dl [97]. CRs are effective as a substitute for maternal colostrum when administered in the first six hours of life and when provided in adequate total mass of IgG (>250 g).

Studies evaluating the use of CRs in beef calves and their efficacy providing API are lacking; however, observations

during practice in our teaching hospital indicate that the administration of at least 250–300 g of IgG from CRs during the first six hours of life are necessary to achieve API. One survey evaluated calf management practices on beef cow-calf operations and found that if a producer intervened because of inadequate suckling, 13% of those producers' first choice was to use a CR [40].

Colostrum Quality

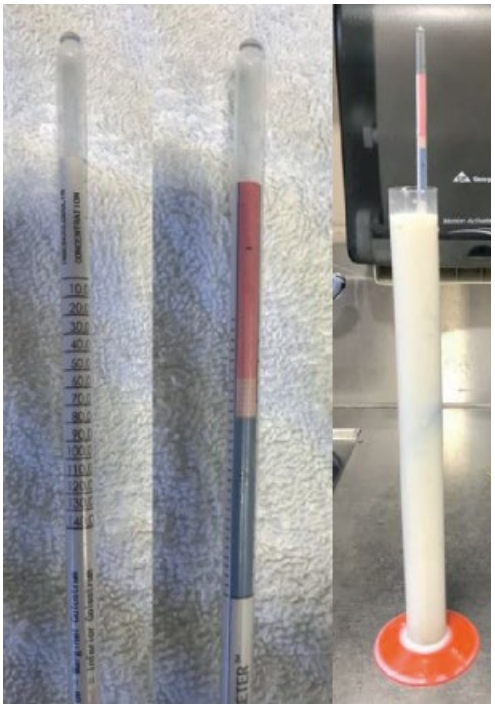
The quality of colostrum is the most important factor in any colostrum management program. Colostrum quality refers to the IgG concentration (grams per liter) present in maternal colostrum. The IgG concentration considered optimal for maternal colostrum is >50 g/l [95]. Colostral quality can be assessed very easily on dairy farms at the time of first milking. Beef cow colostrum is easily stripped from the udder following a dystocia, as well as in times when the cow is caught in a chute to allow the calf to suckle. Assessment of colostrum quality will allow the veterinarian or producer to properly utilize or discard the colostrum based on quality test results. Cost, time, and lack of training all contribute to decreased evaluation of colostrum at the farm level. Quality of colostrum can be tested by measuring IgG concentration with radial immunodiffusion (RID), immunoassays, enzymatic assays, hydrometers (colostrometers), or the Brix refractometers [61, 65, 98–101]. Direct measurement of IgG (RID, other assays) is the most accurate method to evaluate colostrum quality and is considered the gold standard; however, this test is not feasible to do at the farm. An on-farm test needs to be quick, user-friendly, accurate, and reliable [61]. A recent report indicated that 45.1% of all dairy operations used visual appearance to estimate colostrum quality rather than a true test [39]. The colostrometer was used on 11.4% of all dairy operations in the USA and 4% of farms in Quebec, Canada [39, 102]. The Brix refractometer was used on only 4.1% of farms in the USA [39].

Using color and consistency of colostrum as indicators of quality is an inadequate and wrong assumption of the level of IgG present. The goal of assessing colostrum quality is to distinguish between poor (<30 g/l of IgG) and good (minimum >50 g/l of IgG) quality colostrum and then apply that information to develop strategies to improve the colostrum management program. The individual IgG concentration of maternal colostrum is highly variable. Studies have demonstrated that the proportion of low quality colostrum (<50 g/l of IgG) found on dairy operations after assessment of quality with RID, colostrometers, or Brix refractometers varies between 7 and 32% [61, 99, 100, 103, 104].

The colostrometer has been previously validated for the evaluation of colostrum quality [105]. Colostrometers measure the specific gravity of the colostrum and give an estimate of the amount of Ig that is present [61, 105]. Disadvantages of the colostrometer include the following: its fragility (glass); colostral temperature must be at 22 °C (72 °F); other non-Ig solids content usually affects the results; and cleaning after each use [61, 87, 105]. Use of the colostrometer is simple and personnel can easily be trained to utilize this testing modality. Common limiting factors of colostrometer use are an inadequate volume of colostrum and temperature of colostrum.

Brix refractometry is another option for on-farm evaluation of colostral quality. Refractometers measure the total solids within a solution or the refractometric index of a liquid on a Brix scale [99, 103]. Optical Brix refractometers require an individual to utilize the refractometer with the eye piece and determine at what percentage the blue lines fall. Digital refractometers give a Brix score by shining a light through the liquid and measure the index of refraction of that sample [99]. The result is displayed as a percentage. The refractometer also has disadvantages including calibration and sensitivity to light; however, Brix refractometers are less temperature sensitive than the colostrometer. They are easy to use and provide a quick estimate of IgG concentration. An optical and digital Brix refractometer were compared to the standard RID in determining IgG concentrations from maternal colostrum [99]. The mean Brix score of fresh and frozen colostrum samples using an optical and digital Brix refractometer was approximately 26% each and the correlation between the Brix refractometers and RID was moderate ($r = 0.71$ and 0.73, respectively) [99].

Results from one study demonstrated that when using a specific gravity of <1055 with the colostrometer to classify poor quality colostrum (<50 g/l of IgG), it had a sensitivity of 32% and a specificity of 97%, indicating a high chance of misclassifying a colostrum sample as adequate quality when in reality the sample was of poor quality [100, 104]. A study evaluating dairy cow colostrum quality with RID, Brix refractometer, and colostrometer found that 29.1, 14.1, and 34.3%, respectively, were below the cut point recommended for each testing modality [61]. The correlation between the RID and Brix refractometer and colostrometer was moderate ($r = 0.64$ and 0.77, respectively). Accuracy of the Brix refractometer and colostrometer was highest when the Brix reading was 23% and the colostrometer was at 80 g/l [61].



Colostral quality has been investigated using beef cow colostrum [65]. This study evaluated RID and Brix refractometry on 396 colostral samples from 92 suckler herds that included breeds such as Charolais, Belgian Blue, Blonde d'Aquitaine, and Limousin. Results

demonstrated that the mean colostrum IgG concentration was 95.9 ± 36.2 g/l. The mean Brix percentage was 26.3 ± 5.2 and the correlation between the RID and Brix refractometer was good (r = 0.8). Additionally, the authors evaluated different colostral IgG concentrations and determined the Brix percentage associated with each IgG level. For 50, 75, and 100 g/l of IgG in beef colostrum, the associated Brix (percentage) values are 22.5, 25.5, and 26.9%, respectively.

Other assays have been studied to assess colostral quality; however, their use has not been greatly implemented in the dairy industry [101, 106]. The Brix refractometer and colostrometer are the indicated methods to evaluate colostrum quality and to make decisions on storage and overall colostrum management (Figures 75.2–75.4).

Failure in the Transfer of Passive Immunity (FTPI)

Absorption of IgG and other active immune factors from colostrum are critical for the health and survival of newborn calves. Therefore assessing the levels of serum IgG during the first 48 hours of life provides an accurate prediction of future calf health and performance before and after weaning [1, 3, 5, 108]. As mentioned in previous sections of this chapter, high serum circulating levels of IgG (>10 g/l) that result from the timely consumption of an adequate volume of high quality colostrum is what defines API in dairy

1. Collect a first milking colostrum sample from a prepared udder.
2. Please sample in a graduated cylinder leaving approximately 3 cm at the top. Colostrum should be approximately 22°C or 72°F.
3. Put the colostrometer into the graduated cylinder and allow it to "float" for approximately 5 seconds.
4. Read the colostrometer. Refer to Figure 4 for recommendations.

*Images courtesy of Dr. Herris Maxwell.

Figure 75.2 Instructions on using a colostrometer. (Note instructions included in figure.) *Source:* Images courtesy of Dr. Herris Maxwell.

1. Digital reader should be clean of debris.
2. Place a drop of tap water, sterile water, or sodium chloride on the sample area.
3. Press start, the light will flash in the sample area. If the % read does not show "000", press the "zero" button.
4. Discard the water sample and lightly dry sample area with a towel.
5. Add colostrum sample to the sample area and press "Start."
6. Results will be displayed within 2 seconds. Refer to Figure 4 for recommendations.

Colostrum Quality	Colostrometer/Hydrometer	Brix Refractometer (%)	Recommendation for Use
Good	Green (>60–90 g/L)	>23%	Use of Store *
Fair	Yellow (30–50 g/L)	18–22%	Use as a second feed^
Poor	Red (<30 g/L)	<17%	Discard

* Store under refrigeration for up to 48 hours and if not used by this time then should be frozen for up to 1 year.
^ This quality colostrum should only be used if the calf has received good colostrum and the appropriate amount at the first feed.

calves. During the last 30 years or so, serum IgG levels <10 g/l have been used as the cut-off to define FTPI in the dairy industry 30, 66, 109, 110, the, last, within, years.[39]. Dairy calves with serum IgG concentrations of less than 10 g/l when sampled within one to seven days of age are classified as having FTPI. This classification standard was based on significant reduction of preweaning mortality observed in young dairy calves with serum IgG levels >10 g/l between 24 and 48 hours of age [7, 12, 56, 109, 110]. The adoption and implementation of this standard by producers and veterinarians during recent decades resulted in a significant improvement in dairy colostrum management programs and reduction of calf mortality. Today, more than 90% of heifer calves on US dairy operations meet or surpass the current serum IgG standard (10 g/l) [39, 66] and preweaning dairy heifer mortality was reduced from 10.8% in 1992 to 6.4% in 2014 [39, 111]. During the same period and despite overall improvement in the transfer of passive immunity, the rate of preweaning dairy calf morbidity did not significantly change (36.1% in 1991 vs 33.9% in 2014) [39, 110, 111]. Studies suggest that higher serum IgG levels than traditionally recommended are associated with reduced dairy calf morbidity. Results from one study in which 175 neonatal dairy heifers were stratified by serum IgG levels at 30–60 hours of life demonstrated that calves with serum IgG levels ≥15 g/l had lower preweaning rates of respiratory disease and diarrhea compared with calves with lower IgG levels [1]. The authors of another study where 1290 dairy heifers were stratified in categories by IgG and STP at 48 hours of life reported significant reduction of preweaning morbidity and mortality associated with the serum levels of IgG and STP. The reduction of health events occurred in the heifers with serum IgG levels of 20–25 g/l and STP of 5.8–6.3 g/dl compared with other groups [108].

In contrast to the <10 g/l of serum IgG used in dairy calves to define FTPI, the beef industry has adopted a cut-off of >24 g/l of serum IgG to define API, a value much higher than the dairy industry [3, 5]. In one study, the association between serum IgG levels and preweaning morbidity/performance was evaluated in 1568 crossbred beef calves. Results from this study demonstrated significant reduction of morbidity and mortality when serum IgG in calves was ≥24 g/l at 24–72 hours of age. Calves with serum IgG <24 g/l were 1.6 times more likely to become ill and 2.7 more likely to die before weaning. Additionally, increases in individual BW (>3.35 kg) were reported at 205 days of age in calves with serum IgG levels >27 g/l [5]. Results from another study where serum IgG levels at 24 hours were contrasted with preweaning morbidity and mortality in 935 beef calves from 153 different cow-calf farms demonstrated that the odds of treatment and death were greater for calves with serum IgG <24 g/l. [3] Similarly, results from a study involving 1392 beef calves determined that to significantly reduce morbidity and mortality, the optimal 24-hour serum IgG and STP cut-off values needed to be >24 g/l and >6.0 g/dl, respectively [112]. Based on literature reports in dairy calves and data from beef calves, there is strong evidence that the dairy calf standard established to define optimal transfer of passive immunity (>10 g/l) does not reflect the beneficial effects of higher serum IgG levels on reduction of calf morbidity and enhanced health and performance.

A study that involved several US dairy calf experts from government institutions, academia, industry, and private sectors proposed new standards for optimal values of serum IgG, STP, and percentage Brix associated with API in dairy calves based on data collected during the 2014 Dairy NAHMS report [6]. Results from this study demonstrated significant reduction of preweaning dairy calf morbidity at different levels of serum IgG between one and five days of life. Four classification categories, instead of the previous two (adequate vs failure), of serum IgG and corresponding STP and percentage Brix values that reflect different risks of preweaning morbidity and mortality were recommended for implementation in US dairy operations (Table 75.1).

Table 75.1 Herd-level categories and optimal values of serum IgG, STP, and Brix, with recommended proportion of calves for each category.

	Categories of transfer of passive immunity			
Value/proportion at 24–48 hours	**Excellent**	**Adequate**	**Reasonable**	**Failure**
IgL (g/l)	>25	18–24.9	10–17.9	<10
STP (g/dl)	>6.2	5.8–6.1	5.1–5.7	<5.1
Brix (%)	>9.4	8.9–9.3	8.1–8.8	<8.1
Calves (%)	>40	~30	~30	<10

Factors Associated with Transfer of Passive Immunity in Calves

Several factors from the dam, calf, general management, and environment can affect adequate consumption of colostrum and absorption of IgG and other immune factors increasing the risk of FTPI.

Colostrum Quality

Genetic factors such as breed and management factors such as the prepartum diet, pooling practices, and time of collection have a direct influence on the concentration of IgG in colostrum [45, 113, 114]. Holstein cows tend to produce higher volumes of colostrum compared with any other breed. A previous study suggested that Holsteins produced colostrum with mean IgG concentrations significantly lower than other dairy breeds due to a dilution effect [113]. However, studies demonstrated that the average IgG concentration in colostrum from Holstein cows in the USA is >68 g/l, which is higher than the standard for good quality dairy colostrum [66, 103].

Colostrum IgG concentration in beef breeds is usually >95 g/l and values of >100 g/l are considered of adequate quality [65, 115]. One study reported that FTPI was four times more likely in calves born to cows that had a higher frequency of expression of a defective mammary gland Fc-IgG receptor [116]. The expression of the defective Fc receptor was found to be greater in Gelbvieh, Charolais, and Simmental cows in another study [117]. Although in the past it was believed that colostrum from first-calf heifers had lower IgG concentrations compared with colostrum from older cows, more recent studies have demonstrated that colostrum quality of beef and dairy first-calf heifers is adequate and should not be discarded without testing [66, 118].

The effect of the prepartum diet on colostrum IgG concentration in dairy cows is controversial and it has been difficult to establish. Some studies have suggested that restricted protein and energy diets during the last 100 days of gestation in beef cows resulted in lower IgG levels in colostrum and greater risk of FTPI in their calves [114, 119, 120].

Pooling of raw maternal colostrum from different cows is a common practice on US dairy operations. Results from one study indicated that only 25% of pooled maternal colostrum meets the quality standards for IgG concentrations (50 g/l) [79, 103]. Pooled colostrum usually overrepresents poor quality maternal colostrum, increasing the risk of FTPI [79].

Individual variation in colostrum IgG concentrations in addition to the above-mentioned factors introduce a persistent variability in the total mass of IgG fed to each calf, particularly on farms that feed a fixed volume (i.e. 4 l) of maternal colostrum. Ingestion of an adequate total mass of IgG is the single most important factor in acquiring API. The greater the total mass of IgG consumed by the newborn calf, the higher the level of IgG in serum at 24 hours [121]. Variation in IgG concentrations of maternal colostrum could not only affect the presentation of FTPI but also reduce the transfer of specific immunity [122].

Colostrum Cleanliness

Providing the newborn calf with colostrum free from bacteria reduces the presentation of FTPI [42, 123]. Results from some studies suggest that contamination of colostrum with bacteria disrupts absorption of IgG through the intestinal epithelium, reduces the efficiency of absorption of IgG, and increases the risk of neonatal septicemia [13, 42]. Direct competition through non-selective pinocytosis, binding of free IgG in the intestinal lumen, and breakdown of IgG by bacterial enzymes have been proposed as potential mechanisms by which bacterial contamination of colostrum affects IgG absorption and increases the risk of FTPI [42, 123–125]. Results from some studies have demonstrated that heat treatment of maternal colostrum significantly reduces bacterial contamination, reduces transmission of

colostral-borne pathogens, and increases IgG absorption in calves [66, 84, 125, 126].

Time of Colostrum Feeding

Delayed colostrum feeding or delayed suckling increases the risk of FTPI. Results from one study demonstrated that feeding the same source of maternal colostrum to dairy calves at 4, 6, and 12 hours of age compared with feeding within 2 hours of age reduced serum IgG at 24 hours between 10 and 15, 25–30, and 40–50%, respectively [72]. Similarly, a study in beef cow-calf operations suggested that calves that failed to suckle maternal colostrum within the first 4 hours of age had increased odds of FTPI and veterinary treatment compared with calves that successfully suckled within the first 4 hours of age [52]. Results from another study demonstrated that IgG at 24 hours in serum was reduced by 0.32 g/l for every hour delay in colostrum feeding after birth [66]. A prior report indicated that for every 30-minute delay in colostrum feeding after birth, a reduction of 2 g/l of IgG was observed in serum at 24 hours of age [127].

Physiological Status of the Calf

Calves that experience calving stress (dystocia) and different degrees of hypoxia, hypercapnia, and metabolic acidosis have reduced serum IgG levels at 24 hours and increased risk of FTPI compared with healthy calves born from normal parturition [3, 128, 129]. Additionally, factors such as hypothermia, weak suckle reflex, failure to withdraw the tongue after birth, and failure to stand during the first hour of age have been associated with FTPI in dairy and beef calves [52, 58, 130–134].

Method of Feeding

On commercial dairy operations, letting the calf naturally suckle its dam usually results in a higher incidence of FTPI due to inability of suckling enough volume and adequate mass of IgG [135]. The use of a nipple bottle to deliver a high volume of good quality colostrum is effective and preferred by many dairy producers [110, 136]. However, in some instances the use of an esophageal feeder is required to guarantee the delivery of an adequate total mass of IgG and prevention of FTPI. When administering larger volumes (>3 l) of maternal colostrum through an esophageal feeder, calves achieve API and AEA is usually unaffected [137]. Some certified organic dairy operations and all beef cow-calf operations rely on the mothering ability of the dam and the ability of the newborn calf to stand and suckle to acquire colostrum in a timely manner. One study reported an FTPI (<10 g/l) prevalence of 30.8% in 156 calves from 20 organic dairies that allowed calves to suckle their dams to acquire colostrum [138]. In contrast, the prevalence of FTPI (<24 g/l) in 47 beef calves that naturally suckled first-calf heifers (dams) after birth in a single cow-calf operation was 13.6% and the mean serum IgG at 24 hours was >30 g/l [118]. This suggests that when concentration of IgG is adequate in maternal colostrum, suckling the dam results in serum levels of IgG higher than expected. Poor udder conformation can negatively affect adequate suckling of colostrum. Results from one study demonstrated that poor udder conformation (pendulous, teats close to the ground, teats too large or too small) prolongs teat-seeking behavior and delays time of colostrum ingestion in calves [139].

Diagnosis and Monitoring of Transfer of Passive Immunity

Survival and overall health of newborn calves during their first months of life are determined in great proportion by their ability to acquire API. For this reason, monitoring the level of serum IgG as a predictor of future calf health through on-farm diagnostic methods such as STP and serum Brix is an important management strategy to prevent morbidity and mortality associated with FTPI. Assessment of STP and serum Brix in calves is a strategic herd management tool that allows producers to adjust their colostrum management program. Monitoring STP and serum Brix is a common practice on dairy operations because management offers an inherent advantage of sampling calves at 24–48 hours. Beef cow-calf operations are in need of on-farm strategies to monitor transfer of passive immunity in their calves. In beef calves, producers commonly rely on subjective methods such as visualization of suckling and palpation of the calf's abdomen at 24 hours to determine adequate suckling and transfer of passive immunity [52, 58].

The single radial immunodiffusion (SRID) test is considered the gold standard laboratory test to evaluate serum concentrations of IgG in calves and determine success or FTPI [140]. Additional laboratory tests to determine serum IgG in calves include turbidimetric immunoassays (TIA) and enzyme-linked immunosorbent assay (ELISA) tests. The correlation of TIA and ELISA with SRID is good ($r = >0.9$) and these laboratory tests can be used as an alternative to the SRID test [141]. Laboratory testing can be expensive and unpractical for producers because results usually are not readily available to make decisions on management or treatment of individual cases of FTPI. For this reason, on-farm methods to assess transfer of passive immunity in calves that deliver immediate results are preferred by

producers and veterinarians. The most common on-farm methods to evaluate transfer of passive immunity in calves include refractometry (STP and digital serum Brix), whole blood glutaraldehyde coagulation, and sodium sulfite/zinc sulfate turbidity tests. Here we will focus on STP and serum Brix, as these are the on-farm diagnostic methods most commonly used by producers in the USA.

Serum Total Protein (STP)

Measuring serum concentration of proteins is a reliable method to evaluate transfer of passive immunity because IgG makes most of these proteins. Results from previous studies have demonstrated a good correlation between STP and serum IgG evaluated by SRID [142–144]. Additionally, associations between higher STP at 24 hours and decreased calf morbidity and mortality rates have been reported [4, 110, 145, 146]. When using a cut-off value of serum IgG of 10 g/l, STP values of 5.2–5.5 g/dl collected between 1 and 7 days of age demonstrated a good to very good correlation with SRID (r = 0.74–0.97) [143, 144, 147]. With the new standard recommendations on transfer of passive immunity for dairy calves and available data from beef calves, the goal of STP to reach API is >5.8 g/dl for dairy and >6 g/dl for beef calves, respectively [3, 6]. It is important to mention that for individual calves, STP could underestimate true serum IgG levels and careful interpretation of results is necessary in these cases before intervention [73, 148]. Results from some studies suggested that for calf-level decision-making, STP testing is optimum between 24 and 72 hours of age, whilst for herd-level decision-making, STP is good up to 9 days of age [147–151]. As a herd-monitoring tool, less than 10% of the calves should have an STP <5.1 g/dl between 24 hours and 5 days of age, as described in Table 75.1 [6]. Accurate interpretation of STP results is important to adjust colostrum management. Factors such as red cell contamination, hemolysis, dehydration, and inflammation could falsely elevate serum protein concentrations in calves and produce inaccurate readings [144, 148]. Proper maintenance of the refractometer is also essential to obtain accurate results and make sound management decisions. The application surface of the refractometer should be cleaned between each use with 70% alcohol, followed with recalibration of the instrument with distilled water (every 10–20 samples). A reading of 1.000 indicates adequate calibration.

Serum Brix

The level of total solids in milk, milk replacers, colostrum, and serum can be assessed using digital Brix refractometers. Several studies have evaluated the correlation of serum Brix at 24 hours of age and serum IgG by SRID to determine the presence of FTPI in newborn calves [147, 152, 153]. Results from one study of 1756 serum samples collected from calves between one and five days of age demonstrated that a serum Brix value of 8.4% predicted API in 98.3% of the calves when using a serum IgG of 10 g/l [153]. Other studies have equally demonstrated a good serum Brix and SRID IgG correlation (r = 0.74–0.93) when using a serum Brix value of ≥8.4% and serum IgG of 10 g/l [152, 154, 155]. The serum Brix value expected to predict API in dairy calves based on the new standards is ≥8.9% [6]. Similar to STP, the serum Brix is a convenient method to assess FTPI at the herd level, but it could underestimate true serum IgG levels in about 45% of individual samples [153]. As a herd-monitoring tool, less than 10% of the calves should have a serum Brix of <8.1% between 1 day and 5 days of age, as described in Table 75.1 [6]. Factors that affect STP reading as well as maintenance and calibration are similar for proper and accurate function of digital Brix refractometers [156].

Management Strategies to Prevent FTPI

Reduction of dairy- and beef-calf morbidity and mortality is achieved through absorption of high levels of IgG from high quality maternal colostrum very soon after birth. Colostrum management programs should ensure production of high quality colostrum, appropriate colostrum collection, and storage of high quality and pathogen-free colostrum. Delivery of a volume of colostrum that contains an adequate mass of IgG in a timely manner to newborn calves should also be achieved.

Production of High Quality Colostrum

Nutrition and vaccination programs during the prepartum period directly affect the production of high quality maternal colostrum. Results from studies on the effects of prepartum nutrition (last 100–60 days of gestation) in beef and dairy cows on the concentration of IgG in maternal colostrum and serum IgG levels in their calves are controversial [119, 120, 157]. Two studies in beef cows suggested that although protein and energy restriction during the last 90–100 days of gestation in beef cows did not have an effect on colostrum IgG, serum IgG levels at 24 hours were lower in calves that suckled colostrum from cows on the restricted diets [119, 120]. A proceedings report indicated that low energy diets in beef cows 30 days before calving resulted in lower colostrum IgG concentrations and a greater risk of FTPI in their calves [114]. In contrast, colostrum and calf

serum IgG concentrations were not different in a study where high or low energy diets were administered to dairy cows during the dry period and early prepartum [157]. Results from another study suggested that meeting energy requirements of dairy cows during the dry period resulted in greater colostrum IgG compared with colostrum IgG from cows on a diet that exceeded dry period energy requirements [158]. Management recommendations for dietary composition of prepartum dairy and beef cows should follow the National Research Council standards.

High serum IgG levels at 24 hours in calves do not always translate into higher levels of specific antibodies against common enteric and respiratory pathogens that cause disease on each individual farm. Results from one study suggested that FTPI was responsible for an increased presentation of preweaning respiratory disease in dairy calves in 21% of the cases only. Instead, calves with higher colostrum derived bovine respiratory syncytial virus (BRSV) and bovine herpesvirus 1 (BHV-1) antibody titers had lower odds of developing preweaning respiratory disease compared with calves with lower BRSV and BHV-1 titers [159]. Results from studies in dairy and beef cattle demonstrated that vaccination with two doses of a multivalent killed virus (KV) respiratory vaccine during gestation results in higher specific antibodies against BVDV 1, BVDV 2, BHV-1, and BRSV in maternal colostrum. Additionally, calves that suckled colostrum from vaccinated cows had higher initial BVDV 1, BVDV 2, BHV-1, and BRSV antibody titers compared with cows that suckled colostrum from unvaccinated cows [118, 160, 161]. Similarly, several studies documented that vaccination during late gestation with multivalent KV enteric vaccines increases specific immunity against calf diarrhea and respiratory disease-causing pathogens in maternal colostrum and newborn calves [162–165]. Vaccination programs to increase specific immunity in maternal colostrum in cows and transfer of specific antibodies to calves should respond to individual farm needs and individual farm calf-pathogen ecosystems.

Clean Collection of Colostrum

Contamination of maternal colostrum during collection can become a potential route of early transmission of infectious pathogens to newborn calves. Essential steps to avoid colostrum contamination during collection are thorough udder preparation and sanitization, milking with clean and sanitized equipment into a clean and sanitized bucket, and transferring colostrum into a clean and sanitized storage or feeding device. Feeding calves with colostrum contaminated with bacteria results in decreased IgG absorption and increased risk of FTPI [42, 123–125]. Colostrum for calves should contain less than 100 000 colony-forming units (cfu)/ml total plate count and less than 10 000 cfu/ml total coliform count [125]. Immediately after collection, colostrum should be tested, fed to calves, or properly stored because if left at room temperature significant bacterial grow and proliferation occurs.

Storage of High Quality and Pathogen-Free Colostrum

Newborn calves should only receive colostrum with adequate concentrations of IgG and free from infectious pathogens such as coliforms, *Mycobacterium avium subsp paratuberculosis*, *Salmonella* spp., *M. bovis*, BLV, and BVDV. In ideal circumstances, colostrum for calves should come only from cows that have tested negative to the previously mentioned pathogens. Colostrum with IgG concentrations >50 g/l is considered of adequate quality; however, IgG levels of individual colostrum samples should be tested with a hydrometer (colostrometer) or a digital Brix refractometer, as discussed in the section "Colostrum Quality." Maternal colostrum with >23% Brix or >60–90 g/l of IgG on the colostrometer (Figure 75.4) can be fed immediately to newborn calves. When fresh colostrum will not be administered immediately after collection, it should be refrigerated at 4 °C for 12–24 hours or frozen at −20 °C for up to 1 year, ensuring repeated freeze–thawing does not occur [126, 166]. Heat treatment of maternal colostrum at 60 °C (140 °F) for 60 minutes is an alternative to eliminate important infectious pathogens such as *E. coli*, *Salmonella enteritidis*, and *M. bovis* and to significantly reduce the risk of exposure to *M. avium* subsp. *paratuberculosis* while conserving IgG levels [166–168]. Additionally, heat treatment of colostrum reduces overall bacterial contamination and increases aborption of IgG in the calf [66, 125]. Heat treatment of colostrum should occur after IgG testing and before freezing and storage. When ready to use, stored (frozen) colostrum should be thawed avoiding water temperatures >60 °C (140 °F) to prevent inadvertent denaturation of IgG [126, 166].

Delivery of an Adequate IgG Mass in a Timely Manner

To achieve new standards for transfer of passive immunity in dairy calves or API in beef calves, administration of colostrum should consist of a single feeding of at least 300 g of total IgG mass during the first 2–4 hours of age. Alternatively, administration of two feedings of 200 g of total IgG mass each with the first feeding during the first 2–4 hours of age and the second feeding within the first 6 hours of age is recommended [6]. If testing of maternal colostrum for IgG concentrations is not possible, administration of a volume

equal to 10–12% of BW (3–4 l) during the first 2–4 hours of age with an additional feeding of at least 2 l within the first 12 hours of age is recommended for dairy calves. Results from one study demonstrated that feeding dairy calves with 4 l of maternal colostrum at 0 hours and an additional 2 l at 12 hours resulted in higher serum IgG levels (31.1 g/l) at 24 hours compared with calves fed only 2 l at 0 hours and another 2 l at 12 hours (23.5 g/l) [169]. In beef calves, monitoring calving ease and ensuring the newborn has a strong suckle reflex during the first 15 minutes of birth and is standing and suckling within the first hour of age are essential to prevent FTPI [52, 58]. In beef calves born from a dystocia or prolonged calving, with a weak suckle reflex, swollen tongue or poor tongue withdrawal, and inability to stand during the first hour of age, assisting colostrum intake is necessary to prevent FTPI. One option is placing the dam in a chute and allowing the calf to suckle for 15–20 minutes. Alternatively, the cow can be milked thoroughly and maternal colostrum administered to the calf through a nipple bottle or an esophageal feeder. At the teaching hospital, we usually administer 2 l of maternal colostrum or a CR product during the first 2 hours of age and if natural suckling has not occurred within the next 4–6 hours, the calf receives an additional 2–4 l dose of colostrum.

Summary

The administration of an adequate mass of IgG from maternal colostrum or a CR product in a timely manner to newborn dairy and beef calves is a key management strategy to guarantee reduced morbidity and mortality and increase productive performance. Although several factors can affect individual colostrum quality, it is essential to establish an on-farm testing protocol for maternal colostrum to identify colostrum with adequate and poor IgG levels and make appropriate colostrum use and storage decisions. On beef cow-calf operations where a colostrum management program is usually uncommon, monitoring of calving and early evaluation of the calf's vigor after delivery are important factors to make decisions on artificial colostrum feeding. Assessing the level of transfer of passive immunity in newborn calves through on-farm calf diagnostics such as STP and serum Brix refractometry is recommended to make management adjustments to consistently achieving API in the calf herd. Highly competitive performance and productive results of dairy or cow-calf beef operations start with the delivery of clean, pathogen-free, and IgG-loaded maternal colostrum to newborn calves.

Utilization of Genomic Testing for the Selection of Desirable Traits in Cattle

Katherine W. Upshaw, Madison Butler, Justine Henderson, Will Shaffer, and Megan M. Rolf

Kansas State University, Manhattan, KS, USA

Introduction

Genomic technologies have been widely adopted within the beef and dairy industries and their popularity and utility continue to increase. Applications of genomic technologies in the beef and dairy industries include tests for specific causal mutations (largely genetic abnormalities but also Mendelian traits like coat color), parentage testing, and genomic testing for production traits. Inclusion of genomic testing results is now common within genetic evaluation, and this is generally the recommended application of these data for quantitative production traits. This chapter will explain how to utilize basic genomic testing results for Mendelian traits and how genomic analyses are useful in the context of bovine fertility-related traits, and provide a look ahead to the emerging genomic technologies that may impact beef and dairy production, particularly as it pertains to animal reproductive efficiency.

Background

To fully understand the contributions of genomic selection and genomic technologies to the bovine industry, it is very important to have a general understanding of basic genetic principles. Thus, we will review some of those principles here.

The physical characteristics displayed by an animal are known as a phenotype. Broadly, phenotypes are the result of genotype, gene interactions, and (often) environmental factors. A genotype is the combination of alleles found in an organism, and will consist of two alleles (i.e. AA, Aa, or aa) for each location in the genome (locus). Alleles are essentially differences in the nucleotide sequence between organisms, which often lead to differences in phenotypes. Single base changes in the DNA (sort of like typos in the DNA sequence) are known as single nucleotide polymorphisms [SNPs], which are currently the most commonly utilized genetic marker in livestock. As technology has improved, so has our ability to examine large numbers of SNPs at one time. The ability to analyze up to several hundred thousand SNPs at once on products known as SNP chips has facilitated the development of livestock selection at the genome level [1].

Genomic technologies have revolutionized the way in which veterinarians, researchers, and producers understand and evaluate cattle health and productivity. Genomics now contributes to a variety of products and information sources that can be utilized by producers in making selection decisions. Veterinarians can also use genomics for diagnostics. This chapter will review many of the common uses of genomic technology in the beef and dairy industries.

Simple Mendelian Traits

Gregor Mendel laid the foundation for modern genetics back in the 1860s [2]. His recognition of the principles of inheritance allowed for the discovery of what geneticists have termed simply inherited traits, or Mendelian traits. Simply inherited traits are traits in which the phenotype is often determined by a single mutation and is not influenced by the environment. Thus the phenotype will be a direct result of which two alleles were inherited at that locus. Frequently, one allele will be dominant and conceal the other recessive allele in cases where an animal is heterozygous (has two different types of alleles at a locus) [3]. Although the exact mode of inheritance of these traits varies (many are autosomal recessive, but some, like hyperkalemic periodic paralysis in horses, are autosomal dominant), simply inherited traits can

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

easily be selected for in livestock species if a genomic test exists. Examples of simply inherited traits in the beef and dairy industry include the Extension locus that is responsible for black or red coat pigmentation, the POLLED locus that controls the presence or absence of horns, and loci associated with genetic abnormalities [4] (Table 76.1). Figure 76.1 outlines examples of selecting for simple Mendelian traits that are inherited as completely dominant.

One of the most important uses of genomic technologies is for the tracking and management of recessive genetic abnormalities. Recessive alleles only result in an affected individual when two copies of the allele are present (i.e. they are homozygous). However, heterozygote carriers also possess a single recessive allele, which they can pass to their progeny even though the heterozygote does not exhibit the phenotype associated with the recessive allele. This phenomenon is why genomic testing to identify and manage carrier animals is so useful, because they cannot be identified by their phenotype.

Many alleles corresponding to genetic abnormalities are lethal, but there are plenty of exceptions, as compiled in Table 76.1. Most lethal alleles are recessive, as shown in the example in Figure 76.2, and thus two copies of the allele result in death. Dominant lethal alleles are exceptionally rare, because only one copy of the allele is necessary to cause death. Therefore dominant lethal alleles only persist for conditions that are late-onset, after the individual has already reproduced. There are additional classes of lethal alleles as well. Conditional lethals are alleles that cause fatality in response to an environmental stimulus [6]. The most well-known example of a conditional lethal disorder is favism in humans. Affected individuals are deficient in glucose-6-phosphate-dehydrogenase, an enzyme responsible for proper red blood cell functionality, but only experience severe hemolytic anemia when in contact with specific stressors like fava beans or aspirin [7]. Furthermore, alleles can be semilethal in which most affected offspring die but a few individuals in the generation survive [8]. While numerous examples of recessive lethal alleles exist (see Table 76.1), there are no known examples of conditional lethal or semilethal alleles in the beef or dairy industry.

Fortunately, most known genetic abnormalities in cattle are recessive. Thus, as long as ranchers do not breed two heterozygous animals together, they should never observe an affected calf. Figure 76.3 demonstrates this point. Although it may seem logical to eradicate the condition entirely by culling any animals that are carriers of a disease allele, there are several cogent reasons to manage the recessive allele instead. The most important of these reasons are to maintain genetic diversity and to continue to make forward strides in genetic improvement. With genomic testing, producers do not need to indiscriminately cull genetically superior animals that carry a deleterious allele. Instead, producers can utilize genomic testing to slowly reduce the frequency of the allele in the population without sacrificing genetic gain or producing affected calves.

Parentage Testing

Genomic testing can also be used to establish parentage. Parentage verification can be useful for tracking bloodlines in herd books, breed recognition, or proof of pedigree for registration. Parentage testing can be used by producers to confirm an animal's sire or dam [9], but sire verification is most common. Parentage testing involves genotyping offspring and any potential parents to find inconsistencies in the inheritance of genetic markers between the progeny and possible sires or dams. An example of parentage testing can be seen in Figure 76.4. It is based on one of the foundational principles of genetics: that a diploid animal receives one copy of a randomly segregating allele from each parent.

Parentage testing excludes animals that cannot be parents of the offspring in question, rather than definitively determining parentage. Parentage panels will typically have 96 SNP markers, but using as many as 400 SNP markers has been proposed. When performing parentage testing, genotyping errors are accounted for by allowing one exclusion (inconsistent inheritance) out of all the markers in the panel without disqualifying the animal as a potential parent. Two to three exclusions would result in a retest of the sample to rule out contamination, unsatisfactory DNA quality, or poor genotyping results. More than three exclusions would result in elimination of that animal as a potential parent of the progeny in question. As such, it is important that progeny testing abides by the following general principles:

1) Be consistent in the selection of marker panels. All animals should be genotyped with the same panel. For example, if an older animal is genotyped on a microsatellite panel, it will need to be re-genotyped on an SNP panel if the progeny are genotyped on an SNP panel.
2) It is essential to include all possible parents when parentage testing. Do not include animals that could not possibly be the sire or dam. Including too many potential parents increases the risk of receiving ambiguous results or misidentifying parentage of the individual(s) of interest, but failing to include a potential parent can result in an incorrect result. In some cases, potential sires can be eliminated without genotyping if inheritance of simple Mendelian characteristics is impossible (such as a red bull mated to a red cow producing a black calf).

Table 76.1 Allelic control of common bovine Mendelian genetic traits.

Phenotype	Abbr.	Affected breed(s)	Mode of inheritance	Lethal/ non-lethal	Monitored by breed?
Arachnomelia	—	Braunvieh, Simmental	AR	Non-lethal	No
Arthyogryposis multiplex (curly calf syndrome)	AM	Angus	AR	Lethal	Yes
Bovine blood coagulation factor XIII deficiency	F13	Wagyu	AR	Non-lethal	Yes
Bulldog dwarfism (chondrodysplasia)	BD	Dexter	AR	Lethal	Yes
Chediak-Higashi syndrome	CHS	Wagyu	AR	Non-lethal	Yes
Chondrodysplasia	CHO	Angus	AR	Lethal	Yes
Claudin 16 deficiency	CL16	Wagyu	AR	Non-lethal	Yes
Contractual arachnodactyly (fawn calf)	CA	Angus	AR	Non-lethal	Yes
Coat color	CC			Non-lethal	Yes
Red/black		Many beef breeds Limousin, Gelbvieh, Dexter, Hereford, Charolais	Black AD Red AR		
Dilution	DL		Incomplete dominance		
Dun	DN		AR		
Developmental duplication	DD	Angus	AR	Non-lethal	Yes
Deficiency of urine monophosphate synthase	DUMPS	—	AR	—	—
Digital subluxation	DS	—	AR	—	—
Erythrocyte membrane protein band III deficiency (spherocytosis)	Band 3	Wagyu	AR	Often lethal	Yes
Hypotrichosis	HY	Hereford	AR	Nonlethal	Yes
Factor XI deficiency	F11	Wagyu	AR	Non-lethal	Yes
Freemartinism	FM	All	—	Sterile female	Yes
Idiopathic epilepsy	IE	Hereford	AR	Non-lethal	Yes
Alpha-mannosidosis	MA or MAN	Red Angus	AR	Lethal	Yes
Beta-mannosidosis		Salers	AR	Lethal	Yes
Myostatin		Belgian Blue, Piedmontese, Limousin	—	Non-lethal	No
Neuropathic hydrocephalus	NH	Angus	AR	Lethal	Yes
Osteopetrosis	OS	Angus, Herford, Red Angus, Simmental	AR	Lethal	Yes (Red Angus)
Pulmonary hypoplasia with anasarca	PHA	Shorthorn, Dexter, Maine-Anjou	AR	Lethal	Yes
Horned/polled	Polled			Non-lethal	Yes

[AR] Autosomal recessive mode of inheritance.
[AD] Autosomal dominant mode of inheritance.

Example 1a: The Extension Locus

	B	***b***
B	*B*/*B* 	*B*/*b* 
b	*B*/*b* 	*b*/*b* 

Notation

B/*B* = animals with this genotype express the black coat color phenotype and only possess black coat color alleles (B)

B/*b* = animals with this genotype express the black coat color phenotype, but are carriers of the red coat color allele (b)

b/*b* = animals with this genotype express the red coat color phenotype

Coat color is a commonly used simple Mendelian test used in the beef industry. Here we have a heterozygous black bull mated to a heterozygous black female. The resulting offspring are 25% homozygous black, 50% heterozygous black, and 25% homozygous red. The hidden, recessive red allele in heterozygous black parents explains how two black animals can produce a red calf.

Example 1b: The POLLED Locus

	P	***P***
p	*P*/*p* 	*P*/*p* 
p	*P*/*p* 	*P*/*p* 

Notation

P/*P* = animals with this genotype express the polled (hornless) phenotype and possess only polled alleles (P)

P/*p* = animals with this genotype also express the polled phenotype, but are carriers of the horned allele (p)

p/*p* = animals with this genotype express the horned phenotype

The POLLED locus is another example of a simple Mendelian trait important in the beef and dairy industry. Polled animals are often desired because the natural absence of horns prevents the need for dehorning, which is a painful procedure. Horns are often dangerous for the humans managing the cattle as well as other cattle in the herd. Genetically selecting for the polled phenotype allows producers to improve both handler safety and animal well-being. It is important to note that as long as we mate any given animal to a homozygous polled animal, we should never observe horned offspring.

Figure 76.1 Examples of phenotypic outcomes for completely dominant Mendelian traits.

3) Dam genotypes are helpful, but not essential, in sire verification. Often, it may not be economical to genotype the dam. As shown in the example above, parentage can be determined without complete information on the dam. However, if both parents must be verified (such as in the case of pedigree verification or embryo parent verification), the dam must be genotyped.
4) It is more difficult to determine parentage when the potential sires are related. Related sires and dams share the same alleles, so it will be more difficult to definitively determine parentage.

Following these guidelines will help ensure that parentage testing is utilized correctly and with the greatest economy.

Genetic Evaluation of Production Traits

Genotype data can also be utilized in genetic evaluation for production traits. Continuous traits, which are also called quantitative traits, include most economically relevant

	N	***PHA^D***
N	***N/N*** 	***N/PHA^D*** 
PHA^D	***N/PHA^D*** 	***PHA^D/PHA^D*** 

Notation

N/*N* = animals with this genotype express the normal phenotype

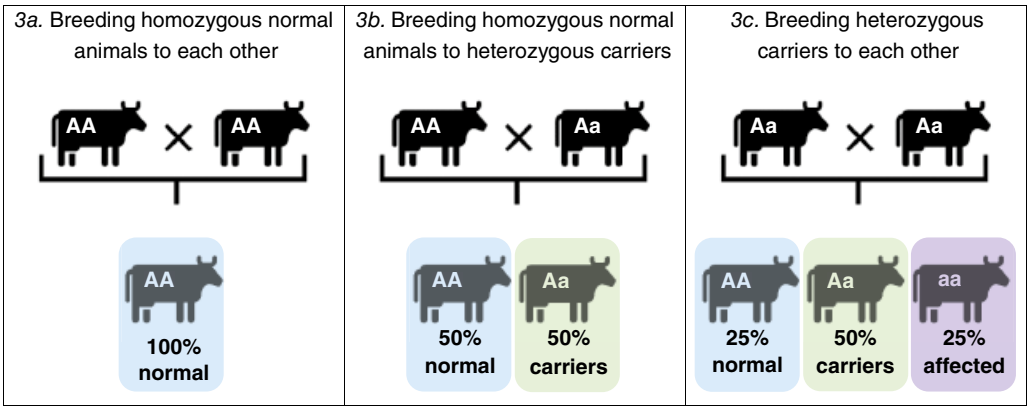
N/*PHA*^{D} = animals with this genotype express the normal phenotype, but are carriers of PHA

PHA^D/*PHA*^{D} = animals with this genotype express the PHA phenotype and are aborted or stillborn

Pulmonary hypoplasia with anasarca (PHA) is an autosomal recessive genetic defect that can affect multiple breeds of cattle, including Maine-Anjou, Shorthorn, and Dexter. It leads to fetal death in calves that are homozygous recessive for the mutation [5]. Animals with the defect have inadequate lung development and severe swelling throughout the body from excessive fluid. Carriers of PHA appear phenotypically normal. When crossing two PHA carriers, we would expect that 25% of the progeny would express the PHA phenotype and perish before, or shortly after, parturition.

PHA is particularly dangerous because affected calves often swell so severely that they also contribute to an increased risk of dystocia for the dam [5]. Occasionally, PHA-affected calves are aborted early in gestation, which is similar to the effect of embryonic lethal alleles (discussed later in this chapter) and can make it difficult to identify the presence of the PHA allele in a population in the absence of genomic testing.

Figure 76.2 An example of recessive lethal alleles.



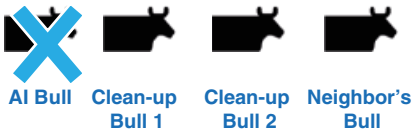


Figure 76.3 Managing breeding decisions can diminish the effect of lethal and deleterious alleles.

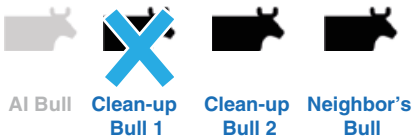
	Locus					
Animal	***A***	***B***	***C***	***D***	E	***F***
Calf	*A/A*	*b/b*	*C/c*	*D/d*	*E/E*	*F/F*
Dam	-	-	-	-	-	-
AI Bull	*a/a*	*b/b*	*C/c*	*D/d*	*E/e*	*f/f*
Clean-up Bull 1	*A/A*	*B/B*	*C/C*	*D/d*	*E/E*	*f/f*
Clean-up Bull 2	*A/a*	*B/b*	*C/C*	*d/d*	*E/e*	*F/f*
Neighbor's Bull	*A/A*	*B/b*	*c/c*	*D/d*	*e/e*	*F/F*



LOCUS A

At the A locus, the calf will receive an *A* allele from its dam and another *A* allele from its sire. Even though we do not know the mother's genotype at this locus, we can exclude the AI bull who does not have an *A* allele.

LOCUS B

At the B locus, the calf will inherit a *b* allele from its dam and another *b* allele from its sire. Since clean-up bull 1 is homozygous *BB* and the calf is homozygous *bb*, clean-up bull 1 can be ruled out as a possible sire.

LOCUS C AND LOCUS D

At these loci, the calf is heterozygous. Since we do not know the dam's genotype, none of the sires can be eliminated from the list of potential sires.

LOCUS E

The calf must have inherited an *E* allele from both the dam and the sire, which means that because the neighbor's bull does not have an *e* allele to give, he can be excluded.

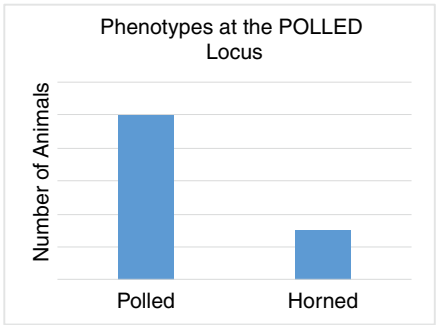
LOCUS F

At this locus, clean-up bull 2 and the neighbor's bull are the only potential donors of the calf's second *F* allele, but from the alleles at locus E, we have already excluded the neighbor's bull, leaving clean-up bull 2 as the only remaining possibility.

From these data, you would conclude that **clean-up bull 2 is the most likely sire of this calf**.

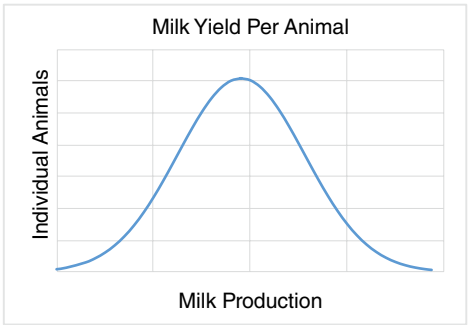
Figure 76.4 Example for the use of parentage testing: You are a cattle producer and recently purchased a promising heifer. You artificially inseminate the heifer and turn her out on native rangeland with two clean-up bulls in a multisire pasture. Unfortunately, your neighbor has poor-quality fences, so his bull jumps the fence and spends some time with your cattle. You are now trying to register the calf, but you need to determine which bull is the sire, so you genotype both the calf and the sires on a standard parentage panel with 96 SNP markers. The results for six loci are shown. Based on the information given in the chart, which bull is the most likely sire?

production traits like weaning weight, milk production, marbling, and age at first calving. Quantitative traits are polygenic, meaning that they are influenced by multiple alleles or mutations throughout the genome. Continuous traits show a range of phenotypic variation due to both genetic and non-genetic factors. The difference between continuous traits and discontinuous traits can be seen in Figure 76.5. Genetic factors encompass those that are both stably inherited (additive effects of alleles) and those that are not (gene combination values that arise due to cross-breeding). Non-genetic factors include environmental effects such as nutrition, health status, and weather.



Genetic evaluation is designed to quantify the additive genetic merit of individuals and reflects only the portion of genetic variance that is stably inherited [10]. In other words, it estimates the additive effects of alleles as a numeric value that describes the merit of an individual as a potential parent for the next generation. Genetic evaluations are frequently used by breeders as selection tools to achieve a variety of breeding objectives and are performed using best linear unbiased prediction (BLUP). The ultimate goal is to provide cattle producers with the tools necessary to increase the production of food and fiber products from their livestock animals. BLUP incorporates data from all of the sources outlined in Figure 76.6 to produce genomically enhanced expected progeny differences (EPDs) or predicted transmitting abilities (PTAs) [11]. These mixed models account for both fixed effects (such as sex, age, year) and random effects (such as animal). Ultimately, BLUP has become the foundational model for the genetic evaluation of domestic animals [12].

Cattle breeders gauge genetic merit by using EPDs in the beef industry or PTAs in the dairy industry. EPDs and PTAs represent the best estimates of genetic merit based on all available phenotypic, pedigree, and genomic information for each animal. EPDs and PTAs represent the predicted differences between the future average progeny performance of individuals for a specific trait. These values are generally not comparable across breed associations, although there are exceptions to this rule. Historically, EPDs and PTAs were generated without genomic information. However, due to the industry-wide utilization of genotyping in the beef and dairy industries, these data are now included in the genetic evaluation for most major beef and dairy breeds.



The genomic data included in genetic evaluation are derived from high-density genotyping, in which a large number of SNPs can be genotyped at one time (often called SNP chips) [13]. This type of genotyping is so useful because, depending on the panel, it can include information on lethal alleles or other markers of interest (like coat color), in addition to information that can be used to augment genetic evaluation for production traits. High-density SNP panels are more affordable than ever, which enables cattle producers, veterinarians, and researchers to more efficiently and cost-effectively use these technologies.

Advantages of Genomic Selection

Estimating breeding values with phenotypic records and pedigree information provides producers with reliable estimates of genetic merit [14], but is most accurate for older, widely used animals that have large numbers of progeny in the breed association database. This is especially challenging for traits recorded late in life, such as longevity, where animals are at an advanced age before highly accurate genetic predictions can be generated. Incorporating genomic data into genetic prediction helps build accuracy on these animals at a younger age.

Discontinuous traits are expressed as a limited number of possible phenotypes. For example, the POLLED locus in cattle is a discontinuous trait because the polled phenotype does not overlap with the horned phenotype.

Milk yield is a continuous trait because individual cows will produce differing amounts of milk. As demonstrated above, continuous traits, like milk yield, typically follow a normal distribution.

Figure 76.5 The difference between continuous and discontinuous traits.

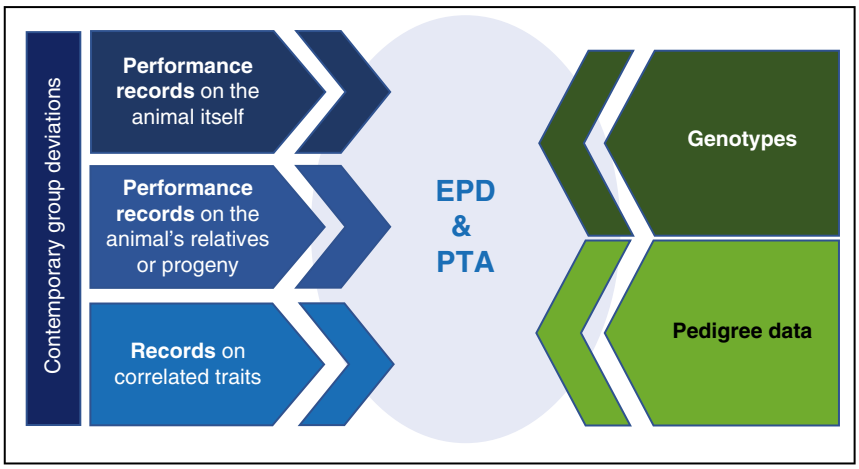


Figure 76.6 The data that go into the calculation of EPDs and PTAs.

Initially, marker assisted selection was the only available method for utilizing genomic information on animals for selection. This created multiple sources of (often contradictory) information that could not be combined into a single metric for selection, which was confusing for producers. Marker assisted selection has been surpassed by the use of genomic selection [11]. Development of SNP-chip genotyping platforms has made genomic selection more cost-effective and tractable for breeders, at least within the seedstock sectors of the industry [11].

In December 2007, the Illumina BovineSNP50 BeadChip (50K SNP chip) was commercially released with a set of 54 001 SNPs. SNP chips have become the most widely used assays in both the beef and dairy industries [14]. Lower density (LD) SNP assays have been developed, as well as a higher density chip, the Illumina 778K SNP BovineHD [15] assay. Unfortunately, even though higher density allows for greater precision for fine-mapping quantitative trait loci (QTL), it does not substantially increase prediction accuracy [16]. Therefore mid-density SNP chips have become the gold standard in the industry. Often, animals are genotyped at a lower density (often called LD genotyping), and higher density genotypes are imputed using software to "fill in" the missing genotypes [17]. This process works well and is widely used, though some ambiguity exists in regions of the genome where recombination occurs.

Genetic evaluations are performed by beef and dairy breed associations as often as weekly in order to incorporate new data collected by breeders (such as newly collected phenotypes or genomic testing results). The addition of genomic data into prediction of genetic merit has led to an increased level of genetic gain. In the beef industry, inclusion of genomic data has resulted in increased growth and carcass quality [18] (such as improved ribeye area and marbling scores). In the dairy industry, genomics has transformed selection of younger animals, thereby decreasing the generation interval and increasing genetic gain [19]. Genomic selection increases genetic gain in highly heritable traits, but the inclusion of genomic information has also been shown to benefit lowly heritable ones, like those associated with reproduction and fertility [20]. In US dairy cattle, the implementation of genomic selection has led to a 50–100% increase in annual genetic gain for highly heritable traits and a 300–400% increase in genetic gain for lowly heritable traits [21]. Genomic selection is now used extensively across the USA and has made the livestock selection process much more efficient and effective.

Achieving Genetic Gain Through Genomics

When employing artificial selection for production traits, there are multiple factors that can dictate the amount of genetic gain that can be achieved. Genetic gain is represented with the following equation:

$$\Delta G = \frac{i \times r \times \sigma_A}{L}$$

In this equation, ΔG represents the rate of genetic gain within a population, i is the selection intensity, r is the accuracy of the breeding value of the animal, σ_A is the additive genetic standard deviation of the specific trait, and L is the generation interval [22]. Rate of genetic gain can also be expressed as the rate of genetic change per unit of time and can be denoted as Δ_{BV}/t, where Δ_{BV} is the change in breeding value of an animal and t is the unit of time used to measure the generation interval [23]. The inclusion of genomic data into genetic prediction can impact genetic gain in several ways: by improving selection intensity due to easier identification of the most superior animals, increase in accuracy of the breeding value (EPD/PTA), and decreases in the generation

interval due to the ability to identify superior animals earlier in life and cycle generations more quickly. A decrease in generation interval is especially meaningful not only because it is in the denominator of the equation, but also because the generation interval in cattle is longer compared to other species. Genomically enhanced EPDs and PTAs, coupled with current reproductive technologies like sexed semen, multiple ovulation and embryo transfer (MOET), *in vitro* embryo production (IVF), embryo genotyping, and cloning, have the ability to dramatically affect genetic gain [22].

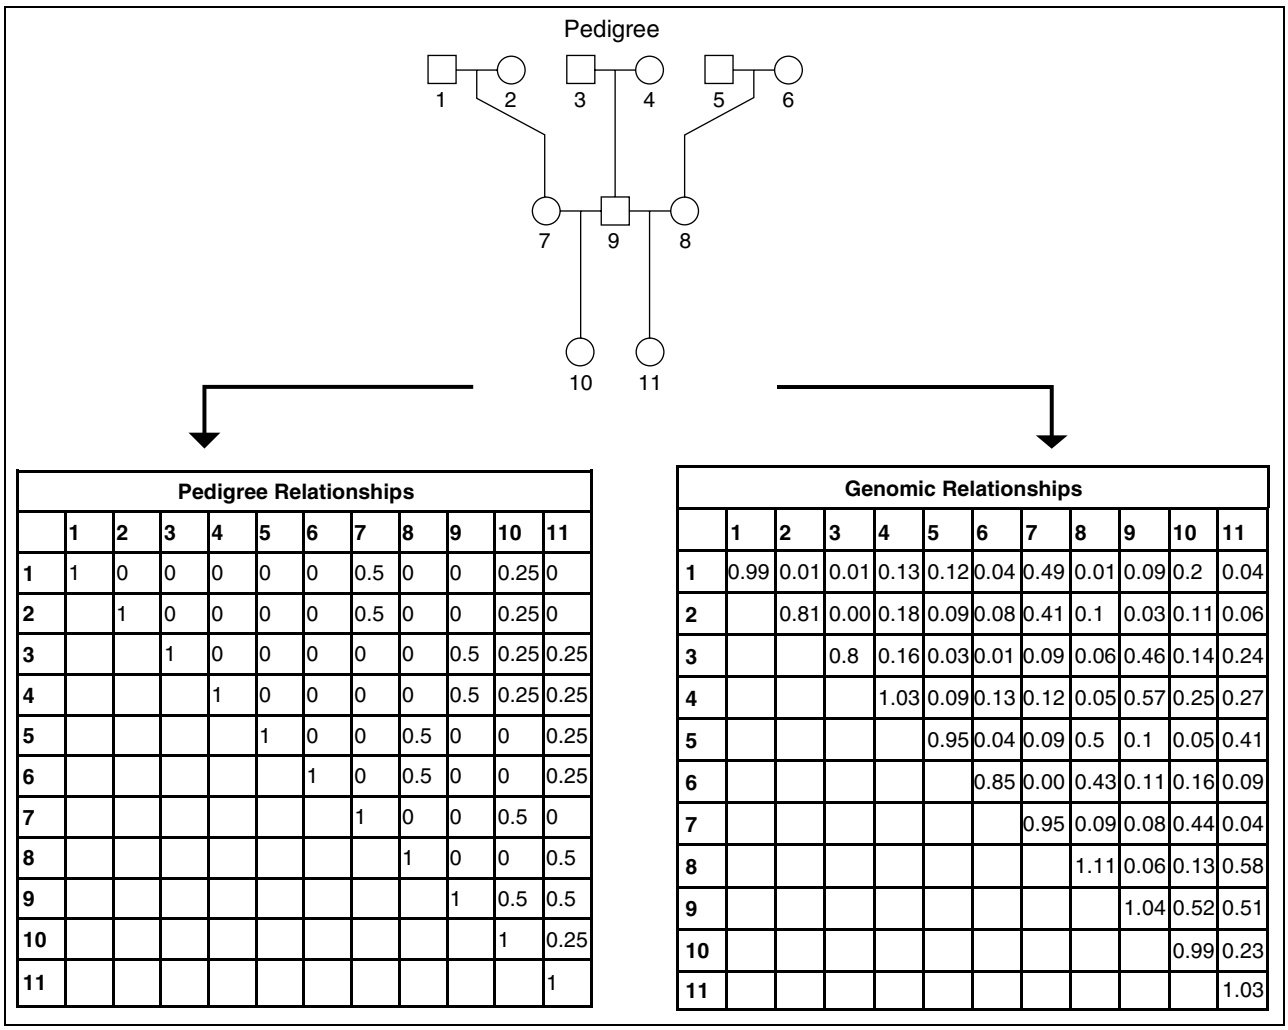
Genomic Evaluations

In the past, genomic evaluations were performed using a complex, multistep method that required a combination of the traditional BLUP evaluation and a summation of estimated marker effects for each trait. Both pieces of information were subsequently blended together using a variety of methodologies that differed among different breed associations to develop the final genomically enhanced genetic merit prediction. Because of the fact that these two pieces of information could sometimes be contradictory (which was confusing for producers) and the methodology was cumbersome, effort was invested in developing "single-step" methodologies for incorporation of genotypes into genetic evaluation.

The development of single-step methods for inclusion of genomic data into genetic evaluation has been a major improvement. Current implementations provide a benefit to genetic prediction for both genotyped and non-genotyped animals. Single step increases accuracy of predictions [24], especially for young genotyped animals [25]. Due to its efficiency and simplicity, single step has become the favored methodology for genomic evaluations in beef and dairy breeds [26]. Current implementations of single-step methodologies can be categorized into either single-step genomic BLUP (single-step GBLUP) or marker effects models that use the Biometry Open Language Tools (BOLT) software. We will briefly overview these two methodologies.

GBLUP

Genomic BLUP incorporates marker information by augmenting the relationship matrix for genotyped animals, instead of simply using pedigree [27]. This additional information assists to correct pedigree errors, accounts for shared alleles from animals beyond the recorded pedigree, and accounts for the fact that animals may be more or less related than expected due to the sampling of alleles inherited from their parents. An example of this can be seen in Figure 76.7 [28]. Though we make assumptions about the number of shared alleles in the genome based on pedigree, the actual relationship between two animals can fall among a distribution. For example, full siblings will, on average, share 50% of their genome, so the relationship between them using pedigree is 0.5. However, SNP data might indicate that they share a greater or smaller portion of their genome, which is reflected in the relationships in a GBLUP. The distribution of grandparent relationship is shown in Figure 76.8 [28]. We expect the grandparent relationships to be 0.25, but with SNP data we can more accurately account for the sampling of alleles, and thus the values will vary (with the average being approximately 0.25). In 2014, the University of Georgia released a program called BLUPF90 that will perform single-step GBLUP [29]. This program is widely used by many different breed associations for genetic evaluation, including the Holstein Association USA and the American Angus Association [26]. While BLUPF90 does have the capability to weight markers more heavily (such as those that are known to have large effects on a trait), current implementations are unweighted.



BOLT

Another option for single-step genomic prediction is BOLT, which was developed by Theta Solutions LLC and introduced as a result of a collaboration between the American Simmental Association (ASA) and Dr. Bruce Golden and Dr. Dorian Garrick. BOLT software offers the ability to fit a variety of models and increases accuracy of genetic predictions [30]. In contrast to single-step GBLUP, BOLT allows certain DNA markers, usually highly associated with the traits in the model, to play a larger role in the prediction of the genetic merit of an animal. BOLT also calculates true accuracy, rather than estimating prediction accuracy. However, since the "approximation" method used to find accuracy usually results in overestimation of the value, the true accuracy calculated by BOLT for animals can be lower than their previous accuracy [31]. BOLT is currently used by International Genetic Solutions (IGS) [31] and the American Hereford Association (AHA) [32].

Use of Genomics in the Cattle Industry

Dairy

Before genomic selection was introduced, dairy producers and AI companies used progeny testing to gather enough data on potential AI sires to provide producers with a higher accuracy PTA. Progeny testing is a system where elite females are chosen and bred to specific sires to produce bull calves that will then be test mated to a population [33].

The daughters of these bulls were then bred and first lactation performance recorded. With progeny testing, the bull's PTA for milk production can achieve an accuracy of 75–80% in approximately 64 months [33]. Since most economically important traits in dairy operations are sex limited and the generation interval is long, it takes numerous years to obtain highly accurate genetic predictions with this method. Progeny testing systems have decreased in popularity due to the ability to produce genomically enhanced PTAs on young prospective herd sires. Producers and artificial insemination (AI) companies are now capable of identifying genetically desirable animals using PTAs enhanced by genomic data at a younger age than by progeny testing [34].

Genomic evaluations were first developed for the Holstein and Jersey breeds in 2009 [14]. Other breeds soon followed, with genomic evaluations released for Brown Swiss in late 2009, Ayrshire in 2013, and Guernsey in 2016 [14]. Today, the release schedule for genomic evaluations depends on

breed association policies. For example, the Holstein Association USA provides customers with preliminary (weekly) genomic evaluations, interim monthly genomic evaluations, and official genetic evaluations. Preliminary evaluations are different than the monthly evaluations because they are made available shortly after a producer sends in a sample, only include genomic-PTAs [35], and are provided to producers and breeders who plan to make early culling decisions. However, the use of these specific evaluations is prohibited for marketing the animals [14]. The monthly genomic evaluations are when haplotypes or genetic test results are provided to the producer [36]. Official genetic evaluations are released three times a year (April, August, and December) [35]. For the Jersey breed, genetic evaluations are updated the first Tuesday of each month [37]. In addition to the USA, other countries like New Zealand, Australia, Canada, and numerous Europeans countries incorporate genomic information into their genetic evaluations [11].

Utilizing genomic information in selection provides the opportunity for a surge in genetic gain within the dairy industry. Greater availability of genotypes on both bulls and females paired with abundant phenotypes on these animals has led to a substantial increase in the accuracy of genomic prediction for production and fertility traits in the dairy industry [11]. The increase in accuracy of estimating the genetic merit for individuals at a young age provides producers numerous advantages when it comes to breeding, purchasing, marketing, and producing high-quality, elite livestock for the industry [14].

Beef

All major US beef breed associations conduct genetic evaluations to estimate EPDs. In the past, genetic evaluation was constrained within breed. However, 12 breeds including the associations for Chianina, Gelbvieh, Limousin, Maine-Anjou, Red Angus, Simmental, Shorthorn, Canadian Simmental, Canadian Gelbvieh, Canadian Limousin, Canadian Angus, and Canadian Shorthorn have begun collaborating to develop a multibreed database through IGS [38]. The IGS breeds as well as many breeds with individual evaluations (including American Angus, Hereford, Brangus, and Beefmaster) offer their members and producers genomic information to aid in selection decisions in the form of genomic enhanced EPDs (GE-EPD).

For the dairy industry, the availability of low-density chips caused whole herd genotyping to increase in popularity, and a large majority of those genotypes are obtained from females instead of males due to the structure of the industry [14]. In the beef industry, the number of genotyped females is dramatically less than males. To increase numbers of genotyped females, some breeds have developed programs that offer their customers an incentive for testing entire herds or progeny groups. For example, the ASA developed a program called Cow Herd Roundup (CHR). The program encourages whole herd DNA testing by offering lower prices on tests and additional savings if producers also provide cow weights with either body condition scores or hip heights [39].

Genotyping and genomic selection have become popular among seedstock producers as both a selection and marketing tool. These practices are far less accepted among commercial producers, mostly due to cost and return on investment. It has been suggested that DNA testing could improve accuracy of replacement female selection in a commercial operation [40]. However, cow replacement rates are lower; thus, genetic gain is achieved at a slower rate than other sectors. These factors contribute to the more difficult economies of using genomic technologies in the commercial sector. In a simulation study that estimated economic returns and costs for four different genetic evaluation scenarios (two included purebred cattle and the other two included purebred and commercial cattle), the 30-year cumulative net present value was determined per commercial calf. Scenarios were separated by type of information (phenotype, genotype, and pedigree) included in the genetic evaluation. In each scenario that incorporated commercial cattle information, genotypes improved accuracy of selection candidates but increased the time to breakeven for the operation by six to seven years [41]. Even if return on investment for genotyping their own progeny is more challenging for commercial producers, they can still utilize genomic technologies by purchasing herd bulls with GE-EPDs, which are more accurate than traditional EPDs for young sires [42].

Male Fertility

Improving fertility in livestock is extremely important to increase the production of food and textile products and the economic efficiency of livestock production. Male fertility is defined as the capability of the male to copulate and produce offspring. Male fertility traits in genetic evaluations have generally focused on scrotal circumference in the beef industry and sire conception rate (SCR) in the dairy industry. However, greater emphasis on male fertility traits in the future is certainly possible and could include numerous semen quality and quantity traits. Currently, AI centers and veterinarians performing bull breeding soundness examinations (BBSEs) record many semen quantity traits, including ejaculate volume, concentration of spermatozoa in ejaculate, and number of spermatozoa in ejaculate. Other semen quality traits include spermatozoa motility, percentage of normal spermatozoa, and spermatozoa abnormalities.

The phenotypes documented by AI centers and BBSE records provide the phenotypic structure for a genetic evaluation of these traits, provided that a framework for the delivery of these data to breed associations were to be developed. Utilizing genomics to find regions of the genome that impact male fertility traits has slowly gained popularity. While the beef industry has reported few SNPs associated with genes affecting fertility traits, the dairy industry has discovered regions of the genome that could be utilized to identify mutations or genes associated with male fertility traits.

Scrotal Circumference

Scrotal circumference is included in some beef breed association genetic evaluations including Angus, Hereford, Limousin, and Charolais. It was initially used in genetic evaluations due to its ease of collection in yearling bulls and relationship with semen quantity and growth traits [43]. However, inconsistent correlations between scrotal circumference and traits like daughter pregnancy rate (DPR) [44], calving interval [45, 46], and average daily gain have been reported [47]. Although it is arguable whether scrotal circumference is an indication of female fertility due to some conflicting results in the literature [48, 49], scrotal circumference is currently the only male fertility-related trait in genetic evaluations of beef breeds. It is a moderately heritable trait (0.36–0.56) [43, 50–54]. Interestingly, as age increases from 12 to 24 months, the heritability of scrotal circumference remains moderate, indicating that age does not greatly impact its heritability [54].

Few studies have reported correlation estimates between scrotal circumference and semen quality traits. It has been reported that as scrotal circumference increases, so does spermatozoa motility [52–54]. As scrotal circumference increases, the percentage of normal spermatozoa has also been shown to increase [51, 54] and the percentage of abnormalities present to decrease [52, 53]. Additional correlations have been reported, but these estimates are contradictory and have high standard errors associated with them.

Sire Conception Rate

In 2008, the United States Department of Agriculture (USDA) proposed a national AI dairy bull fertility evaluation. The SCR evaluation replaced the estimated relative conception rate (ERCR) which was used from 1986 to 2005 to measure dairy bull fertility. The model used to evaluate SCR includes the level of inbreeding of the bull, the level of inbreeding of the embryo from the mating, the age of the bull, the AI center the bull was collected at, the year of collection, and the effect of the bull itself [55]. However, it is difficult to evaluate SCR using AI conception data because bulls with inferior semen quality are already eliminated from the population. Semen collected from AI sires must meet strict quality measurements to be frozen. If a sire's collection has low concentration or motility, the collection is discarded, thereby eliminating the potential variation that could have been captured with low-quality semen collections [56, 57]. The dairy industry has led the cattle industries in identifying genomic regions associated with male fertility traits, and as a result has identified several genes potentially linked to SCR [58–61].

The following traits are not included in any genetic evaluation within the beef or dairy industries but are important candidates for the evaluation of male fertility in future EPD and PTA development efforts.

Semen Production Traits

Several studies have reported semen volume to have a moderate heritability [62–65] (0.18–0.26) in dairy AI bulls. Few studies have estimated the heritability of semen volume in beef bulls, but the currently available heritabilities are calculated with data obtained when bulls undergo BBSEs and are low with high standard errors [66, 67].

Conversely, concentration has been estimated to have a low (0.13–0.20) [50, 65, 67, 68] to moderate (0.26–0.52) heritability [63, 64, 66]. Breed differences and small sample sizes likely account for some of the variance in heritability estimates, but additional research with larger datasets is warranted.

Number of spermatozoa is calculated by multiplying volume and concentration together, which helps to explain why the heritability is similar to heritability estimates for volume and concentration. Number of spermatozoa has been estimated to have moderate heritability (0.22–0.38) [50, 63–65, 68] in both beef and dairy systems as well as when calculated with data from either AI bulls or BBSE data.

Few genes have been associated with semen production traits. Studies with Jersey and Holstein bulls identified genes associated with sperm motility [58, 69]. A study in Austria with Fleckvieh bulls identified four genes associated with number of spermatozoa [70].

Semen Quality Traits

Variable motility heritability estimates and inconsistent collection methods for motility traits make it difficult to compare previously published results. Motility heritability estimates are published under a variety of monikers, such as spermatozoa motility, progressive motility, motility score, and mass activity. Generally, heritability estimates for these motility traits are low to moderate. Although some studies suggest motility is a lowly heritable trait, the majority of heritability estimates that use AI center data report that motility is moderately heritable (0.30–0.43) [63–65, 71, 72].

Likewise, low heritability estimates have been noted for the percentage of normal spermatozoa [68], but most studies

have reported moderate heritability estimates for percentage of normal spermatozoa (0.35–0.47) [54, 67, 73]. This variability in reported estimates indicates that more research on this trait should be conducted to better understand the potential for incorporating percentage of normal spermatozoa into genetic evaluation.

Few studies report heritability estimates for spermatozoa abnormalities, but current estimates suggest that the percentage of abnormalities has a low to moderate heritability (0.19–0.35) [52, 53, 67, 72], depending on if the study evaluates abnormalities by developmental stage (primary or secondary) or specific abnormality. The different reporting systems do not seem to cause great variation in the estimate.

Moreover, few studies have reported genetic correlations among semen quality traits. Reported correlations are inconsistent and have large standard errors, which makes it difficult to determine whether selection on any of these traits would cause unintended changes in another.

While there is a lack of genomic information pertaining to semen quality traits, genes influencing the development of spermatozoa and the ability to fertilize an egg have been discovered [58, 60, 61, 69, 74]. The dairy industry has remained at the forefront of these genomic discoveries; however, the beef industry has additionally begun to search for genes associated with male fertility traits.

The lack of bull fertility studies, paired with the need to increase the efficiency of cattle production, drives the need for more male fertility research. Bull fertility in both the beef and dairy industry could be improved by selection, as these traits are generally moderately heritable. The addition of genomic data into these evaluations would likely bolster traditional selection efforts, as it would provide the same benefits seen for currently evaluated traits. AI centers provide the opportunity to collect bull fertility data on heavily used and highly influential sires, which could then be incorporated into genetic evaluation systems. Additionally, reporting data from routine BBSEs to breed associations could be a complimentary avenue to facilitate the implementation of male fertility EPDs or selection indices. If beef and dairy cattle producers had the capability to make selection decisions for improved fertility based on genetic merit, it would save time and resources as a result of the greater production efficiency and increased profitability.

Female Fertility

Genetic evaluation for fertility in females is relatively new for both the dairy and beef industries. The dairy industry began genetic evaluations for female fertility in the early 2000s, with the beef industry following [75]. Prior to selection for female fertility, the dairy industry observed a steep decline in fertility for over half a century. Selection emphasis was focused on economically important production traits, such as milk yield, which resulted in correlated responses that negatively impacted fertility (i.e. genetic gains in other traits would often lead to reduced fertility) [75, 76]. Although selecting for production traits negatively impacts fertility traits when not jointly considered, the development of properly weighted indexes can limit or constrain the impact on fertility when selecting for production yield [77].

In response to declining fertility, the dairy industry began to vigorously focus on the development of selection tools for fertility traits [75] and it has been successful in making progress in female fertility (Figures 76.9 and 76.10) [78]. Recently, the beef industry has also developed selection tools for female fertility, which has led to an increase in heifer pregnancy (HP) and sustained cow fertility

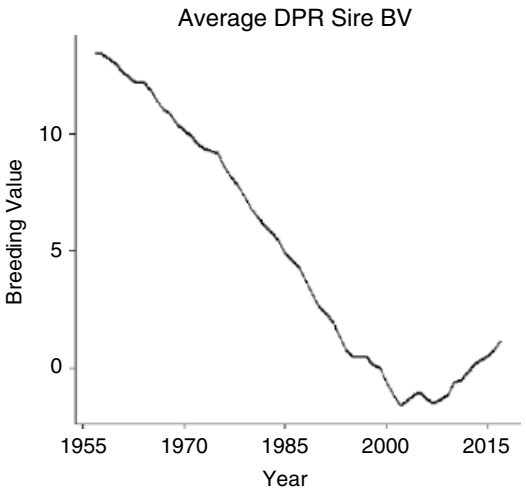

Figure 76.9 Average sire BV for daughter pregnancy rate (DPR) from 1957 to 2017 in Holsteins; selection began in the early 2000s. *Source:* Based on [78].

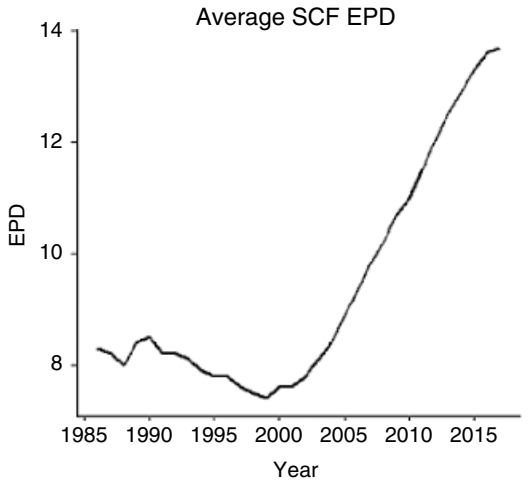

Figure 76.12 Average sustained cow fertility (SCF) EPD in Herefords from 1986 to 2017. *Source:* Based on [152].

(Figures 76.11 and 76.12), which followed declines from around 1990 to 2000. With the development of genetic evaluations for fertility traits and subsequent selection pressure in both the beef and dairy industries, the decline in average EPDs and PTAs for various fertility traits has largely reversed [75, 76, 78].

There are numerous traits that could contribute to the evaluation of female fertility. No formal definition or trait is universally favored within the industry, but traits encompassing various components of conception, pregnancy, and calving have been utilized in the research community. Phenotypes in genetic evaluation are based on producer-submitted data. Thus, the traits that could be developed for national genetic evaluation are limited to traits that can be easily and cost-effectively recorded by producers. Female fertility traits often require substantial numbers of records due to their low heritability, and complete sets of phenotypic records for an entire herd are desirable. Therefore, breed associations often provide incentives for whole herd reporting (WHR), which is especially valuable for fertility-related traits. WHR programs, which are recommended by the Beef Improvement Federation, require producers to submit data on all animals regardless of registration status. Adopting WHR programs improves genetic evaluation, leading to more accurate EPDs and PTAs [80], which are in the best interest of both the producer and the breed association. Standardizing the data collection efforts for female fertility traits may alleviate some of the concerns around availability of phenotypic information for evaluation [81]. Here we will review a variety of female traits, their use in the beef and dairy industries, and their suitability for genetic evaluation and genomic selection.

Conception Traits

Scrotal Circumference

Scrotal circumference tends to be highly heritable (Table 76.2) and has been utilized in the beef industry in Angus, Charolais, Hereford, and Limousin genetic evaluations [79, 152–154] (Table 76.3). Scrotal circumference is thought to serve as an indicator of female fertility due to an inconsistent, but potentially low to moderate genetic correlation with HP [82, 162, 163]. However, the correlation seems to come from underlying genetic effects influencing puberty rather than directly influencing fertility [81, 82]. In this case, selection would increase HP due to more heifers reaching sexual maturity at the time of breeding. It is also unclear as to whether these effects translate into cow pregnancy and fertility [77].

First-Service Conception Rate

First-service conception rate is a binary trait (success or failure) expressed as a probability of success. It emphasizes selection on females becoming pregnant to the first insemination and was designed to select for animals breeding earlier in the breeding season. Animals that conceive earlier, calve earlier, leading to increased weaning weights. They also have more time for uterine involution to take place before the next breeding season, increasing the odds the heifer will be ready to breed in the next breeding season [123]. First-service conception rate is similar to calving to first insemination, a trait used in the dairy industry. Interestingly, a wide range of heritability estimates have been generated (Table 76.2).
