Limit of Liability/Disclaimer of Warranty
The contents of this work are intended to further general scientific research, understanding, and discussion only and are not intended and should not be relied upon as recommending or promoting scientific method, diagnosis, or treatment by physicians for any particular patient. In view of ongoing research, equipment modifications, changes in governmental regulations, and the constant flow of information relating to the use of medicines, equipment, and devices, the reader is urged to review and evaluate the information provided in the package insert or instructions for each medicine, equipment, or device for, among other things, any changes in the instructions or indication of usage and for added warnings and precautions. While the publisher and authors have used their best efforts in preparing this work, they make no representations or warranties with respect to the accuracy or completeness of the contents of this work and specifically disclaim all warranties, including without limitation any implied warranties of merchantability or fitness for a particular purpose. No warranty may be created or extended by sales representatives, written sales materials or promotional statements for this work. The fact that an organization, website, or product is referred to in this work as a citation and/or potential source of further information does not mean that the publisher and authors endorse the information or services the organization, website, or product may provide or recommendations it may make. This work is sold with the understanding that the publisher is not engaged in rendering professional services. The advice and strategies contained herein may not be suitable for your situation. You should consult with a specialist where appropriate. Further, readers should be aware that websites listed in this work may have changed or disappeared between when this work was written and when it is read. Neither the publisher nor authors shall be liable for any loss of profit or any other commercial damages, including but not limited to special, incidental, consequential, or other damages.

Library of Congress Cataloging-in-Publication Data

Names: Hopper, Richard M., 1954– editor.
Title: Bovine reproduction / [edited by] Richard M. Hopper.
Description: 2nd edition. | Hoboken, NJ : Wiley-Blackwell, 2021. | Includes bibliographical references and index.
Identifiers: LCCN 2020054589 (print) | LCCN 2020054590 (ebook) | ISBN 9781119602361 (cloth) | ISBN 9781119602453 (adobe pdf) | ISBN 9781119602460 (epub)
Subjects: MESH: Cattle–physiology | Reproduction | Reproductive Medicine–methods | Reproductive Techniques–veterinary | Pregnancy Complications–veterinary
Classification: LCC SF768.2.C3 (print) | LCC SF768.2.C3 (ebook) | NLM SF 768.2.C3 | DDC 636.2/1–dc23

To Donna *– a wonderful and patient wife who, while not completely sharing my love for cows, nevertheless became skilled at watching expectant heifers from the kitchen window with binoculars and herding escaped yearling bulls from the front yard.*

Contents

List of Contributors *xiii*
Preface and Acknowledgments to the Second Edition *xxiii*
Preface and Acknowledgments to the First Edition *xxiv*
About the Companion Website *xxv*

Section I: The Bull *1*
Anatomy and Physiology *3*

1 **Anatomy of the Reproductive System of the Bull** *5*
Ben Nabors

2 **Endocrine and Exocrine Function of the Bovine Testes** *11*
Peter L. Ryan and Federico G. Hoffmann

3 **Spermatogenesis** *32*
Muhammad Salman Waqas

4 **Thermoregulation of the Testes** *40*
John P. Kastelic and Guilherme Rizzoto

5 **Endocrine Control of Testicular Development and Initiation of Spermatogenesis in Bulls** *47*
Leonardo F.C. Brito

6 **Sexual Development and Puberty in Bulls** *58*
Leonardo F.C. Brito

Breeding and Health Management *79*

7 **Breeding Soundness Evaluation: Comparative Review of Different Standards** *81*
Scott T. Norman

8 **Evaluation of Breeding Soundness: The Physical Examination** *98*
Mike Thompson and James Alexander

9 **Evaluation of Breeding Soundness: The Spermiogram** *102*
Colin W. Palmer

10 **Ultrasound Examination of the Reproductive Tract** *120*
Harry Momont, Mary Keeler, and Michael Nicholson

11 **Management of Breeding Bull Batteries** *130*
E. Heath King

12 **Management of Bulls at Custom Collection Studs** *137*
Gary Warner

13 **Testicular Degeneration** *144*
Albert Barth and John P. Kastelic

14 **Vesicular Adenitis** *151*
Mike Thompson

15 **Inability to Breed Due to Injury or Abnormality of the External Genitalia of Bulls** *155*
Herris Maxwell

16 **Management of Lameness in Breeding Bulls** *173*
Gary Warner and Jacob Warner

Reproductive Surgery **191**

17 **Regional Anesthesia for Urogenital Procedures** *193*
Darcie R. Sidelinger

18 **Surgery of the Scrotum and its Contents** *200*
E. Heath King

19 **Restorative Surgery of the Prepuce and Penis** *210*
Richard M. Hopper and Dwight F. Wolfe

20 **Management of Urolithiasis** *230*
Gretchen Grissett

21 **Preparation of Teaser Bulls** *242*
Gretchen Grissett

Section II: The Cow *249*
Anatomy and Physiology *251*

22 **Anatomy of the Reproductive System of the Cow** *253*
Ben Nabors

23 **Initiation of Puberty in Heifers** *258*
Charles T. Estill

24 **Neuroendocrine Control of Estrus and Ovulation** *269*
Gary L. Williams and Rodolfo C. Cardoso

25 **Ovarian Follicular and Luteal Dynamics in Cattle** *292*
Gregg P. Adams and Jaswant Singh

26 **Maternal Recognition and Physiology of Pregnancy** *324*
Caleb O. Lemley, Leticia E. Camacho, and Kimberly A. Vonnahme

27 **Fetal Programming** *339*
Caleb O. Lemley, Brittni P. Littlejohn, and Derris D. Burnett

Breeding and Health Management *347*

28 Biosecurity for Beef and Dairy Herds *349*
Carla L. Huston

29 Beef Heifer Development *359*
Megan S. Hindman and Terry J. Engelken

30 Dairy Heifer Development from Weaning to Calving *366*
Ricardo M. Stockler

31 Nutrition and Reproduction in the Beef Cow *372*
KC Olson, Eric Bailey, Zachary Duncan, and William Swecker

32 Interaction of Nutrition and Reproduction in the Dairy Cow *389*
Butch Cargile and Dan Tracy

33 Cystic Ovarian Follicles *399*
Jack D. Smith

34 Postpartum Anestrus and Its Management in Dairy Cattle *408*
Divakar J. Ambrose

35 Estrus Detection *431*
Roberto A. Palomares

36 Artificial Insemination *447*
Ram Kasimanickam

37 Pharmacological Intervention of Estrous Cycles *458*
Ram Kasimanickam

38 Examination for Pregnancy: Rectal Palpation *471*
David Christiansen

39 Examination for Pregnancy: Biochemical Tests *479*
Amanda Cain Dempsey

40 Ultrasound Evaluation of the Female Reproductive Tract *486*
Jill Colloton

41 Beef Herd Health for Optimal Reproduction *509*
Terry J. Engelken and Tyler M. Dohlman

42 Dairy Herd Health for Optimal Reproduction *517*
Joseph J. Klopfenstein

43 Herd Diagnostic Testing Strategies *526*
Robert L. Larson

44 Breeding Season Evaluation of Beef Herds *532*
Terry J. Engelken

45 **Dairy Herd Record Analysis** *538*
Robert Lynch

46 **Marketing the Bovine Reproductive Practice: Devising a Plan or Tolerating a System** *554*
John L. Myers

Obstetrics and Reproductive Surgery *561*

47 **Management of Vaginal, Cervico-Vaginal, and Uterine Prolapse** *563*
Augustine T. Peter and E. Heath King

48 **Induction of Parturition and Abortion** *579*
Jennifer H. Koziol

49 **Management to Prevent Dystocia** *590*
Yatta Linhares Boakari and Hossam El-Sheikh Ali

50 **Dystocia and Accidents of Gestation** *597*
Herris Maxwell

51 **Obstetrics: Mutation, Forced Extraction, and Fetotomy** *608*
Kevin Walters

52 **Obstetrics: Cesarean Section** *619*
Cathleen Mochal-King

53 **Retained Fetal Membranes** *629*
Augustine T. Peter

54 **Postpartum Uterine Infection** *639*
Dinesh Dadarwal and Colin Palmer

55 **Surgery to Restore Fertility** *655*
Richard M. Hopper

Pregnancy Wastage *665*

56 **Fetal Disease and Abortion: Diagnosis and Causes** *667*
Wes Baumgartner

57 **Infectious Agents: Campylobacter** *717*
Jessica B. Rush and Misty A. Edmondson

58 **Infectious Agents: Tritrichomonas** *725*
Katelyn Waters and Julie Gard

59 **Infectious Agents: Leptospirosis** *733*
W. Isaac Jumper

60 **Infectious Agents: Brucellosis** *742*
Valerie E. Ragan

61 **Infectious Agents: Infectious Bovine Rhinotracheitis** *753*
Benjamin W. Newcomer

62 **Infectious Agents: Bovine Viral Diarrhea** *758*
Thomas Passler and Manuel F. Chamorro

63 **Infectious Agents: Schmallenberg Virus** *784*
Johannes Kauffold, Matthias Hoops, and Thomas W. Vahlenkamp

64 **Infectious Agents: Bovine Epizootic Abortion** *793*
Jeffrey L. Stott, Myra T. Blanchard, and Mark L. Anderson

65 **Infectious Agents: Neospora** *799*
Clare M. Scully

66 **Infectious Agents: Mycotic Abortion** *809*
Frank W. Austin

67 **Compromised Pregnancy Success Caused by Heat Stress** *814*
Peter J. Hansen

68 **The Reproductive Tract Microbiome: Implications for Fetal and Neonatal Health** *830*
Riley D. Messman and Caleb O. Lemley

69 **Bovine Abortifacient and Teratogenic Toxins** *839*
Brittany Baughman

70 **Heritable Congenital Defects** *863*
Brian K. Whitlock, Jonathan E. Beever, and David J. Steffen

71 **Abnormal Offspring Syndrome** *876*
Rocío Melissa Rivera, Callum George Donnelly, Bhaumik Narendrabhai Patel, Yahan Li, and Edgar Joel Soto-Moreno

Section III: The Neonate *897*

72 **Management to Decrease Neonatal Calf Loss in Beef Herds** *899*
David R. Smith

73 **Management to Decrease Neonatal Calf Loss in Dairy Herds** *909*
Ricardo M. Stockler

74 **Critical Care Management of the Neonate** *916*
Manuel F. Chamorro and Thomas Passler

75 **Colostrum: A Review** *924*
Jenna Stockler and Manuel F. Chamorro

Section IV: Assisted and Advanced Reproductive Technologies *945*
Technological Advances that Enhance the Quantity and Quality of Spermatogenic Production *947*

76 **Utilization of Genomic Testing for the Selection of Desirable Traits in Cattle** *949*
Katherine W. Upshaw, Madison Butler, Justine Henderson, Will Shaffer, and Megan M. Rolf

77 **Technological Advances that Enhance the Quantity and Quality of Spermatogenic Production** *978*
Muhammad Salman Waqas

78 **Cryopreservation of Semen** *986*
Swanand Sathe

79 **Utilization of Sex-Selected Semen** *1000*
Ram Kasimanickam

80 **Control of Semen-Borne Pathogens** *1011*
M. Daniel Givens

81 **Bovine Semen Quality Control in Artificial Insemination Centers** *1019*
Patrick Vincent, Shelley L. Underwood, Catherine Dolbec, Nadine Bouchard, Tom Kroetsch, and Patrick Blondin

82 **Superovulation in Cattle** *1032*
Marianna M. Jahnke and Curtis R. Youngs

83 **Embryo Transfer and Embryo Collection** *1041*
Nicole Noga and Charles Looney

84 **Selection and Management of the Embryo Recipient Herd** *1061*
G. Cliff Lamb, Vitor R.G. Mercadante, Nicola Oosthuizen, and Pedro L.P. Fontes

85 **Evaluation of *In Vivo* Derived Bovine Embryos** *1073*
Marianna M. Jahnke, James K. West, and Curtis R. Youngs

86 **Control of Embryo-Borne Pathogens** *1091*
Julie Gard

87 **Cryopreservation of Bovine Embryos** *1103*
A. Lee Jones

88 **Managing the "Problem Donor"** *1110*
Ky G. Pohler, Lohana Fernández, Rebecca K. Poole, Sydney T. Reese, and Gessica Franco

89 ***In Vitro* Fertilization** *1124*
John F. Hasler and Jennifer P. Barfield

90 **Cloning by Somatic Cell Nuclear Transfer** *1142*
J. Lannett Edwards, F. Neal Schrick, and Jessica L. Klabnik

91 **Application of CRISPR-Cas9 Technology in Bovine Reproduction** *1157*
Vanmathy Kasimanickam

Index *1167*

List of Contributors

Gregg P. Adams, DVM, MS, PhD, Diplomate ACT
Professor
Veterinary Biomedical Sciences
Western College of Veterinary Medicine
University of Saskatchewan
Saskatoon, Saskatchewan
Canada

James Alexander, DVM, Member ACT (Hon)
Alexander Veterinary Services
Bentonia, Mississippi
USA

Divakar J. Ambrose, MVSc, PhD, PAg, PAS, Diplomate ACT
Dairy Research Scientist
Livestock Research Branch
Alberta Agriculture and Forestry
Department of Agricultural
Food, and Nutritional Science
University of Alberta
Edmonton, Alberta
Canada

Mark L. Anderson, DVM, PhD, Diplomate ACVP
Professor Emeritus
California Animal Health & Food Safety Laboratory and
Department of Pathology/Microbiology & Immunology
School of Veterinary Medicine
University of California, Davis
Davis, California
USA

Frank W. Austin, DVM, PhD
Professor (Retired)
Department of Pathobiology and Population Medicine
College of Veterinary Medicine
Mississippi State University
Starkville
Mississippi
USA

Eric Bailey, MS, PhD, PAS
Associate Professor
Division of Animal Sciences
College of Agriculture
Food, & Natural Resources
University of Missouri
Columbia, Missouri
USA

Jennifer P. Barfield, PhD
Department of Biomedical Sciences
Animal Reproduction and Biotechnology Laboratory
Colorado State University
Fort Collins
Colorado
USA

Albert Barth, DVM, MS, Diplomate ACT
Professor (Retired)
Department of Large Animal Clinical Sciences
Western College of Veterinary Medicine
University of Saskatchewan
Saskatoon, Saskatchewan
Canada

Brittany Baughman, DVM, MS, Diplomate ACVP
Associate Professor
Department of Pathobiology and Population Medicine
College of Veterinary Medicine
Mississippi State University
Starkville
Mississippi
USA

Wes Baumgartner, DVM, PhD, Diplomate ACVP
Veterinary Diagnostic Laboratory
College of Veterinary Medicine
University of Illinois
Urbana, Illinois
USA

Jonathan E. Beever, PhD
Professor and Director
UT Institute of Agriculture Genome Center for the Advancement of Agriculture
Knoxville, Tennessee
USA

Myra T. Blanchard, MS
Specialist
Department of Pathology/Microbiology & Immunology
School of Veterinary Medicine
University of California, Davis
Davis, California
USA

Patrick Blondin, PhD
L'Alliance Boviteq Inc.
St-Hyacinthe, Quebec
Canada

Yatta Linhares Boakari, DVM, PhD
Clinical Resident and Post Doctorate Fellow
Department of Clinical Sciences
Auburn University
Auburn, Alabama
USA

Nadine Bouchard, BSc
L'Alliance Boviteq Inc.
St-Hyacinthe, Quebec
Canada

Leonardo F.C. Brito, DVM, PhD, Diplomate ACT
Director Global Quality Assurance
STgenetics
Middleton, Wisconsin
USA

Derris D. Burnett, PhD
Assistant Professor
Department of Animal and Dairy Sciences
Mississippi State University
Starkville
Mississippi
USA

Madison Butler, MS
Graduate Teaching Assistant
Department of Animal Sciences and Industry
Kansas State University
Manhattan, Kansas
USA

Leticia E. Camacho, PhD
School of Animal and Comparative Biomedical Sciences
University of Arizona
Tucson, Arizona
USA

Rodolfo C. Cardoso, DVM, MS, PhD
Assistant Professor
Department of Animal Science
Texas A&M University
College Station, Texas
USA

Butch Cargile, DVM, MS
Progressive Dairy Solutions
Twin Falls, Idaho
USA

Manuel F. Chamorro, DVM, MS, PhD, Diplomate ACVIM
Associate Professor
Department of Clinical Sciences
College of Veterinary Medicine
Auburn University
Auburn, Alabama
USA

David Christiansen, DVM, MS
Assistant Clinical Professor
Department of Pathobiology and Population Medicine
College of Veterinary Medicine
Mississippi State University
Starkville, Mississippi
USA

Jill Colloton, DVM, Member ACT (Hon)
Bovine Services, LLC
Edgar, Wisconsin
USA

Dinesh Dadarwal, BVSc & AH, MVSc, PhD, Diplomate ACT
Assistant Professor
Large Animal Clinical Sciences
Western College of Veterinary Medicine
University of Saskatchewan
Saskatoon, Saskatchewan
Canada

Amanda Cain Dempsey, DVM, PhD
Associate Veterinarian
DeKalb Animal Clinic
Smithville, Tennessee
USA

Tyler M. Dohlman, DVM, Diplomate ACT
Department of Veterinary Diagnostic and Production Animal Medicine
College of Veterinary Medicine
Iowa State University
Ames, Iowa
USA

Catherine Dolbec, MSc
L'Alliance Boviteq Inc.
St-Hyacinthe, Quebec
Canada

Callum George Donnelly, BVSc, Diplomate ACT & DACVIM (LA)
Department of Population Health & Reproduction
School of Veterinary Medicine
University of California, Davis
Davis, California
USA

Zachary Duncan, MS
Graduate Research Assistant
Department of Animal Sciences & Industry
College of Agriculture
Kansas State University
Manhattan, Kansas
USA

Misty A. Edmondson, DVM, MS, Diplomate ACT
Alabama Department of Agriculture and Industries
Montgomery, Alabama
USA

J. Lannett Edwards, MS, PhD
Professor and Graduate Director
Department of Animal Science
University of Tennessee
Knoxville, Tennessee
USA

Hossam El-Sheikh Ali, DVM, MVSc, PhD
Associate Professor of Theriogenology
Faculty of Veterinary Medicine
Mansoura University
Mansoura
Egypt

Terry J. Engelken, DVM, MS
Professor
Department of Veterinary Diagnostic and Production Animal Medicine
College of Veterinary Medicine
Iowa State University
Ames, Iowa
USA

Charles T. Estill, BS, VMD, PhD, Diplomate ACT
Professor
Carlson College of Veterinary Medicine
Oregon State University
Corvallis, Oregon
USA

Lohana Fernández, MS
Department of Animal Science
Texas A&M University
College Station, Texas
USA

Pedro L.P. Fontes, PhD
Assistant Professor
Department of Animal and Dairy Science
University of Georgia
Athens, Georgia
USA

Gessica Franco, MS
Department of Animal Science
Texas A&M University
College Station, Texas
USA

Julie Gard, DVM, PhD, Diplomate ACT
Professor
Department of Clinical Sciences
College of Veterinary Medicine
Auburn University
Auburn, Alabama
USA

M. Daniel Givens, DVM, PhD, Diplomate ACT and ACVM (Virology)
Dean
Virginia Maryland College of Veterinary Medicine
Virginia Tech
Blacksburg, Virginia
USA

Gretchen Grissett, DVM, MS, Diplomate ACVIM
Assistant Clinical Professor
Department of Pathobiology and Population Medicine
College of Veterinary Medicine
Mississippi State University
Starkville, Mississippi
USA

Peter J. Hansen, PhD
Distinguished Professor and L.E. "Red" Larson Professor
Department of Animal Sciences
University of Florida
Gainesville, Florida
USA

John F. Hasler, PhD
Vetoquinol USA, Inc.
Laporte, Colorado
USA

Justine Henderson, BS
Graduate Research Assistant
Department of Animal Sciences & Industry
Kansas State University
Manhattan, Kansas
USA

Megan S. Hindman, DVM, Post Doctorate VDPAM
College of Veterinary Medicine
Iowa State University
Ames, Iowa
USA

Frederico G. Hoffmann, MS, PhD
Associate Professor
Department of Biochemistry and Molecular Biology and
Institute for Genomics, Biocomputing and
Biotechnology
Mississippi State University
Starkville, Mississippi
USA

Matthias Hoops, Dr Med Vet
Bavarian Animal Health Service
Poing-Grub,
Germany

Richard M. Hopper, DVM, Diplomate ACT
Professor
Department of Clinical Sciences
College of Veterinary Medicine
Auburn University
Auburn, Alabama
USA

Carla L. Huston, DVM, PhD, Diplomate ACVPM
Director Enhanced Clinical Education Program
Professor and Beef Extension Veterinarian
Department of Pathobiology and Population Medicine
College of Veterinary Medicine
Mississippi State University
Starkville, Mississippi
USA

Marianna M. Jahnke, MS
Associate Teaching Professor
Veterinary Diagnostic and Production Animal Medicine
College of Veterinary Medicine
Iowa State University
Ames, Iowa
USA

A. Lee Jones, DVM, MS
Associate Professor
Food Animal Health Management Program
College of Veterinary Medicine
University of Georgia
Tifton, Georgia
USA

W. Isaac Jumper, DVM
Population Medicine Resident
Department of Pathobiology and Population Medicine
College of Veterinary Medicine
Mississippi State University
Starkville, Mississippi
USA

Ram Kasimanickam, BVSc, DVSc, Diplomate ACT
Professor
Department of Clinical Sciences
College of Veterinary Medicine
Washington State University
Pullman, Washington
USA

Vanmathy Kasimanickam, DVM, MS, Diplomate ACVPM
Adjunct Faculty
College of Veterinary Medicine
Washington State University
Pullman, Washington
USA

John P. Kastelic, DVM, PhD, Diplomate ACT
Professor and Head
Department of Production Animal Health
Faculty of Veterinary Medicine
University of Calgary
Calgary, Alberta
Canada

Johannes Kauffold, Dr Med Vet, PhD
Faculty of Veterinary Medicine
Leipzig University
Leipzig
Germany

Mary Keeler, DVM
Staff Veterinarian
ABS Global
Deforest, Wisconsin
USA

E. Heath King, DVM, MS, Diplomate ACT
Associate Clinical Professor of Theriogenology
Department of Pathobiology and Population Medicine
College of Veterinary Medicine
Mississippi State University
Starkville, Mississippi
USA

Jessica L. Klabnik, DVM, MPH, Diplomate ACT
PhD Student-Graduate Teaching Assistant
Department of Animal Science
University of Tennessee
Knoxville, Tennessee
USA

Joseph J. Klopfenstein, DVM, Diplomate ABVP (Dairy)
Assistant Professor
Carlson College of Veterinary Medicine
Oregon State University
Corvallis, Oregon
USA

Jennifer H. Koziol, DVM, MS, Diplomate ACT
Assistant Professor
Department of Veterinary Clinical Sciences
College of Veterinary Medicine
Purdue University
West Lafayette, Indiana
USA

Tom Kroetsch, MSc
The Semex Alliance
Guelph, Ontario
Canada

G. Cliff Lamb, PhD
Professor and Head
Department of Animal Science
Texas A&M University
College Station, Texas
USA

Robert L. Larson, DVM, PhD, ACT, Diplomate ACVPM (Epidemiology), ACAN
Professor, Coleman Chair Food Animal Production Medicine
Department of Clinical Sciences
College of Veterinary Medicine
Kansas State University
Manhattan, Kansas
USA

Caleb O. Lemley, PhD
Associate Professor
Department of Animal and Dairy Sciences
Mississippi State University
Starkville, Mississippi
USA

Yahan Li, MS
Rivera Laboratory
Division of Animal Sciences
University of Missouri
Columbia, Missouri
USA

Brittni P. Littlejohn, PhD
Postdoctoral Associate
Department of Animal and Dairy Sciences
Mississippi State University
Starkville, Mississippi
USA

Charles Looney, PhD
Animal Science Department
Division of Agriculture
University of Arkansas
Fayetteville, Arkansas
USA

Robert Lynch, DVM
Dairy Herd Health & Management Specialist
Cornell University PRO-DAIRY
Ithaca
New York
USA

Herris Maxwell, DVM, Diplomate ACT
Clinical Professor
Department of Clinical Sciences
College of Veterinary Medicine
Auburn University
Auburn, Alabama
USA

Vitor R.G. Mercadante, DVM, MS, PhD
Assistant Professor
Animal and Poultry Sciences
Large Animal Clinical Sciences
Virginia Polytechnic Institute and State University
Blacksburg, Virginia
USA

Riley D. Messman, MS
Doctoral Student
Department of Animal and Dairy Sciences
Mississippi State University
Starkville, Mississippi
USA

Cathleen Mochal-King, DVM, MS, Diplomate ACVS
Terri Nunz Endowed Professor of Equine Surgery
Department of Clinical Sciences
College of Veterinary Medicine
Mississippi State University
Starkville, Mississippi
USA

Harry Momont, DVM, PhD, Diplomate ACT
Professor
Department of Medical Sciences
School of Veterinary Medicine
University of Wisconsin-Madison
Madison, Wisconsin
USA

John L. Myers, DVM, Diplomate ACT
Pecan Drive Veterinary Services
Vinita, Oklahoma
USA

Ben Nabors, DVM, PhD
Assistant Clinical Professor
College of Veterinary Medicine
Mississippi State University
Starkville, Mississippi
USA

Benjamin W. Newcomer, DVM, PhD,
Diplomate ACVIM, ACVPM (Epidemiology), ABT
Associate Clinical Professor and
Dairy Cattle Veterinarian
Veterinary Education
Research, and Outreach Center
Texas A&M/West Texas A&M Universities
Canyon, Texas
USA

Michael Nicholson, DVM
Staff Veterinarian
ABS Global
Deforest, Wisconsin
USA

Nicole Noga, MS
Animal Science Department
Division of Agriculture
University of Arkansas
Fayetteville, Arkansas
USA

Scott T. Norman, BVSc, PhD, GCEd, Diplomate ACT, MANZCVS
Kallangur Veterinary Surgery & Oakhill
Assisted Animal Breeding
Kallangur, Queensland
Australia

K.C. Olson, MS, PhD, PAS, Dipl. ACAN
W.M. & F.A. Lewis Distinguished Professor
Department of Animal Sciences & Industry
College of Agriculture
Kansas State University
Manhattan
Kansas
USA

Nicola Oosthuizen, PhD
Postdoctoral Researcher
Animal Science Department
Texas A&M University
College Station, Texas
USA

Colin W. Palmer, DVM, MVetSc, Diplomate ACT
Professor
Department of Large Animal Clinical Sciences
Western College of Veterinary Medicine
University of Saskatchewan
Saskatoon
Saskatchewan
Canada

Roberto A. Palomares, DVM, MS, PhD
Diplomate ACT
Associate Professor
Production Medicine & Theriogenology
College of Veterinary Medicine
University of Georgia

Preface and Acknowledgments to the Second Edition

As I near completion of a task that I promised myself I would never repeat, I have to say that the singular aspect of this project that stands out to me is the incredible work of the contributors. Although a handful of chapters remained virtually unchanged, most received serious updates. Pregnancy wastage rightfully includes neonatal and calf at side loss, but a new section specifically focusing on the neonate was added. The importance of lameness and its impact on fertility necessitated its inclusion. Chapters that represent recent technological advances have been added as well. Due to the broad acceptance of the first edition, an intentional effort was made to recruit more authors from outside North America and I believe this provides a more international perspective for the manner in which we all approach reproductive management of the bovine. Much like the first edition, I again utilized a broad array of both veterinary specialists and animal scientists. I also believe this book benefits from the contributions of practicing veterinarians, a group often underrepresented in veterinary texts.

Thus, I must begin my thanks by acknowledging the tremendous contributions of the chapter authors and acknowledge the guilt I feel when someone refers to this as "my book." I also owe a profound debt of gratitude to the incredible staff at Wiley. Their competence and publishing standards are the reasons that we have such a good reference text. Specifically, Erica Judisch who first displayed the faith in me to shepherd this task and then again thought we should update it. Susan Engelken, though not as directly involved as with the first edition, was again a helpful asset on "the other end" of several e-mails. A special thanks to Merryl Le Roux, who came on midway through to serve as project editor and to see this to completion; and to both Julie Musk and Sandeep Kumar. Julie was the copyeditor who found the many errors that I had missed and also did an incredible job with the numerous suggestions that have made the text so much more readable; and Sandeep handled the final content refinement. I also appreciate my colleagues at both Mississippi State and Auburn for their support.

On a personal note, Joshua Lewis, Elizabeth Marian, and Lucas Michael have joined granddaughter Abigail Betty since the first edition came out and to quote my friend John Myers, "my children are only above average, but my grandchildren are exceptional." I also need to thank my wife Donna for her now 38 years of patience and support, but will refer you to the dedication for that.

A significant portion of my career (15 years) in practice was followed by 26 years at Mississippi State and finally the opportunity to return to Auburn, my alma mater. I feel that I have indeed led a charmed life and being afforded the opportunity to contribute to the profession and specifically the area of bovine theriogenology through this text has been a great blessing.

Auburn, Alabama *Richard M. Hopper*

Preface and Acknowledgments to the First Edition

There is an old fable in which three penniless and hungry travelers come to a small town. Unsuccessful in finding work or even a handout, one concocts a novel plan. He goes to the middle of the village carrying three fist-sized rocks and announces with great aplomb that he is planning to make his famous "stone soup." The skeptical but curious villagers gather. Well of course he needed a kettle and some water. The inquisitive villagers wondered if that was all. "Yes," he replied, "but it is better with a little garnish to improve the flavor." One villager thought that he could spare some carrots, another some potatoes, and a third some meat. This continued with virtually everyone in the village contributing. The result of course was a wonderful soup and everyone enjoyed a fine meal, while experiencing an object lesson in cooperation.

The story bears an ironic resemblance to the development of this text. The editor, like the plucky traveler, personally short on ability and resources but acutely aware of a need, enlisted the assistance of those who possessed both. Excellent reference texts were available on equine and small animal theriogenology, but a current bovine text was much needed. The goal was to produce a text that would service the needs of the veterinary student and bovine practitioner, as well as the graduate student and resident.

While I would readily admit that this text could be improved with respect to the choices made vis-à-vis the organization of the book or the order of some chapters, I honestly do not believe that I could have done any better than the contributors selected. The authors of this text represent a wide array of specialties and educational and experiential backgrounds. I will forever be grateful for their assistance and immensely proud of their individual contributions. I would also like to acknowledge the efforts of my graduate assistant, Amanda Cain, who in addition to contributing a chapter, prepared the glossary of terms and index. Likewise, I would like to thank everyone at Wiley for their help. Erica Judisch, the commissioning editor, was so very helpful in guiding a novice through the early phases of this book. Susan Engelken, the managing editor for this book, was incredible to work with, always patient, always competently and quickly responding to any issue or concern. Dr Joe Phillips, the copy editor Wiley enlisted, deserves the credit for identifying errors that I missed and enhancing the readability of this text.

Additionally, I would like to acknowledge on a personal level those who have been so important to me from the standpoint of my life and career. First of all I would thank my parents, Lewis and Barbara Hopper, who were always supportive of my goals and aspirations, and my family, wife Donna and children Tricia (her husband Caleb), McRae, and Molly, who I will always consider to be my greatest accomplishments. Also, as this goes to press I can announce a wonderful addition, a granddaughter by the name of Abigail Betty Butts.

I would also be remiss to not use this opportunity to thank some of my professors and instructors at Auburn who were so influential to me professionally and important to me personally. First on this list would be Dr Robert Hudson, but also Drs Bob Carson, Howard Jones, Donald Walker, Ram Purohit, John Winkler, and Howard Kjar. Likewise, I need to thank my colleagues at Mississippi State who have both encouraged and tolerated me through this long process.

I sincerely hope the reader finds this text useful.

Starkville, Mississippi *Richard M. Hopper*

Section I

The Bull

Anatomy and Physiology

1

Anatomy of the Reproductive System of the Bull

Ben Nabors

Department of Clinical Sciences, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

The anatomy of the reproductive system of the bull can be grouped functionally into the components of production, transport, and transfer of spermatozoa (Figure 1.1).

Production

The testicular parenchyma contains the cellular machinery for spermatogenesis and steroid production (Figures 1.2 and 1.3). The parenchyma is arranged in indistinct lobules of convoluted tubules called seminiferous tubules. The seminiferous tubules contain the spermatogonia from which the mature sperm cells develop. Sertoli cells are also located within the lumen of the seminiferous tubules. The Leydig cells that are responsible for the production of the male hormone testosterone are located between the seminiferous tubules in the interstitial space [1].

Testes

The testes are housed in the scrotum. The scrotum is suspended between the thighs in the inguinal region. The scrotum consists of external and internal layers. The external layer is made up of the skin, tunica dartos, superficial perineal fascia, external spermatic fascia, cremasteric fascia, internal spermatic fascia, and parietal vaginal tunic. The skin of the scrotum and tunica dartos muscle are closely adhered whereas the fascial layers easily separate from the skin and the parietal vaginal tunic as in a closed castration technique. The coverings of the testicle itself consist of the visceral vaginal tunic and the tunica albuginea [2]. The visceral vaginal tunic is the innermost layer of the vaginal tunic, an outpouching of abdominal peritoneum that passes through the inguinal canal into the scrotal sac. The potential space between the parietal and visceral vaginal tunic is the vaginal cavity (Figure 1.3). The purpose of the vaginal cavity is for temperature regulation of the testicle by raising it closer to the body through contraction of the tunica dartos and cremaster muscles. The tunica albuginea is a thick fibrous capsule that covers the testicle and maintains the testicular contents under pressure [3]. Internally the tunica albuginea forms the axially positioned mediastinum testis from which connective tissue septa divide the testis into indistinct lobules. This connective tissue framework supports the vasculature, nerves, parenchyma, and tubular system of the testicle. The scrotum of the bull is pendulous due to the dorsoventral orientation of the testes contained within [1].

Spermatic Cord

The spermatic cord includes the ductus deferens, vasculature, lymphatic vessels, and nerves of the testicle and epididymis [4]. Essentially the spermatic cord consists of all the tissue within the vaginal tunic so it extends from the vaginal ring within the abdominal cavity to the testicle [5].

Transport

Spermatozoa are transported from the testicles through a tubular system consisting of the convoluted seminiferous tubules, straight seminiferous tubules, rete testis, efferent ductules, epididymis, ductus deferens, and urethra (Figure 1.4). The tubular system allows for maturation and storage of spermatozoa and provides fluid to ease movement of the spermatozoa.

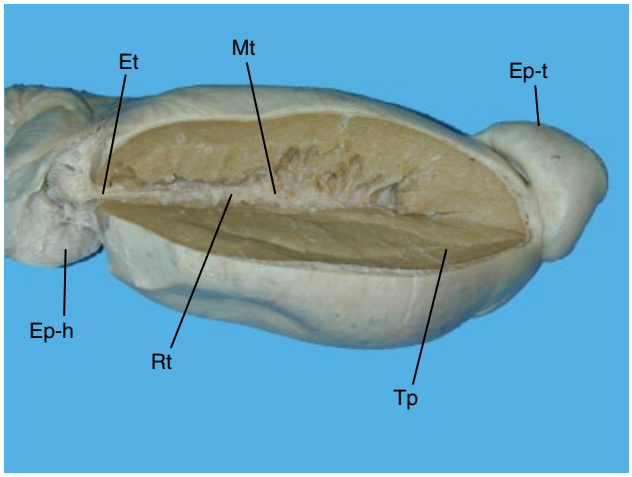

Figure 1.4 Ductules of testicle: Ep-h = head of epididymis, Et = efferent tubules, Mt = mediastinum testis, Rt = rete testis, Tp = testicular parenchyma, Ep-t = tail of epididymis.

Tubular Transport System

The convoluted seminiferous tubules are the location of the spermatogenic process: the development of spermatogonia to primary spermatocytes, to spermatids, and finally to spermatozoa [1]. This process occurs within the wall of the seminiferous tubule. Specific regions of the tubule are devoted to a particular stage of development, so that each stage can be identified by specific histological techniques [6]. Upon completion of spermiogenesis, the spermatozoa are released into the lumen of the convoluted seminiferous tubule to begin transit through the straight seminiferous tubule. The straight seminiferous tubule is simply the connection between the convoluted seminiferous tubule and the rete testis. The rete testis is a "network of irregular labyrinth spaces and interconnected tubules" [2]. The rete testes are located within the mediastinum testis connecting the seminiferous tubules to the efferent ducts that exit the testicle at the extremitas capitata (head). The efferent tubular system continues as the epididymis on the external surface of the testis (Figure 1.5). The epididymis is divided into a head, a body located on the medial surface, and a tail located at the distal extremitas caudate.

Ductus Deferens

The ductus deferens is attached to the medial side of the testicle by the mesoductus [5]. The ductus deferens is the continuation of the tail of the epididymis (Figure 1.6). The ductus deferens enters the abdominal cavity through the inguinal canal, crosses the lateral ligament of the bladder, and before ending at the colliculus seminalis in the urethra widens into the ampulla [5].

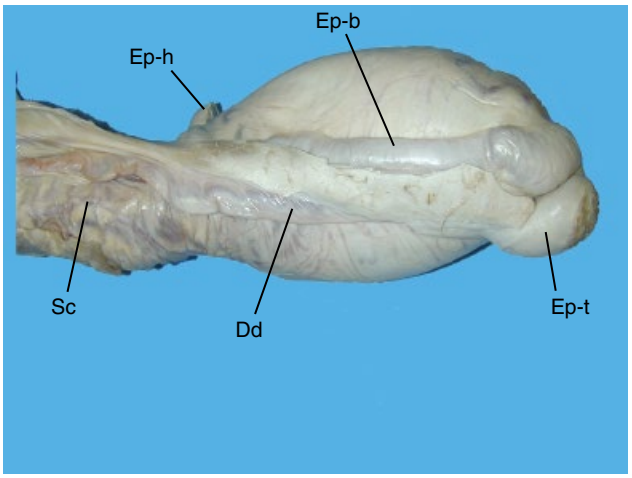

Figure 1.6 Components of epididymis: Sc = spermatic cord, Ep-h = head of epididymis, Ep-b = body of epididymis, Ep-t = tail of epididymis, Dd = ductus deferens.

Transfer

The transfer of spermatozoa from the bull to the cow is achieved by the process of intromission, which requires erection of the penis and ejaculation of sperm. The pertinent anatomy for these processes to occur includes the penis, the musculature of the penis, the vasculature, and the innervations.

Penis

The penis of the bull can be divided into a root, body, and glans penis (Figure 1.7). The root of the penis can be defined as the origin of the erectile tissue that comprises

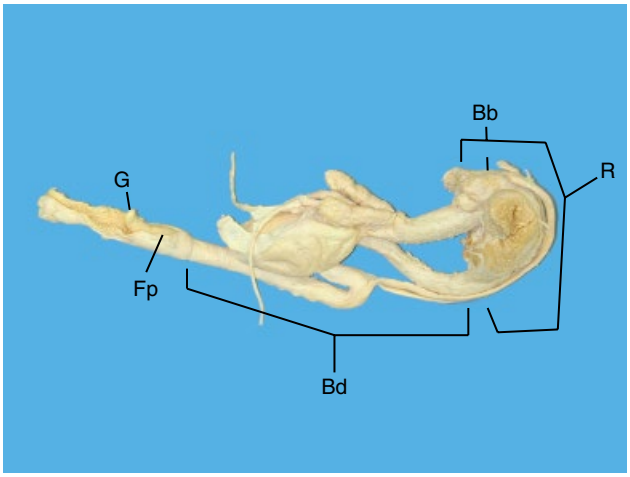

Figure 1.7 Regions of the penis: R = root of penis, Bb = bulb of penis, Bd = body of penis, Fp = free part of penis, G = glans penis.

the penis as well as the origin of the muscles of the penis. The erectile tissue that makes up the bulk of the penis is the corpus cavernosum. The paired corpora cavernosa originate separately on each side of the ischiatic arch medial to the ischiatic tuberosity. These individual limbs are termed the crura of the penis. The crura pass ventromedially until they join to form the body of the penis. The corpus spongiosum is the erectile tissue that surrounds the urethra. The origin of the corpus spongiosum, called the bulb of the penis, originates between the crura along the midline of the ischiatic arch. Therefore the root of the penis is composed of the crura (corpus cavernosum) and the bulb (corpus spongiosum).

The erectile tissue is enclosed in the dense outer covering of the tunica albuginea. The tunica albuginea is a dense covering that consists of an inner circular layer and outer longitudinal layer of fibers. The inner circular layer sends trabecular scaffolds throughout the corpus cavernosum for the attachment of the cavernous endothelium.

Located caudal to the root of the penis are the muscles of the penis: the ischiocavernosus, bulbospongiosus, and retractor penis muscles (Figure 1.8). The paired ischiocavernosus muscles originate on the medial surfaces of the ischiatic tuberosities overlying the crura; the muscle fibers pass ventromedially in a "V" fashion until ending a short distance on the body of the penis [1]. During erection the ischiocavernosus muscle contracts, pushing blood from the cavernous spaces of the crura into the body of the penis [7]. The bulbospongiosus muscle lies caudal to the bulb of the penis, originating along the ischiatic arch and continuing until the junction of the crura [1]. The bulbospongiosus muscle fibers run transversely across the bulb of the penis and contraction of this muscle results in propulsion of the ejaculate through the urethra [7]. The retractor penis muscle

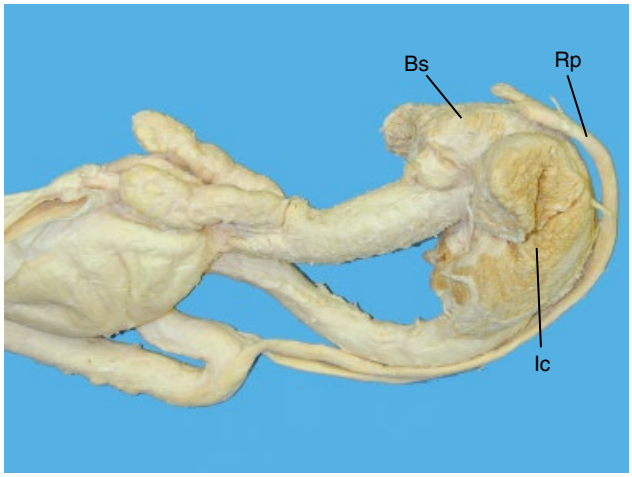

Figure 1.8 Muscles of the penis: Bs = bulbospongiosus muscle, Ic = ischiocavernosus muscle, Rp = retractor penis muscle.

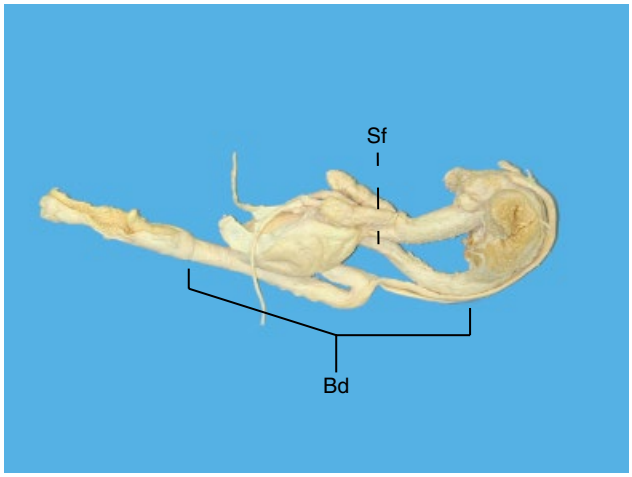

Figure 1.9 Sigmoid flexure of the penis: Bd = body of penis, Sf = sigmoid flexure.

extends from the caudal vertebrae and internal anal sphincter to insert distal to the sigmoid flexure [8]. These paired muscles relax during erection, allowing the penis to extend from the prepuce and contract during quiescence, retracting the penis into the sheath [8].

The body of the penis begins where the two crura meet distally to the ischiatic arch; it extends craniad, along the ventral body wall to become at the mid-ventral abdomen the free part of the penis (Figure 1.9). The body of the penis is bent in an "S" shape called the sigmoid flexure. The proximal bend of the sigmoid flexure opens caudally and is located near the scrotum. The distal bend is opened cranially and the short suspensory ligaments of the penis attach the penis to the ventral surface of the ischiatic arch. The glans penis is a small restricted region at the tip of the free part of the penis [8] (Figure 1.10). The free part of the penis is the distal extent from the attachment of the internal lamina of the prepuce to the glans penis [8]. The free end of the penis is twisted in a counterclockwise direction as viewed from the right side, illustrated by the oblique direction of the raphe of prepuce continued as the raphe of the penis to the urethral process (Figure 1.11). The twist of the free end of the penis is due to the attachment of the apical ligament. The apical ligament of the penis is formed by the longitudinal fibers of the tunica albuginea leaving the body of the penis just distal to the sigmoid flexure and reattaching near the apex of the penis [9].

The prepuce of the penis is composed of an external and internal fold or lamina [8] (Figure 1.12). The external lamina is the haired outer fold of skin attached to the ventral abdomen. The haired skin terminates at the preputial orifice where the external fold turns inward to line the preputial cavity as the internal lamina. The internal lamina serves to attach the external lamina to the penile epithelium.

Blood Supply

Before ejaculation can occur the testis must produce spermatozoa. This requires an adequate blood supply for the metabolic demands of cellular division for spermatogenesis and steroidogenesis. The arterial blood supply to each testis is provided by a testicular artery, a direct branch of the abdominal aorta arising caudal to the renal arteries. The testicular artery crosses the lateral abdominal wall and then passes ventrally through the inguinal canal [10]. As the testicular artery approaches the testis it begins to spiral, with the nearby tortuous pampiniform plexus of the testicular vein forming a vascular cone. This arterial/venous arrangement is an effective thermoregulatory apparatus [11].

An adequate blood supply to the penis and associated muscles is required for the processes of erection, ejaculation, and tissue maintenance. This comes by way of the internal iliac artery. The internal iliac artery is a direct continuation of the abdominal aorta at the entrance to the pelvic cavity. The umbilical artery, a branch of the internal iliac, supplies the ductus deferens and the bladder [4]. The prostatic artery leaves the internal iliac and supplies the prostate, vesicular glands, ductus deferens, ureter, and urethra [4]. As the internal iliac continues through the pelvic cavity it divides into the caudal gluteal and internal pudendal [10]. The internal pudendal gives off the ventral perineal artery and urethralis artery, and continues as the artery of the penis [10]. The artery of the penis gives off the artery of the bulb of the penis, which supplies the bulbospongiosus muscle and the cavernous spaces of the corpus spongiosum [12] (Figure 1.13). The deep artery of the penis is another branch of the artery of the penis that enters the crus of the penis and supplies the erectile tissue, the corpus cavernosum [12]. After the deep artery branches off, the artery of the penis continues as the dorsal artery of the penis which passes along the dorsal aspect of the penis toward the glans penis and prepuce. It is responsible for maintenance of penile tissue during quiescence [13].

Nervous Supply

The innervation of the external genitalia of the bull consists of the pudendal nerve and its branches. The pudendal nerve carries motor, sensory, and parasympathetic nerve fibers [4]. The pudendal nerve passes through the pelvic cavity medial to the sacrosciatic ligament and divides as it approaches the lesser ischiatic notch of the pelvis into proximal and distal cutaneous branches supplying the skin of the caudal hip and thigh [4, 8]. The pudendal nerve continues through the ischiorectal fossa, terminating in a preputial branch, a scrotal branch, and finally the dorsal nerve of the penis [6]. The pelvic nerve provides parasympathetic innervations from the sacral plexus [1]. The hypogastric nerve contributes sympathetic fibers from the caudal mesenteric plexus to the genital system [1] (Figure 1.14).

Accessory Glands

The accessory genital glands of the bull include the vesicular gland, ampulla of the ductus deferens, and prostate and bulbourethral glands (Figure 1.15). The bilateral vesicular gland is the largest accessory gland in the bull and contributes the greatest volume to the ejaculate. It is a lobated gland of firm consistency. It lies dorsal to the bladder and lateral to the ureter and ampulla of the ductus deferens [1]. The body of the prostate lies dorsal to the

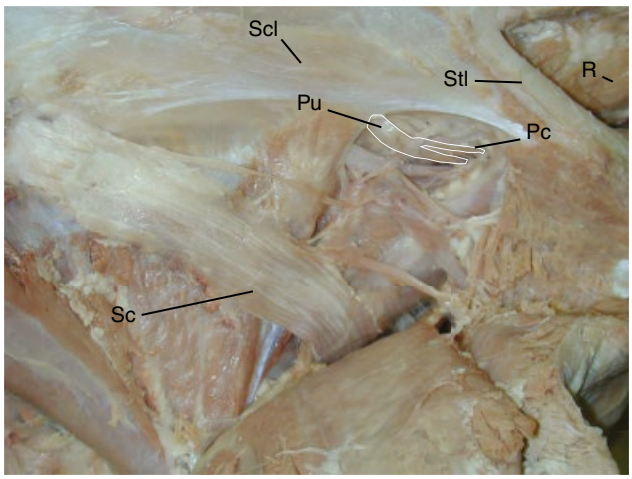

Figure 1.14 Nerves of the penis: Sc = sciatic nerve, Pu = pudendal nerve, Pc = proximal cutaneous branch of pudendal nerve Scl = sacrosciatic ligament, Stl = sacrotuberous ligament, R = rectum.

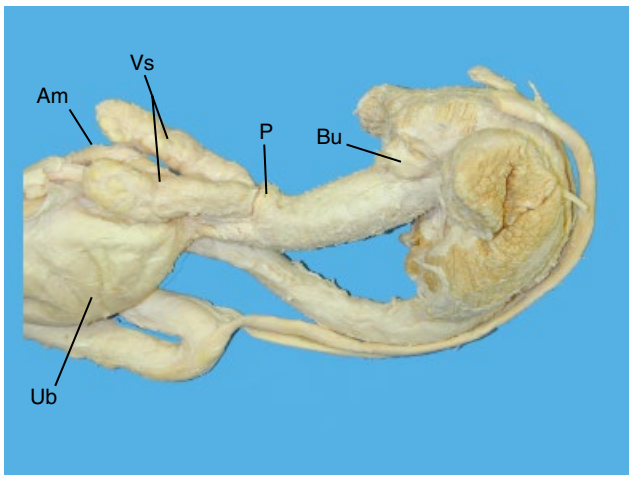

Figure 1.15 Secondary sex glands: Am = ampulla, Vs = vesicular glands, P = prostate, Bu = bulbourethral gland, Ub = urinary bladder.

urethra between and caudal to the vesicular glands. The disseminate part of the prostate is concealed in the wall of the urethra and covered by the urethral muscle [1]. The ampulla, vesicular glands, and prostate all empty their contents into the urethra through the colliculus seminalis. The bilateral bulbourethral gland lies on each side of the median plane dorsal to the urethra; it is mostly covered by the bulbospongiosus muscle. Its duct opens into the urethral recess [1] (Figure 1.15). The urethral recess is a blind pouch that exits dorsally into the penile urethra at the level of the ischiatic arch. The presence of this structure makes it difficult to pass a catheter retrograde into the bladder.

Endocrine and Exocrine Function of the Bovine Testes

Introduction

The normal bovine male reproductive system consists of paired testes retained within a sac or purse-like structure known as the scrotum, which is formed from the outpouching of skin from the abdomen and consists of complex layers of tissue. The testes are accompanied by a number of supporting structures including spermatic cords, accessory sex glands (prostate, bulbourethral, paired vesicular glands), penis, prepuce, and the male ductal system. The testicular duct system is extensive and comprises the vas efferentia found within the testes, epididymis, vas deferens, and urethra, all of which are located external to the testes. The reader is referred to the chapter on the anatomy of the reproductive system of the bull in this book (Chapter 1). The primary functions of the testes are to produce male gametes (spermatozoa) and the endocrine factors, such as steroid (testosterone) and protein hormones (inhibin, insulin-like peptide 3), which help regulate the reproductive function of the bull in concert with hormonal secretions from the hypothalamus (gonadotropin-releasing hormone) and pituitary glands (luteinizing hormone (LH), follicle-stimulating hormone (FSH)). The testes consist of parenchymal tissue that supports the interstitial tissue and includes the steroid-producing Leydig cells, vascular and lymphatic system, and seminiferous tubules within which the germinal tissue develops with the support of the nurse cells more commonly known as Sertoli cells. Chapter 5 discusses in detail the endocrine factors responsible for testicular development and initiation of spermatogenesis in the bull, and thus this chapter focuses more on the regulation and function of the adult testes. This chapter will not undertake a treatise of those conditions that disrupt testicular function but rather will focus, as practically as is possible, on what is known of the endocrine and exocrine function of the bovine testes. Much of the endocrine and exocrine function of the testes is similar across mammalian species, and where specific information is absent for the bovine, examples will be given from other domestic species when possible. It has not been possible to cite the many significant contributions to the field of endocrine and exocrine function of the testes. Thus, where and when possible, the reader is referred to selected citations for additional reading.

Historical Perspective

It has been evident for many centuries that the testes exercise control over the characteristics of the male body. The results of castration in domestic animals and human males made this very clear, but provided no clues as to the mechanism of control. Pritchard [1] noted from Assyrian records dating some 15 centuries BCE that the castration of men was used as punishment for sexual offenders, which suggests that the effect of castration on fertility and behavior was recognized at that time. Knowledge of the effects of castration of livestock dates back to the Neolithic Age (c. 7000 BCE) when animals were first thought to have been domesticated [2]. The effects of castration were understood by Aristotle (~300 BCE) who provided very detailed and clear descriptions of testicular anatomy and function [3]. It was not until the seventeenth century that a detailed account of testicular and penile anatomy was presented by Regnier de Graaf [4] in a treatise on the male reproductive organs. De Graaf indicated the existence of the seminiferous tubules and suggested that the production of the fertile portion of the semen occurred in the testes. The first microscopic examination of the testes was undertaken by Antonie van

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

Leeuwenhoek in 1667 where he demonstrated and reported the presence of germ cells in the seminal fluid [5].

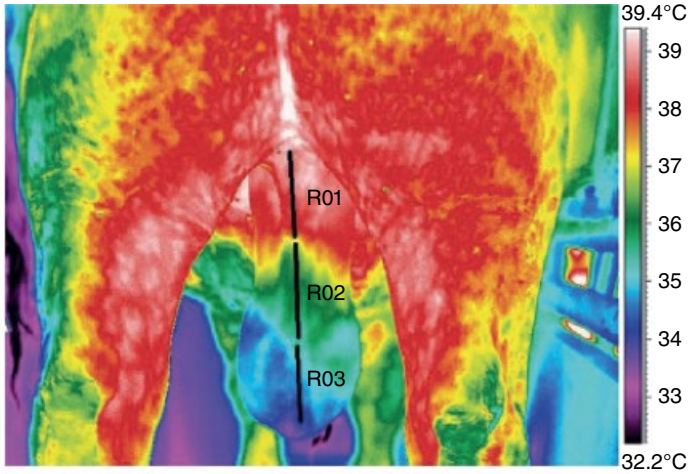
Detailed study of the testis began in the mid-nineteenth century. In 1840, Albert von Köllicker discovered that spermatozoa develop from cells residing in the testicular (seminiferous) tubules. This major discovery was followed by Franz Leydig's [6] description of the microscopic characteristics of the interstitial cells. Later, Enrico Sertoli [7], an Italian scientist, correctly described the columnar cells running from the basement membrane to the lumen of the *tubuli seminiferi contorti* (seminiferous tubules) of the testes, and Anton von Ebner is credited with introducing the concept of the symbiotic relationship between Sertoli cells and the developing germinal cells [8, 9].

The first clear demonstration that the testes are involved in an endocrine role was made by Arnold Berthold in 1849, while studying the testes of the rooster. He concluded that the regulation of male characteristics was brought about by way of blood-borne factors. The most compelling evidence for an endocrine function of the testes being associated with Leydig cells was presented by two French scientists, Bouin and Ancel in 1903. They reported that ligation of the vas deferens in dogs, rabbits, and guinea pigs was followed by degeneration of the seminiferous tubules, but no castration effects were observed and no degenerative changes of the interstitial cells, and thus it was concluded that internal secretions of the testes were synthesized by the Leydig cells [10]. By the mid-1930s it was clear that the male hormone emanating from the testes was testosterone [11] and that the function of the testes was controlled by pituitary hormones [12, 13]. Smith [12] demonstrated that the pituitary gland must secrete substances (now known as gonadotropins) responsible for the stimulation of testicular growth and maintenance of function in the rat. Greep et al. [14] restored Leydig cell function in hypophysectomized rats with crude preparations of LH and reestablished the male secondary sex characteristics. Further evidence was elucidated in favor of a steroid secretory function for Leydig cells from a study on postnatal development in bulls where changes in testicular androgen levels paralleled the differentiation of these cells [15]. Using cell culture techniques, Steinberger et al. [16] provided direct evidence that the Leydig cells are the primary source of steroid hormone synthesis in the testes. Later, it became apparent that the Leydig cells are essential for providing the androgenic stimuli that are required for the maintenance of spermatogenesis in the germinal epithelium [16, 17].

The Testis

The bovine testes are paired, capsulated, ovoid-like structures located in the inguinal region and suspended in a pendulous scrotum away from the abdominal wall. The proximal relationship of the testes to the abdominal wall varies and may depend on season and ambient temperatures. The cremaster muscle plays an important role in thermal regulation of the testis. The size of the testis varies with breed, but typically the adult testis weighs 300–400 g and is about 10–13 cm long and 5–6.5 cm wide [18]. The tough fibrous capsule covering each testis consists of three tissue layers: the outer layer, the tunica vaginalis; the tunica albuginea, which consists of connective tissue composed of fibroblasts and collagen bundles; and the inner layer, the tunica vaginalis, which supports the vascular and lymphatic systems [19]. The capsule is the main structure that supports the testicular parenchyma, the functional layer of the testes, which consists of the interstitial tissue and seminiferous tubules. The interstitial tissue is found in the spaces between the seminiferous tubules and consists of clusters of Leydig cells, which are primarily responsible for steroid hormone biosynthesis and secretion, along with vascular and lymph vessels that supply the testicular parenchyma. The seminiferous tubules originate from the primary sex cords and contain the germinal tissue (spermatogonia, the male germ cell) and a population of specialized cells, the Sertoli cells, which not only support the production of spermatozoa but also form tight junctions with each other, creating one of the most important components of the blood–testis barrier [20]. This structure prevents the entry of most large molecules and foreign material into the seminiferous tubules that may disrupt normal spermatogenesis. The most important substances synthesized by the testes and released into the vascular system are peptide and steroid hormones. However, fluids from the seminiferous tubules may pass into the interstitial tissue via the basal lamina, where they may enter the testicular lymphatic and vascular systems, or into the tubule lumen via the apical surface of the Sertoli cells [19].

The Scrotum and Spermatic Cords



The scrotum is composed of an outer layer of thick skin and three underlying layers, the tunica dartos, the scrotal fascia, and the parietal vaginal tunica. The scrotal skin is extensively populated with numerous large adrenergic sweat and sebaceous glands that are highly endowed with thermal receptors and nerve fibers. Neural stimulation from the thermal receptors enables the tunica dartos, which consists of smooth muscle fibers and lies just beneath the scrotal skin, to contract and relax in response to changes in temperature gradients and facilitates the cooling of the scrotal surface via scrotal glandular sweating [19]. Thus the scrotum not only plays an important role in housing and protecting the testes but also has a role

in thermoregulation of the testes. The spermatic cord connects the testes to the body and provides access to and from the body cavity for the vascular, neural, and lymphatic systems that support the testes. In addition, the spermatic cord accommodates the cremaster muscle, the primary muscle supporting the testes, and the pampiniform plexus, a complex and specialized venous network that wraps around the convoluted testicular artery [21]. This vascular arrangement is very important in temperature regulation of the testicular environment. The plexus consists of a coil of testicular veins that provide a countercurrent temperature exchange system: this is an effective mechanism whereby warm arterial blood entering the testes from the abdomen is cooled by the venous blood leaving the testes. Testicular arteries originate from the abdominal aorta and elongate as the testis migrates into the scrotum [19]. In cattle and other large domestic ruminants these arteries are highly coiled, reducing several meters of vessel into as little as 10 cm of spermatic cord [19]. The arterial coils and venous plexus are complex structures that form during fetal life in cattle [19, 22]. Because of the pendulous nature of the bovine scrotum, testicular cooling is facilitated by the contraction and relaxation of the cremaster muscle, which draws the testes closer to the abdominal wall during cooler ambient temperatures and vice versa during warmer temperatures. Figure 2.1 shows bright-field and thermal images of the bovine testes that demonstrate the change in temperature from the neck to the tip of the scrotum as the testes thermoregulate during elevated environmental temperatures.

Figure 2.1 Bright-field and thermal images of two-year-old Hereford bull testes. The images were taken using an FLIR SC600 thermography unit (FLIR Systems Sweden, AB) on 25 June 2013 at midday with atmospheric temperature of 29 °C and humidity of 75%. (a) Bright-field image of the testes. (b) Thermal image of the testes as seen in (a), identifying three regions of interest (RO1, RO2, and RO3) as indicated by the vertical bars along which temperature values were obtained by means of the software ThermaCAM Research Pro 2.7. The image is pseudo-colorized with temperature scale bar to help visualize the change in temperature gradient from scrotal neck to scrotal tip. (c) Temperature values, minimum (Min), maximum (Max), the difference between Min and Max, average (Avg) temperature for each region of interest (RO), and standard deviation (St dev) which assess the variation of temperature in each region. Note the almost 4 °C change in average temperature from RO1 to RO3.

Scrotal and testicular thermoregulation is a complex process involving a number of local mechanisms that strive to maintain the testes at environmental and physiological conditions conducive for normal spermatogenesis. For additional reading on testicular thermoregulation in the bull the reader is referred to the review by Kastelic et al. [23] and Chapter 4 of this book.

Interstitial Tissue (Leydig Cells)

Franz Leydig, a German zoologist, first described the interstitial cells of the testes in 1850 and these cells have since been known as Leydig cells. The Leydig cells reside in the interstitial tissue of the testis, a meshwork of loose connective tissue filling the spaces between the seminiferous tubules and blood vessels. In mammalian testes, the Leydig cells occur mainly as clusters in the angular interstices between the seminiferous tubules and are closely associated with the walls of small arterioles [8, 24]. The Leydig cell content of testes varies from species to species. The Leydig cells are thought to be the principal source of androgens in the testis. The development of the Leydig cells, via metamorphosis of mesenchymal precursor cells, has been observed to be continuous throughout life after the time of puberty in the bull [25]. Christensen [26] provides a very detailed and interesting review of the history of Leydig cell research dating from Leydig's description of the cells in the 1850s to the confirmation provided in the mid-1960s that these cells were indeed primarily responsible for testicular androgen synthesis and secretion. There is extensive evidence to suggest that early fetal Leydig cells are steroidogenically active in some mammalian species including the pig [27] and sheep [28].

The Leydig cells of most mammalian species studied are basically similar, with some minor variations in appearance, size, and the relation of Leydig cell clusters to the lymph or blood vessels of the interstitial tissue. Some variation in the extent of cytoplasmic structures exists, but ultrastructurally Leydig cells show considerable overall similarity [8]. Fawcett et al. [29] described in detail the morphology of interstitial tissue of several mammalian species, and categorized three groups based on the abundance of Leydig cells and the relationship between volume of intertubular lymph structures and connective tissue. In the first group are the guinea-pig and rodents (rat, mouse). In these species only 1–5% of the testicular volume is occupied by Leydig cells, for example 2.8% in the rat [30]. The bull, monkey, elephant, and human fall into the second group. In these species, the connective tissue of the interstitium is very loose and the Leydig cells are scattered throughout the interstitium and are closely associated with a well-developed lymph system. The Leydig cells comprise only a small portion of the testicular volume (~15%) [8]. In the third group are the domestic boar and horse. In these animals there is abundant interstitial tissue packed with Leydig cells (20–60% of testicular volume) [31]. The reason for the high density of Leydig cells in these species is not known, but Parkes [10] and Fawcett et al. [29] have attributed this phenomenon to the vast amounts of estrogens produced by the boar and stallion and the large quantities of musk-smelling 16-androstenes secreted by the boar testes [32]. For more detailed discussions on the cytology of Leydig cells the reader is referred to an excellent chapter by de Kretser and Kerr [33].

Endocrine Function of the Testis

Hypothalamic–Pituitary Hormone Regulation of the Testis

Hormone action depends on the release of hormones from the appropriate endocrine gland and transportation via the vascular circulatory system to the target tissue where the hormone binds to cellular receptors, thus inducing a physiological response. In some cases these receptors are very hormone-specific. The response at the target tissue may depend on the level of receptor expression and concentration of hormone. Some hormones regulate their own receptors, others may require synergism between two hormones, and others still may have their receptors regulated by other hormones [34]. The general characteristics of neuroendocrine regulation of the mammalian testis by the hypothalamic–pituitary axis are well established [35], but in some species this may be seasonally regulated. Domestic cattle are considered to be continuous or non-seasonal breeding species [36]. However, there is information in the literature to indicate that domestic beef and dairy bulls have a functional hypothalamic–pituitary–gonadal axis that is seasonally regulated and thus may influence levels of gonadal steroidal and germ cell production. In a study using composite breeds of mature bulls, Stumpf et al. [37] observed that season of the year influenced the profile of gonadotropins in the circulation of both gonadectomized and intact males, and that the greatest secretion of gonadotropins occurred at the spring equinox. In addition, these authors observed that season of the year also influenced secretion of testosterone in intact males, but that more testosterone was released in response to LH during the time of the summer solstice. Others have reported similar effects, where location affected reproductive traits of bulls including semen quality and blood concentrations of LH and testosterone [38, 39]. In addition,

sensitivity in responsiveness to exogenous gonadotropin administration and testosterone secretion in bulls was observed to be seasonally influenced [40].

The regulation of testicular function by hormonal mechanisms depends on the integrated actions of gonadotropins, such as LH, FSH, and prolactin, and steroids (androgens and estrogens) on the Leydig cell [41]. Gonadotropin-releasing hormone is the primary hypothalamic hormone governing regulation of the synthesis and release of the gonadotropins LH and FSH by the anterior portion of the pituitary gland. LH is primarily responsible for testosterone production by the Leydig cells, while FSH facilitates Sertoli cell proliferation and support of the germinal cells. Although it has been well established that gonadotropins stimulate testicular function, it was during the 1970s that the basic mechanism and site of action in the testis were identified. LH has been shown to be the gonadotropin essential for the maintenance of testicular testosterone production [41, 42]. Catt and Dufau [43] have reviewed the mechanisms of action of the gonadotropins and concluded that they all elicit target cell response by similar mechanisms. In fact, LH provides the most important physiological regulation of the production of androgens by the Leydig cells of the testis [44, 45].

Leydig cells contain plasma membrane-bound receptors that specifically bind LH. The binding of LH stimulates adenyl cyclase to produce cyclic adenosine monophosphate (cyclic AMP), a second messenger in the cell cytoplasm, which in turn activates cyclic AMP-dependent protein kinase, thereby increasing the conversion of cholesterol to pregnenolone. The action of LH can be readily demonstrated in hypophysectomized and intact males. Removal of the pituitary gland is followed by rapid cessation of testosterone production, loss of enzymes involved in steroidogenesis, and testicular atrophy [46]. There is little direct evidence to support a role of FSH in Leydig cell steroidogenesis, but there is some evidence indicating that this gonadotropin may play a function in the conversion of androgens to estrogens in the Sertoli cells [47]. Bartke et al. [42] have suggested that FSH may act on the aromatizing enzyme system of testosterone biosynthesis, but little evidence exists for action on other steps of the steroidogenesis pathway in the testis. In bulls, testosterone secretion is not tonic, but is characterized by episodic pulses dictated by the release of luteinizing hormone releasing hormone (LHRH) from the hypothalamus and LH from the anterior pituitary gland [48]. Schanbacher [48] reports that a temporal relationship exists between concentrations of LH and testosterone in the blood, and that there is evidence that episodic secretion depends on discrete episodes of LHRH discharge from the hypothalamus.

Prolactin

Prolactin (PRL) is known to enhance the effect of LH on spermatogenesis. The physiological importance of PRL in the regulation of Leydig cell function was first determined using three animal models [41, 42]: the golden hamster, where testicular regression can be induced by short photoperiod; hypophysectomized mice; and the hereditary dwarf mouse with congenital PRL deficiency and infertility. In all three models there is a deficiency in plasma concentrations of PRL and testosterone and testicular atrophy is evident. PRL therapy, on the other hand, stimulates spermatogenesis in the dwarf mouse and restores testicular function in the golden hamster; in hypophysectomized animals, PRL, in the presence of LH, induces spermatogenesis and restores plasma testosterone. In men, PRL has an important role in the control of testosterone and reproductive function [49]. At very high concentrations (hyperprolactinemia), PRL has an antigonadal effect in men, inhibiting testicular function, and is associated with hypogonadism [50].

Other Regulatory Factors

The effects of other regulatory factors, such as growth hormone (GH), on testicular steroidogenesis have not been fully clarified. However, in view of the structural similarities between PRL and GH, it is thought that both hormones may have comparable effects on Leydig cell function [42]. The effect of GH may be more significant during puberty (see Chapter 6). However, administration of gonadal steroids to intact animals is known to cause reduced androgen production, an effect that has been attributed to inhibition of gonadotropin secretion with secondary effects on testicular endocrine function. Estrogen receptors have also been detected in interstitial tissue of the testis and since decreased testosterone levels are not correlated with a corresponding change in plasma LH, some authors suggest that estrogen may exert a direct inhibitory action on Leydig cell function [51, 52]. The effects of corticosteroids on Leydig cell function have been noted. Boars treated with adrenocorticotropin (ACTH) experienced increased testicular testosterone simultaneously with increased secretion of adrenal corticosteroids [53]. A transient increase in peripheral circulation of both corticosteroids and testosterone was first observed in boars following acute treatment with ACTH, while a decrease in testosterone occurred following chronic treatment [54]. These authors concluded that prolonged stressful conditions may lead to chronic elevation in ACTH levels, thus suppressing testosterone production and inducing poor breeding activity.

In reviewing the literature, Tilbrook et al. [55] have determined that stress-related influences on reproduction

are complicated and not fully understood, but the process may involve a number of endocrine, paracrine, and neural systems. The significance of stress-induced secretion of cortisol varies with species. In some instances, there appears to be little impact of short-term increases in cortisol concentrations, and protracted increases in plasma concentration seem to be required before any deleterious effect on reproduction are apparent. In a comprehensive review, Moberg [56] describes the influence of the adrenal axis on gonadal function in mammals. Subsequently, the same author published a detailed review [57] of the impact of behavior on domestic animal reproductive performance and placed particular emphasis on how intensive livestock management practices can contribute to stress-induced disruption of normal reproductive function. However, the emphasis has primarily been on studies investigating the effects of stress-induced ACTH release in females.

Elevated plasma ACTH results in increased adrenal corticosteroid synthesis and under chronic conditions may inhibit gonadotropin-releasing hormone and gonadotropin hormone production, thereby reducing gonadotropin (LH) release from the pituitary gland and thus impacting normal ovarian function in females. Nevertheless, studies have shown that stress-induced elevation in ACTH affects males in a physiologically similar manner by impacting gonadotropin regulation of testicular function. Liptrap and Raeside [58] observed the effects of cortisol on gonadotropin-releasing hormone in boars, while Matteri et al. [59] observed that stress or acute ACTH treatment suppresses gonadotropin-releasing hormone-induced LH release in the ram. In Holstein bulls treated with a bolus of ACTH (0.45 IU/kg), plasma LH or FSH concentrations did not appear to be negatively affected, but it did appear to reduce plasma testosterone concentrations [60]. Pharmacological concentrations of ACTH (200 IU every eight hours) over a six-day period resulted in reduced plasma testosterone in yearling and mature bulls within eight hours and four days of initial treatment, respectively, and this decrease persisted in both age groups for an additional 24 hours after the last ACTH injection [61]. While semen viability, concentration, and sperm output were unaffected by the prolonged ACTH treatment concomitant with a subsequent marked increase in glucocorticoids and decrease in testosterone, a small increase in semen content of immature sperm or sperm with abnormal heads was observed [61]. Thus, it appears that under prolonged stressful conditions, gonadotropin secretion is more likely to be suppressed, thus inhibiting reproductive performance. In addition, studies have demonstrated that glucocorticoids can inhibit gonadotropin secretion in some circumstances. Tilbrook et al. [55] conclude that suppression of reproduction is more likely to occur under conditions of chronic stress and may involve actions at the level of the hypothalamus or pituitary. In addition, they indicate that there are likely to be species differences in the effect of glucocorticoids on gonadotropin secretion, and the presence of sex steroids and the sex of an individual are also likely to be factors.

Cytokines are members of the family of growth factors, and the interleukins in particular may act at the level of the hypothalamus where they may control the release of gonadotropin-releasing hormone, thus influencing the release of pituitary gonadotropins and ultimately gonadal steroid synthesis and release. Svechniko et al. [62] have reported that testicular interleukin (IL)-1 may play a role in the paracrine regulation of Leydig cell steroidogenesis in rats. Others have reported that testicular interleukins may play an important functional role in both normal testicular function and under pathological conditions [63]. There is some evidence in the bovine that cytokines such as tumor necrosis factor (TNF)-α and interferon (IFN)-γ may play a role in nitric oxide regulation in luteal endothelial cells by increasing inducible nitric oxide synthase (iNOS) activity, thereby accelerating luteolysis, while progesterone is thought to suppress iNOS expression in bovine luteal cells [64]. Whether these or other cytokines have similar effects on testicular cells of the bull has yet to be reported.

Steroid Synthesis by Leydig Cells

Since the beginning of the twentieth century, Leydig cells have been considered the probable source of testicular androgens [65]. Berthold [66] was the first to observe from experimentation with the rooster that the testes produced a substance that influenced secondary sex organ development and maintenance [26]. The first isolation of an androgen, androsterone, from human urine [67] and the crystallization of testosterone from bull testes [11] established the major site of testosterone production as the testis. Extensive literature has emerged over the past 50 years on the function of the Leydig cell. These studies, employing a variety of techniques, have identified and confirmed the Leydig cells as the primary source of testicular androgens and elucidated the important pathways in androgen biosynthesis [5, 26, 52, 68]. LH has also been confirmed as the major pituitary hormonal stimulus on the Leydig cells [46]. Ewing et al. [68] have suggested that because Leydig cells are concentrated in clusters in the interstitial tissue of the testis, they must influence seminiferous tubular and peripheral androgen-dependent functions (accessory sex glands) by hormonal signals rather than by cell-to-cell interaction.

The primary steroids produced and secreted by the bull testis are shown in Table 2.1. The conversion of the precursor cholesterol to androgens and estrogen is facilitated by a

Table 2.1 Primary steroid and peptide hormones synthesized and/or secreted by the bull testis.

Hormone family	Hormone	Site of synthesis
Steroid family		
Cholesterol (27 carbons)	Cholesterol 22-hydroxycholesterol 20,22,-dihydroxycholesterol	*De novo* biosynthesis, fat deposits, or from blood
Progestins (21 carbons)	Δ5-Pregnenolone 17α-Hydroxypregnenolone 17α-Hydroxyprogesterone Progesterone	Leydig cells (mitochondria)
Androgens (19 carbons)	Dehydroepiandrosterone Δ4-Androstenedione Δ5-Androstenediol Testosterone Dihydrostestosterone	Leydig cells (microsomal compartments)
Estrogens (18 carbons)	Estrone Estradiol-17β	Leydig cells
Peptide family		
Relaxin-like peptides	Relaxin/insulin-like peptide-3	Leydig cells
Neuropeptides	Oxytocin Glial cell-derived factor	Leydig cells Seroli cells
Cytokine family		
	Activin Inhibin	Sertoli cells Sertoli cells
Glycoproteins		
	Androgen binding protein Testicular transferrin	Sertoli cells Sertoli cells

series of enzymatic reactions involving hydroxylation, dehydrogenation, isomerization, C–C side-chain cleavage (lyase), and aromatase activity. Testosterone is now recognized as the principal steroid responsible for the endocrine functions of the testis since it is synthesized in copious amounts by mammalian Leydig cells. The Leydig cell has also been identified as a major source of other androgens and estrogens [5, 69]. In addition, the Leydig cells of the boar testis produce large amounts of the musk-smelling steroids, Δ^{16}-androstenes [70]. It has become apparent that the primary function of the Leydig cell is the provision of the androgen stimulus required for the initiation and maintenance of spermatogenesis in the germinal epithelium within the seminiferous tubules [71]. Some of the earliest functions of the Leydig cell are associated with regulation of the male reproductive organs, the organization of parts of the brain, pituitary secretion of gonadotropins, and accessory sex organ development of the neonate to ensure the appropriate response by these tissues to testicular steroids in the adult male [69]. The dependence of male sex accessory organs on testicular hormones is not restricted to the early fetal period but occurs also during puberty and throughout male adult life [72].

Cholesterol has been described as an obligatory intermediate in testosterone synthesis [5]. Testosterone is synthesized from a pool of metabolically active cholesterol, which is derived from either de novo biosynthesis of cholesterol, cholesterol esters stored as lipid droplets in the cell cytoplasm, or from blood plasma [68]. The conversion of cholesterol to testosterone involves five main enzymatic steps that include 20,22-lyase, 3β-dehydrogenase isomerase, 17α-hydroxylase, 17,20-lyase, and 17β-hydroxysteroid dehydrogenase, and in some species the conversion of androgens to estrogens via the aromatase enzyme system [73]. Conversion of cholesterol to pregnenolone is the initial step in the pathway and is catalyzed by the cholesterol side-chain cleavage enzyme complex, a three-step process that takes place in the mitochondria of the cell [45]. Briefly, pregnenolone is formed from

cholesterol (C27 sterol) by cleavage of the bond between C20 and C22 catalyzed by the multienzyme complex of the side-chain cleavage system in the mitochondria, and metabolized in the microsomes by the microsomal enzyme complex 3β-hydroxysteroid dehydrogenase/isomerase. Pregnenolone is also an obligatory intermediate in Leydig cell steroid synthesis. Van der Mollen and Rommerts [52] have indicated that the conversion of C21 steroids (i.e. pregnenolone) to C19 steroids (testosterone) may occur in the mammalian testis through two biosynthetic pathways. The crucial step in the biosynthesis of pregnenolone to androgens is the cleavage of the two-carbon side-chain of 17α-hydroxyprogesterone or 17α-hydroxypregnenolone by the 17,21-lyase enzyme complex [74]. This is regarded as an irreversible reaction producing "weak" androgens (androstenedione and dehydroepiandrosterone, respectively). Through the action of 17β-hydroxysteroid dehydrogenase, androstenedione is converted to the more potent androgen testosterone, which occurs in the microsomal compartments of the cell. However, testosterone is converted to dihydrotestosterone (DHT) by the 5α-reductase enzyme system, and is regarded as the more biologically active androgen produced by the testis. A more detailed account of the mechanisms involved in testosterone biosynthesis can be found in the review by Hall [45], but a schematic overview of steroid synthesis in the bovine testis is presented in Figure 2.2.

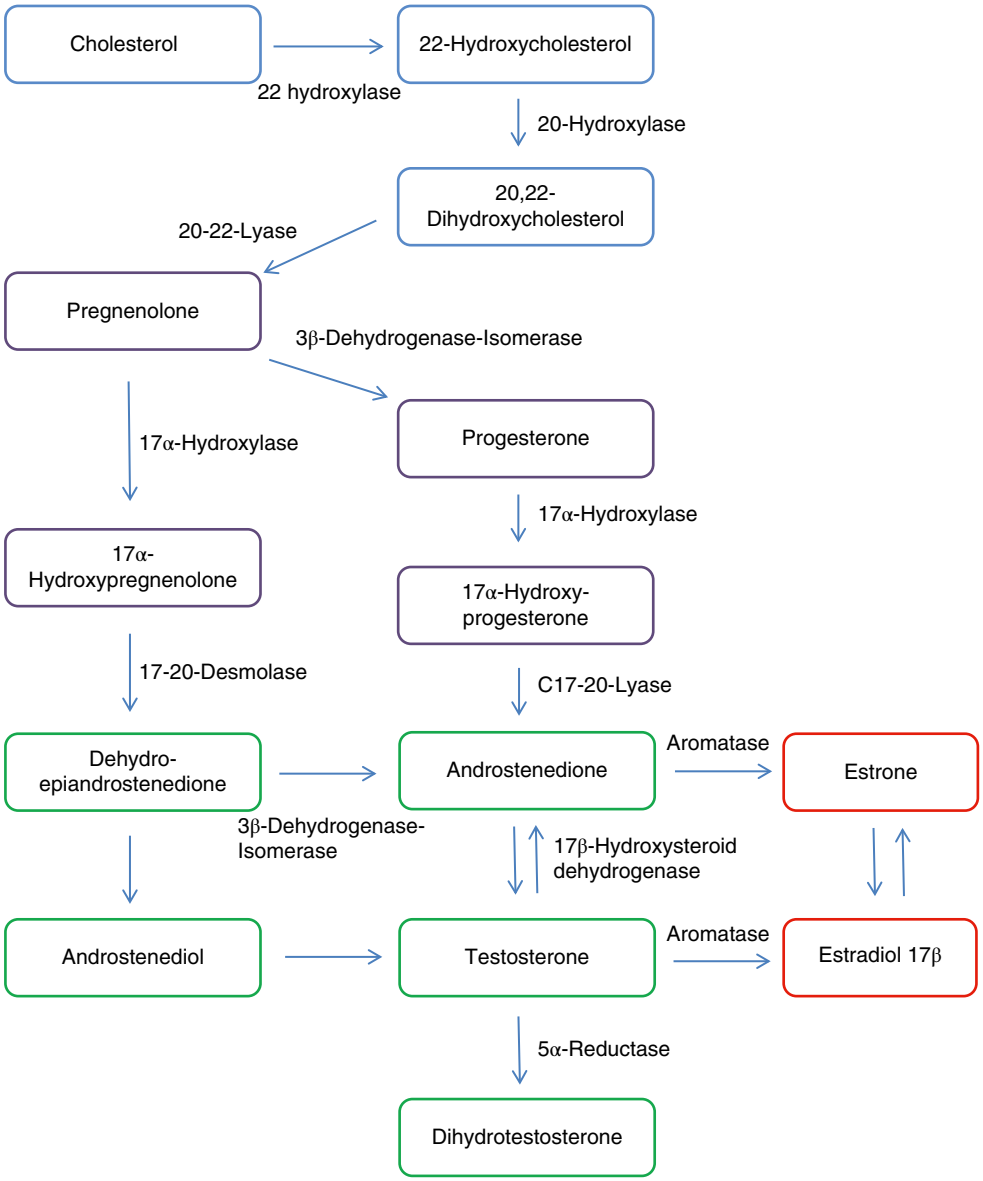

Figure 2.2 Synthetic pathway of testosterone and conversion to active androgen and estrogen metabolites in the bull testis. Relevant enzyme systems involved in the synthesis are shown; in some instances, the enzyme reactions are reversible. Color code: blue, C_{27} cholesterol steroid precursors; purple, C_{21} progestin steroids; green, C_{19} androgen steroids; red, C_{18} estrogen steroids.

The unusual abundance of Leydig cells in domestic boars and stallions promoted the hypothesis that this may be related to the fact that both species secrete significant amounts of estrogens [75], but the significance of the vast quantities of estrogens produced by these two species is unexplained. It has been suggested that estrogens act synergistically with testosterone to enhance both secretory activity of accessory sex organs and sexual behavior in boars castrated after puberty [76]. Estrogens are C18 steroids and are formed by the conversion of androgens by the aromatase enzyme system to produce estrone and estradiol from androstenedione and testosterone, respectively. Of interest in the boar are the musk-smelling Δ^{16}-androstene steroids (pheromones) that are regarded quantitatively as the most abundant steroids produced by the boar testis and contribute to the familiar "boar taint" of pork [77]. However, there is insufficient evidence to demonstrate that bull testis produces estrogens in the quantities found in the boar and stallion, nor is there evidence that the bull secretes much in the way of the Δ^{16}-androstene steroids. However, what is now well documented is that testosterone is the most potent androgen produced by Leydig cells in mammalian testes, and the site of action is primarily on seminiferous tubule target cells, thus influencing the reduction division of the spermatogenic cells [78]. Androgens stimulate production of androgen-binding protein (ABP) by the Sertoli cells [79], and this acts as an intracellular carrier of testosterone and DHT within the Sertoli cells. Testosterone is also the most important determinant of the rate of formation of fructose by the seminal vesicles and of citric acid by the prostate and seminal vesicle glands of the bull, ram, and human [78].

Oxytocin is a nine amino acid neuropeptide hormone normally associated with the hypothalamic–posterior pituitary system and the regulation of parturition and lactation in the female, but has also been shown to have an endocrine and paracrine role in male reproduction [19, 80]. There is evidence reported in the literature that oxytocin is produced and secreted by the male reproductive tract including the testis [81, 82]. Moreover, there is now evidence to show that oxytocin is produced locally by the testis and that it has a paracrine role in modulating testicular steroidogenesis and contractility of the male reproductive tract [83]. In addition, it has been shown that the Leydig cells are the testicular site of production of this hormone, and that oxytocin acts as a paracrine hormone influencing the contractility of the peritubular myoid cells [19]. The contraction of myoid cells in the seminiferous tubule epithelium is thought to facilitate sperm transport through the testicular parenchyma emptying into the rete testis and on into the epididymal system. It has been shown that, within the prostate, testosterone is converted by 5α-reductase to DHT, which stimulates growth of the prostate gland. Nicholson [83] has postulated that oxytocin increases the activity of 5α-reductase, resulting in increased concentrations of DHT and growth of the prostate, but that androgen feedback reduces oxytocin concentrations in the prostate, thereby modulating prostate gland growth. Definitive evidence of oxytocin synthesis within the bovine testis has come from studies on oxytocin gene expression in the seminiferous tubules [84, 85].

Relaxin and Insulin-like Peptide (INSL-3)

Increasing evidence emerging in the literature indicate that relaxin and relaxin-like peptides play an important role in male reproductive function. Insulin-like peptide 3 (INSL3; formerly known as relaxin-like factor 3) is a peptide hormone belonging to the relaxin–insulin family of peptide hormones [86–88] and binds to the RXFP2 receptor complex [89] to initiate physiological responses. It was first identified in the testes of pigs [90] and is now thought to be an important factor in regulating normal testicular decent [87], particularly during the second phase where it acts on the gubernaculum, as demonstrated using knockout mice. The peptide hormone has been identified in male and female tissues of other species, including human, marmoset monkey, sheep, goat, bovine, as well as deer, dog, and other species [88]. It is produced in large quantities by the Leydig cells of both the fetal and adult testes, and circulating INSL3 concentrations have been measured in the blood of adult male mammals including the rat (5 ng/ml) [91], mouse (2 ng/ml) [91], and human (0.8–2.5 ng/ml) [92, 93]. Although INSL3 has been successfully extracted from bovine testis [94] and found to be present in amniotic fluid from human male fetuses [95], it is only recently that Anand-Ivell et al. [96] using new time-resolved fluorescence immunoassay to directly detect INSL3 in the blood and body fluids of ruminants reported that mid-gestation (day 153) cows carrying a male fetus showed significantly higher maternal blood concentrations of INSL3 compared with cows carrying a female fetus. The authors speculate that INSL3 provides the first example of a gender-specific fetal hormone with the potential to influence both placental and maternal physiology. In a recent review, it is reported that INSL3 is a major secreted product of the interstitial Leydig cells of the mature testes in all mammalian males [97]. Moreover, current evidence points to autocrine, paracrine, and endocrine roles, acting through the G-protein coupled relaxin family receptor 2 (RXFP2), although more research is required to characterize these functions in detail. Indeed, recent studies have provided evidence of the presence of both RXFP1 and RXFP2 receptors in porcine spermatozoa [98], which would suggest that relaxin may play an important role in sperm production motility and [99]. Disruption of the INSL3 binding to its receptor complex RXFP2 demonstrated the importance of

this hormone in promoting and maintaining normal sperm production in the boar testis [100]. Pitia and colleagues [101] investigated the functional INSL3 hormone-receptor system in the testes and spermatozoa of several domestic ruminant species including bulls, rams, and goats, and explored the potential of this hormone-receptor to evaluate the fertility of sires. In all ruminants examined, the study identified the presence of RXFP2 in the Leydig cells, testicular germ cells, and sperm (equatorial segment) of fertile males, but in sub-fertile bulls, the expression pattern in these tissues was significantly reduced. Moreover, the study observed a significant reduction in spermatozoa INSL3 binding in semen recovered from sub-fertile bulls [101]. Consequently, the authors proposed that poor INSL3 binding by spermatozoa may have potential in predicting sire fertility.

Relaxin

The physiological role of relaxin has been intensively studied in many species over the years, including domestic ruminants, with most of the emphasis on the role in pregnancy. Experimental evidence suggests that a number of species in the Bovidae family, both domestic and non-domestic species, do synthesize relaxin, but apparently respond to it in a physiological manner [102–104]. Specific studies performed by Bagna et al. [102] and Musah et al. [105] explored the efficacy of purified porcine relaxin on parturition in beef and dairy cattle, indicating the possible presence of relaxin RXFP receptors in the bovid female. Observing the experimental evidence suggesting that cattle may not synthesize relaxin, but appear capable of responding to the hormone physiologically, Malone et al. [106] undertook an investigation to characterize the genomic locus of the relaxin gene (RLN1) in Laurasiatherian mammals to understand how cattle may have lost the ability to synthesize this peptide hormone. The outcome of these studies revealed that both domestic and wild ruminant species, including the cow, giraffe, Tibetan antelope, sheep, and goat, lack a functional RLN1 gene. Moreover, the study documented the progressive loss of RLN1 in the evolutionary lineage leading to cattle (Figure 2.3) and that the cow genome has lost all trace of the gene [106]. Interestingly, the same study confirmed that all bovids examined possess copies of the relaxin receptors, RXFP1 and RXFP2, which may explain why in some studies, dairy and beef cattle respond to relaxin despite the inability to synthesize the hormone [106].

The importance of relaxin is less well studied in male mammals. The presence of relaxin-binding activity has yet to be clearly demonstrated in the male bovid, but with the advent of new technologies this may be possible [107]. However, Kohsaka et al. [108, 109] have demonstrated, utilizing immunohistochemical studies, the binding of relaxin to spermatozoa and suggested that this activity may impart physiological effects on sperm motility and fertility.

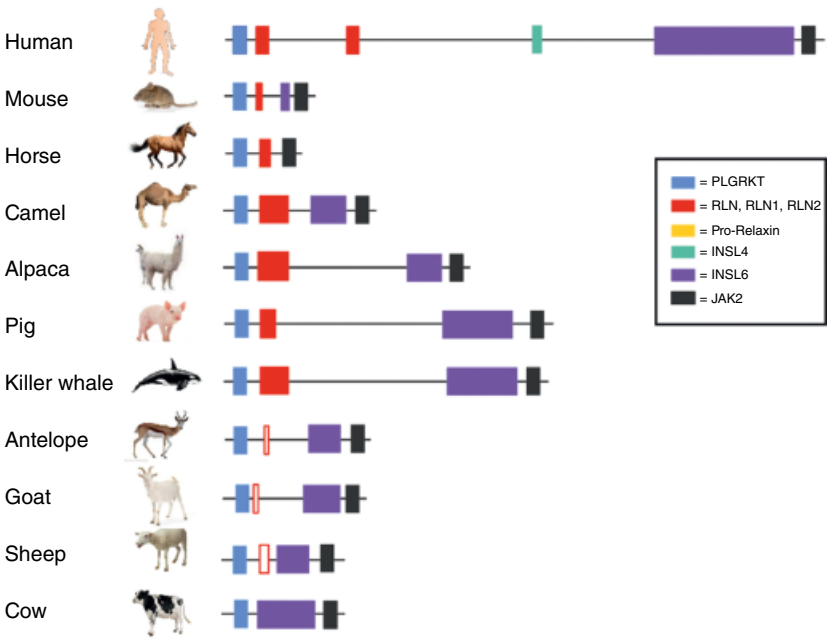

Figure 2.3 Genomic context of the relaxin gene in selected mammals. The cluster containing the RLN, INSL4, and INSL6 genes is flanked by the PLGRKT gene on one side and the JAK2 on the other side. Note that the cow has completely lost the RLN gene, while it has remained as a truncated pseudogene in sheep, goat, and antelope. *Source:* [106].

Moreover, these authors suggested that relaxin activity in its relationship to sperm motility in domestic species may serve as a possible index for predicting the fertilizing ability of sires. Subsequent studies have demonstrated that relaxin improves sperm motility in a number of species, including the human male [110], boar [111], and bull [112]. Furthermore, others have demonstrated that use of relaxin treatment of seminal plasma induces sperm capacitation and acrosome reaction in boar [113] and domestic bull [114] spermatozoa. Other studies have shown that relaxin treatment improved the fertilizing capabilities of fresh boar spermatozoa [115] and fresh or frozen–thawed spermatozoa of the buffalo bull [116, 117] and stallion [118]. Thus, it is evident from these studies that relaxin may play an important role in sperm motility and function. While the RLN1 gene may be lost in the bovid, the physiological benefits of relaxin lie in its potential use as a semen supplement when using either fresh or frozen–thawed bull spermatozoa to facilitate sperm motility and enhance fertilizing capacity during artificial insemination.

Seminiferous Tubules, Sertoli Cells, and Germinal Tissue

Within segments of the testicular parenchyma lie the seminiferous tubules, originally formed from the primary sex cords. The seminiferous tubules contain the Sertoli cells, also known as the nurse cells of the developing germinal cells, the spermatogonia, which are elongated cells found within the tubules. The Sertoli cells were first described by the Italian physiologist Enrico Sertoli in the early 1860s. Structurally, these cells are very important in that they form the blood–testis barrier, which separates the interstitial blood compartment of the testes from the adluminal compartment of the seminiferous tubules. In addition to Sertoli cells nurturing the development and maturation of the germinal cells through the various stages of spermatogenesis, these cells act as phagocytes by removing or consuming residual cytoplasm and surplus spermatozoa material. Sertoli cells, which are also very active secretory cells, produce anti-Müllerian hormone (AMH), a glycoprotein secreted during early fetal life by the testis to direct the appropriate development of the male reproductive tract by causing the regression of the Müllerian ducts [119, 120]. Mutations of the AMH gene lead to persistent Müllerian duct syndrome in male human patients [121]; whether the same observation is true in cattle has not been reported. However, recent studies successfully employed the use of AMH profiles as a novel biomarker to evaluate the existence of functional cryptorchid testis in Japanese black calves [122]. A more comprehensive review of Sertoli cell cytology may be found in the review by de Kretser and Kerr [33].

In addition, Sertoli cells secrete two closely related protein complexes of the transforming growth factor cytokine superfamily (activin and inhibin) that have opposite regulatory effects on the synthesis and regulation of pituitary FSH secretion. Activin upregulates while inhibin downregulates FSH synthesis and secretion [123, 124]. Both of these hormones are secreted after puberty and play an important role in mammalian reproduction, which is coordinated by assorted neural, neuroendocrine, endocrine, and paracrine cell–cell communication pathways [125]. Activin is also thought to facilitate androgen synthesis in the testis by enhancing LH, thereby promoting spermatogenesis. In male mammals, inhibin production is thought to be promoted by testicular androgens and may function locally in the testis to help regulate spermatogenesis. Much less is known about inhibin in relation to its mechanism of action, but it is thought that it may compete with activin for the binding of the activin receptor and/or binding to the inhibin-specific receptor [124]. However, Phillips [126] in reviewing the literature notes that inhibin not only acts as a feedback regulator of FSH in the male, but also may be an important paracrine and autocrine regulator of testis function. It has been shown from molecular studies that both forms of inhibin (A and B) are produced by the bovine testis and that the proportion of the mature forms of inhibin A and inhibin B increases as bulls age, but that total inhibin production by Sertoli cells decreases [127]. In a later study, Kaneko et al. [128] reported that inhibin A and inhibin B increased in the testis of bulls during postnatal development, and that immunoreactive inhibin A could be detected in the plasma of these bulls. Others have attempted to use blood concentrations of inhibin and gene expression along with other endocrine and genetic markers as a predictor of fertility in Brahman bulls [129]. Unfortunately, there appears to be little information in the current literature on the role activin plays in the bovine male. Its role as a paracrine regulator in the testis is presumed but has not been conclusively demonstrated in domestic species, although *in vitro* studies in porcine Leydig cells would suggest a role in androgen synthesis [126]. However, it is thought to be an important intrafollicular factor in the regulation of follicle selection in the bovine female [130, 131]. A role in inflammatory processes for activin has been postulated [126].

Additional factors secreted by the Sertoli cell include ABP, estradiol (by conversion of testosterone via the aromatase enzyme complex), glial cell-derived neurotrophic factor (GDNF), transferrin [132], and the more recently identified ERM transcription factor. Testicular transferrin and ABP are two glycoproteins produced and secreted into the lumen of the tubule by Sertoli cells, and which have important biological effects on differentiation and maturity of sperm [133, 134]. ABP is a glycoprotein that binds spe-

cifically to testosterone, DHT, and 17β-estradiol. By binding to ABP, the steroid hormones testosterone and DHT are less lipophilic and become more concentrated within the lumen of the seminiferous tubules, thereby helping to facilitate spermatogenesis. ABP synthesis is regulated by FSH activity on the Sertoli cells, which may be enhanced by insulin and testosterone. ABP can especially combine with testosterone to maintain a high concentration of androgen in the seminiferous tubule, which facilitates the development and maturation of spermatogenic cells. Androgen is transferred to the target cells and via the nuclear transfer mechanism into the nucleus to combine with androgen receptors, which regulate translation of the target genes. The characteristic of ABP combining with androgen shows that ABP participates in sexual differentiation and maturation of germ cells [132].

Sertoli cell gene products include growth factors, metabolic enzymes, transport proteins (e.g. transferrin, ABP), inhibin, proteases, antiproteases, energy metabolites, and structural components [135]. Transferrin is a major secretory product of differentiated Sertoli cells and is postulated to transport iron sequestered by the blood–testis barrier to the developing germ cells. Fe^{3+} in blood is transferred to Sertoli cells, combined with transferrin synthesized by Sertoli cells, and further transferred to spermatogenic cells at the development stage to promote germ cell growth and maturation. It is well known that the synthesis and secretion of transferrin and ABP are regulated by FSH and androgen. The gonadotropin FSH is an important endocrine hormone required for the regulation of Sertoli cell function [136]. FSH has been shown to regulate the expression of most Sertoli cell genes, including the FSH receptor, ABP, transferrin, plasminogen activator, and aromatase [137–140].

GDNF is a small protein normally associated with the promotion of neuron survival [141]. Its role in testicular function is not fully understood, but there is some evidence to suggest that it may be involved in promoting undifferentiating spermatogonia, which ensures stem cell self-renewal during the perinatal period [142]. Moreover, Johnston et al. [143] demonstrated in the adult rat that cyclic changes in GDNF expression by Sertoli cells are responsible for the stage-specific replication and differentiation of stem spermatogonia, the foundational cells of spermatogenesis. Recent reports in the literature have demonstrated that GDNF, rather than induce proliferation of spermatogonia stem cells, enhances self-renewal and increases survival rate of bovine spermatogonia in culture [144]. An interesting observation reported by Harikae et al. [145] is a rare case of a freemartin calf exhibiting the transdifferentiation of ovarian somatic cells into testicular somatic cells including Sertoli cells, Leydig cells, and peritubular myoid cells, and that the Sertoli cells stained positive for GDNF protein. They speculate that these observations suggest that mammalian XX ovaries may have a high potential for sexual plasticity. For a more comprehensive review of the function and regulation of Sertoli cells, the reader is referred to the excellent review by Russell and Griswold [146].

Overview of Spermatogenesis and Maturation of Spermatozoa

The first studies on the process of spermatogenesis and the spermatogonia of the domestic bull were reported in the latter part of the nineteenth century [147], but it was not until 1931 that the chromosome number of spermatogonia and spermatocytes was determined and that the diploid number was 60 [148]. Subsequent studies in the era after the Second World War described the germ cells and their cytoplasmic structures in more detail [147]. It is now well established that spermatogenesis is a complex cellular process whereby spermatozoa, the male haploid germ cell or gamete, are formed from the diploid spermatogonia stem cells through a series of cellular transformations. These complex transformations occur in the seminiferous tubules of the mammalian testes and may proceed over an extended period of time, which is species dependent. Spermatogenesis has been described morphologically in distinct and recognizable cellular "stages" or "phases" that progress through highly organized and precisely timed cycles [35]. During fetal development primordial germ cells migrate to the embryonic testes where they undergo mitotic division to form gonocytes. Just prior to puberty, gonocytes differentiate into the primary pool of A0 spermatogonia, the stem cells from which all subsequent classes of spermatogonia arise. Spermatogenesis proceeds through three distinct stages within the seminiferous tubules of the testis. The first stage is spermatocytogenesis, a proliferative phase where spermatogonia undergo a series of mitotic divisions to form primary spermatocytes. The second stage is meiosis where the primary spermatocytes undergo reduction division of the chromosomal number, from primary spermatocytes ($4n$) to secondary spermatocytes which are diploid ($2n$) to the final division that produces round haploid ($1n$) spermatids. The final stage is differentiation of the haploid spermatids in a process referred to as spermiogenesis, where the rounded spermatids undergo a series of metamorphic changes to form the elongated and flagellated spermatozoa [35, 149].

Spermatocytogenesis

The initial proliferation occurs at the basal membrane compartment of the seminiferous tubules where the germ cells reside. Spermatogonia emerge from the basal germ

cell layer, where spermatogonia progress through the differentiation cycle and undergo a series of mitotic divisions, the number of which may be species dependent, forming A1 to A4, I and B spermatogonia. Spermatogonia move forward from the basal lamina of the seminiferous tubules as a cohort connected to each other by intercellular bridges, thereby allowing interconnection of cytoplasm between cells. These cytoplasmic bridges may facilitate intercellular communication and thus support the synchronized development of the cohort of spermatogonia. The bull and ram undergo four mitotic divisions during spermatocytogenesis, yielding 16 primary spermatocytes from each active spermatogonium [18]. During this process, a pool of stem germ cells (dormant spermatogonia A1 and A2) is maintained that provides for new generations of spermatogonia (stem cell renewal). This allows the continual production of spermatozoa in the adult male, but the precise mechanism of this regeneration process or renewal of germinal stem cells is not completely understood [150]. During this process, there may be a level of cell loss resulting from cellular degeneration. These cells are resorbed by Sertoli cell cellular phagocytosis.

Meiosis

Mitotic division provides a continuous supply of spermatogonia, while meiotic division is a process whereby B spermatogonia undergo reduction division to form haploid spermatocytes [35]. This meiotic process not only halves the number of chromosomes in spermatocytes, but also ensures genetic diversity by DNA replication and crossing-over, random events that produce genetically unique individual spermatozoa. This replication and crossing-over of DNA material occurs during the first meiotic division, while the second meiotic division results in the formation of the haploid spermatocytes. Spermatocytes may be found at all stages of development in seminiferous epithelium due to the prolonged nature of the meiotic period of spermatogenesis, which ranges from 18 to 21 days in the bull (Figure 2.4a). At the completion of this meiotic process in bulls, each B spermatogonium will result in the production of four haploid spermatids, with a total of 64 spermatids emerging from a single active (A3) spermatogonium [152–154].

Spermiogenesis

The final phase is the differentiation or transformation of the round spermatids into elongated, flagellated, and highly condensed mature spermatozoa that are released into the seminiferous tubule lumen [35]. This process is remarkably similar across domestic species and involves a complex series of events whereby the spermatid undergoes metamorphosis into a highly organized motile cellular structure [33]. Differentiation consists of four main phases that occur in the adluminal compartment between adjacent Sertoli cells: the Golgi phase, the cap phase, the acrosomal phase, and the maturation phase. During the Golgi phase, small Golgi vesicles within the spermatid cytoplasm fuse to form a larger complex structure, the acrosomic vesicle or acrosome. The acrosome is a membrane-bound vesicle or lysosome that contains several enzymes including acid hydrolase, acrosin, esterases, hyaluronidase, and zona lysine. As differentiation progresses, the acrosome begins to migrate to form a cap (capping) over the nucleus of the cell. During capping, the acrosomic vesicle flattens and covers approximately one-third of the nucleus [35]. At the same time the nucleus and cytoplasm undergo elongation, and the nucleus begins to occupy the head region of the spermatid. While the head region of the spermatid is undergoing elongation, the midpiece and tail are being formed, thus initiating the maturation phase. Mitochondria migrate in the cytoplasm to form a spiral assembly around the flagellum posterior to the nucleus, which defines the midpiece of the spermatid. The flagellum originates from the distal centriole that gives rise to the axoneme, which is composed of nine pairs of microtubules arranged radially around two central filaments [21]. The axoneme is connected to the base of the nucleus and extends through the midpiece and continues on to form the principal piece or "tail" of the spermatid. As the cytoplasm from the spermatid is shed during the formation of the tail, a cytoplasmic droplet is formed on the neck of the spermatozoon. Once the metamorphosis is complete, the flagellated and elongated spermatid is now referred to as a spermatozoon (Figure 2.4b). These metamorphic changes are all important developmental steps to ensure that the spermatozoa have the ability to be not only motile but also capable of fertilization and delivery of nuclear material when they come in contact with the female gamete (oocyte).

Spermiation

The final stage of development results in the release of the spermatozoa into the lumen of the seminiferous tubules by a process referred to as spermiation [33]. As the final stages of spermiogenesis are completed, the spermatozoa emerge from the adluminal compartment of the seminiferous tubules tail toward the apex of the Sertoli cells and the tubule lumen. During the process of migration from the rete testis through the epididymis and ejaculate, the spermatozoa shed their cytoplasmic droplets, but not all emerge as normal spermatozoa in the ejaculate (Figure 2.5). Before spermatozoa are capable of fertilization they must undergo additional maturation in the epididymis. Capacitation, the final stage of maturation where spermatozoa gain the

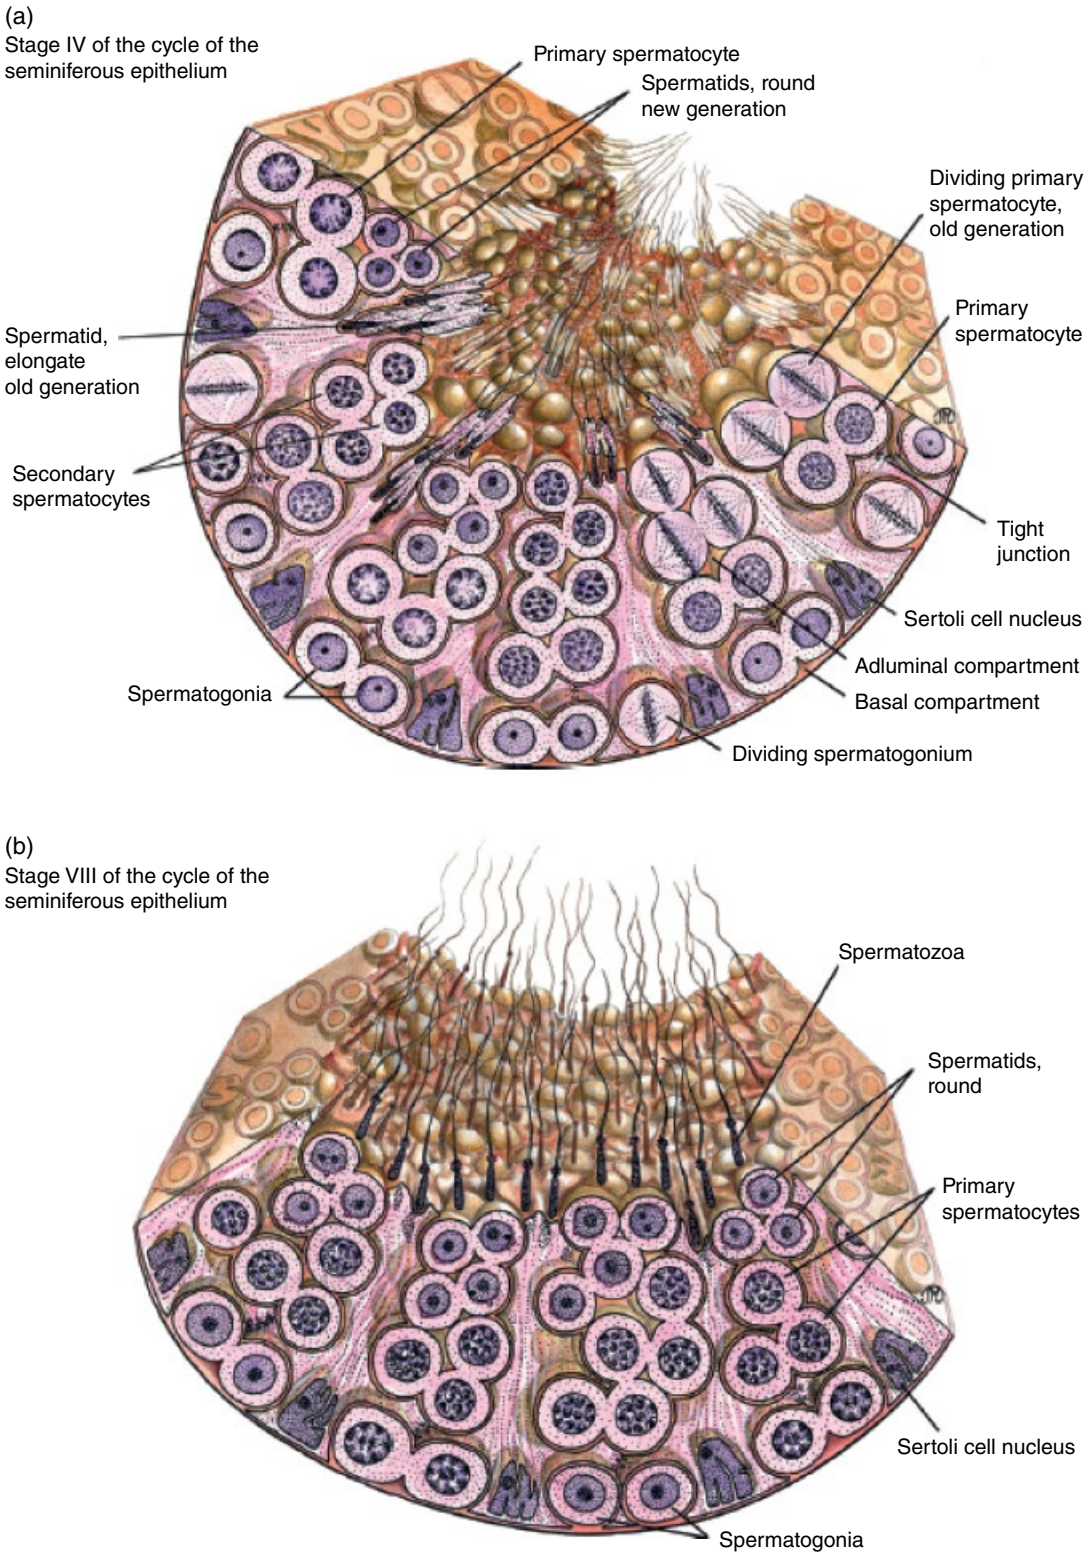

Figure 2.4 Schematic representations of the germinal epithelium of the bull testis during stage IV and stage VIII of the seminiferous epithelium cycle. Stage IV of the cycle (a) is characterized by the very active generation of primary spermatocytes into secondary spermatocytes during meiosis I and progress on with the completion of the meiotic division of meiosis II and the formation of spermatids. Stage VIII of the cycle (b) is characterized by the emerging free spermatozoa that have undergone differentiation from the round spermatids. *Source:* From [151], © 2003, Germinal Dimensions Incorporated.

ability to penetrate the zona pellucida (the outer membrane of the oocyte), occurs in the female reproductive tract. For more specific descriptions of the process of spermatogenesis in the bull the reader is referred to a series of articles by Amann [152], Berndtson and Desjardins [153], and Johnson et al. [154].

Seminiferous Epithelial Cycle and Wave of Spermatogenesis

The cycle of the seminiferous epithelium refers to a cohort of germ cells that progress by clonal expansion within a segment of the seminiferous tubule and change in synchrony with other layers over time through a series of well-characterized cellular associations referred to as stages [35, 149]. Cross-sections along the length of the seminiferous tubules will have different morphological appearances, but within a given section the cellular activity will be similar. Successive sections of the seminiferous tubules will have cohorts of germ cells at sequential stages of development with repetition, thus producing a "wave" effect along the seminiferous tubules [35]. Germ cell development progresses from the basal lamina of the seminiferous tubule, and cells migrate toward the tubule lumen and not in a lat-

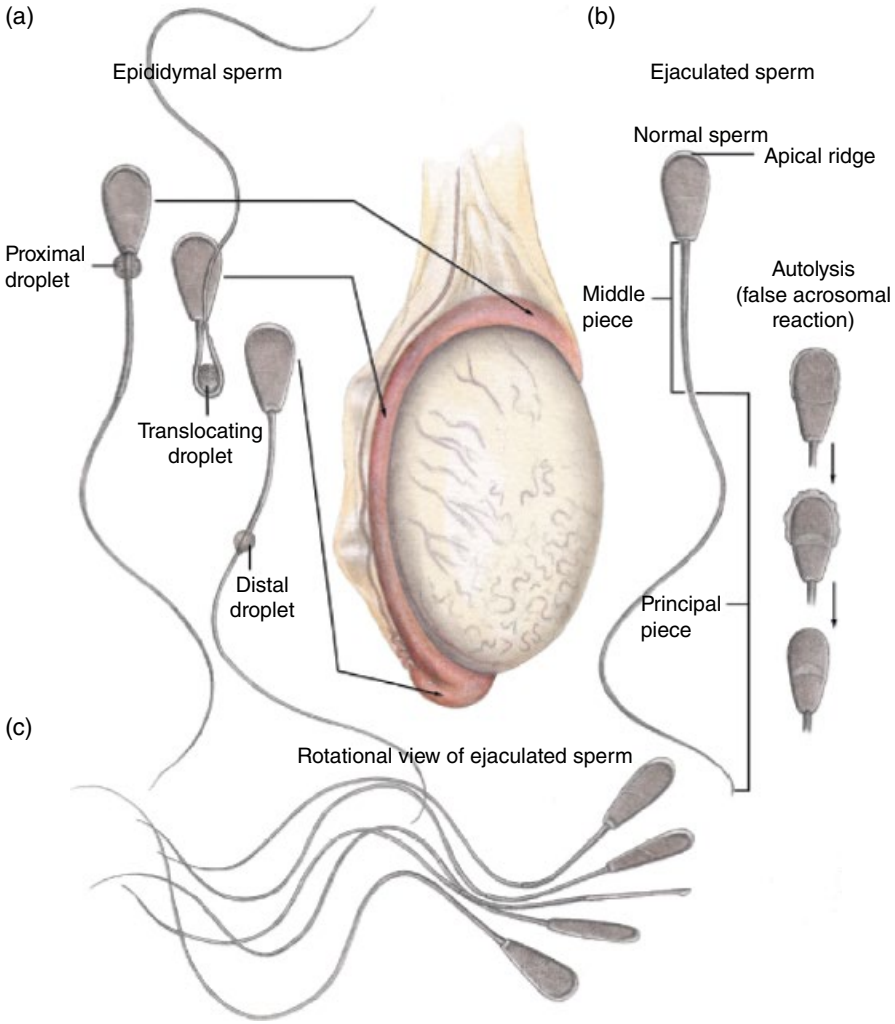

Figure 2.5 Schematic representation of spermatozoa reflecting visible changes as they migrate from the rete testis through the caput (head), corpus (body), and cauda (tail) regions of the epididymis to the ejaculate. Sperm found in the rete testis, efferent ducts, and caput epididymis are identified by the proximal nature of the protoplasmic droplet, while in sperm in the distal caput through to the corpus epididymis the protoplasmic droplet has translocated to the bend of the flagellum; by the time the spermatozoa reach the cauda epididymis the droplet has located at the distal portion of the middle piece of the flagellum (a). Schematic representations of ejaculated normal and autolysis spermatozoa are shown in (b). Normal sperm show an intact acrosome in the form of the apical ridge along the apical edge of the spermatozoan head, while the spermatozoan head images to the right show examples of false or premature acrosomal reactions typically associated with dead or dying spermatozoa. The paddle-shaped nature of the bovine spermatozoon is shown in (c). *Source:* [151], © 2003, Germinal Dimensions Incorporated.

eral direction. This synchronous behavior is thought to be associated with biochemical signaling facilitated by the intercellular bridges, but the process is not fully understood. In the bull, it takes about 4.5 cycles of the seminiferous epithelium to complete spermatogenesis, and each cycle is estimated to take approximately 13.5 days, thus requiring 61 days to complete the process [152, 154]. Spermatogenesis continues throughout the natural lifespan of the postpubertal bull. The domestic bull attains puberty at approximately 10–12 months of age when mature sperm begin to appear in the ejaculate. It is estimated that the daily sperm output of the dairy bull is approximately eight billion and approximately seven billion in the beef bull, with the level of production of spermatozoa increasing from puberty to maximum potential at approximately three years of age. The productivity potential of a bull is determined by the size of the testes, which may be breed dependent, and is thought to be related to being a component of Sertoli cell volume within the seminiferous tubules. Hence, breeding soundness examinations of bulls to be used as sires is dependent not only on sperm quality but also on testicular size and volume [155].

Spermatogenesis

Muhammad Salman Waqas

Department of Theriogenology, University of Agriculture, Faisalabad, Pakistan

Introduction

Spermatogenesis is a highly proliferative and regulated developmental process of multiple germ cell divisions to increase their number and subsequently differentiate to spermatozoa in the seminiferous tubules (ST) of testes. Spermatogenesis is essential for species conservation and genetic diversity within the species [1]. For cattle farming, spermatogenesis yields target spermatozoa for genetic improvement in production potential. Traditionally, the bull has been truly called half of the herd on account of his spermatogenesis. A bull produces more calves per year per herd than a cow. The bull contributes to the genetic and production potential of the herd more extensively and perpetually than does the cow. If the replacement heifers are maintained, the bull affects the production potential of the herd for about 25 years [2]. Spread of male germplasm through artificial insemination is the major tool for genetic improvement in cattle production. In the United States, adaptation of artificial insemination led to a 4.5-fold increase in milk production per dairy cow on average from 1940 to 2009 [3].

Cell and Molecular Biology of Spermatogenesis

Spermatogenesis starts at puberty and human beings produce 1000 spermatozoa with each heartbeat. This enormous spermatogenesis is maintained by spermatogonial stem cells (SSCs) at the basement of the ST [4]. Alkaline phosphatase positive epiblast cells of ectoderm are the embryonic origin of SSCs. About a hundred such cells, which had been lineage restricted from day 7.2 post mating, develop to primordial germ cells (PGCs) in the mouse embryo [5]. The PGCs multiply and reach the genital ridge which is prominent by day 11.5 post coitum [6]. About 10 000 unipotent PGCs are found in each mice gonad. In the gonadal ridge, PGCs harbor the seminiferous cords and become mitotically arrested at day 13.5 post coitum, thereafter termed as gonocytes or prespermatogonia or prospermatogonia. Prospermatogonia, morphologically different from PGCs, undergo extensive epigenetic reprogramming for their later functioning as male gametes [7]. Once prospermatogonia reach basement peripartum, they are morphologically and biochemically different from prospermatogonia and are termed as $A_{undifferentiated}$ spermatogonia. $A_{undifferentiated}$ spermatogonia proliferate but remain connected as A_{single}, A_{paired}, and $A_{aligned}$ through intercellular bridges. Intercellular bridges play a role in cell to cell communication and synchronization of these mitoses. $A_{aligned}$ are syncytia of 4, 8, and 16 undifferentiated spermatogonia. Currently, no method distinguishes among different types of $A_{undifferentiated}$ spermatogonia [1]. An undifferentiated spermatogonia irreversibly differentiates to A_1 spermatogonia under the repeated stimulation of retinoic acid. In rodents, chain identity is maintained upon this transition and it has been estimated that 64% of A_{pair}, 94% of $A_{aligned4}$, and 100% of $A_{aligned8\text{-}16}$ transition to the differentiating A_1 state following a retinoic acid pulse [8]. A_1 spermatogonia undergo six synchronized mitoses through A_2, A_3, A_4, intermediate (In), and B spermatogonia to form primary spermatocyte [4]. In the classical Huckins and Oakberg model, SSCs are contained within the A_{single} population [9, 10]. However, one current model of SSC renewal suggests that syncytia of A_{paired} and $A_{aligned}$ spermatogonia can break to yield SSCs [11].

All undifferentiated spermatogonia other than SSCs are called progenitors. A_{single} undergo symmetric divisions forming syncytia of undifferentiating spermatogonia, or there is asymmetric division forming an SSC and a progenitor A_{single}, thus maintaining steady-state spermatogenesis [4]. Total

Companion website: www.wiley.com/go/hopper/bovine

number of A_{single} in adult mouse testis is estimated at 35 000 and each adult mice testis has about 3000 SSCs, which is about 0.01% of total testis cells [12], and 0.03% of the entire testicular germ cell population. Furthermore, 33×10^4 undifferentiated spermatogonia and 280×10^4 differentiating spermatogonia populate each testis in the mouse [8]. SSCs as well as epiblast and PGCs from days 6–16.5 post coitum embryo can regenerate spermatogenesis upon transplantation to appropriate donor testes [13].

SSCs, capable of self-renewal and generating progenitor cells through symmetrical and/or asymmetrical divisions, reside in a specific microenvironment within the ST termed as a germ line stem cell niche [14]. Within this microenvironment of the niche, SSCs are intermingled with other undifferentiated spermatogonia. Sertoli cells in communication with other somatic cells of the testes secrete factors to maintain the microenvironment of the niche. Within the niche, SSCs are located toward areas of the ST closer to interstitial vasculature [15].

Development of preleptotene spermatocyte from type B spermatogonia marks a cell's detachment and migration away from the basement membrane. Preleptotene spermatocytes cross the tight Sertoli cell junctions and reach the adluminal portion of the ST. Primary spermatocytes first divide mitotically and then form short-lived haploid secondary spermatocytes through meiosis I. During prophase of meiosis, preleptotene spermatocytes differentiate into leptotene, zygotene, pachytene, and diplotene, respectively. Haploid spermatids are formed by equational meiosis II of secondary spermatocytes. Round spermatids mature into spermatozoa through various steps of spermiogenesis without any increase in cell number. Spermatozoa are released into the lumen of the ST through the process of spermiation [16]. Figure 3.1 shows the steps in spermatoogenesis.

Spermatogenesis can be divided into spermatocytogenesis, meiosis, and spermiogenesis. During spermatocytogenesis, germ cells divide by several mitoses to increase the yield of spermatogenesis, renew spermatogonial stems cells, produce more undifferentiated spermatogonia, and finally produce primary spermatocytes. During meiosis, recombination of genetic material happens, homologous chromosomes move apart, and chromosome number is reduced by half to yield haploid round spermatids. Spermiogenesis involves differentiation of haploid round spermatids into mature haploid elongated spermatozoa without mitosis or meiosis [16].

Markers to Study Spermatogenesis

Id4, *Gfra1*, *Bcl6b*, *Lhx1*, and *Etv5* are upregulated in SSCs. *Sohlh1*, *Ngn3*, and *Kit* are expressed by progenitor spermatogonia [17]. THY1, ID4, and GFRA1 are markers for SSCs, NGN3 and KIT for progenitors, PLZF/ZBTB16 for all undifferentiated spermatogonia, and VASA for all germ cells [18].

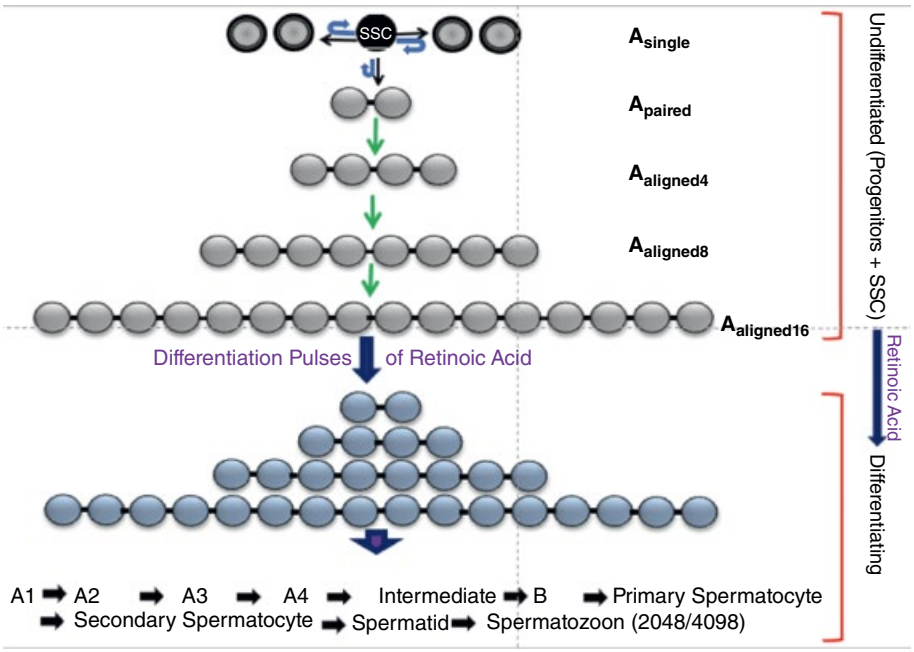

Figure 3.1 Steps in spermatogenesis.

Hormones and Spermatogenesis

Testosterone, follicle stimulating hormone (FSH), and luteinizing hormone (LH) are the main hormones required for spermatogenesis. Deficiency of these hormones causes germ cell apoptosis, while the administration of these suppresses apoptosis. Thus, these hormones are the survival factors required by germ cells. Under testosterone deficiency, round spermatids do not transition to elongated spermatids as the spermatids lose their attachment to Sertoli cells. FSH mainly acts indirectly through Sertoli cells. FSH has been linked to early stages in spermatogenesis, mainly spermatocytogenesis and meiosis, while testosterone is linked to later stages of spermatogenesis, mainly in spermatid differentiation and in potentiating the effect of FSH.

The Cycle of the Seminiferous Epithelium

The cycle of the seminiferous epithelium refers to is the histological fact that at a given section of the ST, different types of germ cells appear cyclically at species-specific time intervals [16]. The notion of the cycle of the seminiferous epithelium was established toward the end of the nineteenth century [19]. Several generations of germ cells are present along the ST because spermatogenesis is a continuous process and subsequent spermatogenesis does not pause to wait for completion of the first generation to the end-product spermatozoa and the release of these spermatozoa in the lumen of the ST [20]. $A_{undifferentiated}$ spermatogonia differentiate to $A_{differentiating}$ spermatogonia (A_1 and subsequent spermatogenesis) regularly after a species-specific fixed time interval. This $A_{undifferentiated}$ to A_1 transition does not wait for the preceding process of "$A_{undifferentiated}$ to A_1 transition and finally to spermatozoon" to complete [21]. Along the section of the ST, the development of germ cells is influenced by neighboring cells, resulting in specific germ cell associations following one another in time at a given section of the ST in a perfectly organized pattern, termed the cycle of the seminiferous epithelium. This results from the fact that (i) at specific points of the ST new spermatogonia enter spermatogenesis at constant time intervals, and (ii) once the cells are engaged in spermatogenesis, their rate of differenation to the next cell type is always a constant and each step of spermatogenesis has a constant and fixed time duration. The specific germ cell associations at a given point of the ST during the cycle of the seminiferous epithelium are termed as stages, or less commonly as phases of the cycle. In the bull, the cycle is divided into eight stages and spermiation is taken as the reference point [22, 23]. In bulls, the duration of the seminiferous epithelium cycle is 13.5 days. The total duration of spermatogenesis is 4.5 times the duration of the cycle, that is 61 days. The durations of spermatocytogenesis, meiosis, and spermiogenesis are 21, 23, and 17 days, respectively [16].

The spermatogenic wave is "a sequence of segments showing the complete series of cell associations corresponding to the stages of the cycle of the seminiferous epithelium. One or more modulations must, however, be excluded from the sequence of the segments considered." While the cycle of the seminiferous epithelium refers to the temporal arrangement of the germ cells at a given point of the ST, the spermatogenic wave refers to the spatial arrangement of germ cells along the ST [24]. However, the wave is not in space what the cycle is in time – the wave is not a dynamic process but is a static way to describe the spatial distribution of the associations along the tubule [16]. Spermatogenesis progresses along the ST in wave form, and the wave is formed by the fact that specific germ associations, i.e. stages, start again and again at specific distance. The regulated order of the wave emergence along the ST follows the numerical order of the stages of the cycle of the seminiferous epithelium [25, 26]. Different waves start as we move along the ST, and at a specific section of the ST, cells from different waves are seen together in a cross-section of the ST according to the stage of the cycle of the seminiferous epithelium. The waves move along the ST in an inward spiral fashion, with $A_{1\ undifferentiated}$ at the outer border of the wave and spermatozoa at the inner border of the wave. One spermatogenic wave starts with initiation of spermatogenesis, i.e. from conversion of type $A_{undifferentiated}$ to type A_1 differentiating spermatogonia under the repeated actions of retinoic acid, and ends with formation of spermatozoa [27]. Histologically, stages of the cycle are identified by two methods: (i) by meiotic status of spermatocytes and changes in the shape and position of nuclei of spermatids; or (ii) by differential morphology of the acrosome of spermatids [24].

Spermatogenesis in the Bull

Spermatogenesis in the bull establishes progressively from 16 weeks to 32 weeks of age. Gonocytes are the main germ cells in the ST until one week of age and are sequentially replaced by undifferentiated spermatogonia by 20 weeks. Meiosis starts at about 16 weeks and is completed by 28–32 weeks. Complete spermatogenesis can be observed in cross-sections of the ST by 32 weeks of age [23].

Histologically, spermatogenesis is evaluated qualitatively by the appearance of the ST and quantitatively by differen-

tial cell count in the ST. Daily sperm production (DSP, millions) per gram of decapsulated testes is an appropriate measure of the efficiency of spermatogenesis and is used for species comparison [28]. DSP per gram of decapsulated testes is 4–6 for the human man, 12 for the bull, 16–19 for the stallion, 21 for the ram, 23 for the rhesus monkey and for the boar, 20–24 for the rat, 24 for the hamster, and 25 for the rabbit [28–30]. DSP is affected by longer duration of spermatogenesis, longer cycle of the seminiferous epithelium, the density of germ cells in the ST, and germ cell degeneration during spermatogenesis [30]. The reason for lower efficiency of spermatogenesis in the bull is not understood [16]. In the bull, germ cell degeneration during transition from A_1 to A_4 and at intermediate spermatogonia stage accounts for 30% losses in DSP. Moreover, degeneration at B_1 and during transition from B_1 to B_2 causes another 30% loss. However, there is no loss during meiosis and spermiogenesis in the bull. In the absence of this degeneration, the bull would have a DSP of around 30×10^6/g of testes [16, 25].

When a bull can produce an ejaculate with 50 million spermatozoa with at least 10% motility, he is pubertal [31]. Age at puberty varies from 38 to 48 weeks of age, with an average age of 42 weeks [32]. After maturity, a bull can give two useable ejaculates daily; commercially, bull ejaculates are collected three times a week for a balance between management and number of artificial insemination doses. Both the quality and quantity of spermatogenesis decrease in old age; however, the aging-related extinction of spermatogenesis in the bull has not been reported. Aging-related decrease in sperm production has not been studied in the bull as breeding bulls are not maintained for senescence. One of the reasons for age-related decline in spermatogenesis is decreased Sertoli cell number in old age [16].

Sertoli Cells and Spermatogenesis

Sertoli cells (SC) play an indispensable role in the regulation of spermatogenesis, establishing the rate of spermatogenesis, and in development and movement of germ cells [33, 34]. SC are one of the most complex and dynamic cells in biology [35].

The cell was first described by and hence named after Enrico Sertoli [36]. SC are large irregular shaped columnar cells extending from the base of the ST to the apex of the ST and occupy 17–19% volume of the tubule [34]. The large surface area of SC allows for interaction with an enormous number of germ cells as the SC to germ cell ratio in adult rats is about 1 : 50 [37]. SC are the most important somatic cells of testes and possess high plasticity synchronized with cyclic evolution of germ cells. The cells change their structure during their development and according to the cycle of the seminiferous epithelium. At any life point, SC of type A and type B are seen in the ST. Type A SC have cytoplasmic crypts for attachment of mature spermatids ready for release into the ST lumen. In type B SC such cytoplasmic crypts are less prominent or absent [38]. The SC nucleus is multilobed and the cytoplasm is rich in endoplasmic reticulum, glycoproteins, and cytoplasmic droplets; the cytoskeleton varies with the cycle of the seminiferous epithelium [39].

The Role of Sertoli Cells in Spermatogenesis

Structural Support

SC in association with peritubular myoid cells secrete basement membrane of the ST [40]. The cytoskeleton of SC participates in organizing and shaping the ST [41]. Major components of SC cytoskeleton are actin, intermediate filaments, and microtubules, and each has a unique distribution pattern according to different stages of the cycle of the seminiferous epithelium [42]. The functions of SC cytoskeleton include (i) maintaining SC shape; (ii) positioning and transporting organelles within the cell; (iii) forming and stabilizing SC membrane at sites of cell–cell and cell–extracellular matrix contact; (iv) positioning, anchoring, and aiding in the movement of developing germ cells; and (v) involvement in the release of mature spermatids from the ST during spermiation [34].

Blood–Testes Barrier

At puberty, neighboring SC develop tight junctions, forming an impermeable blood–testes barrier [40]. The barrier is a modified occluding junction located in the basal third of the seminiferous epithelium [43]. The blood–testes barrier divides the seminiferous epithelium into basal and adluminal compartments [44]. The basal part houses spermatogonia, preleptotene, and leptotene spermatocytes, while further advanced meiotic spermatocytes and spermatids reside in the adluminal part [34].

The blood–testes barrier shields germ cells in the adluminal part of the ST from direct contact with blood, protecting the cells from toxic, mutagenic, and autoimmune reactions. The barrier maintains specific concentrations of androgen-binding protein, inhibin, activin, and enzyme inhibitors within the adluminal compartment of the ST.

It controls transport of molecules and wastes to and from the adluminal compartment [45, 46]. The blood–testis barrier also functions as an immunological barrier to protect novel proteins at spermatocytes and spermatids from autoimmune reaction and inhibits immunoglobulins and lymphocytes from entering the adluminal part [35]. SC and germ cells produce interferons, interferon-induced proteins, interleukins, and cytokines, which maintain an antiviral defense system [47].

Germ Cell Translocation

As germ cells lack the necessary architecture for migration, SC are responsible for germ cell migration across the seminiferous epithelium. SC assist in the translocation of preleptotene spermatocyte from the basal to adluminal compartment of the ST across the blood–testis barrier [34]. Specialized adhesion junctions, ectoplasmic specializations, of SC attach to the spermatid head and translocate spermatids up and down across the seminiferous epithelium. Ectoplasmic specializations consist of regions of SC plasma membrane adherent to the spermatid head, a submembrane layer of tightly packed SC actin filaments, and an attached cistern of SC endoplasmic reticulum. Motor proteins of SC endoplasmic reticulum translocate ectoplasmic specializations and hence spermatids are also translocated [48].

Spermiation

During spermiation, mature spermatids are released from SC into ST lumen prior to their subsequent passage to the epididymis. For spermiation, mature spermatids are oriented toward the lumen of the ST and subsequently released into the lumen by spermiation machinery over several days. Spermiation involves remodeling of the spermatid head and cytoplasm, removal of specialized adhesion structures between SC and mature spermatids, and the final expulsion of mature spermatid heads from the SC crypts [49].

Phagocytosis

After spermiation, SC phagocytose degenerated residual bodies of released spermatids. Moreover, SC phagocytose the germ cell degenerated during spermatogenesis [50]. Moreover, SC are capable of pinocytosis in the adluminal compartment and receptor-mediated endocytosis in the basal compartment of the ST [51].

Secretions

SC secrete different types of proteases, protease inhibitors, hormones, energy substrates, growth factors, paracrine factors, and extracellular matrix components. Proteases and protease inhibitors from SC participate in ST maintenance, repair, growth, remodeling, and restructuring. Protease inhibitors are required for germ cell translocation across the blood–testis barrier and for spermiation [52]. Moreover, protease inhibitors are involved in assembly and disassembly of cellular junctions in the ST [53].

SC secrete adluminal fluid and maintain a specific environment for differentiation of germ cells toward lumen of the ST [33]. FSH-regulated functions of SC include transfer of testosterone and glucose and germ cell nurturing by provision of lactate and pyruvate. Under the influence of FSH and androgens, SC secrete proteins necessary for germ cells and interstitial cells of the testes and secrete androgen binding proteins to ensure bioavailability of androgens [54, 55]. Inhibin and activins from SC act on the hypothalamic–pituitary–gonadal axis and also on Leydig cells [56]. The iron carrier protein, transferrin, is produced by SC and its concentration in seminal plasma is correlated with fertility and spermatogenic capacity in the bull [57]. SC co-cultured with germ cells stimulate DNA and RNA synthesis in the germ cells [58]. Seminiferous growth factor is involved in spermatogonial proliferation, nerve growth factor is required for DNA synthesis in preleptotene spermatocytes, and insulin-like growth factor-1 helps in germ cell differentiation [59].

The germ cells residing in the adluminal compartment cannot receive nutrients directly from blood due to the blood–testis barrier. The spermatocytes and spermatids in the adluminal compartment are nursed by amino acids, carbohydrates, lipids, vitamins, and metal ions from SC [34].

The Junctional Role of Sertoli Cells

SC make and break junctions among themselves and with different types of germ cells. Major junctions formed by SC are tight junctions, anchoring junctions, ectoplasmic specialization, tubulobulbar complexes, and communication junctions. Tight junctions are present between adjacent SC at the level of the blood–testis barrier and function as a semipermeable barrier – the barrier function. Tight junctions divide SC into basal and adluminal, preventing mixing of molecules in the two compartments – the fence function. Anchoring junctions include adherens junctions (also known as zonula adherens), focal contacts or adhesions, desmosomes, and hemidesmosomes. All these anchoring junctions are biochemically and structurally different from one another and mainly function to connect adjacent cells to one another or to extracellular matrix through cytoskeleton, thus maintaining tissue integrity. Anchoring junctions also function in signal transduction to regulate

cell proliferation, differentiation, and translocation. Ectoplasmic specialization is a modified form of adherent junctions and mainly functions in spermiation and maintenance of other junctions present between adjacent SC and, SC and germ cells. Tubulobulbar complexes, also a modified form of zonula adherens, are present between adjacent SC at the level of tight junctions and between SC and mature spermatids ready for spermiation. Focal contacts are actin-based junctions between testicular cells and extracellular matrix and play an adhesive function at ectoplasmic specialization. Desmosomes are intermediate filament-based junctions found between SC and SC, and SC and germ cells. Hemidesmosomes are intermediate filament-based junctions found only between SC and basal lamina; these have adhesive function. Communication junctions are either chemical synapses or gap junctions. Gap junctions, intercellular channels formed by connexons, transduce signals between SC and germ cells and thus participate in germ cell translocation. Gap junctions are present between SC and SC, SC and germ cells, and between two Leydig cells [34].

Sertoli Cells and Spermatogenic Capacity

In the bull, DSP is correlated with total SC number (R = +0.83) and SC per gram (R = +0.47) but is not correlated with the number of germ cells supported per SC. Testicular parenchyma weight is also correlated with total SC number (R = +0.61). Total SC number is the foremost determinant of the variation in DSP among bulls (R^2 = 68.2%) [60, 61]. However, total SC number and the number of germ cells per SC are not correlated with the quality of either fresh or frozen bull semen [62]. Moreover, SC number in the horse (R^2 = 68) and human (R^2 = 39) is also correlated with DSP. The association between SC and DSP goes back to the association between SC and the number of A_1 spermatogonia (R^2 = 55 for the horse) [33].

In the bull, the majority of SC proliferation happens during fetal life in utero. SC number increases by five times from birth until puberty and no increase in SC number occurs after puberty. Once mitosis in SC stops, the cells differentiate to mature SC and continue their adult function for the reproductive life of the bull [63]. However, the stallion being a seasonal breeder has no permanent SC number after puberty and SC number and volume of SC nuclei per testes increase during the breeding season for a 4- to 20-year-old stallion. The size of horse SC does not differentiate with respect to breeding season [33]. A concurrent increase in the number of A spermatogonia accompanies increased SC number during the breeding season [64].

Department of Production Animal Health, Faculty of Veterinary Medicine, University of Calgary, Calgary, Alberta, Canada

Introduction

Since one bull may be responsible for breeding twenty (by natural service in one breeding season) to thousands (artificial insemination) of females, bull fertility is critically important. Although sterile bulls (total inability to reproduce) are uncommon, there can be a wide range in bull fertility, particularly in the absence of selection for fertility [1]. It is well established that a bull's testes must be 2–6 °C cooler than core body temperature for fertile sperm to be produced; consequently, increased testicular temperature, regardless of cause, reduces semen quality [2]. Although the underlying cause of infertility in bulls is frequently unknown, we speculate that it is often increased testicular temperature.

Anatomy and Physiology

Regulation of testicular temperature is dependent on several features. Scrotal skin is typically thin, with minimal hair and an extensive subcutaneous vasculature, facilitating heat loss by radiation [3]. The scrotal neck is the warmest part of the scrotum; a long distinct scrotal neck (and pendulous scrotum) reduces testicular temperature by increasing the area for radiation and enabling the testes to move away from the body. The tunica dartos, a thin sheet of smooth muscle under the scrotal skin, is controlled by sympathetic nerves and contracts and relaxes in cold and warm environments, respectively [4]. The cremaster muscle also contracts to draw the testes closer to the body under cold ambient conditions [4]. Dorsal to the testis is the testicular vascular cone [5], consisting of the highly coiled testicular artery surrounded by the pampiniform plexus, a complex venous network. The testicular vascular cone functions as a classic countercurrent heat exchanger, transferring heat from the artery to the vein, contributing to testicular cooling. Characteristics of scrotal surface temperatures and the testicular vascular cone in bulls aged 0.5–3 years were reported [6]. As bulls age, testicular vascular cone diameter increased; furthermore, increases in testicular vascular cone diameter and a shorter distance between arterial and venous blood in this structure were associated with increased percentage of normal sperm and fewer sperm with defects [7]. In a comparative study of semen quality and scrotal/testicular thermoregulation in *Bos indicus*, *Bos taurus*, and *B. indicus*/*B. taurus* crossbred bulls, there were significant differences among these genotypes in the vascular arrangement, characteristics of the testicular artery (e.g. wall thickness), and thickness of the tunica albuginea; overall, *B. indicus* bulls had the best thermoregulatory capacity whereas *B. taurus* bulls had the worst, with crossbred bulls intermediate [8].

Sweating and whole-body responses also contribute to testicular cooling. In bulls, sweat gland density is highest in the scrotal skin [9]. In rams, apocrine sweat glands in the scrotum discharge simultaneously (up to 10 times per hour) when scrotal surface temperature is ~35.5 °C [10]. In these animals, respiration rate increases in association with scrotal surface temperature, reaching 200 breaths per minute when scrotal surface temperature is 38–40 °C [11].

Surface and Internal Temperatures

In beef bulls, average temperatures at the top, middle, and bottom were 30.4, 29.8, and 28.8 °C (scrotal surface); 33.3, 33.0, and 32.9 °C (scrotal subcutaneous); and 34.3, 34.3, and 34.5 °C (intratesticular), respectively [12]. Therefore, top-to-bottom differences (gradients) in temperature were 1.6, 0.4, and –0.2 °C for scrotal surface, scrotal subcutaneous, and

Companion website: www.wiley.com/go/hopper/bovine

intratesticular temperatures, respectively. Moving dorsal to ventral, the scrotum gets cooler, whereas the testis (independent of the scrotum) gets warmer. These temperature gradients are consistent with their vasculature, as the scrotum is vascularized from top to bottom, whereas the testis is essentially vascularized from bottom to top. In that regard, the testicular artery exits the bottom of the testicular vascular cone, courses the length of the testis (under the corpus epididymis), and at the bottom of the testis ramifies into multiple branches that spread dorsally and laterally across the surface of the testis before entering the testicular parenchyma [13]. Blood within the testicular artery was a similar temperature at the top of the testis compared to the bottom of the testis, but was significantly cooler at the point of entry into the testicular parenchyma (intra-arterial temperatures at these locations were 34.3, 33.4, and 31.7 °C, respectively [14]). Therefore both the scrotum and the testis are warmest at the origin of their blood supply (top of scrotum and bottom of testis), but they both get cooler distal to that point (i.e. bottom of scrotum, top of testis). Remarkably, these opposing temperature gradients collectively result in a nearly uniform intratesticular temperature in situ [15].

In beef bulls, internal temperatures of the caput, corpus, and cauda epididymis averaged 35.6, 34.6, and 33.1 °C (gradient, 2.5 °C), respectively [12]. That the caput was warmer than the testicular parenchyma at the top of the testis was attributed to the proximity of the caput to the testicular vascular cone. Furthermore, it was noteworthy that the cauda, critical in sperm storage and maturation, was cooler than testicular parenchyma.

Bulls fed moderate-energy diets after weaning have better semen quality than those fed high-energy diets. In one study, beef bulls fed a moderate- versus high-energy diet for 168 days after weaning had a larger scrotal surface temperature gradient (3.9 vs 3.4 °C, $P < 0.02$), more morphologically normal sperm (68.8 vs 62.5%, $P < 0.01$), and a higher proportion of progressively motile sperm (53.4 vs 44.5%, $P < 0.006$) [16]. Perhaps increased dietary energy reduced heat loss, thereby increasing temperatures of the testes and scrotum.

Sources of Testicular Heat

Testicular blood flow and O_2 uptake were measured in eight Angus bulls to determine the relative importance of blood flow versus metabolism as sources of testicular heat [17]. Blood flow in the testicular artery averaged 12.4 ml/min. Arterial blood was warmer (39.2 vs 36.9 °C, $P < 0.001$) and had more hemoglobin saturated with O_2 than blood in the testicular vein (95.3 vs 42.0%, $P < 0.001$). Based on blood flow and hemoglobin saturation, the O_2 used by one testis (1.2 ml/min) was calculated to produce 5.8 cal of heat per minute, compared to 28.3 cal/min attributed to blood flow. Therefore blood flow is the major source of testicular heat.

Pathogenesis of Heat-Induced Changes in Sperm Morphology

There is a long-standing paradigm that testes operate in near hypoxia, blood flow does not significantly increase as testes are warmed, and hypoxia disrupts spermatogenesis after increased testicular temperature [18]. However, this had apparently never been rigorously examined until we conducted two studies to test the following hypotheses: (i) hypoxia disrupts sperm quality and production; and (ii) hyperoxia prevents hyperthermia-induced reductions in sperm quality and production.

In one study [19], we exposed 18 rams (nine had an insulated scrotum) to air containing 14, 21, or 85% O_2 for approximately 30 hours. In that study, scrotal insulation (to increase testicular temperature) substantially reduced sperm motility (from 58 to 30%) and proportion of morphologically normal sperm (from 87 to 30%), but effects due to O_2 were minimal. In a second study [20], 96 male CD-1 mice were maintained at 20 vs 36 °C, exposed to 13, 21, or 95% O_2 twice for 12-hour intervals (separated by 12 hours at room temperature and 21% O_2), and euthanized 14 or 20 days after exposure. Interestingly, sperm morphology and specific stages of sperm cell development were altered in mice exposed to 36 °C, including increases in percentage of sperm with defective heads ($P < 0.0001$) or tails ($P < 0.001$) and percentage of altered elongated spermatids ($P < 0.001$). Regarding effects due to O_2 variations, seminiferous tubule diameter and epididymal sperm reserves were reduced in the 13% O_2 group, but sperm quality and production were not consistently disrupted by hypoxia. In addition, no hyperthermia-induced disruptions were prevented by hyperoxia, indicating a major role of increased temperature, but not hypoxia. There were primarily main effects of temperature; mice exposed to 36 °C had smaller testes, fewer morphologically normal sperm, and histologically increased altered spermatids and altered germ cells compared to mice exposed to 20 °C. In both studies, our hypotheses were not supported; sperm quality and production were not consistently disrupted by hypoxia and hyperoxia did not protect against hyperthermia in mice.

We recently conducted two studies in rams under general anesthesia to determine effects of hypoxia and of testicular hyperthermia on testicular blood flow, and O_2 delivery and uptake. In the first study [21], eight rams were exposed to successive decreases in O_2 concentration in inspired air (100, 21, and 13%; 45 minutes at each concentration). As O_2

concentration decreased (100 to 13%), testicular blood flow increased (9.6 vs 12.9 ml/min/100 g of testis, $P < 0.05$). Increased testicular blood flow maintained O_2 delivery and increased testicular temperature by ~1 °C. In the second experiment [22], testicular temperatures of nine crossbred rams were sequentially maintained at 33–35, 37, and 40 °C (45 minutes at each temperature). As testicular temperature increased from 33–35 to 40 °C, there were increases in mean testicular blood flow (9.8 vs 12.2 ml/min/100 g of testes, $P < 0.05$), O_2 extraction (31.2 vs 47.3%, $P < 0.0001$), and O_2 use (0.35 vs 0.64 ml/min/100 g of testes, $P < 0.0001$). In both experiments, there was no evidence of anaerobic metabolism, based on no significant difference in lactate, pH, HCO_3–, and base excess.

Following our studies in rams, we conducted another study to determine the effects of short-term testicular hyperthermia on testicular blood flow, O_2 delivery and uptake, and evidence of testicular hypoxia in pubertal Angus (*B. taurus*) and Nelore (*B. indicus*) bulls (nine per breed) under isoflurane anesthesia [23]. As testes were warmed from 34 to 40 °C, there were increases ($P < 0.0001$, but no breed effects) in testicular blood flow (mean ± SEM, 9.59 ± 0.10 vs 17.67 ± 0.29 ml/min/100 g, respectively), O_2 delivery (1.79 ± 0.06 vs 3.44 ± 0.11 ml O_2/min/100 g), and O_2 consumption (0.69 ± 0.07 vs 1.25 ± 0.54 ml O_2/min/100 g), but no indications of testicular hypoxia (Figure 4.1). Our hypothesis that Angus bulls have a greater relative increase in testicular blood flow than Nelore in response to increased testicular temperature was not supported, as there was no significant breed difference.

Our studies in conscious rams and mice, as well as in anesthetized rams and bulls, challenged the classical paradigm regarding scrotal/testicular thermoregulation, as acute testicular hyperthermia caused increases in blood flow and in delivery and uptake of O_2, with no indications of hypoxia. In contrast to the long-standing paradigm, our data were evidence that effects of increased testicular temperature were due to testicular temperature per se and not secondary hypoxia.

Evaluation of Scrotal Surface Temperature with Infrared Thermography

Infrared thermograms of the scrotum of bulls with apparently normal scrotal thermoregulation were symmetrical left to right, with temperature at the top 4–6 °C warmer than at the bottom [24, 25]. More random temperature patterns, including a lack of horizontal symmetry and areas of increased scrotal surface temperature, were interpreted as abnormal thermoregulation of the testes or epididymides. Nearly all bulls with an abnormal thermogram had reduced semen quality [24, 25]; conversely, not every bull with poor quality semen had an abnormal thermogram. Consequently, infrared thermography is a useful tool for breeding soundness evaluation of bulls, although it does not replace collection and evaluation of semen. In one study, 30 yearling beef bulls, all deemed breeding sound on a standard breeding soundness examination, were individually exposed to approximately 18 heifers for 45 days [26]. Pregnancy rates 80 days after the end of the breeding season were similar (83 vs 85%) for bulls with a normal or questionable scrotal surface temperature pattern, respectively, but were higher ($P < 0.01$) than pregnancy rates for bulls with an abnormal scrotal surface temperature pattern (68%).

Effects of Increased Testicular Temperature

Increased Ambient Temperature

Effects of increased ambient temperature on semen quality have been widely reported. In one study, ambient temperatures of 40 °C at a relative humidity of 35–45% for 12 hours reduced semen quality [27]. Furthermore, *B. taurus* bulls are more susceptible than *B. indicus* bulls to high ambient temperatures [27]. In that regard, decreases in semen quality were less severe, occurred later, and recovered more rapidly in crossbred (*B. indicus* × *B. taurus*) bulls than in purebred *B. taurus* bulls exposed to high ambient temperatures [28].

Scrotal Insulation as a Model of Increased Testicular Temperature

Scrotal insulation is frequently used to increase testicular temperature. In one study [29], scrota of *B. indicus* × *B. taurus* bulls were insulated for 48 hours. The nature and time (day 0, start of insulation) of the morphologically abnormal sperm that resulted were as follows: decapitated, days 6–14; abnormal acrosomes, days 12–23; abnormal tails, days 12–23; and protoplasmic droplets, days 17–23. Therefore scrotal heating affected sperm in the caput epididymis as well as spermatids. Although daily sperm production was not affected, epididymal sperm reserves were reduced by nearly 50% (9.2 vs 17.4 billion), particularly in the caput (3.8 vs 6.6 billion) and cauda (3.7 vs 9.5 billion), perhaps due to selective resorption of abnormal sperm in the rete testis and excurrent ducts. In another study [30, 31], scrota of six Holstein bulls were insulated for 48 hours (day 0, initiation of insulation). The number of sperm collected was not significantly different, but the proportion of progressively motile sperm decreased from 69% (prior to insulation) to 42% on day 15. The proportion of normal sperm

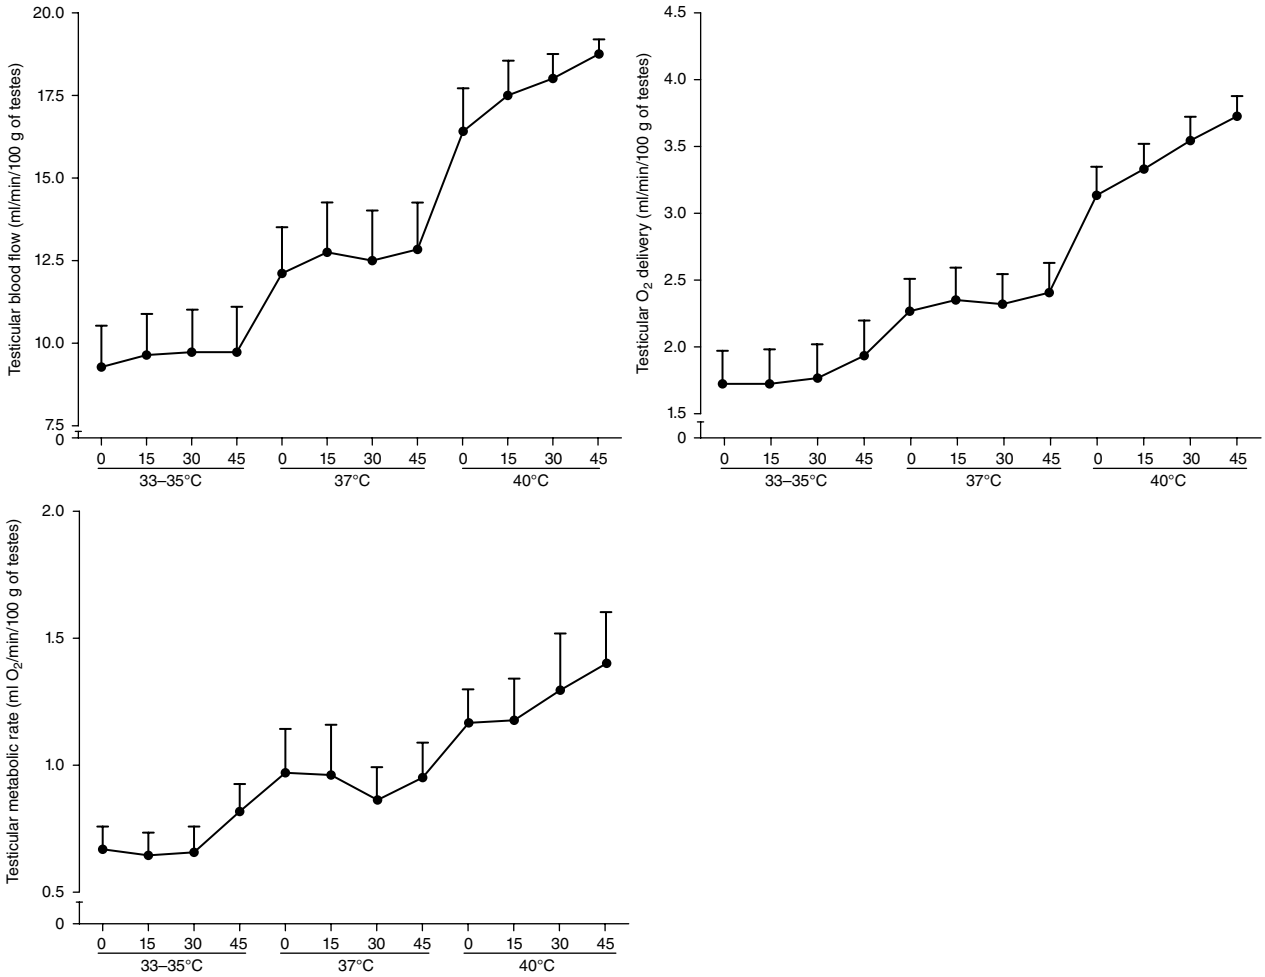

Figure 4.1 Mean (and SEM) blood flow, O_2 delivery, and metabolic rate in testes of 18 bulls (Nelore and Angus) sequentially exposed to three plateaus of testicular temperature (33-35, 37, and 40 °C). Assessment of blood flow and sample collection were done four times at 15-minute intervals and then the testes warmed to reach the next temperature plateau. For each end point, there was a difference ($P < 0.001$) between all temperature plateaus. Testicular temperature increased testicular metabolism; however, testicular blood flow nearly doubled, providing ample O_2 to meet metabolic demands, with no evidence of hypoxia.

was not significantly different from day −6 to day 9 (80%), decreased abruptly on day 12 (53%), and reached a nadir on day 18 (14%). Although there was considerable variation among bulls in both type and proportion of abnormal sperm, specific abnormalities appeared in a consistent chronological sequence: tailless, days 12–15; diadem, day 18; pyriform and nuclear vacuoles, day 21; knobbed acrosome, day 27; and Dag defect, day 30. When sperm were collected 3–9 days after insulation and examined immediately, their motility and morphology were similar to pre-insulation values [30]. Compared to semen collected prior to insulation, following freezing, thawing, and incubation at 37 °C for three hours [30], there were significant reductions in the proportion of progressively motile sperm (46 vs 31%, respectively) and the proportion of sperm with intact acrosomes (73 vs 63%). Freezing plus post-thaw incubation manifested changes that had occurred in sperm that were in the epididymis at the time of scrotal insulation.

In another study [32], scrotal insulation (four days) and dexamethasone treatment (20 mg/day for seven days) were used as models of testicular heating and stress, respectively. Some bulls seemed predisposed to produce sperm with a specific abnormality. Pyriform heads, nuclear vacuoles, microcephalic sperm, and abnormal DNA condensation were more common in insulated than dexamethasone-treated bulls. Conversely, dexamethasone treatment resulted in an earlier and more severe effect on epididymal sperm, an earlier and greater increase in distal midpiece reflexes, and an earlier increase in proximal and distal droplets. Overall, types of defective sperm and the time of their detection were similar between treatments.

Insulation of the Scrotal Neck

The scrotal neck of five bulls was insulated for seven days (days 1–8) as a model of bulls with excessive body condition (which typically have considerable fat in the scrotal neck). Sperm within the epididymis or at the acrosome phase during insulation appeared to be most affected [33]. Insulated bulls had twice as many sperm with midpiece defects and four times as many with droplets on day 5, fewer normal sperm and three times as many with midpiece defects and droplets on day 8, fewer normal sperm on days 15 and 18, and more sperm with head defects on days 18 and 21. Semen quality in insulated bulls had nearly returned to pre-insulation values by day 35. In a second experiment [33], scrotal subcutaneous temperature increased 2.0, 1.5, and 0.5 °C at the top, middle, and bottom of the testis, respectively, and intratesticular temperature was 0.9 °C higher at the corresponding three locations 48 hours after scrotal neck insulation compared to before insulation. Clearly, the scrotal neck is an important site of heat loss.

Increased Epididymal Temperature

In most mammals, the cauda epididymis is cooler than the testes [34], facilitating its sperm storage function. Increasing cauda temperature disrupts absorptive and secretory functions, changes the composition (ions and proteins) of the cauda fluid, and increases (approximately threefold) the rate of sperm passage through the cauda [34]. Consequently, the number of sperm in the first ejaculate declines, with an even more dramatic decline in sperm number in successive ejaculates. In addition, increased temperature seems to hasten sperm maturation [34].

Effects of Increased Temperature on Testicular Cells

Although heating seems to affect Sertoli and Leydig cell function, germ cells are the most sensitive [35]. All stages of spermatogenesis are susceptible, with degree of damage related to the extent and duration of the increased temperature [35]. Spermatocytes in meiotic prophase are killed by heat, whereas sperm that are more mature usually have metabolic and structural abnormalities [36]. Heating testes usually decreases the proportion of progressively motile and live sperm, and increases the incidence of morphologically abnormal sperm, especially those with defective heads [37]. Increased testicular temperature caused a lack of chromatin protamination and subtle changes in head shape of bull sperm [38]. Despite considerable variation among bulls in the nature and proportion of defective sperm, order of appearance of specific defects is relatively consistent [31, 32]. Unless spermatogonia are affected, the interval from cessation of heating to restoration of normal sperm in the ejaculate corresponds to the interval from the beginning of differentiation to ejaculation [37]. Following scrotal insulation in bulls, blastocyst rate (*in vitro* system) was more sensitive than cleavage rate [39]. Even though sperm morphology has returned to normal, their utilization may result in decreased fertilization rates and an increased incidence of embryonic death [40].

Summary

When scrotal/testicular temperature is increased (regardless of the cause), sperm morphology is generally unaffected initially (for an interval corresponding to epididymal transit time) but subsequently declines. In some studies [29, 33], sperm in the epididymis at the time of scrotal heating were morphologically abnormal when collected soon after heating. In another study [30], changes in these sperm were manifest only after they were frozen, thawed, and incubated. Sperm morphology usually returns to pre-treatment values within approximately six weeks after the thermal insult. However, a prolonged and/or severe increase in testicular temperature will increase the interval for recovery. In general, the decrease in semen quality following increased testicular temperature is related to severity and duration of the thermal insult.

Endocrine Control of Testicular Development and Initiation of Spermatogenesis in Bulls

Leonardo F.C. Brito

STgenetics, Middleton, WI, USA

Introduction

The process of testicular development that leads to initiation of spermatogenesis in bulls involves complex maturation mechanisms of the hypothalamus–pituitary–testes axis. Sexual development can be divided into three periods according to changes in gonadotropin and testosterone concentrations, namely the infantile, prepubertal, and pubertal periods. These changes are accompanied by changes in testicular cell proliferation and differentiation (Figure 5.1).

Infantile Period

The infantile period is characterized by low gonadotropin and testosterone secretion and relatively few changes in testicular cellular composition. This period extends from birth until approximately two months of age in *Bos taurus* bulls.

Gonadotropin secretion during the infantile period is low due to reduced gonadotropin-releasing hormone (GnRH) secretion; maturation changes within the hypothalamus result in increased GnRH pulse secretion and drive the transition from the infantile period. Increased GnRH secretion is dependent on either the development of central stimulatory inputs or removal of inhibitory inputs. Hypothalamus weight and GnRH content do not increase during the infantile period, but hypothalamic concentrations of estradiol receptors decrease after one month of age [7]. However, the hypothesis that GnRH secretion is low during infancy due to elevated sensitivity of the hypothalamus to the negative feedback of sex steroids (gonadostat hypothesis) has been questioned in bulls, since castration does not alter luteinizing hormone (LH) pulse frequency or mean concentrations before two months of age [8]. Nonetheless, since GnRH secretion into hypophyseal portal blood is not necessarily accompanied by LH secretion during the infantile period, experiments that use LH concentrations to infer GnRH secretion patterns during this period need to be interpreted with caution [9]. Another possibility is that removal of opioidergic inhibition and/or increased dopaminergic activity may be involved in triggering the increase in GnRH secretion during the infantile period. Opioidergic inhibition of LH pulse frequency during the infantile period has been demonstrated by increased LH secretion between one and four months of age in bulls treated with naloxone, an opioid competitive receptor antagonist [10], whereas concentrations of norepinephrine, dopamine, and dopamine metabolites increased twofold to threefold in the anterior hypothalamic–preoptic area in bulls aged 0.5–2.5 months [11].

Direct evaluation of blood samples from the hypophyseal portal system has demonstrated that GnRH pulsatile secretion increases linearly from age two weeks (3.5 pulses per 10 hours) to 12 weeks (8.9 pulses per 10 hours) in bulls. Although GnRH secretion into hypophyseal portal blood was detected at two weeks, pulsatile LH secretion was not detected in jugular blood samples before eight weeks of age. In addition, GnRH pulses are not necessarily accompanied by LH secretion until 8–12 weeks of age, when all GnRH pulses result in LH pulses. The increase in pulsatile GnRH release from two to eight weeks of age without a concomitant increase in LH secretion may represent a reduced ability of the pituitary gland to respond to GnRH stimulus [9]. The period in which GnRH pulses do not stimulate LH secretion correspond to a period during which there is an increase in pituitary weight, GnRH receptor concentration, and LH content [7]. Moreover, frequent GnRH treatments during the infantile period in calves increases pituitary LH-β mRNA, LH content, and GnRH receptors, with resulting increases in LH pulse frequency and mean concentrations [12], indicating that increased

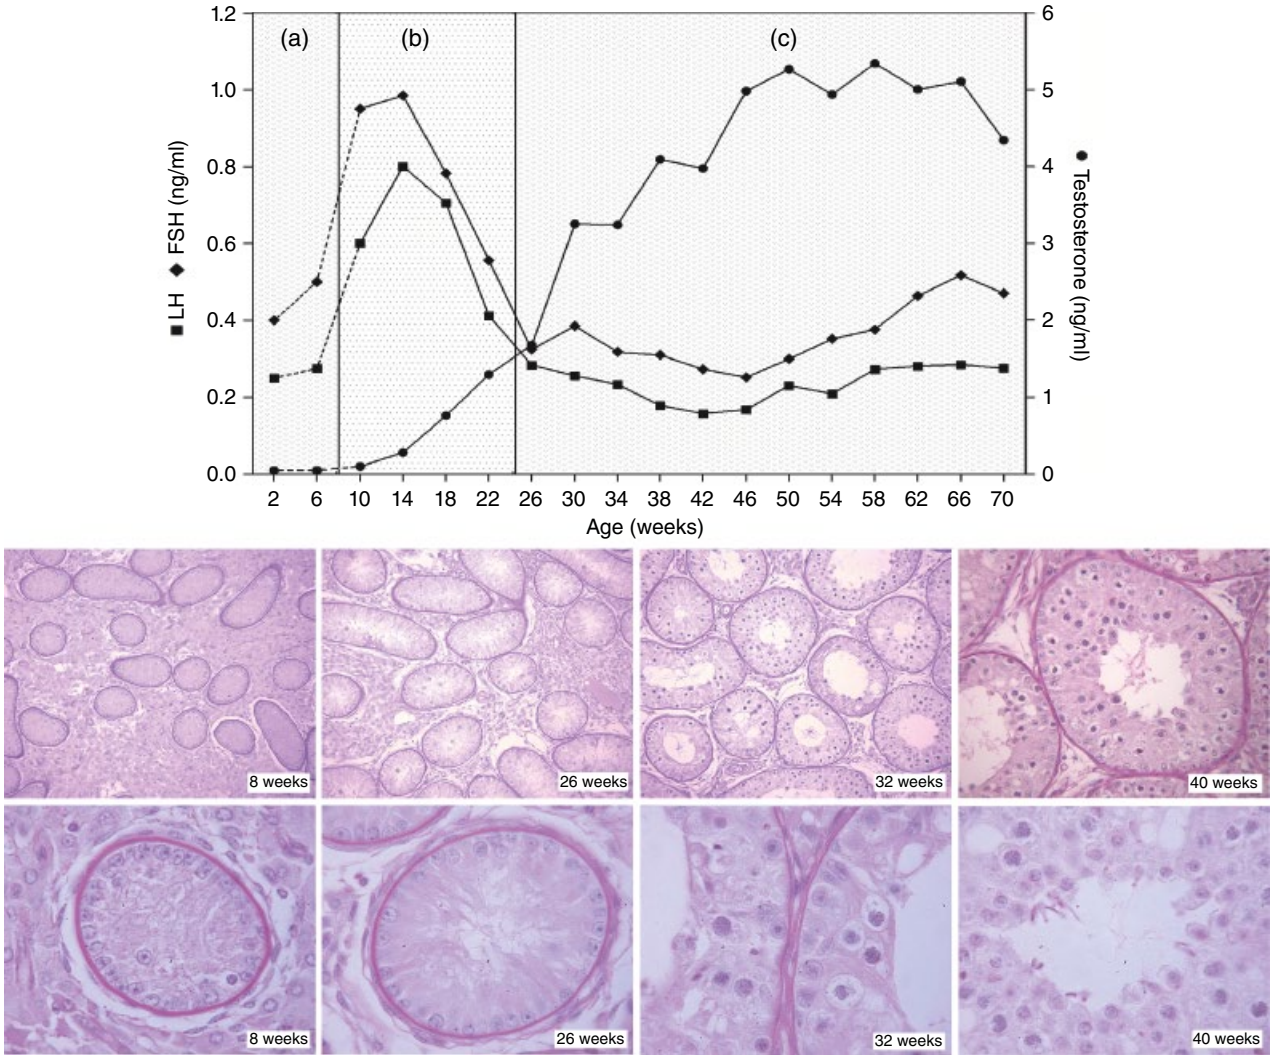

Figure 5.1 Mean serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone concentrations in bulls during the infantile (a), prepubertal (b), and pubertal/postpubertal (c) periods. Data from 2 to 6 weeks are adapted from Hereford × Charolais bulls [1]. Data from 10 to 70 weeks are from Angus and Angus × Charolais bulls receiving adequate nutrition [2–5]. Infancy is the period that extends from birth until approximately eight weeks of age. During this period gonadotropin and testosterone concentrations are low, the testicular parenchyma is occupied mostly by interstitial tissue, seminiferous cords are lined by undifferentiated Sertoli cells, and centrally located gonocytes with large nuclei can be observed. The prepubertal period is characterized by a dramatic increase in gonadotropin concentrations (the early gonadotropin rise) and by slowly increasing testosterone secretion. The prepubertal period extends from approximately 10 to 26 weeks of age and during this period a cord lumen begins to develop and gonocytes migrate toward the basement membrane, differentiating into spermatogonia. Gonadotropin concentrations decrease concomitantly with a rapid increase in testosterone concentration during the pubertal period, which also coincides with the start of a phase of rapid testicular growth. Formation of the tubular lumen is evidence of Sertoli cell differentiation and development of a functional blood–testis barrier that precedes the appearance of primary spermatocytes and spermatids around 32 weeks of age. With continuous increase in diameter, seminiferous tubules occupy most of the testicular parenchyma and start to produce mature sperm at approximately 40 weeks of age. *Sources:* Data from [2, 4–6].

GnRH pulse frequency results in increased pituitary sensitivity to GnRH. With time, the increased GnRH secretion results in the increased LH pulse frequency observed during the prepubertal period.

From birth until approximately two months of age, mesenchymal-like cells comprise the majority of the cells in the testicular interstitial tissue. Typical Leydig cells constitute about 6% of all intertubular cells at one month of age and a number of these cells are found in an advanced degenerative state, probably as remnants of the fetal Leydig cell population. Degenerating fetal and newly formed Leydig cells coexist until two months of age, but only Leydig cells formed postnatally are observed thereafter [13, 14]. The diameter of the seminiferous tubules is approximately

50 µm during the infantile period; tubule is actually a misnomer, since these are in fact solid cords with no lumen at this stage of development. Undifferentiated Sertoli cells (or undifferentiated supporting cells) are the predominant intratubular cells from birth until approximately four months of age. The number of undifferentiated Sertoli cells remains constant until one month of age, but cell multiplication is maximal between one and two months of age, decreasing thereafter until approximately four months of age. During the infantile period, the membranes of neighboring undifferentiated Sertoli cells contain few interdigitations and no special junctional complexes [15, 16]. These immature Sertoli cells produce and secrete anti-Müllerian hormone (AMH) and circulating concentrations increase until two months of age [1]. The germ cell population is composed solely of gonocytes (or prespermatogonia) at birth. Gonocytes are usually centrally located and have a large nucleus (~12 µm in diameter) with a well-developed nucleolus. Gonocyte proliferation slowly resumes between one and two months of age [15, 17].

Prepubertal Period

The prepubertal period is characterized by a temporary increase in gonadotropin secretion, the so-called early gonadotropin rise. The early gonadotropin rise is a critical event in the sexual development of bulls. Not only is it associated with dramatic changes in testicular cellular composition, initial increase in testosterone secretion, and timing of attainment of puberty, but also it has long-lasting effects on testicular growth and sperm production. This period extends from approximately two to six months of age in *B. taurus* bulls.

The early gonadotropin rise is driven by increased GnRH pulse secretion, as demonstrated by a dramatic increase in LH pulse frequency (Figure 5.2); pulsatile discharges of follicle-stimulating hormone (FSH) have been observed in bulls but are much less evident than those of LH. The number of LH pulses increases from less than one per day at one month to approximately 12–16 per day (one or more pulses every two hours) at approximately four months of age. Changes in pulse amplitude during this period are not consistent among reports; amplitude may be reduced, unchanged, or augmented [2, 7, 18–21]. LH-binding sites are present in testicular interstitial tissue at birth and at four months of age and pulsatile LH secretion is an essential requirement for Leydig cell proliferation, differentiation, and maintenance of fully cell differentiated structure and function [22]. Mesenchymal-like cells in the testes cease to proliferate around four months of age and start to differentiate into contractile myofibroblasts and Leydig cells. Differentiating, mitotic, and degenerating Leydig cells are observed in close proximity from four to seven months of age. Leydig cell numbers and mass per testis increase from one month (0.42 billion and 0.15 g/testis, respectively) to seven months of age (6 billion and 5.8 g/testis, respectively), but mitosis after this age is rare [13, 14]. Circulating insulin-like peptide 3 (INSL3), a major product and biomarker of Leydig cell functional capacity, increases linearly between two and six months in bulls [6, 23].

The characteristic pulsatile nature of LH secretion is important for testosterone production, since continuous exposure of Leydig cells to LH results in reduced steroidogenic responsiveness due to downregulation of LH receptors [24]. Initiation of Leydig cell steroidogenesis is characterized by increased androstenedione secretion, which decreases as the cells complete maturation and begin secreting testosterone. During the first three to four months of age, testosterone concentrations are low and secretion does not necessarily accompany LH pulses. After this age, LH pulses are followed by testosterone pulses and mean testosterone concentrations begin to increase. The number of testosterone pulses increases from 0.3–2.3 pulses per 24 hours at one to four months of age to 7.5–9 pulses per 24 hours at five months of age [25–28].

The crucial role of the LH secretion pattern during the early gonadotropin rise in regulating sexual development in bulls has been demonstrated in several studies using a variety of approaches. Prolonged treatment with a GnRH agonist in calves aged 1.5–3.5 months decreased LH pulse frequency, pulse amplitude, and mean concentrations at three months of age, delayed the peak mean LH concentration from five to six months of age, and reduced testosterone concentrations between 3.5 and 4.5 months of age. These hormonal alterations were associated with delayed puberty and reduced testes weight and number of germ cells in tubular cross-sections at 11.5 months of age. On the other hand, treatment with GnRH every two hours to mimic pulsatile secretion from 1 to 1.5–2 months of age increased LH pulse frequency and mean concentration during the treatment period and resulted in greater scrotal circumference, testes weight, seminiferous tubules diameter, and number of germ and Sertoli cells in tubular cross-sections at 12 months of age [29–31]. The LH secretion pattern during the prepubertal period is also associated with age at puberty in bulls raised in contemporary groups, suggesting that this is the physiological mechanism by which genetics affect sexual development. Studies have shown that LH pulse frequency was greater around 2.5–5 months of age and that mean LH concentrations increased earlier and reached greater maximum levels in early- than in late-maturing Hereford bulls (age at puberty 9.5 and 11 months, respectively) [19, 21].

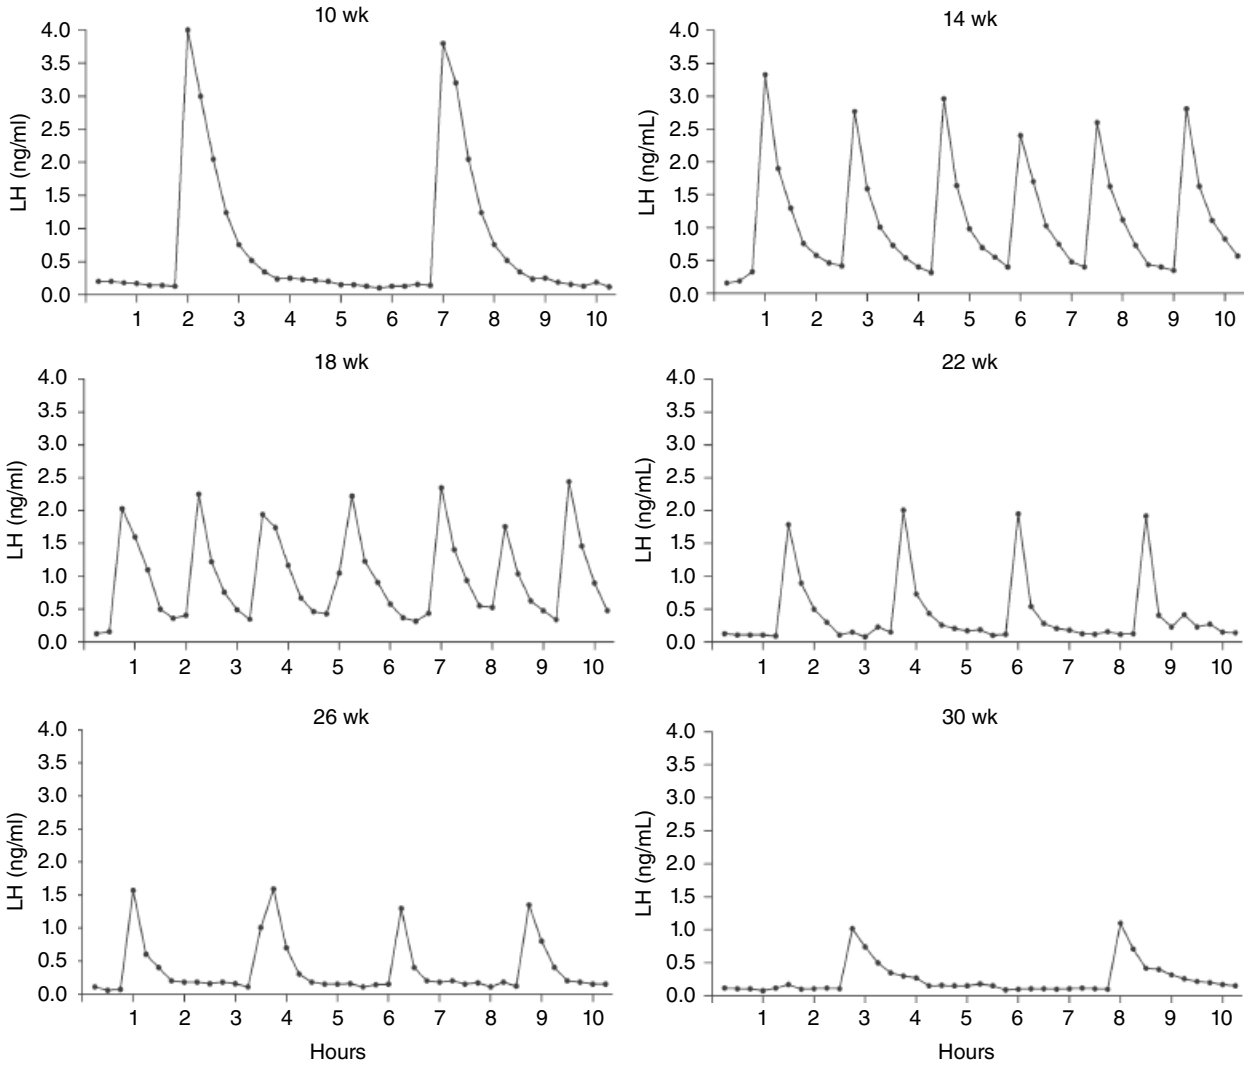

Figure 5.2 Serum LH concentrations between 10 and 30 weeks of age in Angus and Angus × Charolais bulls. Graphs closely exemplify the mean pulse frequency and pulse amplitude observed in bulls receiving adequate nutrition. *Sources:* [2, 4, 6].

Additional support for the crucial role that LH secretion pattern during the early gonadotropin rise plays in sexual development in bulls has been provided by studies demonstrating that nutrition during the prepubertal period affects LH secretion pattern, age at puberty, and testicular development. In studies with beef and dairy bulls receiving different nutrition from 2 to 16 months of age, reduced LH pulse frequency during the prepubertal period resulted in delayed puberty in bulls receiving low nutrition, while a more sustained increase in LH pulse frequency in bulls receiving high nutrition was associated with hastened testosterone production and greater testes weight at 16–19 months of age when compared with bulls receiving low and medium (control) nutrition (results in beef bulls are shown in Figure 5.3). These observations were corroborated by additional studies designed to investigate the effects of nutrition specifically during the prepubertal period. Bulls that received high nutrition only from two to seven months of age also had a more sustained increase in LH pulse frequency, had greater testosterone secretion, were approximately two to four weeks younger at puberty, and had greater testes weight at 16–19 months of age when compared with bulls receiving control nutrition (results in beef bulls are shown in Figure 5.4). On the other hand, reduced LH secretion resulting from low nutrition from two to six months of age was associated with increased age at puberty and smaller testes weight at 16–19 months of age even when these bulls received control or high nutrition after seven months of age and LH and testosterone secretion were

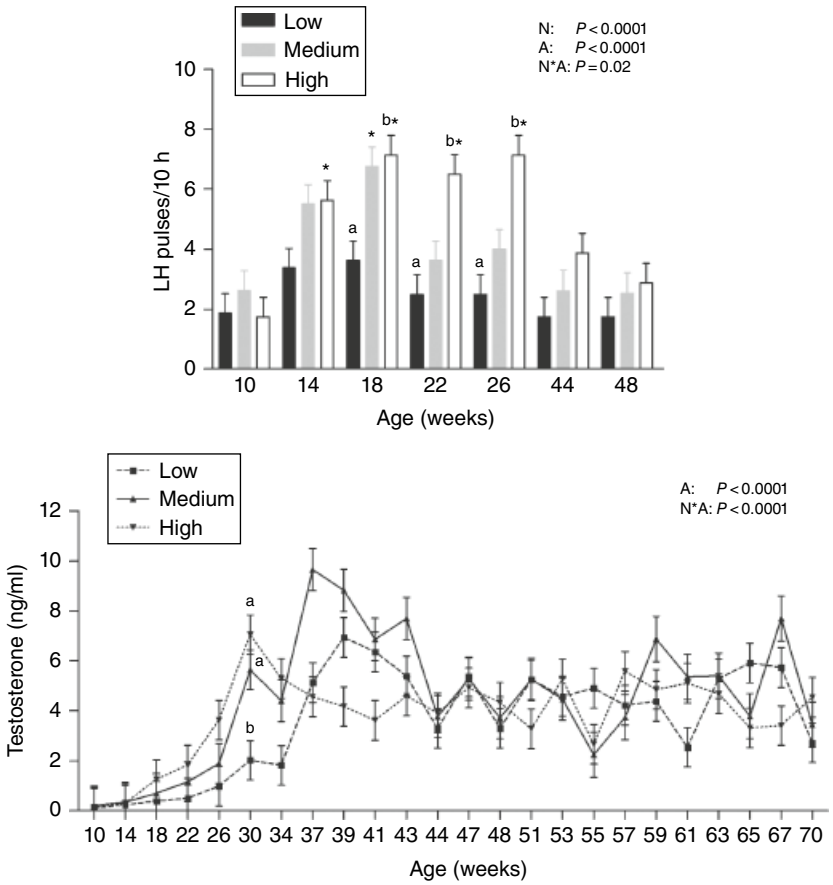

Figure 5.3 Mean (± SEM) number of LH pulses and serum testosterone concentrations in Angus and Angus × Charolais bulls receiving low, medium (control), or high nutrition from 10 to 70 weeks of age. N, A, and N*A indicate nutrition, age, and nutrition-by-age interaction effects, respectively. Superscripts indicate differences ($P < 0.05$): a,b, group differences within age; *, age differences within group. Bulls in the low nutrition group were older at puberty (321 days) than bulls in the medium and high nutrition groups (299 and 288 days, respectively), whereas bulls in the high nutrition group had greater paired-testes weight at 70 weeks of age (655 g) than bulls in the low and medium nutrition groups (520 and 549 g). *Source*: From [2], © 2007, Elsevier.

not different after the change in nutrition (results in beef bulls are shown in Figure 5.5) [2–4, 32–35].

During the prepubertal period there is a progressive increase in the proportion of testicular parenchyma occupied by seminiferous tubules, and seminiferous tubule diameter increases to approximately 125 µm at six months of age [20, 36]. FSH-binding sites can be observed in seminiferous tubules of bull calves at birth and at four months age, and decreased inhibin concentrations, coupled with increased FSH concentrations, stimulate the proliferation of undifferentiated Sertoli cells [6, 22]. Although there is considerable evidence that FSH is essential for normal Sertoli cell function, the period of Sertoli cell differentiation coincides with the initiation of testosterone secretion by the Leydig cells, indicating that testosterone may also be involved in promoting maturation of undifferentiated Sertoli cells. At approximately four months of age, undifferentiated Sertoli cells enter the G_0 phase of the cell cycle for the rest of the bull's life. With the end of the proliferative phase, undifferentiated Sertoli cells begin to transform into adult-type Sertoli cells. Opposing cell membranes of adjacent undifferentiated Sertoli cells start to develop extended junctional complexes above the spermatogonia and in the basal portion of the tubules; "cracking" of the tubular cytoplasm is first detected around six months of age [1, 15–17]. As immature Sertoli cells begin to differentiate they cease to secrete AMH and circulating concentrations of this hormone decrease after four months of age [1]. FSH secretion, maturation of Sertoli cells, and increased testosterone secretion are probably also involved in the differentiation of gonocytes into spermatogonia. Gonocytes are gradually displaced to a position close to the basal lamina and divide by mitosis, originating A-spermatogonia. Differentiation and degeneration result in the complete disappearance of gonocytes from the seminiferous tubules by five months of age. A-spermatogonia divide mitotically

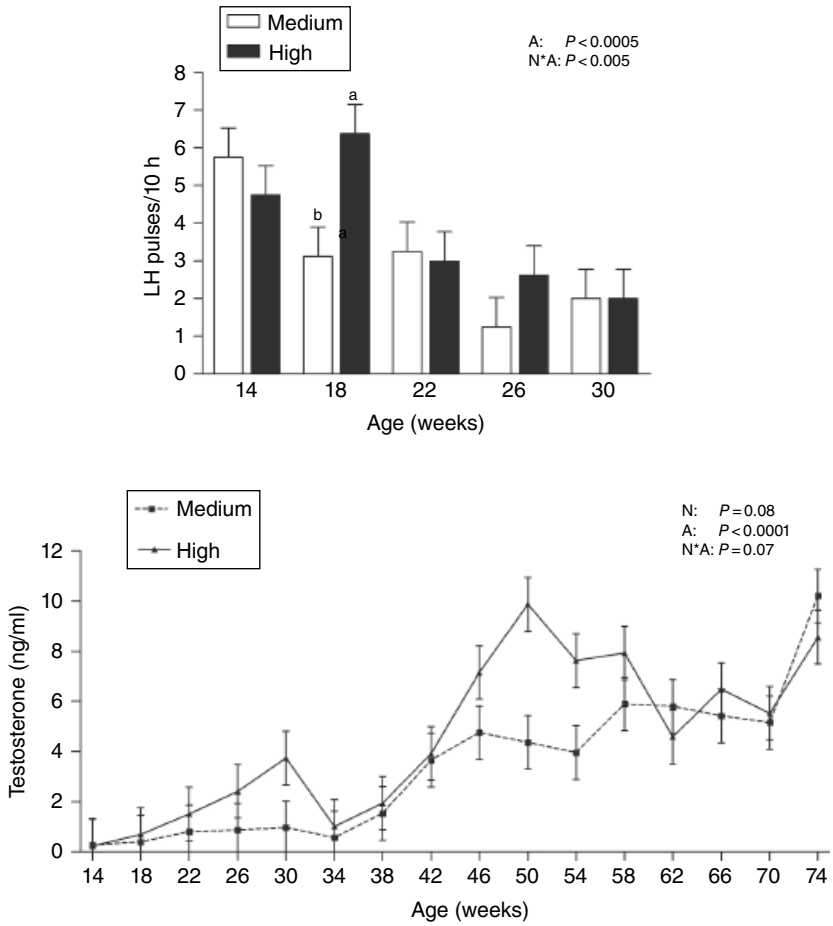

Figure 5.4 Mean (± SEM) number of LH pulses and serum testosterone concentrations in Angus and Angus × Charolais bulls receiving medium (control) or high nutrition from 10 to 30 weeks of age and the same medium nutrition from 31 to 74 weeks. N, A, and N*A indicate nutrition, age, and nutrition-by-age interaction effects, respectively. Superscript a and b indicate differences ($P = 0.09$) between groups within age. Bulls in the high nutrition group were younger at puberty (314 days) and had greater paired-testes weight at 74 weeks of age (610 g) than bulls in the medium group (327 days and 531 g, respectively). *Source*: From [3], © 2007, Elsevier.

to form In-spermatogonia and B-spermatogonia, which in turn enter meiosis around four to five months of age [15, 17, 20, 36, 37].

Pubertal Period

The pubertal period is characterized by reduced gonadotropin secretion, increased testosterone secretion, initiation of spermatogenesis, and the eventual appearance of sperm in the ejaculate. This period also coincides with the start of a phase of rapid testicular growth (see Chapter 6 for testicular growth charts) and extends from approximately 6 to 12 months of age in *B. taurus* bulls.

The rapidly increasing testosterone secretion and possibly increased hypothalamic sensitivity to negative feedback from androgens are likely responsible for the decrease in LH secretion during the pubertal period. Although immunization with inhibin antiserum results in a marked increase in FSH concentrations in prepubertal bulls, whether inhibin produced by Sertoli cells acts on the gonadotrophs to limit FSH secretion is uncertain, since circulating inhibin decreases steadily from birth to seven months of age [6, 38, 39]. After seven months of age, Leydig cell mass increases slowly but continuously to reach about 10 g in the young adult testis at 24 months of age as a result of considerable increase in Leydig cell volume (hypertrophy); Leydig cell mitochondrial mass more than doubles from 10 to 24 months of age [14]. Testosterone pulse frequency does not increase after the peripubertal period and remains at approximately 4.5–6.8 pulses per 24 hours from 6 to 10 months of age. However, pulse amplitude increases during the pubertal period with consequent increase in testosterone mean concentrations until approximately 12 months of age. Elevated testosterone secretion is essential for initiation of spermatogenesis [12, 25–27, 40].

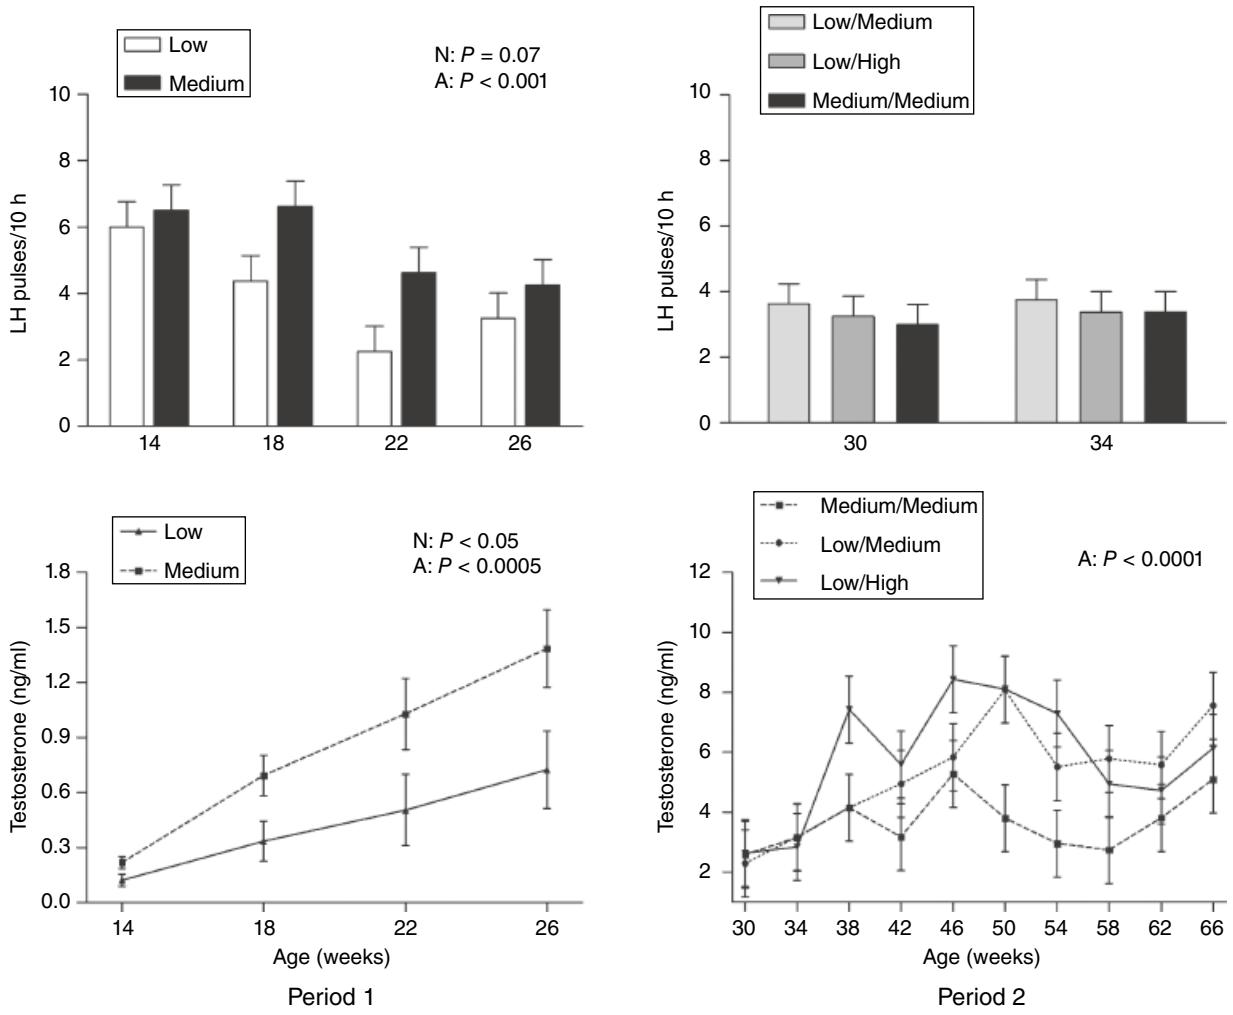

Figure 5.5 Mean (± SEM) number of LH pulses and serum testosterone concentrations in Angus and Angus × Charolais bulls receiving medium (control) from 10 to 70 weeks of age or low nutrition from 10 to 26 weeks of age and either medium or high nutrition from 27 to 70 weeks of age. N, A, and N*A indicate nutrition, age, and nutrition-by-age interaction effects, respectively. Bulls in the medium/medium nutrition group were younger at puberty and had greater paired-testes weight at 70 weeks of age than those in the low/medium nutrition group (293 vs 331 days and 600 vs 528 g, respectively). Age at puberty and paired-testes weight for bulls in the low/high nutrition group were intermediate (313 days and 553 g, respectively). *Source*: From [4], © 2007, Society for Reproduction and Fertility.

Seminiferous tubule diameter increases to approximately 200 µm at eight months of age and reaches 240 µm by 16 months [20, 36, 41]. Total seminiferous tubule length increases from 830 m per testis at three months of age to 2010 m per testis at eight months of age in Holstein bulls [36]. Most Sertoli cells complete their morphological differentiation and attain adult structure after six to seven months of age. Junctional complexes consisting of many serially arranged points or lines of fusion involving neighboring Sertoli cell membranes can be observed. These junctions form a functional blood–testis barrier and divide the tubular epithelium into a basal compartment containing spermatogonia and an adluminal compartment containing germ cells at later stages of spermatogenesis; formation of a functional blood–testis barrier is accompanied by formation of the tubular lumen and precedes the appearance of primary spermatocytes and more advanced germ cells [1, 15–17]. In Holstein bulls, the number of adult-type Sertoli cells increases dramatically from 202 to 8862 million cells per testis between five and eight months of age, respectively [36].

Germ cell proliferation is maximal between four and eight months of age and represents the expansion of the spermatogonial stem cell. In Holstein bulls, the number of spermatogonia increases from 181 million cells per testis at four months of age to 3773 million cells per testis at eight months of age; the number of spermatogonia continues to increase until approximately 12 months of age [36]. Primary spermatocyte numbers increase slowly until eight months

of age, when the numbers exceed the number of spermatogonia. Secondary spermatocytes and round spermatids first appear at approximately six to seven months of age, whereas elongated spermatids appear around eight months of age. The number of spermatids increases rapidly after 10 months of age when spermatid numbers exceed the numbers of any other germ cell. Mature sperm appear in the seminiferous tubules at approximately 8–10 months of age. Testes weighing more than 100 g in Swedish Red-and-White bulls or more than 80 g in Holstein bulls are likely to be producing sperm [15, 17, 20, 36, 37]. Spermatogenesis eventually reaches a level of efficiency (i.e. increasing number of more advanced germ cells resulting from individual precursor cells) that results in the production of a number of sperm sufficient for those to appear in the ejaculate, the physiological event that characterizes puberty (see Chapter 6).

Metabolic Hormones During the Prepubertal and Pubertal Periods

The mechanisms controlling reproduction and energy balance are intrinsically related and have evolved to confer reproductive advantages and guarantee the survival of species. The neural apparatus designed to gauge metabolic rate and energy balance has been denominated the body "metabolic sensor." This sensor translates signals provided by circulating (peripheral) concentrations of specific hormones into neuronal signals that ultimately regulate the GnRH pulse generator and control the reproductive process. Metabolic indicator hormones may serve as signs to the hypothalamus–pituitary–gonadal axis and affect sexual development. The patterns of some of these hormones have been studied in growing beef bulls (Figure 5.6). In contrast to species in which circulating growth hormone (GH) concentrations continue to increase until after puberty, GH concentrations decrease during the pubertal period in bulls [2, 5]. Differences in the stage of body development at which each species attains puberty are likely responsible for the different GH profiles among species. Accordingly, the GH profile in bulls seems to indicate that a relatively advanced stage of body development must be attained before the gonads are efficiently producing sperm. The differences in GH secretion among species may be due to the regulatory role of steroids on GH secretion. In other species, steroids stimulate GH secretion, but GH concentrations do not differ between intact bulls and castrated steers [42]. Moreover, decreasing GH concentrations during sexual development are observed along with increasing testosterone concentrations, indicating that steroids do not have a positive feedback on GH secretion in bulls as in other species [2, 5].

Circulating insulin-like growth factor (IGF)-I concentrations in bulls increase continuously and only reach a plateau (or decrease slightly) after sexual development is mostly completed after 12–14 months of age; increasing circulating concentrations of IGF-binding protein 3 and decreasing concentrations of IGF-binding protein 2 are also observed during sexual development [2–5, 43–45]. The concomitant decrease in circulating GH concentrations with the increase in IGF-I concentrations during sexual

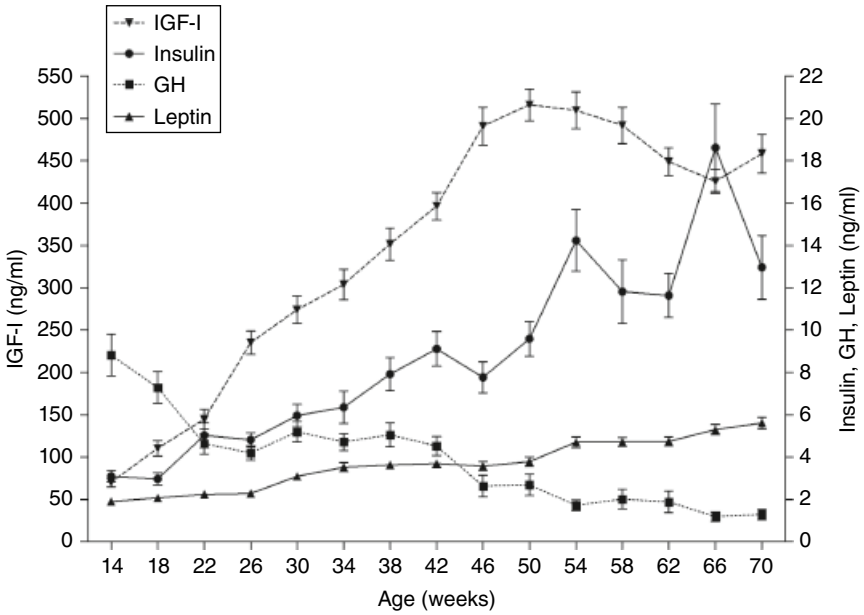

Figure 5.6 Mean (± SEM) serum IGF-I, insulin, GH, and leptin concentrations during sexual development in Angus and Angus × Charolais bulls receiving adequate nutrition. *Sources:* Data from [2–5].

development in bulls indicates that either there are drastic changes in liver sensitivity to GH or other sources are responsible for IGF-I production. A possible IGF-I source might be the testes, since Leydig cells are capable of secreting this hormone in other species. Observations that intact bulls tend to have greater IGF-I concentrations than castrated steers at 12 months of age further support the hypothesis that the testes might contribute substantially to circulating IGF-I concentrations during the prepubertal and pubertal periods in bulls [42]. Close temporal associations observed in a series of nutrition studies strongly suggest that circulating IGF-I might be involved in regulating the GnRH pulse generator and the magnitude and duration of the early gonadotropin rise in beef bulls [2–4, 33].

A possible effect of IGF-I on testicular steroidogenesis in bulls has also been suggested. Leydig and Sertoli cells produce IGF-I, indicating the existence of paracrine/autocrine mechanisms of testicular regulation involving IGF-I [46, 47]. It is assumed that most of the IGF-I in the testes is produced locally and that circulating IGF-I may play a secondary role in regulating testicular development and function. However, the temporal patterns and strong associations among circulating IGF-I concentrations, testicular size, and testosterone secretion observed in bulls receiving different nutrition argue for a primary role for this hormone [2–4, 33, 35]. The primary role of increased circulating IGF-I during the pubertal period may be to promote the increase in testosterone concentrations by regulating Leydig cell multiplication, differentiation, and maturation. Since testosterone upregulates IGF-I production and IGF-I receptor expression by Leydig and Sertoli cells [48], the establishment of a positive feedback loop between IGF-I secretion and testosterone production may be important for sexual development.

Circulating leptin and insulin concentrations also increase during the pubertal period in bulls. However, developmental and nutritional differences in LH pulse frequency are not related to differences in leptin or insulin concentrations in beef or dairy bulls [2, 3, 35]. Other studies have also demonstrated that leptin does not stimulate *in vitro* GnRH secretion from hypothalamic explants or gonadotropin secretion from adenohypophyseal cells collected from bulls and steers maintained at an adequate level of nutrition [49]. These results indicate that the role of these hormones in regulating GnRH secretion, if any, might be purely permissive in bulls.

GnRH-Independent Testicular Development

The rapid testicular growth observed after six months of age in bulls occurs when circulating gonadotropin concentrations are decreasing, which points to the existence of important GnRH-independent mechanisms regulating testicular development. The period of accelerated testicular growth coincides with increasing circulating IGF-I and leptin concentrations, and strong associations between these hormones and testicular size have been observed in growing beef and dairy bulls [2, 5, 6, 33], indicating that metabolic hormones may be involved in regulating GnRH-independent testicular development. Since there was no association between circulating metabolic hormones and gonadotropin concentrations in these studies, the possible effects of metabolic hormones on testicular growth are likely direct and independent of the hypothalamus and pituitary. Accelerated testicular growth in bulls involves increases in seminiferous tubule diameter and length, volume of testicular parenchyma occupied by seminiferous tubules, and total number of germinal cells [15, 36]. Although IGF-I and leptin concentrations are associated with testicular size, there are no associations between these hormones and seminiferous tubule diameter and area, seminiferous epithelium area, or volume occupied by seminiferous tubule (L.F.C. Brito, unpublished results). These observations suggest that increased circulating IGF-I and leptin concentrations are associated with increased length of the seminiferous tubules and likely with overall increases in the total number of testicular cells. Considering the cellular events in the testis during the pubertal period, the temporal patterns of metabolic hormone concentrations indicate that circulating IGF-I and leptin could be involved in regulating Leydig cell multiplication and maturation, Sertoli cell maturation, and germ cell multiplication during the period of accelerated GnRH-independent testicular growth in bulls.

Testicular concentrations of LH and FSH receptors in beef bulls decrease around five to six months of age, but increase thereafter until at least approximately 13 months of age, which might increase the sensitivity of Leydig and Sertoli cells to the low concentrations of gonadotropins during the rapid testicular growth phase [37]. Other mechanisms that might be associated with GnRH-independent testicular growth include changes in testicular concentrations and bioavailability of growth factors such as transforming growth factor (TGF)-α and TGF-β1, TGF-β2, and TGF-β3 and interleukin (IL)-1α, IL-1β, and IL-6 [50, 51]. In addition, experiments evaluating the effect of nutrition on sexual development have demonstrated that the impact of gonadotropins on target tissues during the prepubertal period has long-term effects on testicular development in bulls. Bulls with either greater LH pulse frequency or more sustained increase in LH pulse frequency during the early gonadotropin rise had a more prolonged period of increased testicular growth and greater testicular size at 15–16 months of age, even when no differences in metabolic hormones or testosterone concentrations were observed after six months of age. These results indicate that the putative effects of circulating metabolic

hormones, gonadotropins, local growth factors, and other unknown factors during the period of rapid testicular growth might be dependent on previous LH exposure during the prepubertal period. The LH secretion pattern during the early gonadotropin rise seems to "prime" testicular development and dictates maximum testicular size in bulls [2–4, 33].

Sexual Development and Puberty in Bulls

Leonardo F.C. Brito

STgenetics, Middleton, WI, USA

Introduction

Age at puberty is a major determinant of cattle production efficiency. The ability to breed animals at younger ages reduces generation intervals and increases genetic gains. However, reduced sperm production and poor semen quality due to immaturity are common causes of poor reproductive performance of young bulls and represent a serious loss of superior genetic stock. The ability to collect and freeze semen from younger bulls is also desired to reduce the time required for progeny testing and to accelerate the process of artificial insemination and sire selection. Therefore an understanding of pubertal changes and the factors that affect sexual development is required in order to promote the successful use of young bulls for reproductive purposes.

Testicular Development

Sexual development is associated with marked gonadal growth. Scrotal circumference (SC) is highly correlated with testicular weight (Figure 6.1) and is the most common endpoint evaluated to determine testicular development. The testicular growth curve in bulls shows an initial period of little growth followed by a rapid growth phase and then a plateau (Figures 6.2 and 6.3). Although the overall pattern of testicular growth is somewhat similar in all breeds, the characteristics of the growth curve are greatly affected by genetics. In general, the rapid growth phase is shorter and testicular growth plateaus sooner in bulls from breeds that mature faster (reach puberty earlier) than in bulls from late-maturing breeds, resulting in marked differences in the curve slope. This is especially evident when *Bos taurus* bulls are compared with *Bos indicus* bulls, which in general reach puberty later than the former. The asymptotic value of the testicular growth curve, namely adult testicular size, also differs considerably among breeds (Figures 6.2–6.6) [1–8]. These same differences can be observed within breeds between early- and late-maturing bulls (Figure 6.7), emphasizing the effects of genetics on testicular growth [9–11].

SC is a moderately heritable trait in cattle; yearling heritability estimates are 0.36–0.55 in Angus [12–16], 0.28 in Brahman [17], 0.40–0.71 in Hereford [14, 15, 18–24], 0.67 in Holstein [25], 0.46 in Limousin [26], 0.39–0.60 in Nelore [27–30], 0.32 in Red Angus [31], and 0.48 in Simmental bulls [14]. Therefore direct selection can have a very significant impact on SC. For example, selection of Santa Gertrudis bulls based on minimum SC over a 10-year period resulted in significant changes in average SC in one herd [32], whereas testicular weight at weaning was greater in the progeny sired by Limousin bulls with high expected progeny difference (EPD) for SC compared with progeny sired by bulls with average or low EPD [33]. Results from the Swedish performing station involving beef bulls of various breeds revealed an increase in SC of approximately 1 cm between 1997 and 2010 [34]. Similarly, comparison of data obtained from Canadian veterinary practices and testing stations between 2008 and 2011 from various beef breeds, with data compiled from the literature between 1972 and 1998, revealed that mean SC increased 0.8–2 cm in yearling bulls and 0.4–3.5 cm in two-year-old bulls [35]. Several studies have also demonstrated moderate to high phenotypic correlations between SC and growth traits and estimates of the genetic correlations with growth traits are generally positive (Table 6.1). Therefore the combination of direct selection for SC and indirect selection for growth traits is likely responsible for the general trend of increasing SC over the years in several breeds (Figure 6.4).

Heritability estimates for SC vary according to age. Studies have demonstrated that heritability estimates increase with age until approximately one year of age

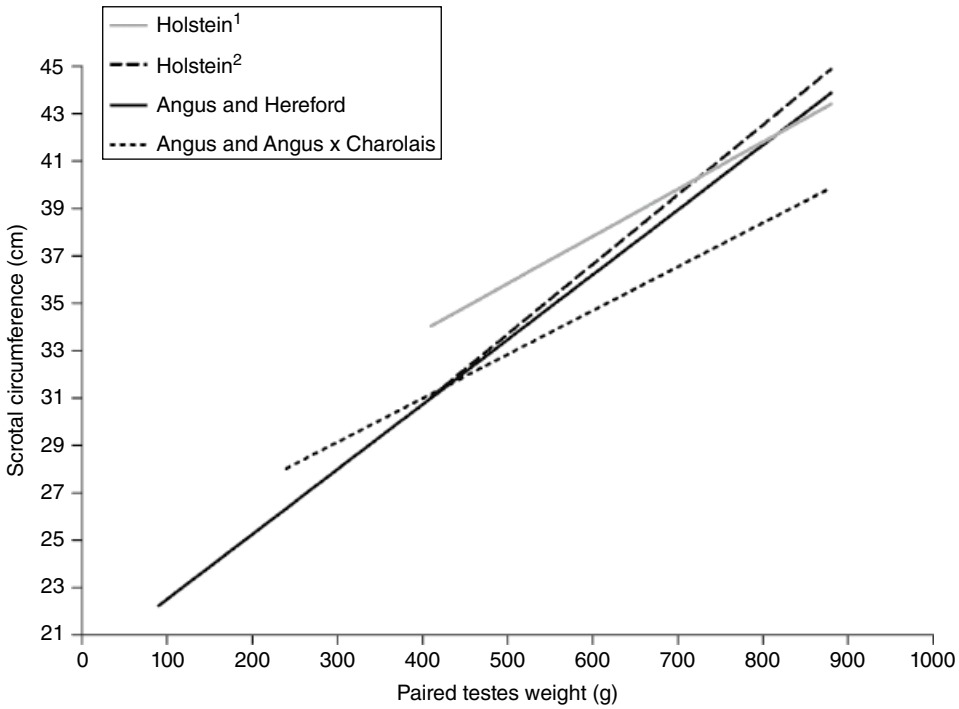

Figure 6.1 Regression lines for paired testes weight (PTW) according to scrotal circumference (SC). Holstein[1] measurements obtained from mature Holstein bulls (n = 35); PTW = −1298.5 + (50.2 × SC) [116]. Holstein[2] measurements obtained from Holstein bulls (n = 47) 19 to 184 months old; PTW = −654.4 + (34 × SC) [117]. Angus and Hereford SC measurements obtained from Hereford (n = 199) and Angus (n = 136) bulls 11 to 30 months old; PTW = −722.28 + (36.53 × SC) [3]. Angus and Angus × Charolais SC measurements obtained from Angus and Angus × Charolais bulls (n = 111) 14–16 months-old; PTW = −1274 + (54.04 × SC). *Source:* L. Brito, unpublished results.

(or 15–18 months of age in *B. indicus* bulls), whereas estimates for two-year-old bulls are lower [4, 15, 18, 25, 27, 28, 30, 36]. Therefore selection based on yearling SC is recommended over selection based on measurements obtained at other ages. Yearling SC is commonly recorded in performance evaluation programs for beef bulls, but age effects are very pronounced around this age since testicular growth is rapid during this stage of development (Figure 6.5). In order to adjust SC measurements to age 365 days, the Beef Improvement Program recommends use of the adjustment factors described in Table 6.2. Correlation coefficients between SC at one year of age and SC and paired testes weight at two years of age in Angus and Hereford bulls were 0.76 and 0.65, respectively, demonstrating that a bull with relatively small or large testes as a yearling will generally have comparable testes size as a two year old [3].

Attempts to establish guidelines for selection of bulls at weaning based on the likelihood of attainment of certain minimum yearling SC have produced mixed results. In one study, it was recommended that the minimum SC in Angus and Simmental bulls 198–291 days old should be 23 or 25 cm to ensure an SC of 30 or 32 cm at 365 days of age, respectively; the same recommendations for Hereford bulls were 26 and 28 cm [7]. In another study, differences between bulls that attained a minimum yearling SC of 34 cm and bulls that did not were observed for adjusted SC at 200 days of age (23.3 vs 20.5 cm, respectively). Based on these results, it was suggested that SC at weaning could be used to select bulls for breeding and 23 cm was proposed as the minimum SC standard at 200 days [37]. However, this study included bulls from several breeds with known differences in patterns of testicular growth and mature size, while using a singular and very strict yearling SC minimum. SC at 240 days of age could be used as a tool to select bulls with a high probability of meeting the minimum requirements for SC at 365 days of age (i.e. Simmental 32 cm; Angus, Charolais, and Red Poll 31 cm; Hereford 30 cm; Limousin 29 cm); sensitivity and specificity analysis for determining cutoff values indicated that the probability of Charolais bulls with SC ≥24 cm, Simmental and Limousin bulls with SC ≥22 cm, and Angus, Hereford, and Red Poll bulls with SC ≥21 cm attaining minimum requirements was greater than 80%. However, SC at weaning was not useful as a culling tool, since a large portion of bulls, irrespective of breed, met the minimum requirements at 365 days of age even when SC was below 21 cm at 240 days of age [38].

Although the heritability of semen traits is generally low, SC is positively associated with sperm production and

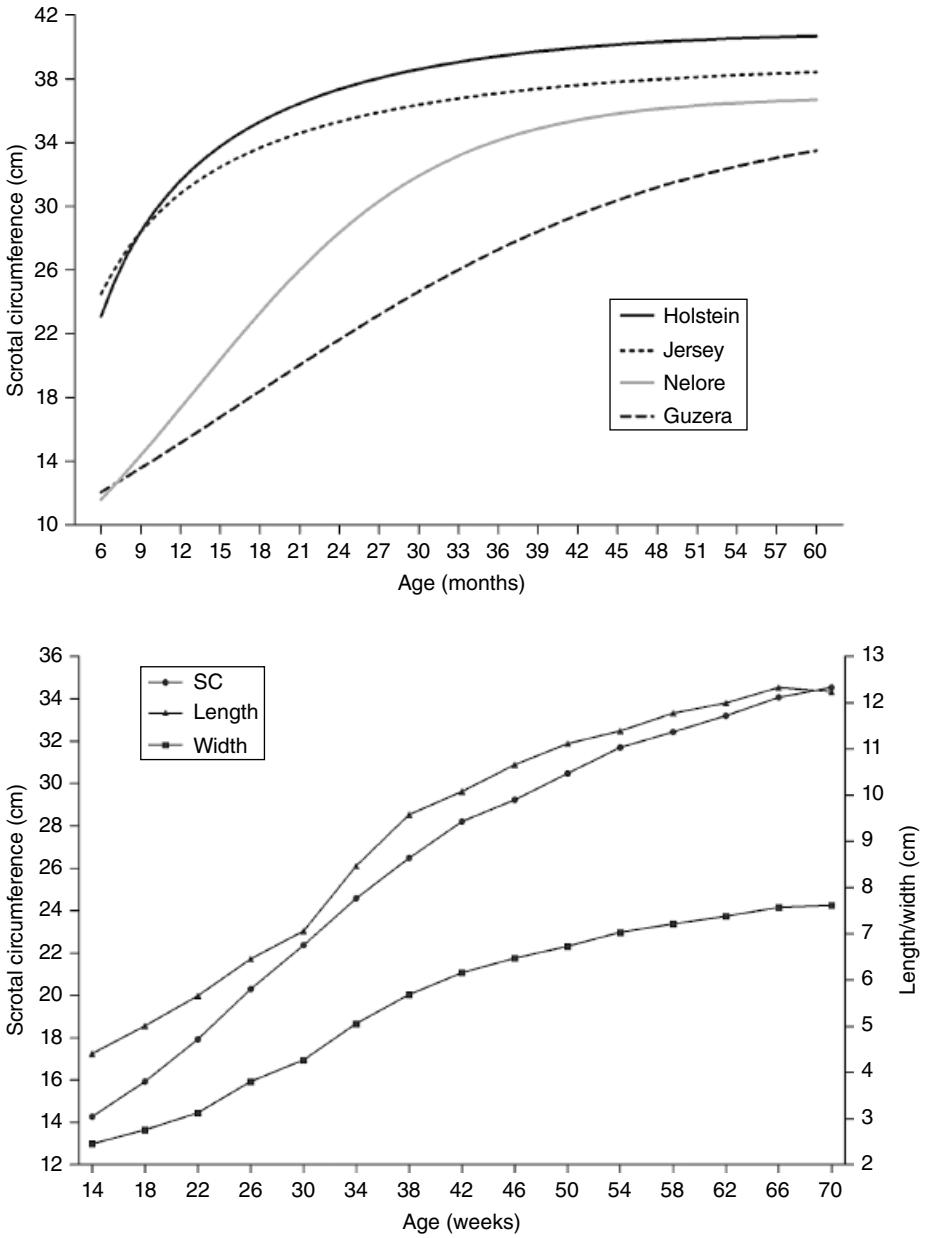

Figure 6.2 *Top*: regression curves for scrotal circumference (SC) according to age in Holstein, Jersey, Nelore, and Guzera bulls. Holstein measurements (n = 9614) obtained from bulls 6 to 77 months old; SC = −11.75 + [56.7 × (log AGE)] − [15.3 × (log AGE)^2]. *Source:* ASB Global Inc., unpublished results. Jersey measurements (n = 1038) obtained from bulls 7 to 75 months old; SC = −0.6814 + [40.26 × (log AGE)] − [10.27 × (log AGE)^2] (ABS Global Inc., unpublished results). Nelore measurements obtained from bulls (n = 532) 7 to 43 months old; SC = 36.9/1 + [4.22$^{-(0.11 \times \text{age})}$] [118]. Guzera measurements (n = 7410) obtained from bulls 2 to 69 months old; SC = 35.96/1 + [2.86$^{-(0.002 \times \text{age in days})}$] [119]. *Bottom*: testicular length and width associations with SC between 3 and 16 months of age in Angus and Angus × Charolais bulls (n = 111) receiving adequate nutrition. *Source:* L. Brito, unpublished results.

semen quality, and genetic correlations between SC and semen traits are generally favorable (Table 6.1). This suggests that direct selection for SC would be more effective in bringing about sperm production and semen quality improvement than direct selection pressure on semen traits themselves. In addition, several studies have reported an association between sire SC and daughter puberty. In Brahman and Hereford cattle, genetic correlations between SC and heifer ages at first detected ovulatory estrus, first breeding, and first calving were −0.32, −0.39, and −0.38, respectively [17, 39]. In another study with beef cattle, favorable relationships between greater sire SC and ages at puberty and at first calving were demonstrated by negative correlation coefficients between the two traits [40]. ADG, Average daily gain.

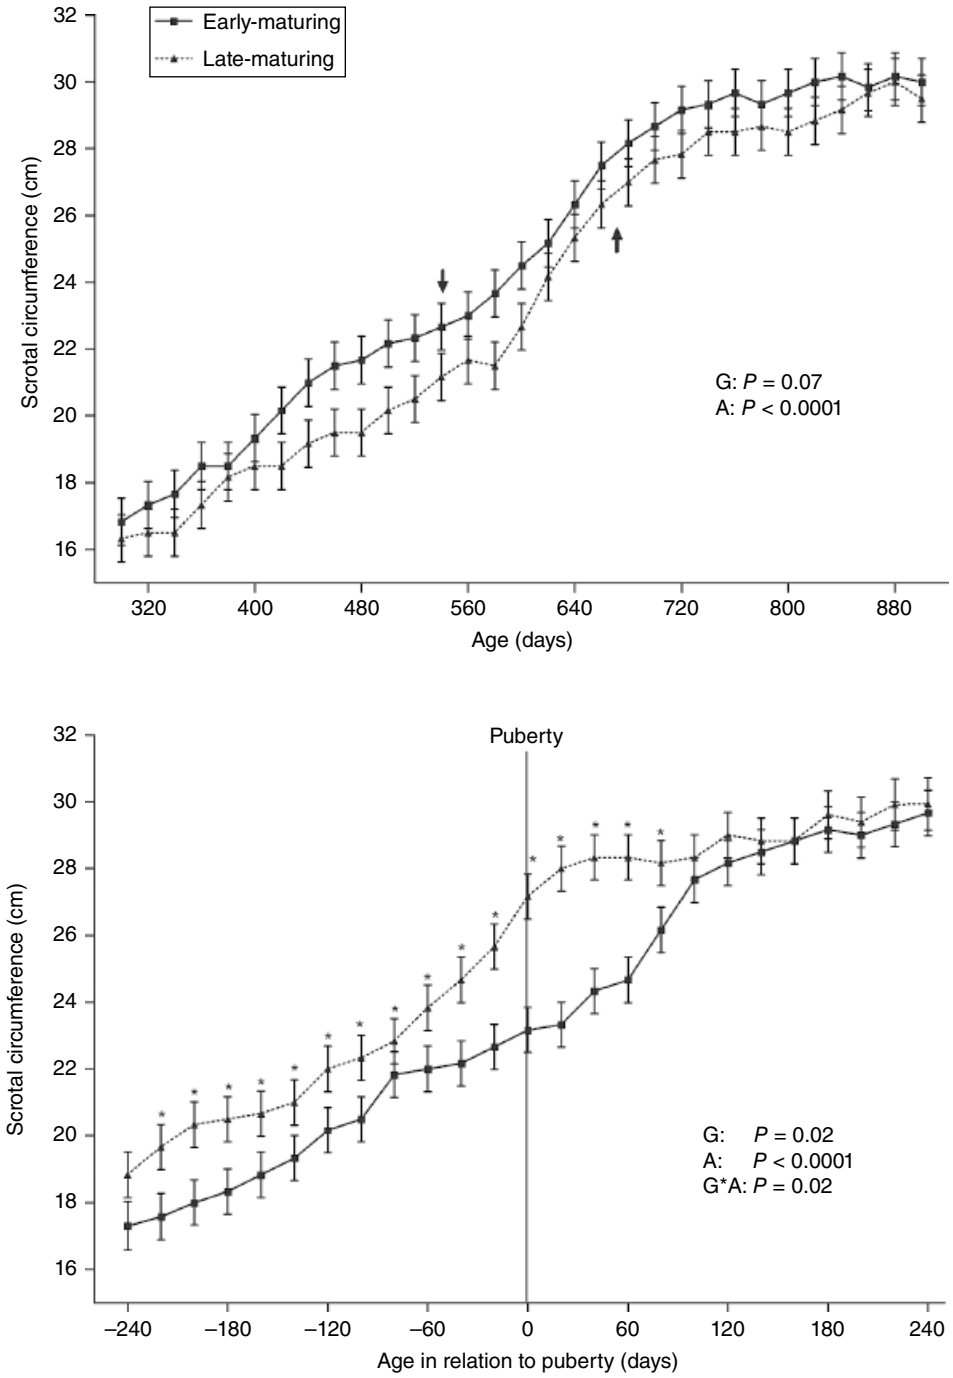

Figure 6.7 Mean (± SEM) scrotal circumference (SC) according to age (*top*) and age at puberty (*bottom*) in early- and late-maturing Nelore bulls (n = 6 per group). Arrows indicate mean age at puberty (ejaculate containing ⩾50 × 10^6 sperm with ⩾10% motile sperm; downward arrow indicates early; upward arrow indicates late). Early-maturing bulls had greater body weight (not shown) and SC than late-maturing bulls during the entire experimental period. In addition, early-maturing bulls were lighter and had smaller SC at puberty than late-maturing bulls, indicating that sexual precocity is not related to attainment of a threshold body or testicular development earlier, but that these thresholds are lower in early-maturing bulls. G, A, and G*A indicate group, age, and group-by-age effects, respectively. Means with superscript asterisks indicate differences between groups within age. *Source:* From [10], © 2004, Elsevier.

population of composite beef cattle, the correlation coefficient among parental breed group means for SC and percentage of pubertal females at 452 days of age was 0.95, whereas the correlation with female age at puberty was −0.91 [5]. A significantly greater proportion of females had reached puberty at 11 and 13 months of age when sired by Limousin bulls with high SC EPD compared with females sired by bulls with low or average EPD [33].

Although sire SC is associated with daughter puberty, evaluation of the genetic correlation between SC and

365-day SC = actual SC + [(365 – age) × age adjustment factor].

pregnancy rates has produced low estimates that in some cases are not different from zero [29, 31, 41]. A possible explanation for these observations is a non-linear relationship between the traits. One study in Hereford cattle indicated that the effect of SC breeding values on heifer pregnancy exhibits a threshold relationship. As SC increases in value, there is a diminishing return for improved heifer pregnancy, suggesting that selection for a high SC breeding value may not be an advantage for increased heifer pregnancy over selection for a moderate SC breeding value [23]. Although it would seem that the favorable genetic relationship between SC and age at puberty does not completely translate to heifer pregnancy, it is important to note that the experimental design might have confounded some of the referred results, since it is obvious that when the entire group of heifers reach puberty before exposure to breeding, those heifers reaching puberty at younger ages would have no advantage in conception over those reaching puberty at older ages. Moreover, end-of-season pregnancy rates were used in these studies as opposed to per-cycle pregnancy rates and the value of having heifers conceiving early rather than late in the season might have been lost.

Puberty

After spermatogenesis is established, there is a gradual increase in the number of testicular germ cells supported by each Sertoli cell and an increase in the efficiency of the spermatogenesis, i.e. an increase in the number of more advanced germ cells resulting from the division of precursor cells. The yields of different germ cell divisions, low during the onset of spermatogenesis, increases progressively to the adult level [42–44]. Testicular histological changes and increasing efficiency of spermatogenesis are accompanied by increasing testicular echogenicity. Testicular ultrasonogram pixel intensity starts to increase approximately 12–16 weeks before puberty and reaches maximum values right around puberty [45] (Figure 6.8). If the initial changes in testicular echogenicity are associated with Sertoli cell differentiation and meiosis is not completed until formation of a functional blood–testis barrier, then 12–16 weeks seems to be the interval required for the gradual increase in the efficiency of spermatogenesis that eventually leads to the appearance of sperm in the ejaculate. That testicular echogenicity does not change significantly after puberty indicates that a certain developmental stage of the testicular parenchyma must be reached before puberty, a conclusion corroborated by the observation that testicular echotexture at puberty did not differ between early- and late-maturing bulls [10]. In addition, testicular echogenicity did not change with age in mature bulls [46], suggesting that the composition of testicular parenchyma remained relatively consistent after puberty.

In general terms, puberty is defined as the process by which a bull becomes capable of reproducing. This process involves development of the gonads and secondary sexual organs and development of the ability to breed. For research purposes, however, puberty in bulls is usually defined as an event instead of a process. Most researchers define attainment of puberty by the production of an ejaculate containing 50 million or more sperm with 10% or more motile sperm [47]. The interval between the first observation of sperm in the ejaculate and puberty as defined by these criteria is approximately 30–40 days in *B. taurus* bulls [48, 49]. Age at puberty determined experimentally can be affected by the age that semen collection attempts are performed, the interval between attempted collections, the method of semen collection (artificial vagina or electroejaculator), the response of the bull to the specific semen collection method, and the experience of the collector(s). Moreover, age at puberty is affected by management, nutrition (see below), and genetics. Table 6.3 describes weight, SC, and age at puberty in different breeds. Although data from large trials comparing bulls of different breeds raised as contemporary groups are scarce, some liberties could be taken to make some generalizations. Dairy bulls usually mature faster and attain puberty earlier than beef bulls. Bulls from continental beef breeds (with the exception of Charolais) usually attain puberty later than bulls from British beef breeds, especially Angus bulls. Bulls from double-muscled breeds are notorious for being late-maturing. Puberty is delayed in bulls from tropically adapted *B. taurus* breeds and in non-adapted bulls raised in the tropics. In general, *B. indicus* bulls attain puberty at considerably older ages than *B. taurus* bulls.

There is large variation in age and body weight at puberty across breeds and within breeds. Although on

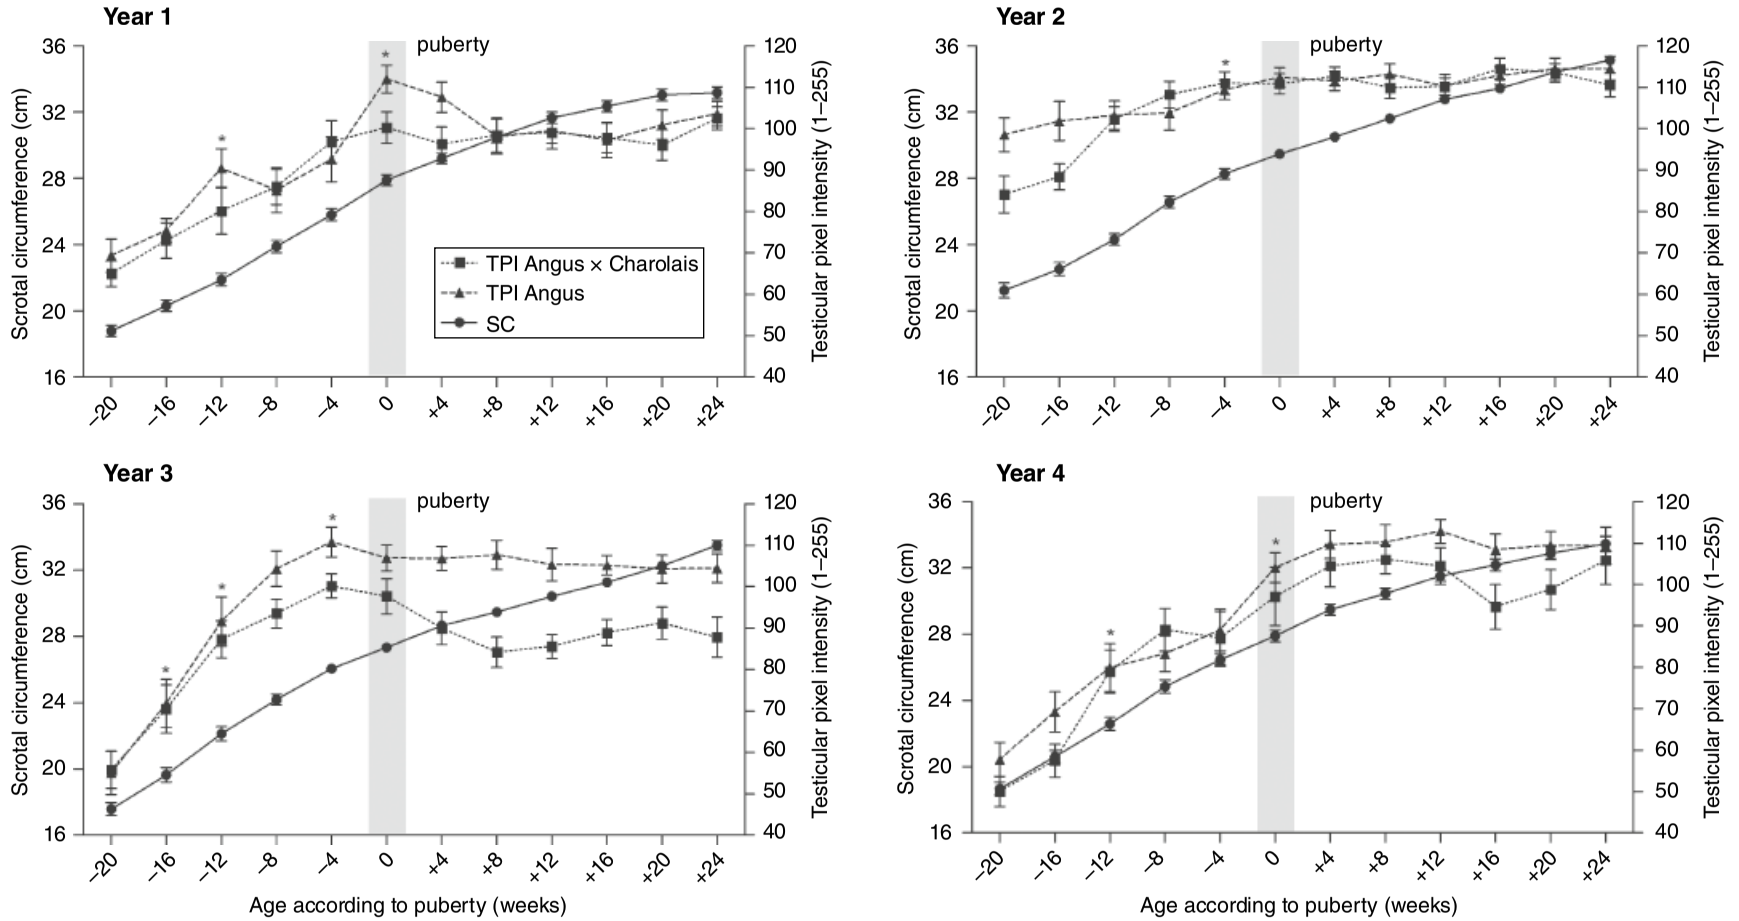

Figure 6.8 Mean (± SEM) scrotal circumference (SC) and testicular ultrasonogram pixel intensity (TPI) according to age at puberty in Angus and Angus × Charolais bulls (Year 1, $n = 37$; Year 2, $n = 39$; Year 3, $n = 43$; Year 4, $n = 33$). TPI, determined on a scale of 1 (black) to 255 (white), started to increase 16–12 weeks before puberty and reached maximum values four weeks before or at puberty. These results indicate that a certain developmental stage of the testicular parenchyma must be reached before puberty and that the composition of the parenchyma remains consistent after puberty. Overall, TPI was greater ($P < 0.0001$) in Angus × Charolais than in Angus bulls. TPI means with superscript asterisks indicate overall change ($P < 0.05$) with age. *Source:* From [45], © 2012, Elsevier.

average *B. taurus* bulls attain puberty with SC between 28 and 30 cm regardless of the breed, the fact that there is still considerable variation in SC at puberty is sometimes overlooked. Interesting observations have been reported in studies evaluating differences between early- and late-maturing bulls. Bulls that attain puberty earlier were generally heavier and had greater SC than bulls that attained puberty later; however, both weight and SC were smaller at puberty in early-maturing bulls [9, 10, 50] (Figure 6.7). These observations not only indicate that precocious bulls develop faster, but also suggest that sexual precocity is not simply related to earlier attainment of a threshold body or testicular development. In fact, these thresholds seem to be lower in early-maturing bulls, and late-maturing bulls must reach a more advanced stage of body and testicular development before puberty is attained.

Spermatogenesis efficiency reaches adult levels at approximately 12 months of age in Holstein bulls [42, 51] and 2.5–3.5 years of age in *B. indicus* bulls [52]. Individual variation in spermatogenesis efficiency is relatively small and is not affected by ejaculation frequency; values between 10 and 14 million sperm per gram of testicular parenchyma have been reported for bulls [1, 6, 42, 51–57]. Since spermatogenesis efficiency is somewhat constant among bulls, daily sperm production of a bull is largely dependent on the weight of the testes. Considering testicular weight at different ages, yearling *B. taurus* bulls are expected to produce around four to five billion sperm per day, whereas adult bulls are expected to produce around seven to nine billion sperm per day. Sperm output (number of sperm in the ejaculate) in bulls ejaculated frequently is essentially the same as sperm production [54]. One important difference between young and older bulls is the capacity of the epididymis to store sperm. Evaluation of sperm numbers in the tail of the epididymis in 15- to 17-month-old Holstein bulls demonstrated that sperm available for ejaculation corresponded to approximately 1.5–2 days of sperm production, whereas in 2- to 12-year-old bulls stored sperm numbers corresponded to approximately 3.5–5 days of sperm production [58, 59]. These observations are especially important for artificial insemination centers and indicate that more frequent semen collection is necessary to maximize sperm harvest from young bulls, whereas semen collection intervals of less than three days have smaller effects on increasing sperm harvest from older bulls. Sperm output increases with increased ejaculation interval up to the number of days required for epididymal storage capacity to reach its limit. Sperm that are not ejaculated are eliminated with urine or during masturbation.

Semen quality in peripubertal bulls is poor and a gradual improvement characterized by increase in sperm motility and reduction in morphological sperm abnormalities is observed after puberty. The most prevalent sperm defects observed in peripubertal bulls are proximal cytoplasmic droplets and abnormal sperm heads (approximately 30–60% and 30–40% at puberty, respectively; Figure 6.9) [9, 50, 60]. The difference between age at puberty and age at satisfactory semen quality (≥30% sperm motility, ≥70% morphologically normal sperm) was 110 days in *B. indicus* bulls [10] and 50 days in *B. taurus* beef bulls; 10% of the

latter did not have satisfactory semen quality by 16 months of age [61] (Figure 6.9). In western Canada, the proportions of *B. taurus* beef bulls with satisfactory sperm morphology (≥70% morphologically normal sperm) at 11, 12, 13, and 14 months of age were approximately 40, 50, 60, and 70%, respectively [62]. Similarly, only 48% of *B. taurus* beef bulls 11–13 months old in Sweden had less than 15% proximal cytoplasmic droplets and less than 15% abnormal sperm heads [63]. In Australia, sperm morphology evaluation of bulls of various breeds submitted to breeding soundness revealed a significant negative relationship between age and the occurrence of proximal droplets (Figure 6.10), whereas there was no association between age and other sperm abnormalities [64]. These observations have profound implications on the ability of producers to use yearling bulls and the ability of artificial insemination centers to produce semen for progeny testing at the youngest possible age.

Development of Accessory Sex Organs

Anatomical changes of the testicular vascular cone as the bull ages and starts to produce sperm are indications that the efficiency of the counter-current heat exchange mechanism between the testicular artery and veins in the pampiniform plexus needs to improve in order to cope with

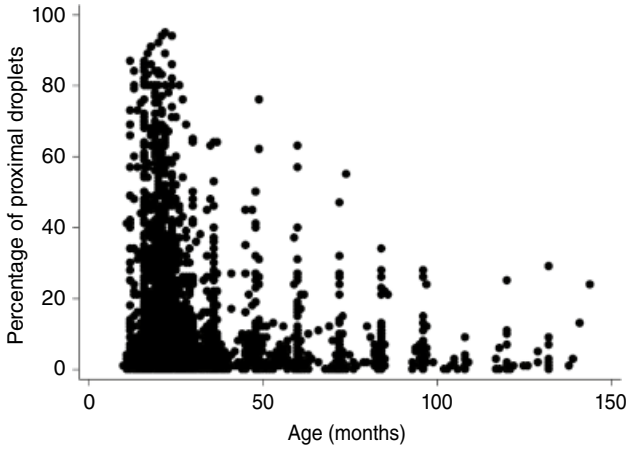

Figure 6.10 Prevalence of proximal droplets in ejaculates from bulls of various breeds according to age (n = 7284). *Source:* From [64], © 2020, Elsevier.

increasing testicular metabolism. In *B. taurus* beef bulls the testicular vascular cone diameter measured by ultrasonography increases until approximately 13.5 months of age, or until 1–8 weeks before SC reaches a plateau [65] (Figure 6.11). In crossbred beef bulls, the length and diameter of the testicular artery in the vascular cone increased from 6 to 12 months of age (1.8 m and 1.9 mm vs 3.1 m and 3.5 mm, respectively), but did not increase significantly thereafter [66]. The testicular artery length and volume in the vascular cone were 1.6 m and 6 ml in 15-month-old Angus bulls and 2.2 m and 11.4 ml in 28-month-old crossbred bulls, respectively [57]. Other studies have reported that the testicular vascular cone length is approximately 10–15 cm and that testicular artery length varies from 1.2 to 4.5 m in adult beef bulls of several breeds [67–69]. In addition to the lengthening of the testicular artery, the distance between the arterial and venous blood in the testicular vascular cone also decreases with age as a result of thinning of the artery wall (317 and 195 µm at 6 and 36 months of age, respectively) and reduction of the distance between the artery and the closest veins [66].

The epididymis continues to grow until at least 6 years of age in Holstein bulls and epididymal weight increases from 9 g at 8 months of age to 15, 23, 27, and 38 g at 12, 18, 25–48, and 73–96 months of age, respectively [51, 70]. The greatest dimension of the epididymis tail measured by ultrasonography from an oblique plane near the distal pole of the testis in Friesian bulls increased from 0.9 cm at 3 months of age to 1.8 and 2.7 cm at 12 and 24 months of age, respectively [71]. The tube-like vesicular glands in newborn calves increase in length and become lobulated during development. The weight of the vesicular glands increased until approximately 4 years of age in Holstein bulls, from 13 g at 8 months of age to 26, 35, 54, and 78 g at 12, 18, 25–48, and 73–96 months of age, respectively [51, 70]. The maximum diameter of vesicular glands in Friesian bulls increased significantly only from age 3 months (1.1 cm) to 9 months (1.6 cm), suggesting that further increase in gland weight is a result of increase in length [71]. Prostate diameter also only increases significantly until 12 months of age (0.85 cm from 0.49 cm at 3 months), whereas maximum diameter of the bulbourethral glands increased from 1.2 cm at 3 months of age to 1.5 and 2.1 cm at 12 and 24 months of age, respectively [71].

In *B. taurus* bulls, the sigmoid flexure of the penis begins to develop at about 3 months of age, penis length increases by up to five times by the onset of puberty, and length continues to increase until sexual maturity [72]. The penis in Friesian bulls 13–19 months old measured 73–89 cm [73], whereas the penis in Holstein bulls aged 25 months or older measured 95–106 cm [70]. First protrusion of the penis during mounting was observed at approximately 8 months of age, whereas complete separation of penis and sheath was observed at approximately 8.5 months of age in Angus, Charolais, and Hereford bulls [47, 74]. Complete sheath–penile detachment evaluated during electroejaculation was observed around the same time of puberty, whereas first completed service evaluated during libido testing was only observed approximately one month after puberty [48].

Development of Sexual Behavior

Development of sexual behavior has been studied in Hereford bulls. Mounting in response to an estrual female was first observed by 3, 6, and 9 months of age in 18.5, 26, and 48% of the bulls, respectively. By 12 months of age 59% of the bulls had their first ejaculations, whereas by 15 months 78% of the bulls registered a complete service. The number of services increased with age until 18 months of age [75]. In Angus, Brown Swiss, Hereford, Angus × Hereford, and Red Poll the first completed service was observed around 11 months of age [48]. Rearing seems to affect development of sexual behavior, since Hereford calves raised in individual pens had a greater number of services when tested for the first time than bulls raised in groups, although the differences quickly disappeared once these bulls were grouped together [76]. In another study, the influence of the presence of females during bull rearing was evaluated. In the first two hours of being exposed to females in estrus, males raised with females had 73% more services than bulls raised in isolation. However, bulls reared in isolation compared favorably in further tests, illustrating the fact that a learning process occurred rather quickly after exposure to females [77].

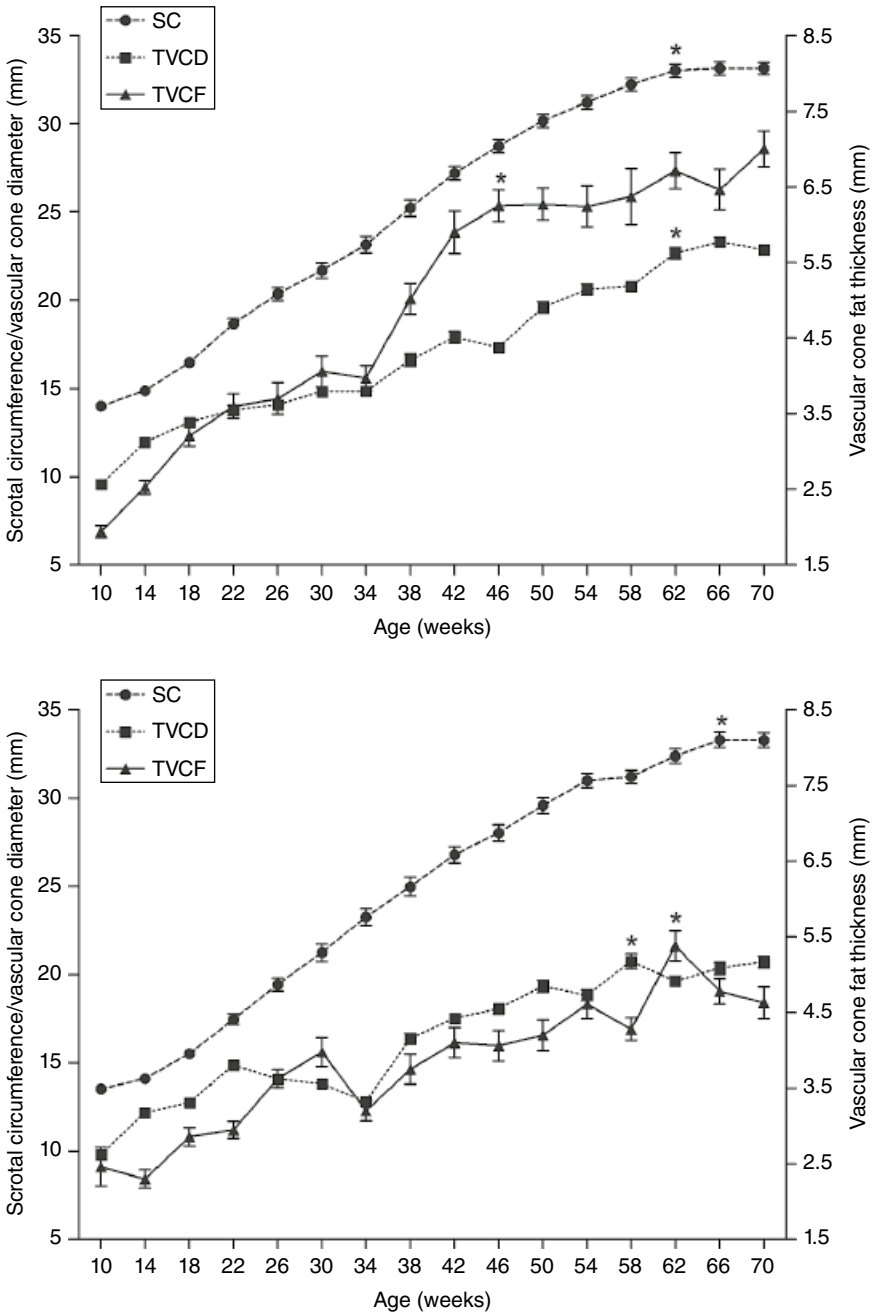

Figure 6.11 Mean (± SEM) scrotal circumference (SC), testicular vascular cone diameter (TVCD), and fat thickness (TVCF) in Angus and Angus × Charolais bulls in two years (*top*: $n = 37$; *bottom*: $n = 33$). Testicular vascular cone diameter increased with age following testicular development, whereas vascular cone fat thickness increased similar to a pattern observed for body backfat. Means with superscript asterisks indicate last significant ($P < 0.05$) change with age. *Source:* From [65], © 2012, Elsevier.

Age and experience have major effects on libido and serving capacity test results. An overall increase in test scores has been observed in several studies with yearling bulls when tests were conducted repeatedly over relatively short intervals, indicating that a maturing and/or learning process occurs rapidly after exposure of bulls to females. Exposure of yearling bulls classified as low serving capacity to estrual females for four days resulted in increased serving capacity score when bulls were tested within a week later; 85% of these bulls moved into the medium- or high-serving capacity category [78]. No correlations between the numbers of services at 12 months of age with sexual performance at older ages were observed in Hereford bulls. Only when bulls reached 18 months did individual

differences in serving capacity remain consistent from one age to another, i.e. 18, 21, and 24 months [79]. In one study, only 53% of 113 yearling bulls completed a service during 10 minutes of libido testing [80], whereas in a different study with yearling Angus and Hereford bulls the variance of the score obtained during eight libido tests conducted over a two-month period ranged between 69 and 73% [81]. These observations suggest that attempts to predict sexual performance are likely to be unproductive until bulls can fully express their inherent sexual behavior and serving ability. When adult Angus bulls were evaluated, the time required to complete six services when exposed individually to 10 estrous females increased with age from 31 minutes in two-year-old bulls to 43, 55, and 67 minutes in three-, four-, and five-year-old bulls, respectively [82]. However, in another study no difference in libido score or servicing capacity test results between two- and three-year-old Angus and Hereford bulls was observed [83].

Effects of Nutrition on Sexual Development

In early studies evaluating the effect of nutrition from birth to maturity on sexual development and reproductive function in bulls, Holstein bulls receiving low nutrition (approximately 60–70% of requirements) were older at the time the first ejaculates containing motile sperm were collected and had smaller testes, whereas bulls receiving high nutrition (approximately 160% of requirements) had earlier puberty and larger testes when compared with bulls receiving control nutrition (100% of requirements) [84, 85]. Several recent studies involving manipulation of nutrition during prepubertal and pubertal periods in both beef and dairy bulls have provided unequivocal evidence that (i) most pronounced effects of nutrition occur during the prepubertal period, (ii) effects of nutrition during the prepubertal period cannot be compensated with changed nutrition during the pubertal period, and (iii) high nutrition during the peripubertal period hastens puberty and results in larger testes (SC and testes weight), whereas low nutrition produced opposite results. With optimal prepubertal nutrition, puberty can be hastened by 1–1.5 months and testicular mass at approximately 1.5 years of age can be increased by 12–18% (Table 6.4) [86–91].

The effects of nutrition on sexual development and reproductive function in bulls are mediated through the hypothalamic–pituitary–testes axis. Nutrition affects the gonadotropin-releasing hormone (GnRH) pulse generator in the hypothalamus, since differences in luteinizing hormone (LH) pulse secretion in bulls receiving different nutrition can be observed even in the absence of differences in pituitary LH secretion capability as determined by GnRH challenge [87, 88]. Interestingly, though, when low nutrition was imposed on bulls by limiting the amount of nutrients in a ration fed ad libitum, only reduced LH pulse frequency was observed, whereas reduced LH pulse frequency, mean and peak concentrations, and secretion after GnRH challenge were observed when nutrition was controlled by restricting the availability of food [86]. These results seem to indicate that the inhibitory effects of limited availability of nutrients on LH secretion appeared to be exerted only on the hypothalamus, whereas the combination of limited availability of nutrients and the sensation of hunger experienced by bulls with restricted intake affected both hypothalamic and pituitary function, producing a much more severe inhibition of LH secretion. The effect of nutrition on Leydig cell number and/or function in bulls receiving different diets was demonstrated by differences in testosterone secretion after GnRH challenge even in the absence of differences in LH secretion after the challenge [87, 88].

Table 6.4 Effect of prepubertal nutrition (before 6 months of age) on age at puberty (transformed from days from original reports) and paired testes weight at 16–19 months of age in bulls. Values reported as ranges indicate bulls received varying nutrition in the pubertal period.

	Age at puberty (months)			Paired testes weight (g)			
Breed	**Low nutrition**	**Control**	**High nutrition**	**Low nutrition**	**Control**	**High nutrition**	**Reference**
Angus and Angus × Charolais	10.3–10.8	9.6	–	528–553	600	–	[86]
Angus and Angus × Charolais	–	10.7	10.3	–	531	611	[87]
Angus and Angus × Charolais	10.5	9.8	9.4	520	549	655	[88]
Holstein	–	10.6	9.9	–	535	636	[89]
Holstein	12.1	10.7	10.6	562	611	727	[90]
Holstein	10.4–10.6	–	9.3–9.8	594–627	–	658–660	[91]

Differences in yearling SC due to age of the dam in beef bulls could also be interpreted as an indication that nutrition during the pre-weaning period affects sexual development, although possible in utero effects cannot be completely ruled out. SC in *B. taurus* beef bulls increases as age of the dam increases until five to nine years of age and decreases as dams get older. Adjustment factors of 0.7–1.4, 0.2–1.0, 0.1–1.0, and 0.3–0.75 cm for yearling SC have been suggested for bulls raised by 2-, 3-, 4-, and ≥10-year-old dams, respectively [19–23, 92]. In these studies, the inclusion of weight as a covariate in the models describing SC resulted in decreased effects of age of the dam, indicating that the effect of age of the dam on testicular growth seems to be primarily the result of age of the dam effects on bull's body weight, likely related to differences in milk production. This theory is also supported by reports that, similarly to that observed in bulls receiving low nutrition, LH secretion after GnRH challenge was greater from 3.5 to 6 months of age in bulls raised by multiparous than in bulls raised by primiparous females [93].

Several studies reported in the literature describe the effects of nutrition only during the pubertal period, in other words after the initial hormonal changes that regulate sexual development have occurred. In general, these studies indicate that low nutrition has adverse effects on growth and sexual development. In one study, bulls receiving one-third of the amount supplied to their twin controls had lower body and vesicular gland weights, vesicular gland fructose and citric acid contents, and circulating and testicular testosterone concentrations, whereas circulating androstenedione concentrations were increased [94]. In another series of experiments, beef bulls 8–12 months old receiving diets with low levels of crude protein (8, 5, and 1.5%) for periods of three to six months had markedly reduced testes, epididymis, and seminal glands weights compared with control bulls fed diets containing 14% crude protein. Moreover, seminiferous tubule diameter and seminiferous epithelium thickness were smaller in bulls with a restricted protein intake [95, 96].

Although low nutrition during the pubertal period has adverse effects on reproductive function, the potential beneficial effects of high nutrition after weaning are questionable at best. Effects of energy on sexual development were not consistent in a study with Simmental and Hereford bulls fed diets with a low, medium, or high energy content (approximately 14, 18, and 23 Mcal/day, respectively) from 7 to 14 months of age. Dietary energy affected sexual development in Simmental bulls, but not in Hereford bulls. Simmental bulls in the high-energy group were heavier and had greater SC and testosterone concentrations than bulls in the low-energy group (in general, the medium-energy group was intermediate). However, increased dietary energy did not hasten age at puberty. The only semen trait affected by dietary energy was semen volume, which was depressed in Simmental bulls in the medium-energy group. Serving capacity was greater for Hereford bulls on the high-energy diet, but medium- and high-energy diets were associated with a decrease in the number of services between two testing periods in Simmental bulls. There was a trend for lower sperm motility and proportion of normal sperm in Simmental bulls fed the low-energy diet [97, 98].

In Holstein bulls producing semen for artificial insemination, high energy intake was associated with visual evidence of weakness of the feet and legs and increased reaction time after three years of age [85]. Under field conditions, post-weaning high-energy diets are frequently associated with impaired reproductive function in bulls, likely related to altered testicular thermoregulation due to excessive fat deposition above and around the testes in the scrotum. In one report, sperm motility decreased and the proportion of sperm defects increased with age in Hereford bulls fed to gain more than 1.75 kg/day, which was significantly different from bulls fed to gain approximately 1 kg/day (control). Even after the high-nutrition diet was changed to a control diet, bulls previously receiving high nutrition continued to have lower semen quality. There was greater deposition of fat around the testicular vascular cone in the scrotal neck in bulls in the high-nutrition group and the difference between body and testes temperature was reduced in this group compared with bulls in the control group. This difference was still present after the high-energy diet was changed and the bulls had lost a considerable amount of weight, indicating that fat accumulated in the scrotum is more difficult to lose than other body fat [99].

In another series of experiments, Angus, Hereford, and Simmental bulls were fed high nutrition (80% grain and 20% forage) or medium nutrition (forage only) from approximately 6.5 until 12–24 months of age. In general, bulls receiving high nutrition had greater body weight and backfat, but paired testes weight was not affected by diet. Moreover, bulls receiving high nutrition had lower daily sperm production and epididymal sperm reserves and a greater proportion of sperm abnormalities. The authors indicated that increased dietary energy may adversely affect sperm production and semen quality due to fat deposition in the scrotum, which reduces the amount of heat that can be radiated from the scrotal skin, thereby increasing the temperature of the testes and scrotum [100–103]. Observations from a different study indicated that bulls fed high-nutrition diets had greater SC and scrotal weight than bulls fed medium-nutrition diets, but paired testes weight was not different between the two groups [104]. Growth rate between 6 and 16 months of age did not affect sexual

development and reproductive function in Angus and Angus × Charolais bulls. However, greater body weight at various ages was associated with reduced age at puberty and maturity and with larger testes at 16 months of age, indicating that improved nutrition might be beneficial, but only when offered before six months of age. Average daily gains of 1–1.6 kg/day did not result in excessive fat accumulation in the scrotum, increased scrotal temperature, or reduction in sperm production and semen quality, and could be considered "safe" targets for growing beef bulls [61].

In summary, low nutrition has adverse effects on sexual development and reproductive function regardless of the bull's age. However, most research indicates that high nutrition is only beneficial during the first six months of life, which presents a challenge to bull producers. Beef bull calves are usually nursing until six to eight months of age and very little attention is paid to their nutrition, whereas nutrition offered to dairy bull calves is often suboptimal. Efforts to obtain maximum weight gain during the first months after birth by offering high-nutrition diets and adopting management practices like creep-feeding will be compensated by reduced age at puberty and greater sperm production capacity in adult bulls. It is also clear that although high nutrition diets after six months of age might be associated with greater SC, this effect is likely the result of fat accumulation in the scrotum and not actually greater testicular size. Moreover, sperm production, semen quality, and serving capacity are all compromised in bulls receiving excessive nutrition after this age. Adjusting diets accordingly to maximize growth but to prevent overconditioning after the peripubertal period is advisable.

Implications of Sexual Development and Puberty for Breeding Soundness Evaluation

In general terms, evaluation of bulls for breeding soundness involves a general physical examination, a specific examination of the reproductive system (including measurement of SC), and examination of the semen. According to the guidelines of the Society for Theriogenology (SFT), bulls must be free of any physical abnormalities, have a minimum SC of 30–34 cm depending on age, have 30% or more progressively motile sperm, and have 70% or more morphologically normal sperm in order to be classified as satisfactory potential breeders [105]. Since developing bulls experience significant changes in SC and semen quality over relatively short periods of time, the effect of age and the interaction of age with breed need to be considered for breeding soundness evaluation. The SFT guidelines list the breeding soundness category "classification deferred," which is used for bulls that the veterinarian considers likely to improve with time after reflecting on the bull's signalment, history, test results, and nature of the deficiencies. Most bulls classified in this category are young animals that may not have reached the suggested minimum for SC and semen quality by the time of the examination.

The proportion of yearling *B. taurus* beef bulls classified as satisfactory potential breeders increases from approximately 55% at 10 months of age, to 72% at 11 months, and 78% at 12 months of age as more bulls reach minimum requirements for SC and semen quality [106, 107]. Since there are breed differences in sexual development, a larger proportion of bulls from early-maturing breeds are expected to obtain satisfactory classification at a younger age than bulls from late-maturing breeds. An extreme example was found with tropically adapted Senepol bulls; the proportion of satisfactory yearling bulls was only 25–50%, but this increased to 70–85% at approximately 24 months of age [108, 109]. It has also been reported that the proportion of satisfactory bulls decreases after five to six years of age as bulls become more prone to develop physical and reproductive problems [110, 111].

Special consideration must also be given to *B. indicus* bulls, since these animals in general attain puberty at considerably older ages than *B. taurus* bulls. Although SC in selected mature *B. indicus* and *B. taurus* bulls does not differ [46], using SC guidelines for young bulls devised for the latter unjustifiably penalizes the former. Satisfactory semen quality is also observed at older ages in *B. indicus* bulls. In Florida, Brahman and Brahman × Nelore bulls only had greater than 70% normal sperm after 24 months of age [108]; these observations are consistent with those in Nelore bulls in Brazil [10]. In addition, the proportion of total sperm defects was approximately 57% in Nelore bulls 12–18 months old [112] and 20% of Nelore bulls were still considered immature at two years of age based on the spermiogram [113]. Less than 5% of *B. indicus* bulls were considered satisfactory potential breeders before 15 months of age and the proportion increased to only 20–50% between 18 and 22 months of age [108]. Accordingly, it might be prudent to delay breeding soundness evaluation for *B. indicus* bulls until two years of age.

In breeds that selection pressure has demonstrably resulted in significant increases in the mean SC, suggestions have been made for veterinarians and breed associations to consider updating minimum SC requirements accordingly. Minimum requirements designed to cull the bottom 5–10% of the population should help maintain adequate selection pressure [35].

Breeding Soundness Evaluation: Comparative Review of Different Standards

Scott T. Norman

Kallangur Veterinary Surgery and Oakhill Assisted Animal Breeding, Kallangur, QLD, Australia

Introduction

The overarching goal for a bull breeding soundness evaluation (BBSE) is to provide a standardized, unambiguous report on the suitability of a bull to be used in a breeding program. A secondary goal may be to utilize the data to facilitate genetic selection for fertility traits. The evaluation process needs to be repeatable, reproducible, efficient, and safe for both the bull and the clinician. There also needs to be flexibility in the process to accommodate differing managerial requirements. Within each managerial situation there needs to be consistency in the process of data collection, data interpretation, and classification of the evaluation outcomes, with results readily understood by the end user. Such consistency helps to maintain the credibility of the BBSE, assisting veterinarians, cattle producers, and researchers alike.

Foundations for the knowledge that underpins the current practices used in the assessment of bull fertility are attributed to research performed in the first four decades of the twentieth century [1]. Seminal research into specific aspects of bull fertility arose out of the USA [2, 3] and Sweden [4]. Following the understanding that many individual factors affect bull fertility, there was a progressive realization of the need to assimilate this knowledge to enable the development and application of minimum standards for each fertility parameter. The assimilation of fertility parameters into a bull fertility evaluation process formed the foundation of BBSE procedures. The earliest documentation in western literature of standardized procedures, interpretation, and reporting for BBSEs was described in 1954 by a group called the Rocky Mountain Society for the Study of Breeding Soundness of Bulls. Following several iterations, this group evolved in 1974 into the American Society for Theriogenology (SFT), with the basis for current protocols, data recording, and reporting being developed [5].

Following on from these initial developments, BBSEs are now conducted by veterinarians throughout the world to estimate the potential for a bull to sire calves under a range of management conditions. These conditions vary from the assessment of bulls pre-sale for seed-stock producers; commercial producers using natural mating in multi-sire or single-sire situations; assessment for the ability to collect and process frozen semen; and assessment for insurance purposes. These varied contexts coupled with differing production goals mean that the processes for determining and reporting the suitability of a bull for breeding have evolved with a degree of autonomy in different regions. While there are many similarities, there are also variations in the techniques employed, interpretation of the findings, reporting of results, and systems for oversight of the processes within the veterinary profession.

General Concepts

Based on cattle industry requirements for efficiency, financial viability, and reliability, the defined needs for veterinary BBSE include [6]:

1) A system for breeders/vendors to provide assurance that bulls have a high probability of being fertile at the point of sale.
2) A system for buyers/users of bulls to understand evaluation reports and to have confidence that bulls have a high probability of being fertile at the point of sale.
3) A system whereby veterinarians can meet industry needs that is consistent with their own professional opinions, enables them to produce professional reports, and enables electronic reporting and storage of data.

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

4) A system that is flexible enough to suit bull transactions, insurance examinations, and routine screening of herd bulls.
5) A system that is applicable to wide variations in geographical, cattle genotype, and management situations throughout the world, and equally applicable to dairy and beef bulls.

The early iteration of the BBSE developed by the SFT set the general template for the procedures, data recording, interpretation, and reporting of results. The details of these procedures are described in Chapters 8 and 9, but in summary the BBSE process can be condensed into the following seven categories:

1) General physical examination
2) Reproductive physical examination
3) Measurement of scrotal circumference (SC)
4) Semen evaluation – bull-side
5) Semen evaluation – morphology and other laboratory evaluations
6) Serving ability or capacity
7) Testing for specific infectious or genetic diseases may be carried out on an as-needed basis.

Of these seven aspects of the BBSE, the first three are considered compulsory in systems investigated in all regions. The remaining four categories may be variably included depending on the managerial situation, or the geographical location. While all BBSE systems agree or imply that full semen evaluation is desirable, some systems allow for semen evaluation to be either truncated to just a bull-side, fresh-semen evaluation or removed from the process in cases where large numbers of bulls in remote areas need to be assessed over short time-periods. Additionally, systems from all regions recognize the logistical effort required for testing serving ability or serving capacity, and so do not routinely include this aspect in the BBSE.

With these variations of procedure in mind, this chapter focuses on comparing how BBSE services for the first five categories are delivered in selected regions throughout the world. There is also reflection on the guidance and oversight different regions provide to veterinarians in order to provide a standardized service.

An International Overview of BBSE

The USA

Within the USA, the SFT has taken leadership in the development of BBSE data collection, recording, interpretation, and reporting. Having been in development for more than 60 years [7], the processes employed by the SFT have also served to set a standard for performing the BBSE worldwide. While there is always concern regarding truncated or poorly executed examinations [8], veterinarians in the USA have long had access to clear guidelines for performing the BBSE procedure. The SFT BBSE process has evolved through three main iterations over the past five decades [8–10]. The most recent progression came in 2018 with the production of an updated manual containing evidence-based information for veterinarians on the BBSE process [10]. One of the stated aims of this document is to instil a belief in cattle producers and veterinarians in the integrity of the veterinary BBSE process. This sentiment seems to be a recurring theme for BBSE practice throughout the world.

Due to the commonality in basic procedures throughout the different regions, a detailed coverage of the SFT BBSE form as described in the SFT BBSE manual is presented [10], as it provides an overview of the type of information recorded in all regions.

The SFT BBSE process offers reporting options in either hard-copy or electronic form. The form can be broken down into sections as shown in Figure 7.1, with the first section consisting of the client's information and general information about the bull including age, breed, and identification. The name or ear tag of the bull along with some form of permanent identification (tattoo, hot brand, freeze brand, electronic identification (EID) tag number, or United States Department of Agriculture (USDA) official metal ear tag) is included. The age of the bull is recorded in months up to two years of age to ensure SC measurements are categorized and interpreted correctly in young bulls.

Below the client and bull information, a box is provided to record any known history about the bull's fertility or medical history. Practitioners utilizing the SFT electronic BBSE software can allow automatic filling of this box with the bull's previous breeding soundness examination if it was completed in the software. At the bottom of the box there is a statement regarding the fact that the responsibility is on the producer to evaluate the libido and mating ability of the bull when placed with females.

The next section of the form is the physical examination portion of the examination and begins with the body condition score. The scale for both beef and dairy bulls is present on both form types, with consideration given to the score as well as circling the appropriate descriptor of obese, good, moderate, or thin. The physical examination is completed with the assessment including examination of the bull's eyes; conformation including feet and legs; examination of the scrotum, testes, and epididymides; SC measurement; transrectal examination of the accessory sex glands and internal inguinal rings; and examination of the penis and

prepuce during the ejaculation process. Each item has an open box beside it to be checked following examination to indicate that the item was assessed and found to be without abnormalities. If an abnormality is noted, an explanation of the abnormality is placed in the box to the right of the checkbox.

SC is part of the reproductive physical examination and is recorded in centimeters just below the physical examination checkboxes on the form. Tables of the expected SC by age are given on the back of the form. In the SFT system, a bull with an SC below the minimum cannot receive the classification of satisfactory potential breeder even if the rest of the physical examination is passed and semen quality is satisfactory.

When filling in the semen examination portion of the form, the method of semen collection is marked, followed by whether the bull obtained erection, full protrusion of the penis, and ejaculation. Protrusion of the penis and examination of the prepuce is essential before deeming a bull a satisfactory potential breeder in this system.

The SFT manual provides good detail on preparing semen for evaluation so that repeatable results can be achieved. These guidelines describe the common requirement to dilute concentrated samples in order to assist visualization of individual spermatozoa for motility assessment. But there is little detail on the practicalities of the dilution process and dilution rates.

The SFT lower threshold for individual motility is set at 30%. It is notable that the measurement of gross motility is no longer recommended as part of the BBSE semen assessment process in the current SFT guidelines.

The SFT no longer classifies morphology defects as primary/secondary or major/minor, but simply records them as they are seen. They are then grouped into Normal or Abnormal Head, Midpiece, and Tail categories for the report. If there is a high percentage of abnormal sperm, notes on what was found are made in the comments. The SFT lower threshold for normal sperm is 70%.

Following the evaluation, the data are interpreted and the bull is classified into one of three categories – satisfactory potential breeder; classification deferred; or unsatisfactory potential breeder. The classification deferred category is used when potentially treatable abnormalities are detected, or when the practitioner considers that aberrations to the spermiogram may be related to a specific insult and time is needed for recovery.

Australia

The BBSE process within Australia has oversight from the Australian Cattle Veterinarians (ACV), with input from the Australian Reproduction Veterinarians (ARV). From the 1970s to the end of the 1990s, BBSEs in Australia were broadly based on the SFT recommendations. Yet, there was variation throughout the veterinary profession in the ability to reliably collect data, the depth of the evaluation, the interpretation of findings, and the quality of reporting [11]. However, over these three decades, there was a steady progression to a more standardized approach as information was disseminated throughout the veterinary profession via improved undergraduate training and continuing professional education. There was also a push from industry stakeholders to ensure consistency in the process, particularly prior to Breed Society sales of young bulls. This consistency was essential so that bull producers could have confidence their bulls were not disadvantaged at sale-time due to variation between veterinarians in data collection or interpretation. In 2002 there was a major progression toward improving the quality and consistency of BBSEs with the ACV commitment to implement a BBSE accreditation scheme for veterinarians [12].

Prior to the implementation of the BBSE accreditation scheme by the ACV in 2007 came an overhaul of the BBSE processes. Initially, the scientific literature was reviewed [13] and the needs of stakeholders were considered in preparing the substantive manual *Evaluating and Reporting Bull Fertility* [14] that outlined standards for assessing and reporting bull breeding soundness. A further progression was the development of software to assist with the recording, interpretation, and reporting of the process [15].

Driven by legal advice and industry requirements, the ACV elected to develop the BBSE process to provide a description of risk, rather than reporting an overall result for the bull. Therefore the BBSE process was divided into five fertility categories, with results for each individual category reported on the certificate. The results provide information on whether the minimum standards for each category were assessed, or met, but the bull is not given an overall Pass/Fail classification.

The bull fertility categories are Scrotum, Physical, Crush-Side Semen, Sperm Morphology, and Serving and are shown on the certificate in Figure 7.2.

The SC is reported in centimeters. The results for all other categories are reported as either a T (Tick), Q (Qualified), X (Cross), or NT (Not Tested). As with the SFT system, the option to report a category as "Q" is chosen if aberrations deemed to be treatable are encountered. Professional, standardized, easy-to-read reports are produced electronically. There are no booklet recording options, but the veterinarian can print out customized field recording sheets for each job once the client and job details have been entered into the database. There is also the option for electronic data entry if the animal handling facility is suitable.

A compulsory database must be collected for all BBSEs, but, informed by veterinary advice, the client can select

General Comment

Figure 7.2 An example of the BBSE report from the Australian system. The certificate includes the identity of the client and place of examination; bull ID, breed, and age; an area for summary of the veterinary interpretation for each aspect of the examination; a signed statement by the veterinarian that the procedures outlined in the ACV BBSE manual have been followed; and a signed statement by the vendor that there has been no surgical or medical intervention. Multi-bull report formats are also available. *Source:* From AVA, BBSE report from the Australian system, © Australian Veterinary Association Ltd.

additional categories they wish to have included in the evaluation to suit their specific purposes (Figure 7.3). In this context, breed societies can select additional parameters they wish to have evaluated for bulls in their respective stud sales with the knowledge that the outcome of that evaluation will be reflected in the result shown in the respective fertility category.

If owners or veterinarians choose to truncate the evaluation procedure, that is possible. But the certificate clearly shows a potential purchaser the testing procedures that are available and which ones were performed. The bull owner or their agent is required to sign the certificate to affirm that bulls have not undergone procedures to rectify faults that may have otherwise caused them to fail the standards.

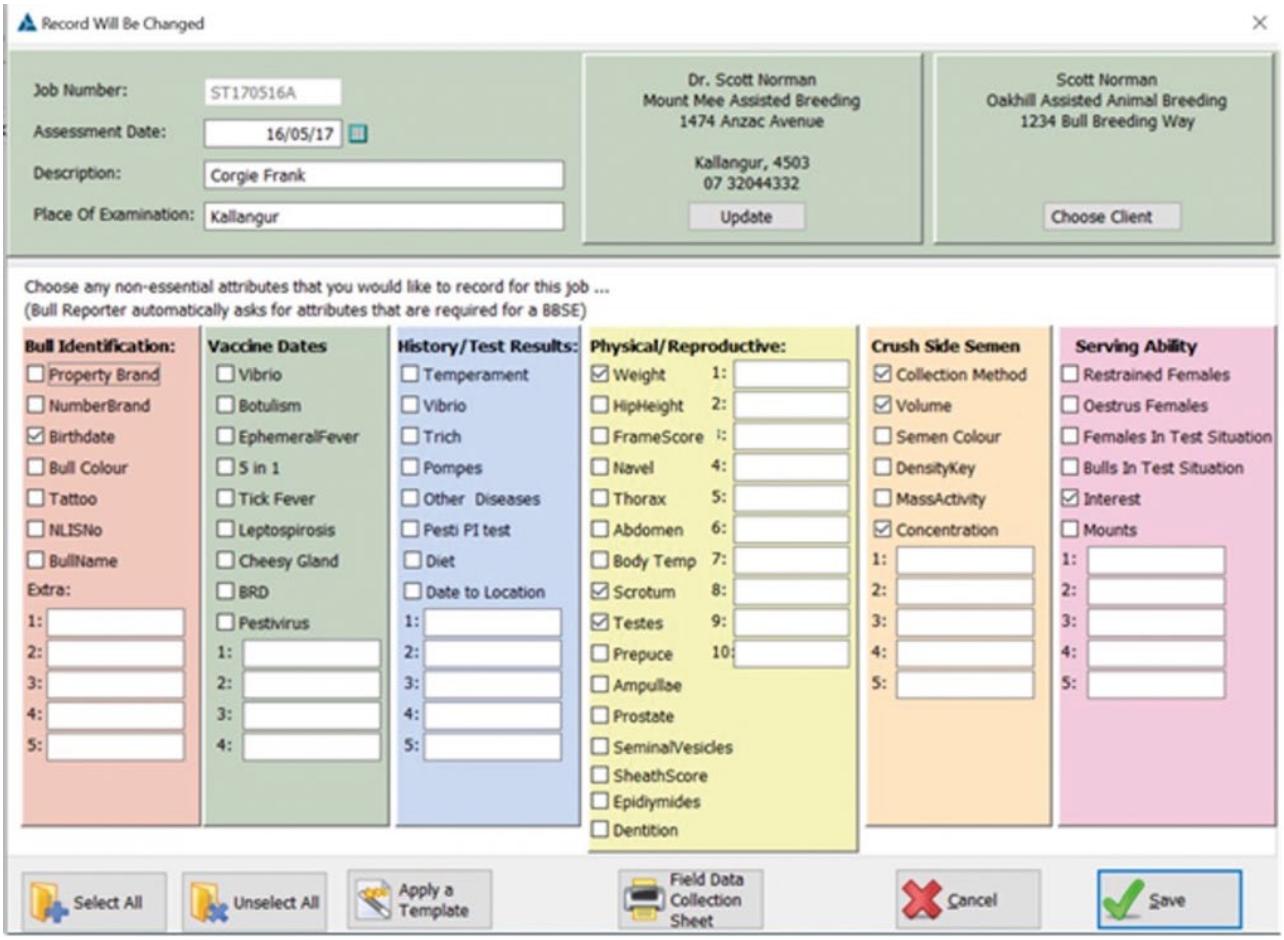

Figure 7.3 An example of BBSE data collection options provided by *BullCheck* software as used by veterinarians accredited in the *BullCheck* accreditation program managed by the ACV. *Source:* Used with permission from ACV, Australia.

The veterinarian is required to sign the form to confirm the evaluation was in accordance with ACV standards.

An important feature of this approach is that the veterinarian is not required to make an overall judgment of whether the bull has normal capacity to sire calves under natural mating management. Instead, the veterinarian assesses each category to determine if standards are met and the client receives a report informing them of whether it meets the individual category standards. This report, with adequate room for veterinary comments, allows clients or potential purchasers to make an informed decision on how to proceed with the bull.

With the current software iteration called *BullCheck*, there is seamless integration with morphology software, which allows the veterinarian to either perform their own morphological assessments or follow the ACV recommendation and export the bull data to a dedicated morphology laboratory that will receive the fixed semen samples and import the results back into the *BullCheck* program for assimilation into the report. To assist with reducing ambiguity in the process, the back page of the report (Figure 7.4) explains in plain language the symbols used on the report, the limitations of the evaluation, and qualifiers to the interpretations.

The Australian system differs to that of other regions with the requirement for veterinarians using this system to become accredited with the ACV. The goal of the accreditation system is to ensure consistency in data collection, interpretation, and reporting. While the process requires effort for both ACV administration and veterinarians wishing to become accredited, the primary goal is anecdotally being achieved. An added benefit is that accredited veterinarians may be securing a market advantage as breeders and breed societies realize the advantages of a well-regulated process. The summary of this system is that veterinarians must demonstrate meeting a threshold of BBSE experience or attend an ACV BBSE training day; they must demonstrate having suitable equipment to perform the procedures, including having a binocular microscope with warm stage, a portable incubator or slide warmer, and

Evaluating and Reporting Veterinary Bull Breeding Soundness

Purpose: **The Veterinary Bull Breeding Soundness Evaluation (VBBSE) is a tool used to identify risk factors that may affect bull fertility in a natural service situation.**

Definitions:

ACV Standards: as published in Beggs et al (2013) *Veterinary Bull Breeding Soundness Evaluation. Published by ACV in 2013 and available from the ACV office.*

Components of the VBBSE

Australian Cattle Veterinarians (ACV) uses the following components to evaluate bull as part of the VBBSE:

Scrotum- Scrotal circumference measured as per published ACV method and reported in cm.
Physical- Examination of bull's structure and genetalia
Semen- Crush-side visual and microscopic assessment
Morphology- Standardised high-magnification microscopy of preserved sperm.
Serving Ability- Standardised test used to evaluate the ability of a bull to mate normally
ACV recommends that all of the above components be assessed.

Report Indicators

Detailed data is reported as either actual measurements, Yes/No, Normal/Suspect/Abnormal, or on a scale as indicated in published ACV standards. A summary risk assessment of each VBBSE component is provided and uses the following key:

✓ Tick - All attributes for this component measured were consistent with the ACV standards. No risk factors for reduced fertility were identified during for this part of the VBBSE examination.	Q Qualified - Not all attributes for this component were consistent with ACV standards but these abnormalities may not necessarily preclude the bulls use. A further comment will be provided. **The client should seek advice from their cattle veterinarian as to the suitability of this bull for a particular purpose. Retesting may be recommended.**
✗ Some attributes for this component measured were not consistent with ACV standards. This bull has a significant risk of reduced fertility in the short term at least. Because some conditions may be temporary, the client should seek advice from their cattle veterinarian.	NT This VBBSE component was not evaluated or not fully evaluated either at the owners request or as indicated.

Using a Veterinary Bull Breeding Soundness Evaluation (VBBSE) report

The report indicates ***the level of risk of reduced fertility*** at the time of testing the bull, and helps predict whether a bull is likely to be able to seek out oestrus females, mate them repeatedly, impregnate them with good quality semen, if the bull were to be put into a paddock mating situation in the short term. The published standards have been selected as the best indicators, but are ***not a guarantee*** that the bull is either fertile, sub-fertile, or infertile.

The ***VBBSE report applies tothe date of the examination*** and no responsibility can be taken for any subsequent events that may affect the ability of the bull to breed satisfactorily or otherwise. In consultation with a cattle veterinarian, clients should consider all aspects of bull fertility when requesting an examination and choose whichever evaluation procedures will best minimise the risk of herd sub-fertility or infertility due to bull failure, or are necessary to meet specific transaction requirements.

The report can only indicate whether bulls meet thresholds for the traits measured based on objective measures and professional judgement of the cattle veterinarian. **Overall judgement of a bull as fertile or sound is not appropriate.** However, bulls may be deemed at risk of being sub-fertile or infertile if the VBBSE detects indicators of this. A prognosis (predicted future status) based on detailed data collected may be provided where thresholds are not achieved or there are other indicators of sub-fertility or infertility.

Limitations of the VBBSE report

The report indicates a level of risk – ***it does not indicate future status***, especially following relocation or management changes. (Bulls, and especially fat bulls, experiencing these events should be re-examined after acclimatisation.) As all possible components of a VBBSE may not be conducted, there always remains a risk that bulls may not reach their full potential.

ACV recommends that all bulls should be vaccinated against/tested for local endemic diseases.

Figure 7.4 As with the South African system, Australian BBSE reports have a back-page description explaining the process, report symbols, and limitations and qualifiers to the process. *Source:* From AVA, The South African system, Australian BBSE reports, © Australian Veterinary Association Ltd.

a computer loaded with a current version of the *BullCheck* software; and they must pass an open-book, online examination. Accredited veterinarians must agree to be in a trace-back system so that disputes can be investigated, and currently in development is a process for accreditation maintenance.

The ACV also temporarily ran an accreditation program for sperm morphologists. This process initiated the development of standardized procedures and quality assurance programs surrounding morphology assessment and reporting. However, the accreditation program had to be abandoned as the ACV did not have effective regulatory authority over non-veterinarians performing the work, meaning they could not follow through with proposed trace-back programs. Currently the ACV provides endorsement for morphologists who have agreed to meet the required laboratory standards.

Canada

In Canada, there have been two systems utilized for BBSE [16]. Some practitioners follow the American SFT guidelines described previously, while the Western Canadian Association of Bovine Practitioners (WCABP) has produced its own guidelines and forms. The WCABP BBSE process is similar to the SFT guidelines except for varied thresholds for SC, morphologically normal sperm, and sperm motility [16].

In contrast to the SFT system, the WCABP system considers breed and age when setting the SC threshold. In the SFT system, the lower SC threshold is the same (30 cm) for bulls of any *Bos taurus* breed between 12 and 15 months of age [10]. However, in the 2018 version of the SFT BBSE manual there is recognition of the profound influence of breed and age on SC, providing veterinarians with information to tailor recommendations to clients with different breeds. The WCABP system sets the SC threshold for each breed and age as one standard deviation below the mean [17], which means that 16% of bulls with the smallest SC may be culled. Both systems classify bulls as having either satisfactory or unsatisfactory SC scores, but do not further categorize satisfactory bulls to allow positive selection pressure based on SC.

For sperm motility and sperm morphology, the SFT system categorizes bulls as either satisfactory or unsatisfactory, while the WCABP system adds another category called questionable for bulls whose values are slightly below the set threshold. As a result, in the WCABP system there are four possible overall classifications for bulls, ranging from satisfactory, questionable, decision deferred, or unsatisfactory breeders. The decision deferred classification is used for bulls that are expected to show a substantial improvement in semen quality before the breeding season, thereby warranting a re-evaluation within several weeks [18].

The UK

The use of BBSE procedures in the UK is a relatively recent development, with the use of formal reporting and certificates commencing in 2009 [19]. Oversight of the standards is provided by the British Cattle Veterinary Association (BCVA) and in general they follow the SFT guidelines, with some influence from the ACV and South African systems. An important distinction with the UK system is that in contrast to other systems that call the process a Breeding Soundness Evaluation, the BCVA considers it more prudent to describe the process as a Pre-Breeding Examination (PBE) [20]. Removal of the word "soundness" presumably reduces legal liabilities within the UK. Like the South African system described later in this chapter, the UK PBE certificates are provided in carbon-copy pads with assessment standards detailed on the reverse of the form. The certificates provide options for selecting one of three reasons for performing the examination, either pre-sale, pre-breeding, or insurance. The main categories assessed are divided into: Physical examination; Semen examination; and Assessment of mating ability. As with other systems, the bull can receive a classification without the mating ability test being performed. Similar to the South African system, the UK PBE certificate requires the bull to be classified as either Suitable or Unsuitable for Breeding. Within the Suitable for Breeding category, the veterinarian identifies whether an assessment of mating ability was performed or whether the classification was based solely on the physical and semen evaluations. While there is no opportunity to place bulls in a "questionable" or "deferred" category, the system encourages the use of the comments section to provide further information and prognoses for bulls not meeting the standards.

The Netherlands

In the Netherlands, BBSE procedures closely follow those described by the SFT [21]. The reason for mentioning the BBSE procedures used in this region is to highlight the emphasis placed on consistently diluting semen in order to gain an accurate individual motility assessment. Bulls can fail a BBSE based on a poor individual motility assessment, and poor semen handling or an inability to clearly visualize individual sperm can adversely affect the result. In the Netherlands, a routine 1 : 80 dilution of semen with physiological saline warmed to 37 °C prior to individual motility assessment is described. In the absence of direct concentration estimates, such a process will result in

diluted concentrations of 2.5×10^6 to 13×10^6 cells/ml in the assessment sample. Concentrations such as this allow clear visualization of individual spermatozoa. This process is relatively easily performed in the field by adding 790 µl of warmed saline or PBS to 10 µl of semen.

South Africa

The Livestock Health and Production Group of the South African Veterinary Association took the initiative to standardize BBSE within South Africa [22]. As was the case in other regions, this group recognized that advances in knowledge in BBSE had led to variation in what services were being offered by veterinarians. Such variation was identified as a source of dissatisfaction to clients and practitioners, with both groups experiencing inconsistency in the costs and outcomes of bull examinations [22]. This group proceeded to produce a paper-based recording and reporting system for BBSE utilizing evidence-based standards for the selected parameters.

In this system, the veterinarian, in consultation with the client, has the option of selecting the purpose of the examination as either:

A) A natural service sire for sale or owner use
B) A donor of semen for sale
C) An examination for insurance purposes.

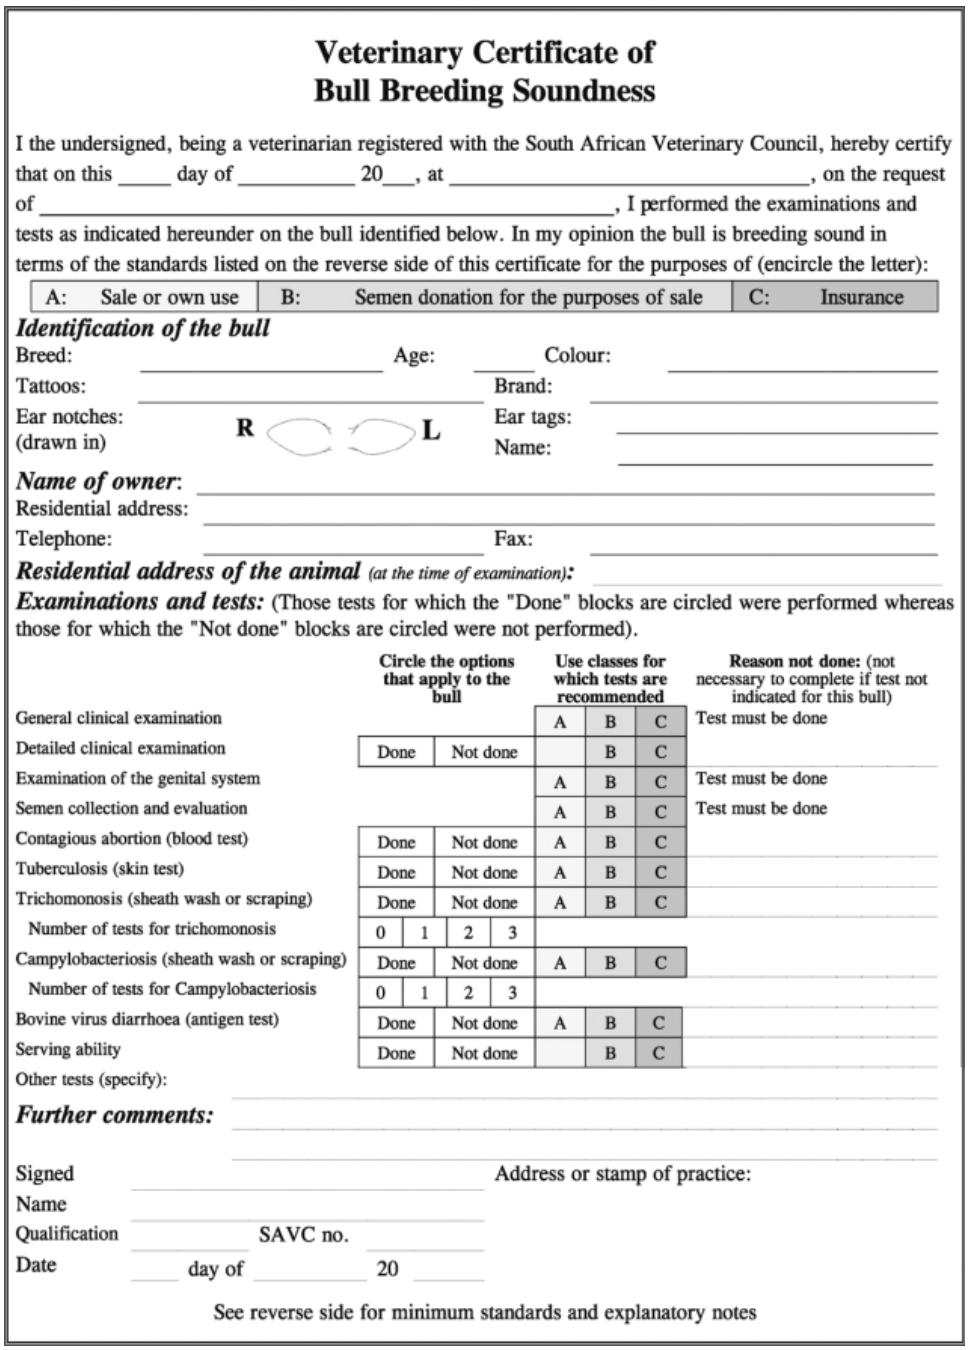
There are compulsory aspects of the testing, which include:

1) A general clinical examination
2) Physical examination of the genital system
3) Semen collection and evaluation

Other procedures such as disease testing are optional and depend on conversations between the veterinarian, the client, or the insurance company.

The certificate record (Figure 7.5) provides a list of the recommended examinations and tests for the bull. The veterinarian is required to circle on the certificate which testing was performed and to circle the purpose for which it was performed as noted in items A, B, or C above. Certificates are available in book form, with a carbon copy, which remains in the book. The reverse of the form (Figure 7.6) provides the standards for each parameter and explanatory notes, similar to the Australian system.

A unique aspect of the South African system is that certificates are only issued if the bull meets the BBSE standards and is classified as breeding sound. Other than the provision of space for some qualifying comments, there is no facility on the certificate to classify the bull any other way. Therefore bulls are effectively classified as suitable or unsuitable for breeding. Accordingly, the first component of the certificate is a declaration by the veterinarian that the bull complies with the minimum standards set for BBSE examinations for the selected purpose.



Another unique aspect of this system is that no actual parameters are indicated on the document. The reasoning for this is that the evaluation is designed to provide a yes/no answer to whether the bull is "Breeding Sound" at the time of evaluation. The system acknowledges the risk of artifact affecting the result for many of the parameters when different veterinarians assess bulls in varied field situations. Removing quantitative data from the form is seen as a method of removing inappropriate comparisons between bulls. Therefore if a bull meets or exceeds the parameter standards, the actual number is considered irrelevant. This paradigm contrasts with other systems that aim to both answer the "Breeding Sound" question and provide quantitative data in a way that might assist with genetic selection for improved fertility.

While there is no suggestion of an accreditation process for South African veterinarians to utilize the certificates, there is inference that undergraduate training and routine continuing professional education are adequate to maintain the integrity of the system.

BBSE – How the Categories Compare Internationally

The General Physical Examination

All BBSE standards recommend performing a general physical examination as a compulsory part of the process. There is minor variation regarding the scope of the examination, but in general it consists of an overall visual inspection for abnormalities and conformation, assessment of body condition score, examination of eyes, bite, legs/hooves, and gait assessment. In most systems, there is a general implication that the process be streamlined for efficiency. However, the UK system specifically requires auscultation of the heart and thorax in order to complete the BCVA certificate. If abnormalities are detected, all systems provide for a more detailed physical examination either by using written comments or by selecting further options within the available software. Yet, in all systems, there was either minimal guidance or ambiguity surrounding the decision-making process when conformational and possibly heritable abnormalities were detected. For example, conditions that can have varied degrees of severity such as interdigital fibromas, joint effusion in the hocks, sickle hocks, post-leggedness, and scissor-claw were all mentioned as possible reasons for bulls failing the evaluation. To guide clinicians in these instances, the UK and South

Veterinary Certificate of Bull Breeding Soundness

Figure 7.5 The standard veterinary BBSE certificate used in South Africa.

African systems provide brief instruction on the back of the certificates, but leave the assessment of severity and final classification to be based on the clinical judgment of the attending veterinarian. Similarly, while the SFT manual provides detailed descriptions of many of the abnormalities that will be encountered, clear guidance on when to pass or fail the bull is lacking. For many of the conditions, the Australian system provides descriptions and, in some instances, scoring templates to assist classification. Yet, commonly the advice simply states that "severe" cases should not pass, leaving it up to the veterinarian to determine what is severe and what is acceptable. This situation may result in enough variation in the results to adversely affect the integrity of the process in the eyes of some producers.

In reviewing the processes of the general physical examination and the possibilities for variation in interpretation of the information both within and between systems, the question is raised of whether it is the role of the BBSE process to fail a bull based on the possibility it may have a

Explanatory Notes and Minimum Standards

Definition

A bull is certified as breeding sound if it passes a specified battery of tests relating to reproductive well-being. The extent of the list of tests and, hence, the scope of a breeding soundness certificate may vary, depending on the need. A breeding soundness certificate does not guarantee fertility or the absence of risk of transmitting ill-effects to herds the bull is used on, but it suggests a reduced risk due to certain causes.

Bulls for which a breeding soundness certificate is not issued are not necessarily infertile, of low fertility or pose a risk of transmitting ill-effects to herds they are used on. It is not essential to have a breeding soundness certificate in order to use, buy, sell or insure a bull but the associated risk is carried by the user and (or) seller and (or) buyer and (or) insurer.

Clinical examination

A **general clinical examination** must be done in all cases. It is accepted to consist of visual inspection of general health status, condition score (2-3½ out of 5 acceptable), eyes, bite, legs, gait, and conformational defects. A **detailed clinical examination** includes assessment of the digestive, respiratory, circulatory, and locomotory systems and integument in addition to the above.

Examination of genital system

Must be done in all cases.

Sheath: Inspect and palpate. Should not hang lower than the line from the knee to the hock

Penis: Palpate the whole penis from the S-bend distally. Attempt to extrude and visualise during semen collection. If the penis was not seen with a full, normal erection this should be indicated under "Comments".

Scrotal circumference:
Minimum standards according to breed and age (months)

Breed	18 m.	21 m.	24 m.
Bos taurus	32cm	33cm	34cm
Zebu (Brahman)		32cm	32cm
Synthetic Bos taurus x Bos indicus		32cm	33cm
Indigenous			32cm

Alternatively, breed minima may be applied where available, providing they exceed these guidelines.

Testes: Mobile, symmetrical, firm, elastic, with no palpable irregularities. Rotation and slightly uneven height acceptable unless specified by breed society.

Epididymides: Symmetrical, even consistency, normal size throughout.

Scrotum: Neck and scrotal skin normal, testes mobile, ventral cleft ≤3cm.

Internal genital organs: No palpable abnormalities of ampullae, prostate, vesicular glands and pelvic urethra.

Semen evaluation

All of the following evaluations should be done in all cases:

Volume: Only reliable if collected by artificial vagina, but should be recorded in all cases

Colour: White, ivory or yellow

Consistency: Classified as follows:

Description	Approximate sperm concentration
Thick creamy	2,5 x10^9/ml
Creamy	1,75 x10^9/ml
Thin creamy	1,0 x10^9/ml
Milky	0,5 x10^9/ml
Watery	0,2 x10^9/ml

Minimum standard: Milky or thicker

pH: 6,2 – 7,4

Mass motility: Scored as follows:

0 No motility
1 Few motile sperm, < 10% alive
2 Many motile but no wave motion
3 Slow waves visible
4 Well-defined, strong waves with rounded turns, reaching periphery
5 Waves as for 4, but with a whiplash effect

Minimum standard: ≥2 out of 5

Individual sperm motility: ≥70% linear motile

Foreign cells: High numbers of spermatogenic cells are unacceptable. Leukocytes and bacteria are unacceptable if there are indications that they do not originate from the preputial cavity.

Morphology: ≥75% normal sperm with no indication of a progressive disorder of the reproductive tract or known heritable morphological defect.

Contagious abortion and Tuberculosis:

In cases where the herd is known by the practitioner to be negative for contagious abortion and tuberculosis, this status has been confirmed at a recent herd test, and the herd is closed, this is acceptable justification for not retesting each animal.

Trichomonosis and Campylobacteriosis:

Currently available tests are only 75-90% sensitive. Three tests are therefore necessary to certify an animal free of these diseases with a high degree of certainty. Practical implications may preclude complete testing of all animals.

Serving ability

This test is required for animals in use classes B and C and recommended for category A. A healthy female in oestrus or restrained in service stocks is required. The bull's reaction time and ability to mount, achieve intromission and to thrust are assessed. Covering should be achieved within 5 minutes in experienced bulls, and within 10 minutes in young bulls. Longer periods may be allowed for *Bos indicus* bulls.

Other examinations or tests

Optional additional tests include a serving capacity test, tests for other infectious diseases such as leptospirosis, tests for genetic defects and additional tests that an insurer may require.

General recommendations

This certificate indicates the status of the animal at the time of examination. However, arrangements for examinations should be made a month before the certificate is required to allow for the complete evaluation of all bulls.

The user must observe the bull for breeding activity and serving ability at the beginning of the breeding season.

In the case of purchase of a bull, show this certificate to the local veterinarian and consult him/her regarding further actions which should be taken prior to use of the bull.

Copies of certificates, records and smears are retained by the veterinarian for a minimum of three years.

Figure 7.6 Explanatory notes accompanying the South African BBSE certificate.

defect that may affect it at some stage in the future. It may be prudent to cull such a bull if it is to sire seed-stock, but not so relevant for a bull entering a commercial herd. Consequently, there is a need for all parties to be clear on why the evaluation is being performed, and also to have the option to vary the examination so it is relevant to the managerial context.

The Reproductive Physical Examination

All BBSE standards recommend performing a physical reproductive examination. There is general agreement across the regions that it should involve the following:

1) Transrectal palpation of the accessory sex glands, with emphasis on assessing the vesicular glands.

2) Examination of the sheath, with some standards providing the non-compulsory option of assigning a sheath score.
3) Palpation or ideally visualization of the penis.
4) Palpation of the scrotum and assessment of the scrotal cleft.
5) Palpation of the testes, epididymides, and scrotal cords.
6) Measurement of SC.

Transrectal palpation of the accessory sex glands is a compulsory part of the BBSE in all regions evaluated. While all structures are evaluated, the clear emphasis is on assessing the vesicular glands, as they most commonly have pathology and their condition is considered to reflect pathology that may be present in other parts of the tubular tract. None of the standards provided clear guidelines on what level of pathology of the seminal vesicles would result in the requirement for reassessment or a fail. The general implication from all regions was that the presence of any of the following would mean the bull would not meet the requirements for the reproductive physical examination: palpable, acute infection; a high concentration of neutrophils in the semen; or enlarged seminal vesicles in conjunction with sperm morphology defects consistent with inflammatory changes to the tubular tract. One area that was not clear in some of the guidelines was what was meant by a "high concentration of neutrophils."

Evaluation of the sheath is recognized as a compulsory part of a BBSE and bull selection in all regions except the BCVA [10, 22–26]. In most regions, failure of the bull in this aspect is based on the veterinarian's opinion of the presence of pathology. In the ACV and SFT systems, a non-compulsory scoring system is utilized to assist veterinarians with pass/fail and genetic selection decisions, but the provision of a sheath score is not considered an essential aspect of the BBSE in any region. The ACV sheath-scoring system has developed over the past 20 years, with current recommendations providing a score on a scale of one to five. Where a score of one represents a small sheath and five represents a large pendulous sheath [23]. There is a plan to upgrade the ACV scoring system [27], but there is still conjecture regarding the relevance of including factors in the scoring system such as the presence of preputial eversion.

There was no variation in the regional recommendations for the assessment and interpretation of penile defects. All standards recommended visualization of the penis during the assessment. Visualization was ideally at electroejaculation or natural service but could at a minimum be during rectal massage. The South African and ACV systems provide the option of providing a BBSE report with accompanying comments in situations where the penis can only be palpated through the sheath. But the SFT system does not allow a classification of the bull as Satisfactory unless the penis has been visualized.

Scrotal Circumference Measurement

All systems agree that the measurement of SC is a compulsory requirement of the BBSE. Additionally, the systems that provide manuals or accreditation programs (ACV and the SFT) emphasize the importance of correct technique when performing the procedure and provide detailed information on how to obtain reliable measurements. They also highlight the need for adequate practical training to master the skill necessary to obtain repeatable measurements.

The interpretation of the SC measurement varies between regions. The traditional interpretation is based on SFT guidelines, where SC standards are based on bull age, with minimal consideration for breed, body condition, or weight. This is the case for the SFT, South Africa, BCVA, and Canadians utilizing the SFT system. The ACV and WCABP systems introduce more complexity in the interpretation, considering more breed and age categories. An example of how the WCABP system differs from the SFT system is that later maturing breeds such as Limousin, Salers, and Blonde d'Aquitaine have a lower SC threshold of 32 cm at 24 months of age compared to the 34-cm threshold in the SFT, South African, and BCVA systems. The ACV system also considers body weight at the time of SC measurement, recognizing the effect body weight and body condition have on SC [23]. On this point, the ACV system was unique in that for young sale bulls it emphasized the need to interpret SC measurements considering the relationships between breed, age, and weight. In the ACV manual, there is a detailed table providing this information for five breed-groups of bulls ranging in age from 12 to 27 months. Consistent with the ACV system moving away from a Pass/Fail approach and more toward a risk assessment paradigm, the SC is simply noted on the top of the report (Figure 7.2), with the veterinary interpretation included in the comments section of the report. The information can still be used by breeders to apply selection pressure, but a low reading does not necessarily result in a fail in that category and the bull may still be suitable for sale for use in a commercial herd if semen assessment and other evaluations meet the standards.

Perhaps the most influence these variations in SC interpretation have on the outcome of the BBSE can be attributed to whether the information is used for a direct assessment of whether the bull is ready to join the breeding herd on a given date or whether the information is being used to leverage fertility selection pressure. In this context, a direct measurement regardless of age, weight, or breed

would provide useful information on whether a bull is mature and suitable to be introduced into the breeding herd on a given date. In contrast, if information is to be used to generate accurate selection data, variably referred to as estimated breeding valuations (EBVs) or expected progeny differences (EPDs), then interpretation based on weight, age, and breed become important.

These variations on how the SC information can be used leads to the need to be clear on the purpose for which the BBSE is being performed. The argument could be made that the primary purpose of the BBSE is to determine if an individual bull is suitable for purpose on a specific date. In this instance, a one-off SC measurement close to the time of entering the breeding herd may be suitable. Conversely, the question is raised of whether it is the role of the veterinarian to fail a bull that is producing semen of acceptable quality if the SC measurement, often taken without important context such as accurate age, breed, weight, and body condition score information, doesn't meet the threshold.

Bull-Side Semen Evaluation

All standards recommend the collection of semen as part of the routine BBSE. However, not all standards explicitly state semen evaluation as a compulsory element of the examination. The ACV standards provide for the option of no semen evaluation, but mandate the compulsory reporting on their certificates of whether semen assessment is included in the evaluation.

For most regions, there was the option for assessment of gross motility (mass activity), apparently based on tradition. But in regions where standards were accompanied by a manual, practitioners were cautioned against using this parameter as part of the BBSE. Notably, the SFT no longer recommends the use of gross motility as part of the semen assessment process and has now removed it from the BBSE form.

All regions recommend assessing individual motility as a compulsory aspect of the BBSE. In regions where manuals are available there is clear recognition that individual motility is readily affected by artifact. To counteract this, detailed procedural guidelines are provided including the requirement for clean, warmed contact surfaces, the use of a binocular microscope, and the recommendation to dilute the semen to ensure the activity of individual cells can be readily assessed. Two of the four regions recommending semen dilution prior to motility assessment provide explicit guidelines for this dilution process, where semen is recommended to be diluted to turbid consistency (between 60 and 200 million/ml) with warmed phosphate buffered saline to ensure repeatable estimates [16, 23]. In the Netherlands, the recommendation is for a 1 : 80 dilution of semen to diluent, providing sperm concentrations of less than 20×10^6 for assessment.

Variation exists in the interpretation of the individual motility assessment. The South African system has the toughest standard, requiring individual motility to be greater than 70%. The ACV, BCVA, and WCABP systems don't consider that the bull meets the requirements for this standard unless it is greater than 60% motile. But the ACV system also accepts that although semen quality may not be suitable for freezing, bulls used solely for natural mating can have commercially acceptable fertility if the motility is greater than 30%. The ACV system therefore allows a "qualified" rating for this standard for individual motility scores between 30 and 60%. The SFT lower threshold for individual motility has been 30% since the first iteration of its BBSE system in the 1970s. This figure recognizes the need to confirm there are motile spermatozoa, but also recognizes that assessments are made in varied field conditions that can adversely affect motility.

Laboratory Assessment of Semen

Semen Morphology

The standards from all regions recommend collection of semen and the assessment of sperm morphology when performing a BBSE. The South African, BCVA, and SFT standards explicitly state that bulls must exceed the morphology threshold of 70% normal spermatozoa to pass the examination and receive the respective certification. The ACV risk-assessment model explicitly provides for the option of no morphological evaluation but mandates the compulsory reporting on their certificates of whether morphology is included in the assessment. In this latter standard, options are provided for separating the semen evaluation into "bull-side" assessment (see section "General Concepts") and morphological assessment. If morphological assessment is performed in the ACV system, a count of 70% normal is required to meet the category requirements, but a "Qualified" assessment can be assigned to this category for bulls with normal sperm percentages between 50 and 69%, which is justified based on industry-specific research [25].

All regions other than the ACV recommended morphology be assessed with either a nigrosin-eosin stained slide or with a preserved, fixed sample under phase-contrast or differential interference contrast (DIC) microscopy. The ACV does not provide the option of nigrosin-eosin stained slides for morphology, instead recommending that bull-side samples be preserved in warmed fixative, such as formal buffered saline, or phosphate-buffered saline (PBS) glutaraldehyde for subsequent assessment.

There are definitive recommendations for the morphological classification of sperm in the SFT, ACV, and BCVA systems. In these systems sperm abnormalities are recorded as seen. There is no clear recommendation regarding morphology classification in the South African system, but the inference is a focus on assessing the number of normal spermatozoa, with abnormalities individually recorded. The conclusion is that morphology assessment for all regions has moved away from previous classification systems such as primary/secondary or major/minor abnormalities. There is still reference to the compensable/uncompensable classification method in the SFT and ACV manuals, with suggestion it may be suited to assessing sperm morphology in samples that will be inseminated, but not relevant to the BBSE process [10, 23].

One specific morphological defect that is the subject of varied opinion is that of distal cytoplasmic droplets (DDs). The SFT no longer considers DDs as having an adverse effect on fertility and counts them as normal (technically a variation of normal) in the spermiogram. The ACV had previously recommended counting DDs as normal sperm, but currently they are recorded as abnormal sperm. The ACV recommends that if the percentage of DDs is great enough to influence whether a bull meets the morphology standard, then the percentage of DDs, accompanied by an interpretation, should be clearly noted in the comments section for this category so that vendors and purchasers can make an informed decision.

The range of regulatory control over morphology assessment processes and efforts to standardize the procedure varies considerably between regions. The South African and BCVA systems simply state that morphology be performed as part of the evaluation, relying on veterinary undergraduate training and personal continuing professional development (CPD) to maintain integrity of the process and interpretation. The SFT provides a detailed manual on sperm morphology assessment and details current knowledge of the influence of morphology on bull fertility to assist practitioners with their interpretations. The ACV system also provides a manual with detailed morphological assessment and interpretative information. But uniquely, while any veterinarian may perform their own morphology assessments, the ACV strongly recommends samples be sent to an ACV endorsed andrology/morphology laboratory to ensure all bulls are assessed by a standard procedure under high-quality optics. The inference from the ACV recommendation is that current Australian undergraduate veterinary training and the quality of microscope optics in the clinical setting may not adequately equip veterinarians for performing repeatable and reproducible morphological evaluations that will stand up to commercial scrutiny. While this position is not necessarily relatable to other regions, it does raise the question of whether the assessment, recording, and reporting of sperm morphology should be subjected to quality assurance practices that are followed for many other laboratory processes. The commercial implication of aberrations in morphology assessment or interpretation is that the sale price of any bull failing to meet minimum standards for sperm morphology will be reduced or the real-world fertility may not reconcile with the anticipated fertility. It therefore seems reasonable for a producer to expect that standards are being applied in an equitable way regardless of the personnel performing the evaluation.

The Use of Vital Stains

In all systems except that of the ACV, the use of nigrosin-eosin staining is one of the recommendations for preparing samples for morphological examination. None of the regions recommends incorporating the Live/Dead aspect of vital staining into the BBSE assessment. The ACV does not recommend the use of vital stains for morphology assessment due to the recommendation of utilizing an endorsed morphologist for the assessment process. In this scenario, the morphologists unanimously prefer samples in fixative such as formal buffered saline (FBS) solution as this enhances the detection of defects under phase-contrast or DIC microscopy. There is also concern that the osmolality of the vital stain may vary widely if not stored carefully, adversely affecting sperm morphology.

White Blood Cells in Semen

The ACV and SFT manuals both describe the detrimental effects of white blood cells (WBCs) in the semen. The ACV suggests that if more than several WBCs are identified per high-power field or if purulent material is observed grossly in the ejaculate, the veterinarian should use clinical judgment regarding treatment and prognosis, with a Q or X applied to the category.

Discussion

While exploring the evolution of the BBSE throughout the world, it is apparent from all regions that variation in the early processes of assessment, interpretation, and reporting of results led to uncertainty in the outcomes of the testing. There was a perception from seed-stock producers and their veterinarians that bull sale opportunities may not be equitable if some bulls were placed under more or varied scrutiny compared to contemporaries. In most regions this variation was arguably the biggest driver toward a standardized BBSE procedure. Regardless of other reasons for performing a BBSE, the requirement for a process that

provides equitable comparison of all sale bulls is critical to the integrity of the BBSE. The understanding is that the primary driver to standardizing the approach to BBSE may not necessarily be the science behind the ideal of improving bull fertility, but more the necessity to make the collection and interpretation of data on which bulls are compared when presented for sale as equitable as possible. If this goal is not achieved, then the credibility of BBSE will be reduced to the point of it no longer being considered by producer bodies to be relevant.

When reviewing BBSE standards from different regions, most provide clear guidelines on what aspects are compulsory and what aspects are suggested recommendations. Ideally these compulsory and suggested processes can be tailored to different bull management scenarios. The South African and BCVA systems have addressed this requirement by stipulating "Use Classes" (Figure 7.5). On similar lines, the ACV system works on a risk assessment format where non-compulsory aspects of the testing can be included or removed depending on the management scenario or breed society requirement. While the SFT system doesn't explicitly provide the option for tailoring the evaluation, there is room to provide comments on options for bulls that fall into the decision-deferred category.

What is not so clear from the standards of different regions is the process of interpreting some aspects of the findings. This is not surprising, as cattle veterinarians are in the unenviable position of having to apply clinical judgment to the continuum of a biological system, while cattle producers are expecting clear "yes/no" answers. To assist with standardized interpretation and reporting it seems there are two requirements: (i) a standardized data recording and reporting system, which all regions provide; and (ii) CPD to ensure there are standardized data collection techniques and interpretation. While two of the regions have provided comprehensive manuals to assist with CPD, other regions appear more dependent on undergraduate training providing a sound knowledge base. Yet, with the knowledge surrounding BBSE constantly evolving, there is a need for experience and on-going training to attain and retain competency. For example, anecdote from the ACV suggests there can be 2- to 5-cm differences in the SC measurements between experienced and inexperienced operators. Similarly, there can be confusion and variable recommendations when conditions such as hocks with joint effusion, interdigital fibromas, aberrations in leg conformation, or neutrophils in the semen are encountered. Assessing extremes in these conditions is not difficult, but standardizing the interpretation of mild to moderate presentations appears less straight-forward. One way to reduce this variation is to provide supervised training, recurrent updates, and where relevant, abnormality scales with exemplars.

For the BBSE to maintain integrity, it is essential that producers have a clear understanding of what to expect when they have their bull assessed. The corollary to having a clear process to follow is that veterinarians will need ready access to CPD in order to maintain currency in the process. The SFT in the USA has taken the lead in the CPD area for close to 50 years, as evidenced in their current and prior manuals for the breeding soundness evaluation of bulls [10]. But perhaps the most extreme evolution of CPD identified in this review is the BBSE Accreditation scheme developed by the ACV in Australia. This scheme provides veterinarians with the opportunity to submit themselves for compulsory postgraduate education and assessment in order to receive accreditation. The accreditation provides them with the commercial advantage of marketing themselves as having industry-recognized skills and competency in the BBSE process.

For credibility of the BBSE process to be maintained, the following points seem important:

1) The system must have standardized data collection processes.
2) There must be standardized data interpretation.
3) There must be standardized reports to allow the end users to easily interpret the findings in order to compare bulls.
4) It seems suitable to move away from a system that places veterinarians in the position of having to "pass" or "fail" bulls using a system that is based on incomplete science – particularly when there is limited opportunity for a detailed assessment and there is incomplete understanding of all factors affecting future fertility. To this end, using a reporting system that simply states the findings for each category and allows for interpretive comments may be a good option.
5) There must be continuing professional education in the processes of BBSE for veterinarians so that producers have confidence in the outcome for their bull.
6) Consideration should be given to an accreditation program for veterinarians performing these procedures. This point is particularly important considering the profound influence outcomes from these evaluations can have on the financial viability of seed-stock producers.

Considering points 5 and 6, the three parameters that commonly concern bull producers are the measurement of SC, the individual motility percentage, and the assessment of sperm morphology. Effective, worldwide extension surrounding the influence of these three parameters on bull fertility means that poor results can lead to a bull not passing the BBSE and either not being able to be sold through normal channels or having a reduced sale price. Alternatively, the bull may have a reduced sale price even if the result meets fertility standards but is lower than contemporaries.

Due to the physiologic and economic importance of these parameters and their highly visible nature to producers, it is essential that veterinarians are adequately trained in these techniques to provide consistent results.

A summary of notable variations in the bull evaluation processes from different regions that may help inform future iterations include:

- Removal of the word "soundness" from the description of the process.
- Provision of opportunities to tailor the evaluation process based on varied managerial contexts.
- Consideration to moving away from a "Pass/Fail" concept to a risk assessment paradigm.
- The provision of more robust guidelines and abnormality scales for interpreting some of the findings.
- Consideration of increasing the opportunities for veterinarians to gain and maintain competence in the processes, which may or may not include an accreditation program.
- Consideration of a quality assurance program for morphology assessment that may, in part, include all veterinarians and morphologists registered with respective regulatory bodies receiving QA samples for evaluation on a regular basis.

Evaluation of Breeding Soundness: The Physical Examination

Mike Thompson[1] *and James Alexander*[2]

[1] *Willow Bend Animal Clinic, Holly Springs, MS, USA*
[2] *Alexander Veterinary Services, Bentonia, MS, USA*

Introduction

When a bull breeding soundness examination (BBSE) is performed for the purpose of evaluating a bull's potential to breed in a natural service situation, the physical component takes on paramount significance. In fact, as soon as any physical abnormality that would impede natural service is observed, or the bull does not meet the minimum standards for scrotal circumference (SC), the examination need not proceed to evaluation of semen characteristics. Thus, goals of the physical examination portion of a BBSE are the identification of undesirable genetic traits, structural or physical impediments to breeding, and pathology of the reproductive tract. Even though it is common for inadequacies to exist in this area of the BBSE, it is often ignored or rushed through without attention to detail or in a consistent systematic manner. Therefore it is of utmost importance that the physical examination be done using a consistent protocol. Additionally, the SC, which is an indirect metric for testicle size and thus sperm production potential, must be measured and meet minimum standards.

History

The history can be addressed prior to or during the physical examination. The history can provide the examiner with insight into genetics, condition, management, vaccination, any disease testing programs, and history of disease in the herd. The breed or breed composition should be obtained to help establish what genetic abnormalities or which conformation traits, maturity rates, and age of puberty may be common to that breed. The ration fed previously and at present should be established as well as the level of each ingredient in the rations and the poundage fed to each bull. The veterinarian needs to determine what body condition scores were attained at different stages of development. Management practices should be established with regard to large or small group facilities, parasite control, pasture or dry lot, through space, and water availability. These management practices can influence the level of foot problems and increased incidence of diseases such as vesiculitis. The herd vaccination program should be ascertained, if for no other reason than for buyer information. Information on disease control programs should be established for buyer information and the reason for those programs. The history of disease in the herd may explain the results of the BBSE examination and again be useful information to the herd owner and/or buyer.

Basic Physical Examination

For a bull to survive and function as a natural service sire (pasture or range environment), he must be able to walk, eat, see, and bear weight on his back legs. Thus, a basic examination should begin with a history, examination at a distance, and an assessment of a bull's conformation, gait, and overall appearance.

Examination at a Distance

If possible, the bulls should be observed from the fence of the holding pen while they are standing quietly. This is a good time to observe their conformation, and overall appearance. Bull identification numbers are collected for those that will need closer examination for any problems that may be seen. Move through the bulls slowly while noting any other problems. This is a good time to observe each bull's gait, possible foot issues, sight deficiencies, and bilateral symmetry. If they are being unloaded at a veterinary

Companion website: www.wiley.com/go/hopper/bovine

facility for BBSE, watch them as they are being unloaded as stepping off a trailer can exacerbate lameness signs that you can check more closely. The absence of bilateral symmetry is the examiner's guide to areas of potential abnormalities.

Conformation

Selection for conformation has been influenced by judges for show purposes and is not always the conformation most desirable for durability of the bull in a pasture or range environment. Because a bull is required to cover large areas and mount and lunge multiple times in a single day, feet and legs are often the trait that determines his ability to service cattle and his longevity as a sire. Hoof and hock abnormalities lead to lameness, which affects his ability to accomplish this purpose, as well as lowering sperm quality. Screw claw, chronic laminitis, and interdigital fibromas are common. The incidence of screw claw (Figure 8.1) appears to be increasing in beef breeds and is considered heritable by the American Association of Bovine Practitioners Lameness Committee [1]. Moving up the legs, stifle and hock injuries such as collateral ligament rupture, meniscal injuries, and anterior cruciate ligament (ACL) rupture should all be investigated as they will interfere with copulation and fertility [2]. Less common and sometimes more difficult to diagnose are shoulder injuries and spinal injuries or disease [2]. These abnormalities should be recorded in the feet and legs section of the BBSE form. Defects that may be inherited should be listed in the comment block with a statement that recommends use in a terminal cross only. Research has shown that animals with shorter hoof length and greater dorsal hoof angle develop less hoof lameness [3]. Dorsal hoof angles of 50 and 55° in the rear and front hooves, respectively, appear to be the more desirable. The angle of the hock should be between 155 and 170° – this being based on information derived from the Conformation Determination System (CDS), which was a method of relating hock angles of dairy heifers with other anatomical landmarks and then correlating those metrics with the incidence of future unsoundness [4].

Examination Close Up

Once the bull enters the chute, the examination should begin with the head. The areas on and around the eyes should be examined for squamous cell carcinomas, corneal damage, and lymphomas. The nasal passages are checked for even and equal air flow, the oral cavity is examined for abnormalities, and the age of the bull is confirmed by checking the dentition (Figure 8.2). This is also a good vantage from which to observe the front feet for interdigital fibromas and the screw claw abnormality.

Examination of the Reproductive System

Scrotum and Testicles

The scrotum, testes, and spermatic cord should be examined carefully for fluid, fibrotic tissue, size, symmetry, shape, and texture. The scrotum should be examined for scars and its ability to extend or stretch to allow the testicles to cool. The testes should be palpated and have the texture of meat and be freely moveable within the scrotum. Any fibrotic or swollen areas should be noted. The epididymides should be palpated from the head dorsally, down the body,

Figure 8.1 A three-year-old Angus bull that exhibits the screw claw abnormality. This bull will require annual hoof trimming to remain sound.

Figure 8.2 Examination of the oral cavity and dentition to assess aging.

ventrally to the tail, for abnormalities such as epididymitis or fibrosis. The spermatic cord is palpated from the external inguinal ring distal to the testicle for abnormalities such as hernias, hematomas, fibrosis, or fluid. The external prepuce should be observed and palpated for abscesses and swellings, as well as hematoma of the penis directly anterior to the scrotum. Problems identified during scrotal examination can include scrotal skin lesions such as frostbite, dermatitis, scrotal edema, and blood warts. There are several normal variations of scrotal shape and testicular positioning within the scrotum. Thus, the presence of hydroceles and hematoceles as well as inguinal hernias must be ruled out in bulls with aberrances in scrotal size and shape [2, 5].

Ancillary testing utilizing ultrasound or thermography, although usually not necessary to classify a bull by the SFT standards, can be useful to further investigate abnormalities discovered during the physical examination [2].

Internal Reproductive Genitalia

A transrectal examination is utilized to evaluate the internal reproductive genitalia and can be aided or enhanced with the use of ultrasound. Each of the secondary sex organs should be carefully identified and palpated for any changes from the norm. The urethralis muscle is the first to be encountered and should be palpated for abscesses and tumors. As you palpate forward, the prostate and seminal vesicles (vesicular glands) are encountered. Palpation of both vesicular glands should begin at the bifurcation with the vesicle surrounded by the hand as it is palpated toward and to each distal endpoint. Texture, size, the presence of heat or pain, and distinction of the lobulations should be noted. Vesicular adenitis is one of the most common abnormalities suggested by the internal reproductive examination. Evidence of previous infection or injuries to the seminal vesicles can also be diagnosed by the presence of fibrosis and adhesions. Approaches to the diagnosis and treatment of vesicular adenitis are discussed in Chapter 14. The paired ampullae should be examined next for abnormalities as well as gently massaged to aid in semen collection. The examiner should use the transrectal examination as an opportunity to palpate the internal inguinal rings for size and the presence of hernias. The caudal abdomen should also be palpated for the presence of enlarged lymph nodes that could be suggestive of infection or neoplasia [5].

Penis and Internal Prepuce

The penis has already been palpated during the examination of the external prepuce but must be carefully examined and palpated while extended during the collection stage of the BBSE. Problems such as warts, hair rings, lacerations, and persistent frenulum will be discovered at this point. The internal prepuce presents itself for thorough examination during erection, allowing the opportunity to observe lacerations, warts, and fibrotic areas from old injuries that may cause deviations of the penis preventing coitus. The necessity of completely extending the penis at some point of the examination cannot be overemphasized as the previously mentioned conditions will be missed if this is not done. In-depth coverage of urogenital injuries and their diagnosis, management, and correction are covered in Chapters 15, 18, and 19.

Example of an Examination Protocol

The examination begins with a history and examination at a distance. Evaluate conformation and be certain to record observations and identification of those bulls that have issues. Watching each bull approach the chute is a good time to observe the gait of the bull and overall appearance. Once in the chute, the bull's identification (tag, tattoo, or brand ID), eyes, head, and front claws are observed and observations recorded [6]. From the side of the bull, the testicles are palpated and SC measured (Figure 8.3), the prepuce is palpated for abnormalities, and the hind feet are observed. At this point the scrotal measurement and any observations are recorded. The rear of the bull is then approached and the back, hind legs, and especially the hock joints are observed and/or palpated. Transrectal palpation is then performed, again using a constant sequence. In the pelvic area, the urethralis muscle is followed forward to the seminal vesicles, which are palpated and massaged,

Figure 8.3 The correct way to measure SC. The testes are pushed toward the bottom of the scrotum and the scrotal tape is placed at the widest area. The scrotal tape should be pulled tightly.

Figure 8.4 Transrectal palpation to evaluate the internal reproductive tract and prepare the bull for electroejaculation.

the fornix of the seminal vesicles is located, and the ampullae are palpated and massaged, as are the inguinal rings, pelvic lymph nodes, the kidney, and any viscera within reach. The ampullae and the seminal vesicles are then massaged again. The urethralis muscle and the prostate are identified and massaged while progressing toward the anus. In addition to identifying abnormalities or eliciting a painful response, which may indicate a problem, palpation and massage serves to stimulate the bull and facilitate ejaculation (Figure 8.4). Thereafter, the electroejaculator is placed on the standard program and the probe is inserted into the rectum. At this point any observation or abnormalities from palpation are recorded. As erection and protrusion occur, the internal prepuce and the penis are examined by observation and palpation for abnormalities. After microscopic examination of the semen has been done, the bull is then released from the chute. The bull is observed leaving the chute and the chute area for lameness. It is of utmost importance that a standard protocol be developed to ensure that all areas of the physical examination and SC are checked and recorded [2, 5].

Scrotal Circumference

The SC measurement is obtained while doing the general and reproductive examination [6]. It can be obtained from the side or the rear, depending on preference, facilities, and the bull's temperament. After gently forcing both testes to the bottom of the scrotum, the primary considerations are to avoid spreading the testes apart and to ensure sufficient pressure that the top surface of the measuring tape is level with the skin (Figure 8.3). Record the measurement at this point. If the circumference is below the minimum requirement, there is no need to continue the examination. Young bulls or emaciated bulls may receive a deferred classification in some cases. The SFT minimum thresholds [7] for SC are listed below:

- 30 cm at <15 months
- 31 cm at >15 to ≤18 months
- 32 cm at >18 to ≤21 months
- 33 cm at >21 to ≤24 months
- 34 cm at >24 months.

Evaluation of Breeding Soundness: The Spermiogram

Colin W. Palmer

Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, SK, Canada

Introduction

The cost of purchasing and maintaining a bull is substantial yet is easily overshadowed when a group of cycling female cattle fail to become pregnant and a complete calf crop is lost. Fortunately, this worst case scenario is a relatively rare occurrence but can have financial implications on a par with any unforeseen natural disaster. Especially in single-sire breeding systems, this should be reason enough to have a breeding soundness evaluation prior to every breeding season; however, the most costly losses associated with poor fertility are much more insidious. Profit margins in the cow-calf sector continue to shrink; therefore all producers must look for ways to improve productivity. In well-managed herds, it is expected that 95% of the breeding females will become pregnant in a 60-day breeding season, with 65% pregnant during the first 21 days. Anything less than this may be considered subfertility. Most mature beef bulls are expected to successfully mate with at least 25 cows, with lower ratios of one bull to 30, 35, and even 40 or more being used in an effort to improve efficiency while capitalizing on superior genetics. To achieve these goals, bulls must meet a set of standards below which subfertility is likely to occur.

The Society for Theriogenology (SFT) has developed a set of standards for bull breeding soundness examination (BBSE) based on available scientific data combined with input from veterinary practitioners. The SFT standards, including how the breeding potential of the bull is classified, differ almost unnoticeably from the standards adopted in other countries [1, 2]. The intent of this chapter is to provide an overview of the semen collection and evaluation in the bull. For a more indepth review, readers are encouraged to access a breeding soundness examination manual identified in the references and to review other chapters in this textbook.

Utilizing the SFT classification system, following a BBSE the animal may be classified as (i) a Satisfactory Potential Breeder, also known as "Passing" the BBSE; (ii) Classification Deferred; or (iii) an Unsatisfactory Potential Breeder. The BBSE focuses on three major categories: (i) physical soundness; (ii) scrotal circumference; and (iii) semen quality. To be classified as a Satisfactory Potential Breeder a bull must meet the described standards for all of the categories. Exceeding the standard in one category does not supersede failing the standard in another [1].

The number-one reason bulls do not receive a satisfactory classification is because of semen quality, specifically, abnormal sperm morphology.

Semen Collection

Evaluating semen quality is an integral part of a BBSE. Electroejaculation (EEJ) has been a reliable method of obtaining a semen sample for many years. Alternatives to EEJ include using an artificial vagina (AV), transrectal massage (TM) of the accessory sex glands, and aspiration of semen from the vagina of a cow following a recent natural service. Compared to these other techniques, EEJ is fast and efficient, eliminating the need for mount animals, animal training, and specialized laboratory and animal handling equipment. Nearly anyone can be trained to use an electroejaculator, and in recent years automated machines that use a preprogrammed series of electrical stimulation have been developed, enabling even the most inexperienced individual to operate with confidence. The one significant disadvantage of EEJ,

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

however, is the widely held misperception that it is painful. Due to this its use has been forbidden in several countries. [3]

In the USA, EEJ is still widely used to collect semen from bulls for presale or prebreeding breeding soundness evaluations, but as is the case with many other previously accepted management practices, the potential discomfort of animals enduring these procedures is being increasingly scrutinized. At the core of the problem has been lack of widely disseminated critical knowledge to determine if EEJ is painful and to quantify the intensity of the pain. Certainly it was known that EEJ without anesthesia was painful for humans [4, 5]; therefore it must also be painful for bulls [3]. (Editor's note: see also [6].)

The first published report on the use of EEJ in domestic animals was in 1936 [7–9]. Rams were the first animals experimented with, and although attempts to electroejaculate most species of animals have been made, the technique has been most successful with rams and bulls [9]. Electroejaculators are designed to use AC or DC power and consist of a box containing a step-down transformer to reduce the source current and a variable transformer to enable the electrical stimulation to be modified [10]. Electrical stimulation must be carried to the pelvic nerves; specifically, the pudendal nerve, located near the prostate over the pelvic urethra responsible for erection; and the hemorrhoidal nerves, located in the area of the ampullae and seminal vesicles responsible for ejaculation [9]. To accomplish this task, a solid rectal probe at least 30 cm long and at least 6 cm in diameter containing bipolar electrodes is used. Rectal probes on early models consisted of alternating, bipolar electrode strips or rings capable of providing electrical stimulation over their entire circumference. This design resulted in unnecessary stimulation of the muscles of the hindquarters reportedly causing undue discomfort and temporary paralysis in some animals [11]. This led to the development of finger-electrodes in which bipolar rings were fitted to the index and middle fingers in such a way as to avoid them coming in contact with each other. This device enabled the operator to apply electrical stimulation specifically to the urethral muscles to cause erection, followed by stimulation of the seminal vesicles to achieve ejaculation [11]. A disadvantage of the finger-electrode system was that two persons were needed to coordinate semen collection because the principal operator was unable to see if erection had occurred and when stimulation should be moved to the seminal vesicles [9].

Most probes in use today have three longitudinal electrodes. Probes with the electrodes divided into three segments have also been developed and are referred to as segmented probes. There are three caudal electrodes, three middle and two at the cranial end, and each segment can be activated as needed. Much like the finger-electrodes, the intent of this probe design is to enable stimulation of specific areas with minimal stimulation of non-target tissue [12]. The caudal segment is used to achieve erection and then the middle segment is used to achieve ejaculation. In some bulls, the activation of the cranial segment may be required to cause ejaculation [12]. The segmented probe is no longer popular due, at least in part, to its being complicated to use. In comparison with a conventional rectal probe it was shown that it was much easier to obtain full penile protrusion using the conventional probe, but ultimately both probe types were equally effective for obtaining semen emission. In a study comparing the pain response associated with the use of a conventional three-electrode probe and the segmented probe for an equal number of stimulations, and with the segments activated according to the operator's manual, no differences in cortisol or progesterone release were detected [13]. Weighted probes and probes with two longitudinal electrodes are now available. The intent of these design changes is to target the appropriate nerves with as little stimulation of surrounding tissue as possible. No critical studies have been done comparing weighted and two-electrode probes to conventional (three-electrode, no additional weight) probes; however, the clinical impressions of the author are that they are at least as effective as conventional probes yet appear to be more comfortable for the bull.

Electroejaculator probes are inserted into the rectum with the electrodes oriented ventrally and rotation of the probe is prevented by a U-shaped tail cradle or yoke. The tail cradle helps to maintain the probe in the rectum, properly oriented with the electrodes down. Until the sequence of electrical stimulation is begun it is a good idea to hold the probe in place simply by pressing the tail into its relaxed position. Horizontal or vertically (upright) oriented yokes are available. Damage to the electrical cord connecting the probe to the electroejaculator is less likely with the upright yoke in the event that bull lies down during the collection procedure, whereas horizontal yokes invariably catch on

Figure 9.1 Lane Pulsator V and two-electrode probe with vertical yoke. *Source:* Courtesy of Lane Manufacturing, Inc.

the butt bar often at the electrical connection. Upright yokes are also easy to grasp, facilitating probe extraction. Figure 9.1 shows a Lane Pulsator V and the two-electrode probe with upright yoke.

Modern electroejaculators use a sine-wave pulse at a frequency of 20–30 cycles per second [14, 15]. Other wave forms and frequencies have been tried but have been proven less effective [14]. The maximum voltage of a very common electroejaculator in use today, the Lane Pulsator IV (Lane Manufacturing, Denver, CO, USA), is 16 with a maximum current of 900 mA [12]. With this machine, ejaculation occurs with electrical impulses less than 8 or 9 V [12]; however, some bulls, usually older bulls, may require more electrical intensity to elicit ejaculation.

Electroejaculation Technique

Before attempting to electroejaculate a bull ensure that the electroejaculator is in good working order. Electrical cords and connections are most likely to be the cause if the electroejaculator unit is functioning and the probe is in place yet the bull is not responding to stimulation. Always turn the electroejaculator off before making even the slightest adjustments to trouble-shoot electrical connections. A suddenly restored connection, even if the electrical intensity is relatively low, will unduly startle the bull. The rectal probe selected should be of sufficient diameter to enable full contact with the rectal mucosa, but not so large as to prevent its insertion. Usually, a probe with a diameter of 6.5–7.5 cm will suffice. Very large (>900 kg) or older animals may require a 9-cm probe to ensure contact with the rectal mucosa [16]; 6- to 6.5-cm yearling probes are available and are much easier to use on smaller bulls [17]. Bulls must be suitably restrained to prevent side–side and back–forth motion and should not be handled in such a way as to cause excitement. Overly excited animals tend to vocalize more during the procedure [18] and are more difficult to collect [16]. Cattle squeezes generally work very well for BBSE provided there is enough room for larger bulls to fit into them. Earlier models were designed mainly for use with cows and often are not long enough to accommodate a mature bull. A post, often referred to as a butt bar or kick post, placed horizontally across the chute immediately behind the bull will prevent the bull from moving backward or kicking the examiner. Ideally, the butt bar should be placed immediately behind the bull so that any kick action is softened, yet at a level that enables examination of the scrotum and testes. Modern hydraulic squeezes are the author's preferred system for examining bulls. Side–side pressure is infinitely variable and easy to apply, virtually eliminating any kicking. The side–side squeeze pressure and squeeze pressure on the neck must be relaxed prior to beginning the EEJ process. Failure to obtain a semen sample, bulls lying down in the chute, and poor quality ejaculates have all been caused by excessive squeeze pressure. Giving bulls room to move and to get their feet placed under them will go a long way toward shortening the duration of the EEJ procedure and yielding good quality samples.

A per rectum examination of the bull's ampullae, seminal vesicles, prostate, pelvic urethra, and inguinal rings should be conducted accompanied by a thorough clean-out of feces from the rectum. Massage of the pelvic urethra and accessory sex organs lasting 30–60 seconds will provide sexual simulation for the bull and relaxation of the anal sphincter to enable insertion of the probe. An elbow to wrist, back and forth rectal massage with immediate insertion of the probe following arm removal works best, coupled with the smallest probe that is still effective for the size of bull being collected. The smaller yearling probes have proven effective in at least 9 out of 10 mature bulls when matched with well-designed, late-model electroejaculators. Lubrication of the probe with palpation sleeve lube or even water will facilitate insertion and enhance contact with the rectal mucosa [16].

Electroejaculators available today are similar in function with features that appeal to a variety of users. Advances in electrical circuitry and battery technology have been adopted by manufacturers, resulting in enhanced portability without the need for a constant electrical supply. Machines available today may be used to electroejaculate over 100 bulls on a single charge (Bob Green, Lane Manufacturing Inc., personal communication). A significant innovation has been preprogrammed, automated EEJ sequences that increase electrical voltage in a step-wise fashion, bridging the gap between the art and science of collecting a bull. Manual control of voltage intensity is still available via a rheostat knob and step-wise control buttons, allowing the operator to use the machine according to personal preferences. Experience is a great teacher when collecting semen from bulls using EEJ. Effective stimulation sequences vary with the breed, age, size, temperament, handling system, weather, and individual animal. For the novice a great deal can be learned by using the preprogrammed sequences, then try to emulate a sequence using the manual controls. Learn to watch the response of the bull not the indicator systems on the machine. The initial application of electrical stimulation must be applied carefully while observing the response of the bull. The operator should increase the electrical intensity just enough to cause a slight contraction of the muscles of the hind limb. Thereafter, with each successive stimulation the intensity of the voltage should be increased slightly and should last 1–2 seconds followed by ½–1 second of rest until erection, then ejaculation occurs [12, 16]. Some bulls are more difficult to collect than others for a variety of reasons. Common

problems are inadequate contact between the probe and the rectal mucosa (excess feces, small probe, or a buildup of dried mucus or lube on the electrodes); insufficient voltage; bulls that have been recently used for breeding [16]; and excessive squeezing pressure on the neck or sides of the bull. Even when these potential problems are addressed, EEJ may still be unsuccessful with a small number of normal, fertile bulls.

Semen collection handles are useful for safely extending the operator's reach to obtain a sample. Disposable, single-use, funnel-shaped collection cones have largely replaced reusable latex rubber cones and are designed so that the wide end can be spread open inside the cylinder of the collection handle and held in place with a rubber ring on the outside of the cylinder. Commercially available semen vials or a urinalysis tube can be passed, bottom end first, through the collection cones and pulled snuggly through the smaller opening to make a tight seal near the opening of the vial (Figure 9.2). Bovine semen is sensitive to chilling, with the most noticeable effect being a rapid decline in sperm motility. Vials and collection cones should be kept in a warming area and only brought out just prior to use. Spare vials can be kept warm in a chest pocket or on a microscope warming stage. Warming jackets containing water can be fashioned from plastic bottles and attached to the collection handle using adhesive tape. Styrofoam coffee cups can also work well as a collection vial, with their insulating capability being an additional benefit when ambient temperatures are cool.

Numerous anesthetic protocols have been employed to evaluate and potentially reduce potential pain or anxiety associated with EEJ, but none of them can be considered to be viable alternatives to conventional EEJ. Caudal epidural anesthesia with 2% lidocaine appeared to be just as effective as conventional EEJ with lesser elevations in cortisol, but did not significantly affect heart rate change [13, 19]. The benefits did not appear to justify the time and effort expended administering the epidural. Xylazine, administered in an epidural or intravenously was effective for reducing pain, but because of associated ataxia and recumbency its use is not practical [12]. Intrarectal lidocaine reduced intrarectal smooth muscle contractions, but its effect is only superficial as heart rate change remained unchanged compared to conventional EEJ [3]. Although not all studies agree, the majority have shown that EEJ can be mildly painful [12] and stressful to bulls; however, heightened awareness and improvements in probe and electroejaculator technology coupled with careful, conscientious use have substantially decreased these concerns.

Figure 9.2 Semen collection handle, cone, and vial.

A mainstay in bull studs, the AV and a mount animal are very useful for collecting semen from trained animals, but are not practical for use with most beef bulls used for pasture breeding. Phantom cows, similar in design to the phantoms used for stallions, complete with an AV mounted within the frame were tested with untrained beef bulls. Not even the application of estrus cow urine sprinkled on the hides that covered the phantoms would entice the bulls to mount and serve [12]. Serving capacity tests are used to evaluate libido and the ability to mount and complete service [20–22]. These tests are conducted by introducing one or more bulls into a pen containing at least one cow restrained in stocks. Having cows in estrus may increase the sexual interest of some bulls [20]; however, willingness to stand to be mounted is a major cue used by breeding bulls that the female is ready to be mated. Therefore because they are restrained the cows used in these tests do not need to be in estrus. Although serving capacity tests are not considered to be reflective of true breeding behavior in juvenile bulls, most mature bulls will express sexual interest in and mount a restrained cow [20].

Early attempts to modify the serving capacity test to enable the collection of semen involved having a person deflect the bull's penis away from the cow and into an AV. Most untrained bulls were unwilling to mount with a person standing close by, so attempts were made to conceal the operator behind drapes while the bull mounted and semen was collected [12]. High libido bulls were undeterred by this system, but medium to low libido bulls seemed to be distracted by the drapes or the presence of humans behind the drapes and refused to serve. [12]. The next modification was to design an AV that could be fitted inside the cow's vagina, called the internal artificial vagina (IAV). The IAV consisted of a wire frame supporting a 7.5-cm length of rubber tubing with a plastic specimen bag attached to the end placed closest to the cervix [23]. Once the bull had mounted the cow and completed service the IAV could be quickly removed and the semen sample recovered. Over a two-year period, the IAV was compared to EEJ as a method of collecting semen from 165 range bulls. Fifty four and

seventy percent of the bulls served the IAV in years one and two, respectively versus a 100% success rate when EEJ was used. Five percent of the bulls were found to be unable to serve cows due to physical abnormalities. Bulls that were unwilling to serve the IAV in year 2 were given a second opportunity, but the result remained the same. Over the subsequent breeding season, the breeding behavior of 15 of the bulls that did not serve the IAV was compared with 15 that did. Most of the bulls that would not serve the IAV were observed breeding cows but mounted less frequently than their counterparts [23]. The IAV proved useful for identifying bulls with physical abnormalities but was not a viable substitute for EEJ. Other concerns included the spread of venereal disease and the welfare of the restrained mount animals [12].

Transrectal massage of the seminal vesicles, ampullae, and pelvic urethra has been used as a method of obtaining a semen sample but is not as reliable as EEJ. In one experiment, TM was shown to be nearly as effective as EEJ for obtaining a semen sample [24], but the percentages of motile and live sperm were less than those of EEJ samples. This was attributed to the tendency of massaged bulls to dribble semen slowly, thereby exposing the sperm to cool temperatures for a longer period of time [24]. Two more experiments were conducted comparing TM with EEJ in infrequently handled, mature breeding bulls (range bulls) and yearling bulls. In an attempt to prevent chilling of the sperm, semen collection tubes were suspended in a 37 °C water jacket during the collection. Despite this effort, fewer motile and live sperm were recovered from TM samples in the range bulls, but there was no difference in percentages of motile sperm in the yearling bulls [25]. These differences were attributed to lack of penile protrusion during semen collection with TM – a problem that was particularly evident with the range bulls [25]. The differences in live and motile sperm percentages were not large, but these authors cautioned that poor semen sample quality and an inability to examine the penis could jeopardize the quality of a BBSE [25]. Transrectal massage of the seminal vesicles and ampullae can be useful following an unsuccessful attempt to electroejaculate a bull. In these cases, the maximum voltage has been reached but only preseminal fluid has been emitted. One useful trick is to rest the bull for at least 30 seconds and restart the collection at a much lower setting. If this quick fix fails, then the probe can be removed and TM may be effective.

Aspiration of semen from the vagina of a recently bred female is a last resort method of obtaining a sample as it is time consuming and requires a female in estrus that must be restrained to allow a sample to be obtained. A syringe and infusion pipette will facilitate the collection of mucus and semen from the anterior vagina.

Semen Evaluation

Once the semen sample has been collected the vial can be easily detached from the semen collection cone. To avoid spillage it works best to pull the cone sideways and slightly downward away from the vial, which has the effect of stretching and shearing the cone off on the edges of the vial. Always keep the semen vial protected from the cold prior to evaluation. A simple and effective method is to hold the vial in a warm hand with the fingers completely encircling it. If evaluation is not going to occur right away the sample should be transferred to a 37 °C water bath. The chest pocket of a close-fitting pair of coveralls has also worked well for short-term storage, especially if the hands are needed for other tasks.

Although not always recorded, the skilled examiner should know how to assess each of the following when examining a semen sample:

- Color and consistency
- Volume
- Concentration
- Gross motility
- Individual motility
- Sperm morphology
- Percentage staining alive

Color and Consistency

A good quality ejaculate should be opaque, creamy-white in color. A yellow, buttery hue may also be seen and is a variation of normal when it occurs in concentrated samples with no apparent aberrations. The yellow coloring may be associated with riboflavin in the diet [26] and is different from a yellow tinge that may be evident with urine contamination. A urine-contaminated semen sample will usually be variably diluted and will have an odor of urine. (Editor's note: if unsure, utilization of a "BUN strip" [blood urea nitrogen] will confirm or rule out.) Preseminal fluid is clear, watery, and odorless. Semen samples diluted with preseminal fluid will not be opaque but rather have a degree of clarity on a spectrum, comparable with skim-milk, watered-down juice, or even clear fluid. Generally, preseminal fluid emission is noted during the EEJ process, but it is not collected in favor of waiting for the appearance of the sperm-rich fraction. Especially in difficult collections, a variable amount of preseminal fluid will be collected, thereby diluting the sample. A pink or red hue or even streaks of red in the semen sample are usually indicative of blood contamination. The source of the blood should be addressed. Blood-contaminated samples are common when semen

collection follows preputial scraping for *Tritrichomonas foetus* and *Campylobacter foetus*, especially if penile protrusion did not occur during EEJ. Clumps of white cellular material in the vial are highly suggestive of a high neutrophil content.

Volume

Always note the volume as it is an indication that a representative sample was collected; however, volume is influenced by the collection process and is therefore not a relevant measure. In other words, the volume of an EEJ-derived semen sample should not be compared with ejaculates from the same or different bulls. The one exception is in cases of sperm accumulation, the "rusty load phenomenon," where 25–40 ml of concentrated semen may be collected easily during a single ejaculation [2]. A typical EEJ-derived semen sample is 1–5 ml.

Concentration

A subjective evaluation of concentration should be made by examining the tube containing the semen to ensure that a representative sample has been obtained. A poorly concentrated sample will be watery and translucent containing <250 million sperm per milliliter, whereas a concentrated sample, typical of a mature bull, will appear creamy and grainy when examined against a dark background containing at least one billion sperm per milliliter. Very concentrated, high-volume ejaculates occur in cases of sperm accumulation. A watery, poorly concentrated sample from a mature bull is typical in cases of testicular degeneration. Closely linked to volume, the concentration of a semen sample also varies with the collection technique. EEJ is not an appropriate method of determining the sperm-producing capability of a bull.

Gross Motility

Gross motility or gross wave motion is influenced by the percentage of progressively motile sperm, the sperm concentration, and the vigor or rate of speed of the motile sperm. Determining gross motility is a fast and simple method requiring just a drop of semen on a microscope slide which is then viewed using bright field microscopy at 40–125× magnification [2]. Vigorous swirls and eddies are indicative of a concentrated semen with a very high proportion of vigorous motile sperm. A depression affecting one or more of the three factors will, in turn, have a negative effect on gross motility. For example, sperm motility may be very high in a poorly concentrated semen sample yet the gross motility appears poor. Another common occurrence is when a highly concentrated sample becomes chilled, negatively affecting sperm vigor. As a result, gross motility should be interpreted carefully, leaving individual motility as a more reliable method of assessing sperm motility.

Individual Motility

Individual motility or more precisely percentage of progressively motile sperm is determined by placing a 2- to 4-mm drop of semen on a clean microscope slide over which a cover slip is dropped in place. The seminal fluid should spread just to the edge of the cover slip to form a thin layer in which the sperm can be viewed within the same focal plane [2]. Too much semen and the cover slip will float, making visualization of individual sperm more difficult, and very concentrated samples may be impossible to evaluate without dilution. Although readily available, the low pH of physiologic saline can diminish sperm motility. Warmed sodium citrate solution [17], commercial semen extender, or even fresh sperm-free seminal fluid are better choices to use as a diluent [2]. Individual motility is recorded as a percentage, with minimum acceptable proportions of 30% [1] and 60% [2] being used by the respective SFT and Western Canadian Association of Bovine Practitioners' guidelines. Several fields should be examined at 400× magnification, observing the proportion moving forward versus those that are immotile, or barely motile, and an average of the percentage motile sperm can be estimated, usually rounded to the nearest multiple of 10. Individual sperm motion is most effectively observed using phase contrast microscopy. Most modern microscopes can be fitted with phase contrast for a modest cost. Sperm motility can be easily affected by heating, chilling, and contamination with urine or other fluids, soaps, etc. A finding of poor motility should be substantiated by sperm morphology and vitality (percentage staining live) before it is considered reflective of fertility. If a finding of poor motility cannot be substantiated then a second sample should be evaluated.

Sperm Morphology

An Assessment of sperm morphology should always be performed. In most cases, irregularities noted with one or more of the other parameters will be evident in the sperm morphology assessment. The minimum percentage of morphologically normal sperm is 70.

Percentage Staining Alive

Percentage staining alive requires the use of a vital stain (see section "Preparation of Semen Smears") wherein eosin will cause the dead sperm to stain pink. The percentage

staining alive is a good indicator of sperm vitality which will be positively correlated with progressive motility when semen handling and slide preparation have been performed correctly. Example reasons that the percentage staining alive may be high but motility is poor could occur with midpiece/principal piece defects or if there has been urine or other chemical contamination of the semen sample.

Preparation of Semen Smears

Evaluation of sperm morphology begins with a well-prepared smear. Eosin-nigrosin is the most recommended and widely used stain in use for evaluation of bull sperm. Eosin penetrates damaged sperm membranes to stain dead and non-viable cells pink, hence it is referred to as a vital, or vitality, stain. Nigrosin provides a dark, purple background, enhancing the appearance of both live and non-viable cells. Eosin-aniline blue is another vital stain that is less popular nowadays. Aniline-blue (blue color) takes the place of nigrosin (purple color) as the background stain. Live sperm do not take up the eosin stain and appear white; half-stained sperm are protected by the acrosomal membrane covering the anterior end, but eosin is able to penetrate the non-acrosomal membrane distal to the equatorial region. These half-stained sperm are more common in semen smears prepared under less than ideal conditions such as cold ambient temperatures. They are non-viable, but in the opinion of the author they are iatrogenic in origin versus the entirely pink sperm that was non-viable or dead for a sufficient period of time before staining to lose or suffer damage to the acrosomal membrane. When semen samples are handled correctly and there are no morphologic defects affecting sperm motility, the proportion of sperm staining live and the percentage of progressively motile sperm should be close to the percentage of live sperm, being approximately 5–10% higher.

Non-vital stains such as modified Wright Giemsa (Diff Quik) and India ink provide a dark background, but do not have a cell wall-penetrating component. They may be used to evaluate sperm morphology but should be used only if eosin-nigrosin is not available. Diff Quik is a superior stain for definitively identifying white blood cells, displaying the characteristic bean-shaped nucleus of neutrophils very well (Figure 9.3). Neutrophils appear as large, white, circular structures, often one and a half to two times the size of a sperm head when viewed on eosin-nigrosin stained smears (Figure 9.4). Diff Quik is a superior stain for definitively identifying white blood cells. A distinct advantage associated with the use of eosin-nigrosin is the rapidity with which slides can be prepared and evaluated. Stains that require long periods of air drying and several steps not only are time consuming but also can result in the loss of

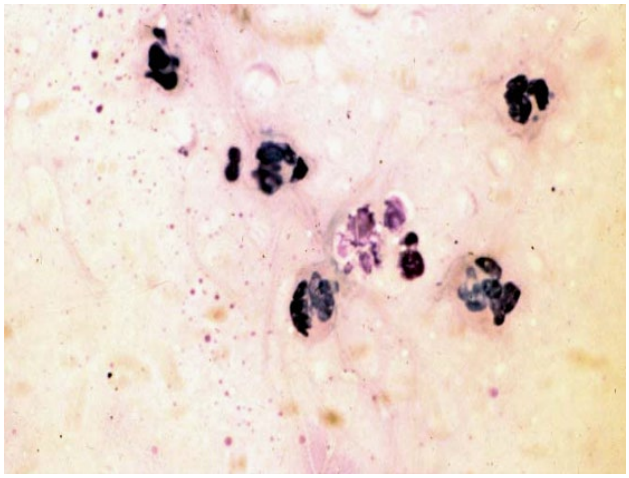

Figure 9.3 White blood cells (neutrophils) on a Diff Quik stained smear. Note the faintly stained sperm.

Figure 9.4 White blood cells (wbc), a speroid cell (sc), detached head (dh), a shed droplet (sd), and distal midpiece reflexes (dmr) on an eosin-nigrosin stained smear.

cells. Unstained wet mounts should never be the sole means of evaluating sperm morphology – the ability to identify many sperm defects is inadequate. Wet mounts are useful for observing the unusual motility patterns of live sperm with midpiece defects and for verifying whether a perceived staining artifact is real or not.

Prior to beginning the evaluation of a semen sample, clean slides should be warmed on a warming stage for several minutes to prevent any artifactual, cold-related changes. To prepare a semen smear, place a 4- to 5-mm drop of stain at one end of the slide, adjacent to the frosted end if applicable. Frosted slides are ideal for labeling, which will facilitate the filing of semen smears as part of the medical record. Stain should always be placed first to limit exposure of the sperm to the damaging effects of chilling and desiccation before fixing with stain. Place a slightly smaller drop of semen adjacent to the stain and immediately mix the two together.

Lifting the slide off of the warm stage with one hand and mixing with the other hand is far less awkward then leaving the slide on a flat surface. Wooden applicator sticks (Applicators, Puritan Medical Products Company LLC, Guilford, ME, USA) work well for obtaining droplets of semen and mixing. Using the stir stick, spread the mixture down the length of the slide in a stopping and starting fashion which will effectively create thick and thin areas of stain (Figure 9.5). This will help to provide the ideal area to count approximately 10–20 sperm per microscope field once the slide is dry. Another way to prepare a smear is to first mix the semen and stain as described above then use a second microscope slide to make the smear, similar to making blood smear. A better result will be achieved if the second slide is pulled back slowly, not rapidly as is the recommended practice when preparing a blood smear. Smears should be dried as quickly as possible to prevent the occurrence of bowed tails, an artifactual occurrence due to the hypotonic nature of eosin-nigrosin. This may be accomplished by returning the slide to the slide warmer and by blowing on the slide to speed drying.

The Feulgen staining technique is a multistep procedure that begins with an air-dried smear. The exposure of the dried sperm cells to hydrochloric acid exposes aldehyde groups in the DNA which then bind with the Schiff's reagent, resulting in magenta staining of the DNA [27]. Feulgen staining is an excellent way to augment eosin-nigrosin stained smears, particularly when abnormal DNA condensation is suspected or to get a more accurate differential count of the number and type of nuclear vacuoles.

Figure 9.5 Semen smear preparation.

Classification and Evaluation of Sperm Morphology

Differential counts of sperm morphology are done with oil immersion, bright field microscopy at 1000× magnification. Always use immersion oil labeled for microscopy. Other oils, e.g. mineral oil, have a different refractive index and may penetrate the objective and effectively ruin it. Blood cell counters relabeled for use as sperm cell counters are an invaluable tool for the practitioner who evaluates more than a few bulls each year. At the Western College of Veterinary Medicine we label keys by the location of the defect on the sperm as shown in Table 9.1.

An image of a labeled sperm cell counter is shown in Figure 9.6. "Detached" or "loose" refers to detached heads. Detached heads with abnormalities, for example, the pyriform shape or nuclear vacuoles, should be counted as "detached abnormal." Heads without abnormalities are counted as "detached normal." Every sperm within a field should be counted to avoid bias. Exceptions will be if clumps of sperm are present obscuring other sperm, or if there are simply too many sperm preventing the complete inspection of individual cells. Fields should be inspected in systemic fashion – left to right, top to bottom has been an effective method for the author.

Differential counts are reported as "defects per 100 cells." Each time a key is pushed a cell is counted and added to the total. In cases where a sperm cell has more than one defect the respective keys should be depressed simultaneously. The two defects are counted, yet only one cell is added to the total. When the counter reaches 100 cells a bell is sounded. Counting just 100 sperm cells will be sufficiently representative if just a few abnormalities are recorded. When many abnormalities are encountered it is advised to count at least 300 cells to improve the reliability of the morphology assessment. Reliable counts should not differ by more than 10%, or, in other words, 10 cells. When reviewing my counts, I generally disregard any outliers in favor of completing another 100-cell count. Once satisfied that my counts are representative I will report the average of the suitable counts.

When sperm morphology is examined, several questions may arise about the specific type of defects observed:

- Is it an aberration or a significant abnormality?
- What would be the effect on fertilizing ability (sperm transport, binding to the oocyte, oocyte penetration, zygote formation)?

Table 9.1 Layout of an example label for keys used by the Western College of Veterinary Medicine, Saskatoon.

Head	Midpiece	Principal piece	Detached (loose) abnormal	Detached (loose) normal	Proximal droplet	Acrosome (other)	Normal

Figure 9.6 Cell counter with keys labeled for sperm cell morphology.

- What would be the tolerable level for bulls in natural service, or semen used in AI?
- What are the implications for the bull (cause, prognosis)?

Readers of this chapter are encouraged to review sperm structure and spermatogenesis to develop a more complete understanding of sperm morphology (see Chapter 3). Classification systems have been developed to try to simplify semen evaluation; however, there appears to be quite a lot of misunderstanding of them. The earliest system used was the primary/secondary sperm defect system. By definition, a primary defect is one that originates during spermatogenesis – within the testicle – and a secondary defect is one that originates within the epididymis [28]. All head defects, such as knobbed acrosomes (KAs), microcephalic sperm, pyriform heads, and nuclear vacuoles, would thus be primary defects. Some tail defects would be primary, but others, notably the Dag defect and the distal midpiece reflex defect, develop in the epididymis and would thus be secondary defects. However, if these defects developed in the epididymis because of a weakness in structure that occurred in spermatogenesis they might be defined as primary defects. Following this line of reasoning there would then really be very few secondary defects. Distal midpiece reflexes and proximal droplets appear to develop in sperm that were structurally normal upon entering the epididymis. However, it could be argued that sperm with malformed heads or tails are more likely to retain a cytoplasmic droplet in the proximal position. The supposed origin of a defect bears little relevance to the effect of the defect on fertility and probably is only useful for determining when a defect might appear in the spermiogram following an insult to spermatogenesis.

The "major and minor" system of sperm morphology classification was created to remove some of the confusion associated with the primary/secondary sperm defect system. In this system a major defect was a sperm aberration which had been associated with infertility. Minor defects were those that had not been shown to be associated with infertility [29, 30]. Over time, more evidence has been gathered, including the reporting of defects not included in the original list. Sperm aberrations that were categorized as minor have been found to have a significant effect on fertility. In defense of the early work, it would seem that at that time very few bulls had been found that produced high numbers of some of these defects. It is notable that two sperm aberrations that were listed as minor defects, abaxial tails and distal droplets, have been shown to have no effect on fertility and should be disregarded when classifying sperm as normal or abnormal.

Use of the primary/secondary and major/minor sperm defect classification systems has been replaced by the differential count of sperm defects system described previously, where the predominant defects are listed as a percentage and the effect on fertility is determined based on the current knowledge of each type of defect.

A system of classifying sperm defects that has proven useful in predicting the effect on fertility is the compensable/uncompensable system. Based on the understanding that a certain population of live, motile sperm must travel to the site of fertilization and that some abnormal sperm can penetrate the ovum while others cannot, the compensable/uncompensable system has been particularly useful for determining sperm concentrations per insemination dose for the artificial insemination industry. Sperm with impaired motility that are unable to travel to the site of fertilization, or that can travel but cannot penetrate the ovum, can be compensated for by motile sperm – compensable defects. Defective sperm, which are able to penetrate the zona pellucida and initiate the zona block are uncompensable [31, 32]. Noteworthy examples of uncompensable sperm are those with diadem vacuoles or abnormal DNA condensation. Although fertilization by a sperm with an uncompensable defect is equally as possible as a normal sperm, the risk of early embryonic loss is much greater with the uncompensable sperm defect.

As mentioned previously, differentially counting sperm defects to produce a spermiogram is a much less confusing approach to assessing sperm morphology. There are approximately 25 recognized sperm abnormalities – some are artifactual and some have no effect on fertility. Table 9.2

Table 9.2 Listing of recognized sperm defects.

1) Pyriform heads
2) Tapered heads
3) Microcephalic/macrocephalic heads
4) Vacuoles – diadem, single vacuoles, confluent vacuoles
5) Clumped DNA
6) Detached (loose) heads – normal, abnormal
7) Decapitated defect
8) Rolled-crested-giant head syndrome
9) Teratoids
10) Knobbed acrosome – beaded, flattened
11) Ruffled and detached acrosomes
12) Distal midpiece reflex
13) Mitochondrial sheath defects
14) Dag defect
15) Stump tail defect
16) Corkscrew defect
17) Pseudodroplet defect
18) Coiled principal piece
19) Proximal cytoplasmic droplets

lists 19 defects; however, some defects have been grouped together. Examiners should regularly review abnormal sperm types. Comparing differential counts with colleagues and experts in sperm morphology are good ways to ensure that one is performing consistent, quality evaluations. Taking the time to compare a single sperm with a questionable appearance with images of known defects is an effective way to learn.

A good quality, well-maintained microscope and some knowledge on how to optimize image quality are important. Oil easily captures dust and debris, so it is good practice to clean the oil immersion objective regularly. A solution of 70% ethanol on a lens-appropriate cloth works well.

Sperm Abnormalities

Several of the most common or noteworthy sperm defects are presented below.

Normal Sperm

Nearly all novice examiners will be able to recognize a normal sperm at first glance, but if questioned they will be unsure. An effective technique is to develop a system so that each sperm is thoroughly examined. Normal sperm vary in shape both within a single smear and more so between bulls. Heads may appear short and wide or elongated and narrow. Sometimes a sperm head may look excessively narrow, but if there are no other, more obvious, disturbances in head shape and most of the sperm in the ejaculate appear similar then these sperm can be considered to be normal (Figure 9.7).

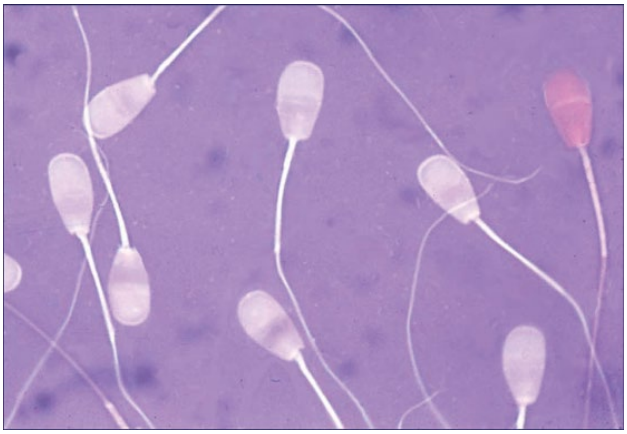

Figure 9.7 Normal sperm stained with eosin-nigrosin. The dark staining sperm is dead.

Sperm Morphology – Minimums and Maximums

The widely accepted minimum proportion of morphologically normal sperm is 70%. Below this threshold it is expected that fertility will be impaired and a bull cannot be classified as a satisfactory potential breeder. Generally, bulls that are at or near this threshold have at least two or three sperm defects; however, as a precaution, it is recommended that the proportion of sperm with nuclear defects or proximal droplets should not exceed 20% and the proportion with acrosome or midpiece abnormalities should not exceed 25%.

Artifacts and Debris

Commonly found artifacts include bowed midpieces (also called bowed tails) and bent tails (also called simple bent tails and hypotonic shock). Neither of these anomalies should be counted as abnormal in the differential count. Bowed midpieces are easy to recognize as rainbow-shaped, C-shaped, or U-shaped. A key characteristic is that the tails (midpiece and principal piece) do not fold as is the case with the distal midpiece reflex. The occurrence of bowed midpieces is associated with faulty slide preparation, most often when slides and the stain are cold. Examination of motile sperm on a wet mount can be used to confirm that this aberration is artifact [27].

Hypotonic shock is usually manifested as terminal whipping or looping of the principal piece and is caused by prolonged exposure to hypotonic stains (eosin-nigrosin and eosin-aniline blue) before drying. Drying is often prolonged when stains and slides are cold. The looping may appear similar to the distal midpiece defect (DMR) except that

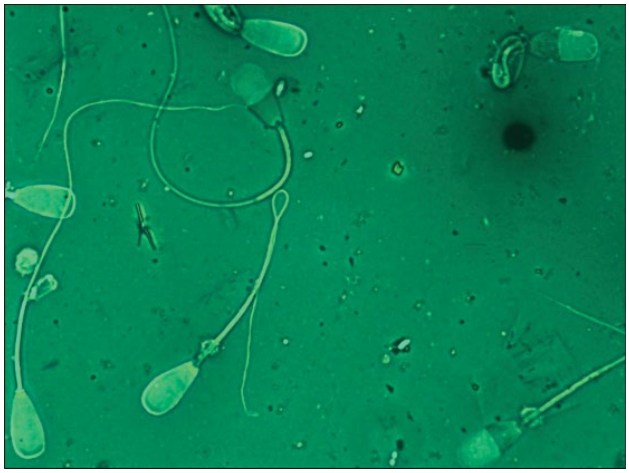

Figure 9.8 A sperm with a bowed midpiece and a sperm displaying hypotonic shock (looped tail).

there will be no trapped droplet material. Closely examining the terminal portion of the midpiece and comparing the aberrant sperm with other sperm on the smear will facilitate classification (Figure 9.8).

Other debris includes white blood cells, shed droplets, and spheroid cells (shown in Figure 9.3) as well as epithelial cells, bacteria, and red blood cells.

Morphological Aberrations that Are Counted as Normal Sperm Cells

Arguably, sperm cells displaying a distal cytoplasmic droplet or abaxial tails are not normal; however, the presence of very high proportions of either of these aberrations has not been shown to negatively impact fertility. Distal droplets are shed after a period of exposure to vesicular fluid and will often be seen as tiny white circular structures on the smear (Figure 9.3). If there are no other defects visible, sperm displaying a distal droplet or an abaxial tail should be counted as normal (Table 9.3).

Head Defects

Pyriform and Tapered Heads

Pyriform (pear-shaped) heads are commonly recorded in spermiograms, usually with other sperm defects. The pyriform shape is very distinctive, with varying degrees of severity. The apex of the sperm head is very rounded and the sides are sharply tapered all the way to the base of the sperm head. Many severely pyriformed heads are much smaller overall than normal sperm. Appearing narrow from the apex to the basal plate, truly tapered heads are not as common as pyriform heads. A good rule of thumb is that if the examiner must wonder if a sperm is tapered or not, then it probably is not. Tapered heads and pyriform heads frequently appear together in semen smears. As mentioned in the discussion of normal sperm, it is quite common for individual bulls to produce sperm with narrow heads. Studies have shown that moderately narrow sperm heads do not have any effect on fertility; however, the fate of pyriform heads depends on the severity of the aberration. Severely misshapen pyriform heads are not capable of fertilization and are likely compensable. Mildly pyriformed heads, on the other hand, are capable of fertilization but with a much greater odds of embryonic loss. Pyriformed and tapered heads often appear with other sperm defects within a few weeks following a heat- or stress-related insult to spermatogenesis [2] (Figure 9.9).

Table 9.3 Abnormal sperm morphologies, artifacts, and other cells not included in a sperm morphology differential count.

Morphology	Artifact	Other cells
Abaxial tails	Bowed midpiece	White blood cells
Distal droplets	Simple bent tail (hypotonic or cold shock)	Medusa cells
		Spheroids
		Epithelial cells

Nuclear Vacuoles

Vacuoles arise from invaginations into the inner nuclear membrane that extend into the sperm nucleus. On eosin-nigrosin stain smears, vacuoles appear as dark areas on the sperm varying in size and location according to their type. Small pale or white-colored spots are occasionally seen that are most often shed distal droplet material or other artifact. There are three types of vacuoles: (i) diadem vacuoles (Figures 9.10 and 9.11); (ii) apical vacuoles; and (iii) large confluent vacuoles (Figure 9.12). Diadem vacuoles are the most common type, appearing as a partial or complete arrangement of vacuoles on the equatorial region of

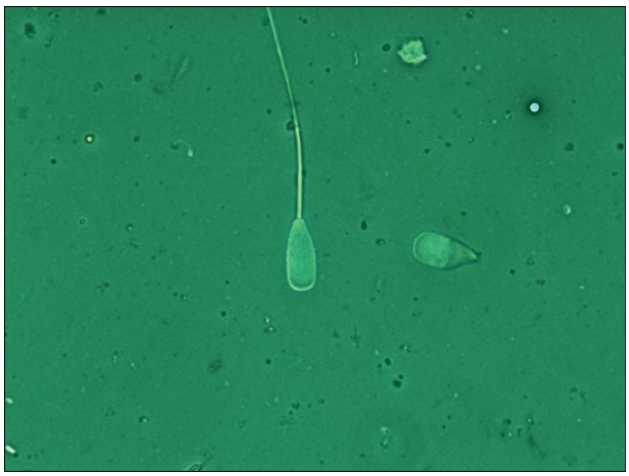

Figure 9.9 Tapered head and a detached, pyriform head.

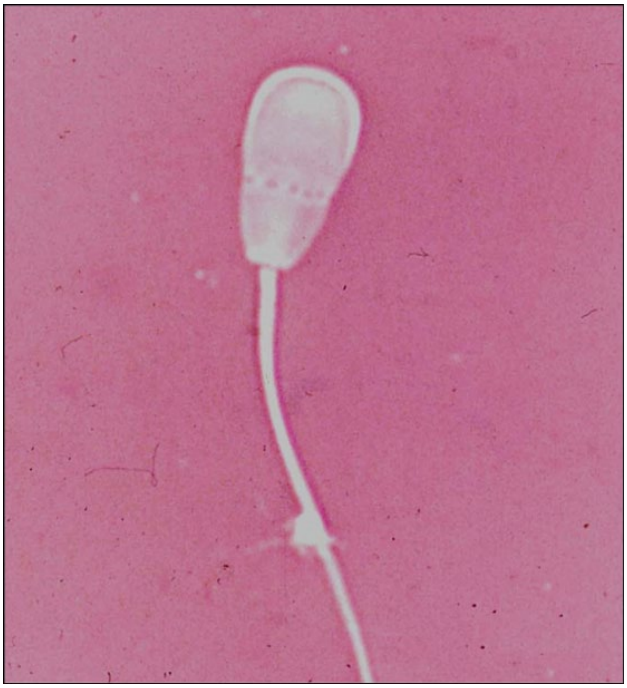

Figure 9.10 Sperm with diadem vacuoles (presentation 1).

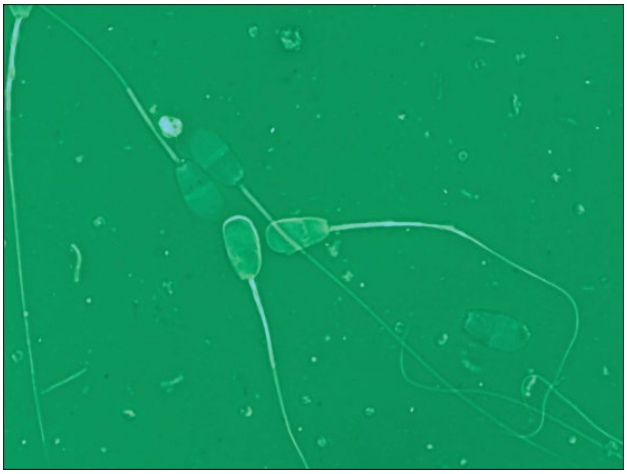

Figure 9.11 Sperm with diadem vacuoles (presentation 2).

the sperm. When the vacuoles form a complete line across the sperm the arrangement has the appearance of a necklace, hence the name diadem which means diamond necklace. Apical vacuoles occur as single or multiple small vacuoles appearing most commonly in the apex of the sperm head. Apical vacuoles may occur alone, affecting few to several sperm, but most often appear in spermiograms with diadem vacuoles. Confluent vacuoles are the most easily visualized of the vacuoles as they are made up of several vacuoles that become joined together, usually distorting the shape of the sperm head.

Diadem and apical vacuoles are easily missed on eosin-nigrosin smears. Clean objectives, a quality microscope,

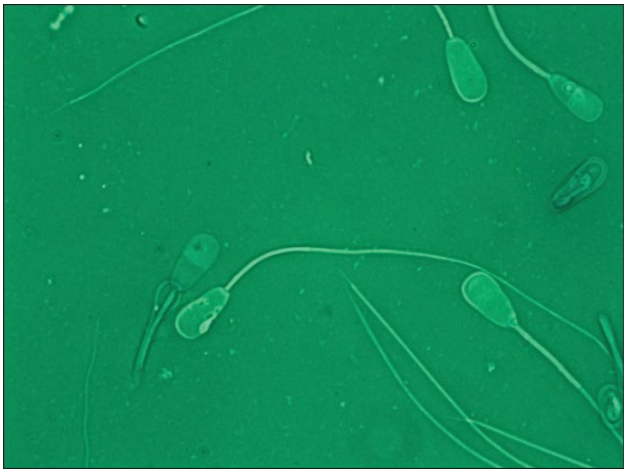

Figure 9.12 Sperm with confluent vacuoles and sperm with distal midpiece reflexes.

good quality smears, and close examination of the sperm heads looking specifically for vacuoles will improve the examiner's success. Feulgen stained smears are superior for identifying nuclear vacuoles where they appear as pale circles (diadem and apical) or large pale areas (confluent) on the sperm heads. Oftentimes if a few vacuoles are noted on an eosin-nigrosin stained smear, many more will be seen on the Feulgen stained smear.

The effect of apical vacuoles on fertility is inconclusive, whereas there is substantial evidence condemning the diadem as a significant cause of infertility. The diadem vacuole is not a compensable defect. Studies evaluating the effect of purely large confluent vacuoles on fertility are limited, but available information does indicate that fertility is impaired by a high proportion of these vacuoles being present [2].

Stress, heat, toxins, and genetics have all been proven or suspected to be associated with the appearance of diadem vacuoles in bull sperm. Some bulls have been shown to have variable proportions of diadem vacuoles in their spermiograms throughout their lives, while others have small numbers that only appear following a stressful event. Bulls having modest to large numbers of sperm with diadem vacuoles should be considered suspect and at the very least monitored for several months to see if the condition resolves. In the opinion of the author, this may occur with some bulls following the resolution of a stressful event, but there is no certainty the problem will not reoccur sometime later in life.

Microcephalic and Macrocephalic Heads

Sperm heads that are clearly smaller or larger than others are called microcephalic or macrocephalic (Figure 9.13), respectively. Representing a mistake made during spermatogenesis, they are believed to contain either too little or too much nuclear chromatin. These sperm are not believed to

Figure 9.13 Macrocephalic sperm with double tail (center).

be capable of fertilization themselves, but when they are present in a spermiogram they account for no more than 2–5% of the differential and are probably compensable.

Knobbed Acrosome

The most common morphological aberration affecting the acrosome is the KA defect. There are two forms of this defect: indented and beaded (Figure 9.14). The indented form is the most common presentation, showing up in spermiograms from a few to most of the sperm being affected. Instead of having the gentle convex curve that typifies the top or apex of the head, sperm with indented KAs will have a flattened to indented apex and variable thickening of the acrosomal ridge. A smaller proportion of sperm will not show the flattened apex but instead have a small white (eosin-nigrosin stained smear) semicircular structure just below the apex. These sperm often serve as an indication that the other sperm should be carefully scrutinized to look for flattening and indentation. A few sperm with the indented form may be noted in spermiograms with other defects and have been shown to appear three weeks following a thermal (heat) shock to spermatogenesis [33]. When differential counts showing 30%, 50%, or greater proportions of KA are present the bull should be considered suspect and further investigation is warranted. The indented form occurs in several breeds of cattle. To date, the indented form of the KA has not been conclusively proven to be heritable, but evidence suggests that it likely is.

The beaded presentation is relatively rare and believed to be heritable. Unlike the indented form, there is usually no flattening of the apex. The acrosome has become enlarged and stretched and then folded back on itself over the head of the sperm. Eosin stain does not penetrate the folded, thickened acrosome, resulting in a very distinctive semicircular white structure covering the apex of the sperm head. Typical beaded KA spermiograms contain high percentages of affected sperm and few to no other defects.

KAs seem to have variable, almost confusing effects on fertility. When considering the impact of a high percentage of KAs on fertility it is helpful to consider the two forms. Bulls producing the beaded form are extremely subfertile. Although there were normal-appearing sperm in their ejaculates, it appears that the beaded KAs were not compensable, or that there was an undetected abnormality affecting even the normal sperm. Results of breeding trials using bulls producing high numbers of indented KAs have been variable. In single sire mating situations and artificial insemination studies little to no differences in pregnancy rates were recorded; however, when similarly affected bulls were used in competitive mating trials the KA bulls sired significantly fewer calves. These results implied that normal appearing sperm coexisting with the KA sperm were not as capable of fertilization when competing with normal sperm produced by unaffected bulls [34].

Midpiece Defects

Detached Heads

Detached heads, also termed *free heads or loose heads*, are commonly found in low numbers in semen samples collected during late winter and early spring, suggesting that their occurrence is due to senescence. In these cases, the sperm take up the eosin stain uniformly, indicating that they were dead before ejaculation. Detached heads, both normal and abnormal forms, are also found in variable numbers with other defects following an insult to spermatogenesis. Large numbers of detached normal heads may be seen in cases of sperm accumulation associated with a failure to void aging sperm in the urine. Detached heads may occasionally be encountered that stain alive, usually in the presence of a variety of other defects, indicating an insult to spermatogenesis that has affected the formation of the connection between the head and the midpiece. Detached heads are not a normal phenomenon. Although a few are acceptable they should always be included in the differential count. The one notable exception is when assessing the true proportion of knobbed acrosomes (KAs) in a sample. Dead sperm eventually lose the acrosome; therefore acrosomal anomalies will not be visible. Disregarding dead, detached heads in this case will give a more accurate proportion of KAs present in the spermiogram. (Editor's note: a normal detached or free head may be classified as a midpiece defect because it results from separation at the junction of the midpiece and head.)

Proximal Droplets

Proximal (cytoplasmic) droplets appear in stained preparations as dense white circular structures obscuring the proximal midpiece (Figure 9.15). During the epididymal phase of sperm maturation proximal droplets normally migrate to

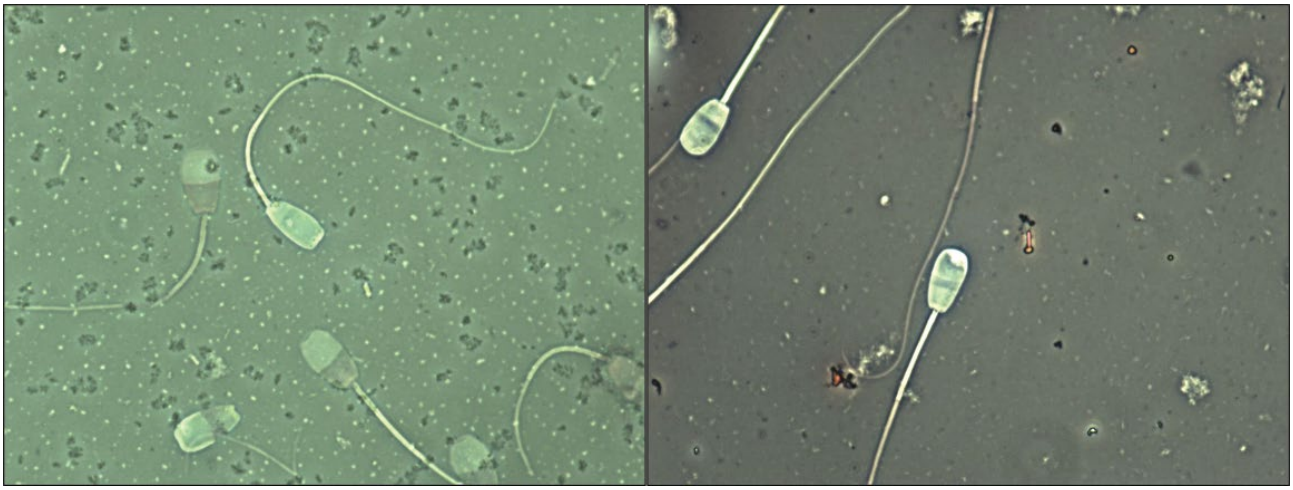

Figure 9.14 Sperm with the knobbed acrosome defect: indented form (left); beaded form (right).

Figure 9.15 Proximal cytoplasmic droplets.

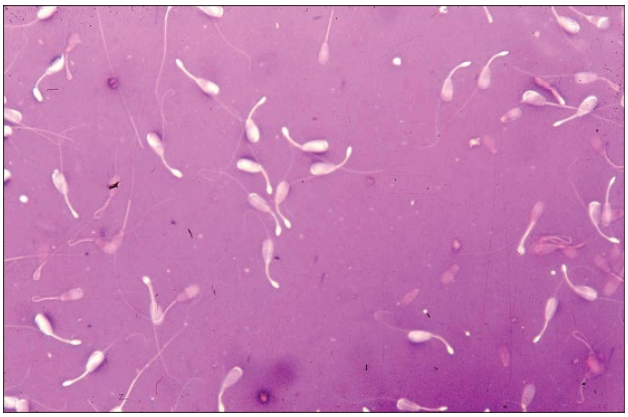

Figure 9.16 Distal midpiece reflexes with and without droplet material and detached heads on an eosin-nigrosin stained smear.

the distal position and are then shed at or around the time of ejaculation. Presence of proximal droplets in a semen smear is indicative of a disturbance of spermatogenesis at the epididymal or testicular level. Within approximately one week of an insult to spermatogenesis, proximal droplets appear in the ejaculate. The short, less than 10-day, time to first appearance of proximal droplets suggests an epididymal origin; however, the reoccurrence of proximal droplets three or four weeks after an insult to spermatogenesis and the well-documented association of high numbers of proximal droplets with sexual immaturity in bulls suggest the involvement of abnormal spermatogenesis at the testicular level as well. Sperm motility is unrelated to the presence of proximal droplets, yet it has been shown that affected sperm lack the ability to bind to ova. This inability to induce a zona reaction would suggest that normal-appearing sperm should be able to compensate for those with droplets, but that is not the case. Normal-appearing sperm produced at the same time as high numbers of sperm with proximal droplets have been shown to have an impaired ability to bind to and penetrate ova. Breeding studies utilizing bulls expressing high numbers of proximal droplets have reported poor conception rates. Proximal cytoplasmic droplets are a serious sperm defect with a profound negative effect on fertility. Clinicians must resist the temptation to give a satisfactory classification to a young bull with a high percentage of proximal droplets in his spermiogram because the amount of time required to clear the defect varies between bulls.

Distal Midpiece Reflexes

Occurring in all breeds of cattle, the DMR is the most common midpiece defect (Figures 9.16 and 9.17). The classic appearance is that of a "J" hook involving the very distal end of the midpiece causing the rest of the tail to be whipped around 180°. Cytoplasmic droplet material is usually trapped in the loop but not always; in the absence of droplet material, examiners should look for the classic "J" hook. Other manifestations include a less-severe 90° bend in the midpiece and second bends involving the principal piece that cause the midpiece and principal piece to loop in a

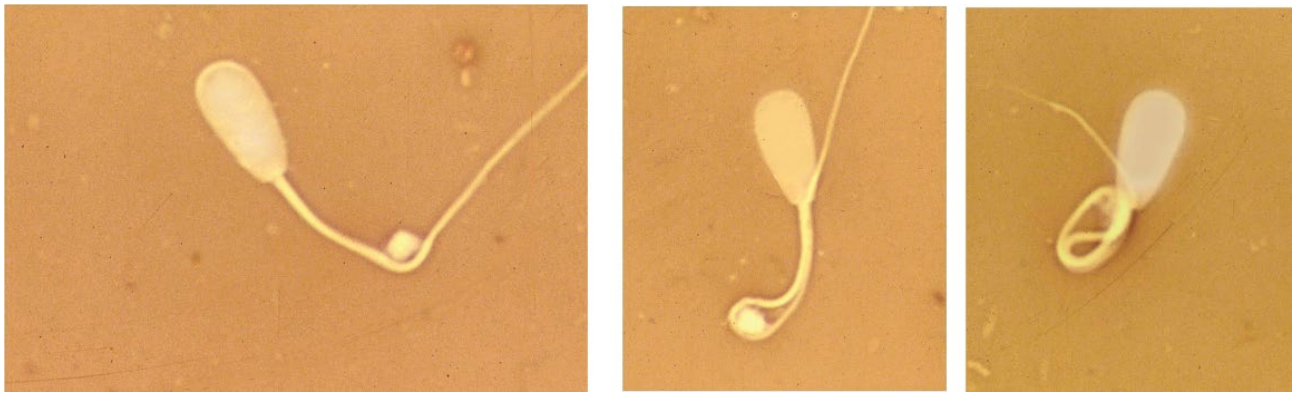

Figure 9.17 Three images all showing distal midpiece reflexes.

circle. The DMR defect occurs in the epididymis associated with a hormonal chain reaction which ultimately causes a decline in testosterone levels. Sperm are stored in the cauda epididymis prior to ejaculation and epididymal sperm possess a distal cytoplasmic droplet which gets trapped in the reflex and is unable to be shed. Both heat and stress may cause a decline in testosterone and the appearance of DMRs. The DMR defect is most often associated with stress insults to spermatogenesis, appearing within just a few days of a stress occurrence. Common stressful events include severe weather, injuries, and illness of at least three or four days duration. With more severe or long-standing events, other defects will appear in succession following the DMR according to where they occur during spermatogenesis. In cold, northern regions DMRs are frequently recorded in semen samples collected during the late winter and early spring, suggesting that photoperiod and/or nutrition may be a cause. This defect is seen in all breeds; however, some animals within a breed appear to be more affected than others by stressful events experienced by the group. When a bull fails to meet the minimum morphology standards for a satisfactory classification due at least in part to a high proportion of DMRs it is appropriate to reevaluate the bull in as little as two weeks. Not only do DMRs appear fast following an insult, but also if all goes well the numbers of affected sperm will decline rapidly.

Mitochondrial Sheath Defects

Surrounding the inner core of the midpiece the mitochondrial sheath is laid down during spermatogenesis, beginning at the attachment of the midpiece to the sperm head all the way to completion at the annulus on the very distal end of the midpiece. Any disruptions in mitochondrial sheath development can result in one or a few tiny gaps appearing along the length of the midpiece (Figure 9.18). Incomplete development of the sheath at the annulus causes the appearance of larger gaps and a propensity for the tail to break at this point. Mitochondrial sheath defects are usually seen in low numbers, but there

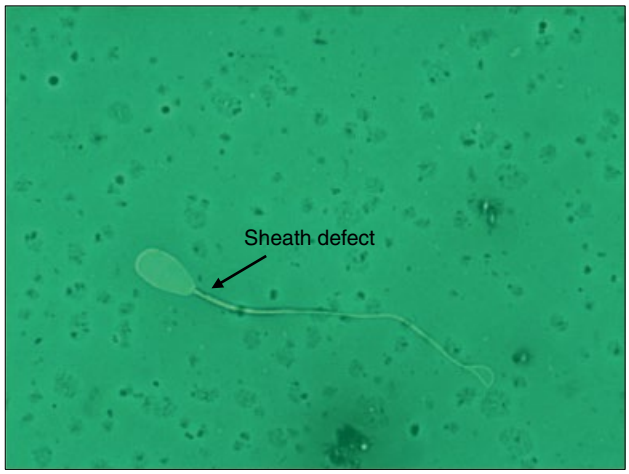

Figure 9.18 Mitochondrial sheath defect.

have been a few bulls that produced a high percentage of sperm with sheath gaps. Surprisingly, these bulls had normal fertility [2]. A conclusive link between the feeding of gossypol in cottonseed meal to bulls and the occurrence of high numbers of mitochondrial sheath defects has been shown [2, 17]. Despite reports of bulls producing high numbers of affected sperm with apparently normal fertility, mitochondrial sheath defects are considered abnormal; therefore any bulls producing high numbers of these defects should be flagged for further examination, including an investigation of possible causes. The more common occurrence is that of a few mitochondrial sheath gaps being noted in spermiograms – usually in the presence of other sperm defects.

Accessory Tails

Accessory tails are an uncommon occurrence affecting a small number to as much as 35% of a spermiogram. Closely related to the abaxial tail aberration, accessory tails, multiple tails, and abaxial tails are often present in the same spermiogram [2]. Differing from abaxial tails, however, accessory tails have been shown to have a negative effect

on fertility. Accessory tails may be partially obscured by droplet material; therefore the proportion of affected sperm may be underestimated. This defect has been recorded in a number of breeds of cattle and is believed to have a heritable basis [27].

Stump Tail

The stump tail defect (Figure 9.19) is unmistakable, with usually more than 50% of the spermiogram affected. Other sperm will have broken midpieces and midpiece defects. Cytoplasmic droplet material often obscures the stump tail from view. This is believed to be a heritable defect reported in Charolais, Hereford, and other breeds of cattle [2].

Dag Defect

The Dag defect is a rare heritable midpiece defect that carries the name of a Jersey bull who produced it in large numbers along with his full brother. The unusual and distinctive name of this defect is often highlighted in the minds of students, leading to a tendency to refer to DMRs as the Dag defect. Differing from the DMR, unique features of the Dag defect include a swollen, disrupted mitochondrial sheath and fractures of the midpiece (Figure 9.20). Oftentimes, midpiece fractures result in coiling of the tail very similar to the DMR. By studying the fractures closely, broken axonemal fibers that can be likened to broken structural cables can be seen. In addition to the Jersey breed, the Dag defect has been reported in the Hereford, Swedish Red and White, and Galloway breeds [2]. Sperm showing the true Dag defect are usually produced in very high numbers. Although very uncommon, a few sperm displaying mitochondrial disruption identical to the Dag defect may be noted in spermiograms, but in the presence of other defects. These defective sperm are called Dag-like to differentiate their occurrence from the rare, heritable condition where high numbers of sperm express the defect in the absence of any other evidence of an insult to spermatogenesis.

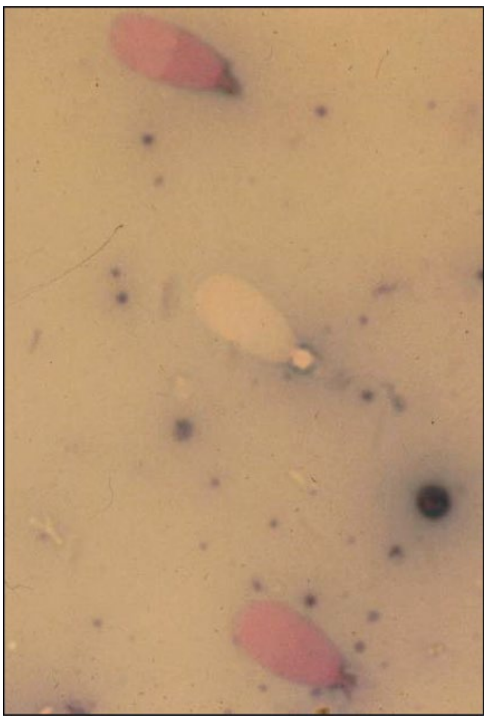

Figure 9.19 Stump tail defect.

Figure 9.20 Dag defect.

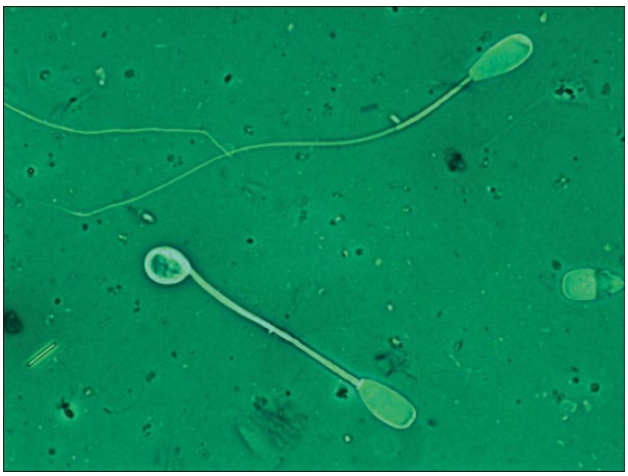

Figure 9.21 Coiled principal piece.

Principal Piece Defects

Coiled Principal Piece

Coiled principal pieces can be found in small numbers on many smears, often with other defects (Figure 9.21). They usually appear at the same time as nuclear vacuoles following an insult to spermatogenesis. Sperm with coiled principal pieces are not capable of normal motility.

Bent Principal Piece

Occasionally, sperm displaying a loop bend in the principal piece with cytoplasmic droplet material trapped in the loop are encountered. The loop begins just past the midpiece, so technically it is not a DMR. Most of the sperm with bent principal pieces are noted in spermiograms where DMRs are present and are believed to have the same origin.

Ultrasound Examination of the Reproductive Tract

Harry Momont[1], Mary Keeler[2], and Michael Nicholson[2]

[1] *Department of Medical Sciences, School of Veterinary Medicine, University of Wisconsin-Madison, Madison, WI, USA*
[2] *ABS Global, DeForest, WI, USA*

Introduction

Diagnostic ultrasound has become the standard for medical imaging of soft tissue. The genital tract is an obvious target for this diagnostic modality and while ultrasound is routinely employed for evaluation of the female genital system its use in male domestic animals remains much less common. In the bull, for example, the routine bull breeding soundness examination (BBSE) as recommended by the Society for Theriogenology does not require ultrasonographic assessment of the genital system [1, 2]. In many cases of infertility in the bull, adequate diagnostic and prognostic information is obtained without the use of ultrasonography. A major advantage of ultrasonography is the ability to localize and objectively assess morphologic changes in tissue.

A thorough history, complete physical examination, and a BBSE should accompany an ultrasound examination of the bull's genital system. We routinely perform ultrasound evaluations for bulls with palpable or visible abnormalities of the genital system; those with pyospermia, hemospermia, azoospermia, or oligospermia; those with low semen volume; and bulls that persistently produce high numbers of morphologically abnormal or immotile sperm. As with any medical technology, the use of ultrasonography for examination of the bull will expand as veterinarians become more familiar with the modality and its applications.

Equipment and General Methodology

A wide variety of ultrasound equipment is available for diagnostic imaging. Most veterinary clinics providing service to cattle owners will already have a portable, real-time, B-mode system with a linear intrarectal probe that is used for reproductive examination of cows. All illustrations in this chapter were obtained with this type of system. Typical probe frequencies range from 5 to 7.5 MHz and are more than adequate for imaging the bull's reproductive tract. More detailed images of the epididymis and penile tissues can be obtained using probes with a smaller footprint and higher frequency. Representative images may be captured, labeled, measured, and saved for inclusion in the medical record. These applications are available with most ultrasound systems.

In order to adequately assess a machine that you intend to purchase, it is advisable to use it in an actual clinical setting so you can critically evaluate functionality and image quality under real-world conditions. Beyond the primary issue of image quality, durability and resistance to damage from dirt and moisture are important considerations when purchasing an ultrasound unit to be used in cattle environments.

Operator safety is always a concern when working with bulls. A chute or stock with a head catch and squeeze option is ideal. For added security, the bull's head can be secured with a halter. Most bulls will tolerate scrotal, perineal, and rectal examinations with little restraint beyond confinement in the chute. If a kick bar is used behind the bull, extreme caution is needed to avoid placing the arms and hands in a dangerous position. For fractious bulls or for examination of the prepuce and penis cranial to the scrotum, we prefer sedation (xylazine 0.01–0.02 mg/kg IV).

While it is beyond the scope of this chapter, a fundamental understanding of ultrasound principles and an appreciation for common image artifacts are essential for anyone offering diagnostic ultrasonography services. For those requiring a more expansive treatment of the basic principles of veterinary ultrasonography, excellent texts are

Companion website: www.wiley.com/go/hopper/bovine

available [3, 4]. A bovine reproductive anatomy monograph is available from the National Association of Animal Breeders [5] and McEntee [6] is an excellent resource for those seeking a review of the pathology of the male genital system.

Images are obtained by either a transcutaneous or transrectal scan depending on the anatomical location of the tissue to be examined. If long or dense hair covers the area, the quality of the transcutaneous image is improved by first shaving the skin. Shaving is usually not required for examination of the scrotum and testes. Image quality is enhanced when the scrotal skin is stretched tightly over the testes. To do this, firmly grasp the scrotal neck dorsal to the testes and pull the testes ventrally while conducting the examination.

In all cases of transcutaneous ultrasonography, a coupling agent is required to achieve good contact between the probe and skin. Any air or gas between the probe and the tissue to be examined will interfere with the acquisition of an image. The use of ultrasonic coupling gel as a coupling agent has the advantage of long duration, since it does not evaporate. Additionally, it is approved by most manufacturers for contact with the probe surface. Alcohol (70% isopropyl) also makes a good coupling agent, with the advantage that it does not have to be cleaned from the probe or patient after the examination is completed. A disadvantage of alcohol is that it evaporates and often needs to be reapplied to complete the examination. Additionally, not all probe surfaces are approved for contact with alcohol or other solvents. Placing a protective cover containing a small amount of coupling gel over the probe will prevent alcohol from contacting the probe surface. A disposable examination glove works well for this purpose.

For transrectal examination of the pelvic organs, the probe is covered with an examination sleeve containing just enough coupling gel to provide good contact between the probe and sleeve. Most probes designed for transrectal use in horses and cattle will fit snugly within a finger of a glove or sleeve. The feces are evacuated from the rectum and a manual examination is conducted before the covered probe is inserted. No coupling agent is necessary to maintain contact between the sleeve and rectal mucosa beyond the lubricant normally used to facilitate insertion of the probe and arm. If a protective cover is not used, the probe should be cleaned and disinfected between examinations following the recommendations of the probe manufacturer.

While diagnostic ultrasonography is generally regarded as safe for examination of reproductive tissues and fetuses [4], few published data exist in the veterinary literature. Coulter and Bailey [7] exposed yearling beef bulls to ultrasound (three minutes for each testis, one time, using a 5-MHz linear transducer) and found no discernible effects on sperm numbers, morphology, or motility during a 70-day period after the examination. They concluded that diagnostic ultrasonography should be safe for examination of the bull scrotum and testes. A reasonable approach is to use the minimum power and contact time necessary to complete your examination.

Examination of the Scrotum

B-mode ultrasonography of bull testes was first described by Pechman and Eilts [8] in 1987. A thorough visual and manual examination of the scrotum and its contents should always precede the ultrasound examination. The scrotum and testes are then examined by ultrasound in both a sagittal and transverse plane, with the probe applied to the cranial, lateral, or caudal surface of the testis depending on the examiner's preference. A complete examination includes the spermatic cord, the entirety of the testis parenchyma, the epididymis, and the scrotal wall. The body of the epididymis and the ductus deferens are difficult to detect unless they are grossly abnormal.

Normal ultrasonic appearance of the testis is shown in Figure 10.1. The testis parenchyma appears as a homogene-

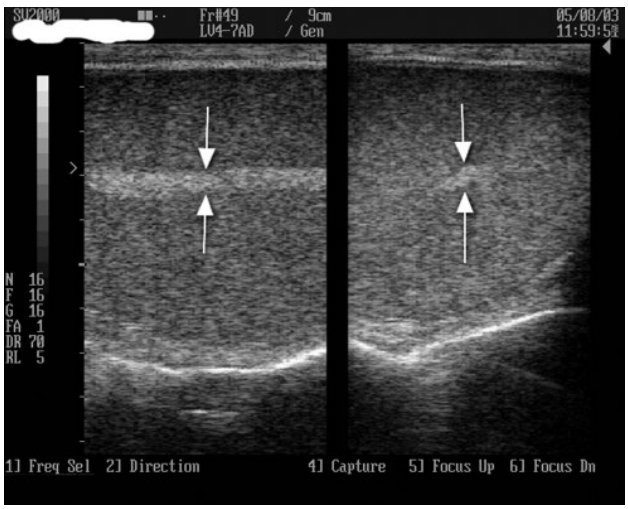

Figure 10.1 Caudal ultrasonographic views of the left testis of a yearling dairy bull. Caudal is at the top and cranial at the bottom of each ultrasound image. On the left is a sagittal view, with the mediastinum testis (between arrows in each image) appearing as a more hyperechoic linear structure running through the approximate center of the less echoic testis parenchyma. On the right side of the image is a transverse view of the same testis, with the mediastinum in cross-section, again in the middle of the less echoic parenchyma. The scrotal wall is visible adjacent to the probe on the top (caudal) and on the bottom (cranial) of the testis in each image. The bright white line at the bottom of each image is a gas artifact that marks the far side of the scrotal skin.

ous tissue with a stippled medium echogenicity that surrounds the centrally located and more hyperechoic (whiter) mediastinum testis. The mediastinum testis is normally less than 5–6 mm wide. The parenchyma consists primarily of convoluted seminiferous tubules that contain the sustentacular (Sertoli) and germinal cells but also includes the adjacent interstitial (Leydig) cells along with associated vascular, neural, and stromal tissues. The seminiferous tubules are connected by the straight tubules to the rete testis that comprises a series of interconnected channels within the mediastinum testis. Sperm pass dorsally through the rete testis to the efferent ducts that in turn penetrate the capsule of the testis before uniting as the epididymal duct.

Changes in the ultrasonic appearance of the testis parenchyma can reflect normal events around puberty as well as pathology. An increase in echogenicity (increased pixel intensity, or a whiter parenchyma) has been reported to occur in association with sexual development around the time of puberty [9, 10], but ultrasonography was no better at predicting puberty than was measurement of scrotal circumference [10]. While pixel intensity has been correlated with attainment of sexual maturity as assessed by semen quality [11], it seems to be a better predictor of future semen quality than the present status of the bull [12]. Subsequent studies in mature bulls have failed to correlate pixel intensity with semen quality at BBSE [13] or with histologic measures of spermatogenesis [14].

In any event, objective assessment of these subtle changes in pixel intensity is not possible by real-time visual interpretation of an ultrasound image. To accurately assess pixel intensity, images must be obtained and digitally preserved using rigorously standardized methods. The digital files are then sampled and evaluated using computer software that can objectively assess the gray scale of each pixel in the sampled area, providing both an average intensity and measure of variation. Given the limited clinical utility and the great effort required, Brito et al. [10] concluded that "though testicular ultrasonogram pixel intensity might be useful for research purposes, clinical application of this technology in the present form for bull breeding soundness evaluation is not justifiable."

The majority of the discrete anomalous ultrasonographic changes detected in the testis are more hyperechoic than normal tissue. These may appear as small foci scattered throughout the testis (Figure 10.2) or they may be more localized (Figure 10.3). Larger hyperechoic lesions are often seen to radiate from the rete to the periphery of the testis, suggesting the complete involvement of one or more seminiferous tubules (Figure 10.4). The histologic basis for the increase in echogenicity is usually fibrosis [15] but the echogenicity itself does not confirm histology or etiology. Where a specific histologic diagnosis is provided in the accompanying ultrasound images, it is based on histopathologic assessment of excised tissues.

Figure 10.2 Sagittal view of the left testis of a mature bull with small hyperechoic foci distributed throughout the testis parenchyma.

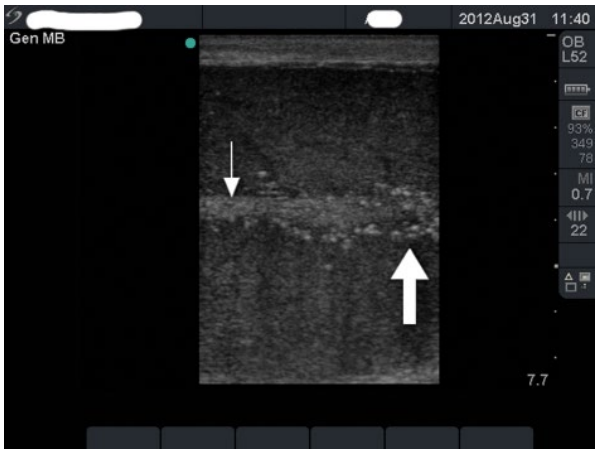

Figure 10.3 Sagittal view of a testis with small hyperechoic foci (large arrow) surrounding the mediastinum (small arrow) suggestive of lesions in the straight ducts that drain the seminiferous tubules into the rete testis.

Figure 10.4 Sagittal view of a testis with multiple linear radiating hyperechoic lesions, two of which are highlighted by the smaller arrows. A normal mediastinum testis is shown (large arrow).

Tumors are generally more hyperechoic than the normal testis parenchyma (Figure 10.5), but mixed or hypoechoic echogenicity is also possible [4]. Mineralized lesions are extremely hyperechoic and are usually accompanied by intense or complete shadowing causing a loss of image distal to the lesion (Figure 10.6).

Barth et al. [15] have proposed a scoring system for fibrotic lesions in the bull testis based on the size and frequency of hyperechoic lesions detected by ultrasonography in a single transmediastinal plane. They found that the occurrence of fibrotic lesions in young bulls aged between 3 and 20 months was not associated with decreased semen quality. This is consistent with their histologic findings, where seminiferous tubules within the area of fibrosis were generally affected, but immediately adjacent germinal tissue was quite often completely normal. However, bulls that experienced a dramatic increase in fibrosis score at a second examination (≥4 points, 4–13 months later) were more likely to have poor semen quality than bulls that did not experience this degree of change [15]. While bulls in this report with up to 50% of their parenchyma affected were able to produce mostly normal sperm, it is reasonable to suspect that they would have reduced production capacity.

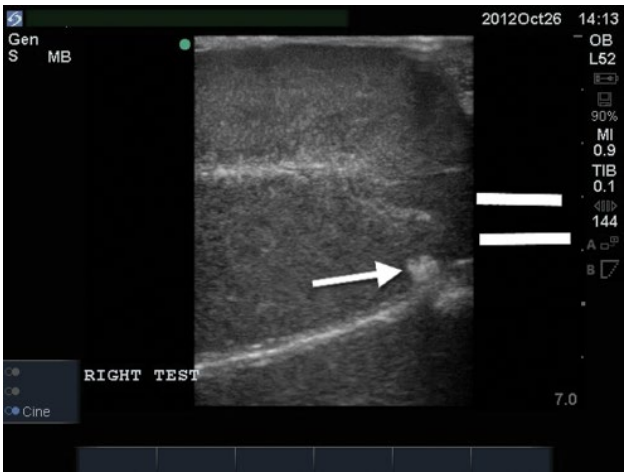

Figure 10.5 Sagittal view of the right ventral testis of an aged beef bull. Histologically, the hyperechoic lesion (arrow) was a Sertoli cell tumor.

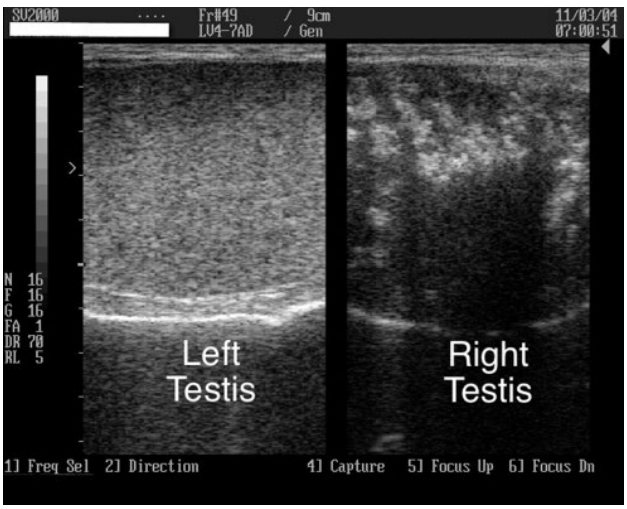

Figure 10.6 Sagittal views of the left and right testes of a yearling dairy bull. The left testis is normal, while the hyperechoic areas of the right testis cast prominent dark shadows in the distal tissue and represent areas of mineralization.

The cause of fibrotic lesions in the testis is unknown. Possible etiologies include infectious or inflammatory conditions, developmental defects of the seminiferous tubules or their connecting ducts, autoimmunity, degenerative conditions, or aging. Ram testes inoculated with *Trueperella pyogenes* (formerly *Arcanobacterium pyogenes*) eventually developed hyperechoic lesions that consisted of fibrotic tissue [16]. A severe outbreak of bovine respiratory syncytial virus (BRSV) in a group of bulls was associated with an increased prevalence of fibrotic lesions in one report, though a cause-and-effect relationship could not be confirmed [15]. On the other hand, scrotal insulation resulting in a dramatic decrease in semen quality did not cause fibrosis or any other ultrasonically detectable change in the testis within four months [17] or six months [12] after the insulation event. A progressive fibrosis that is more marked in the ventral testis has been described as a histologic feature of aging in the bull [18].

Distinct hypoechoic lesions in the testis parenchyma are seen less commonly (Figure 10.7). Intratesticular inoculation of *T. pyogenes* in rams caused an initial hypoechoic change associated with edema, neutrophilic infiltration, and degenerative changes in the seminiferous tubules [16]. Tumors may present as hypoechoic areas in some cases. Since an increase in echogenicity is seen at puberty in association with proliferation of the spermatogenic tissue, it seems reasonable to speculate that areas affected by a degenerative process would be more hypoechoic by contrast.

A hypoechoic distension of the rete testis was first reported in Ayrshire cattle [19]. Most of the bulls in this report had bilateral distension and were azoospermic by 16 months of age, suggesting a block to sperm outflow. A genetic predisposition to the condition was suspected. A similar unilateral lesion was reported in a mature Holstein bull in conjunction with agenesis of the ipsilateral seminal vesicle, epididymal body and tail, as well as low semen volume [20]. Figure 10.8 shows an ultrasonogram from a yearling Holstein bull with a history of oligospermia and low semen volume. Note the enlarged hypoechoic appearance of the mediastinum. The contralateral testis and mediastinum appeared normal (not shown). Surgical removal of the

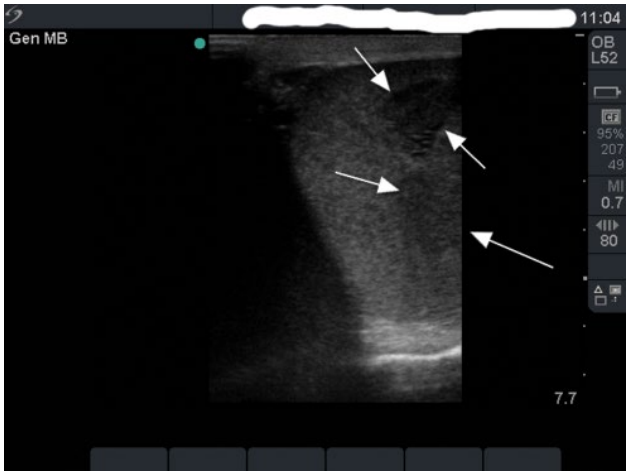

Figure 10.7 Transverse view of the testis containing two discrete hypoechoic wedge-shaped areas (between arrows) of unknown etiology or significance.

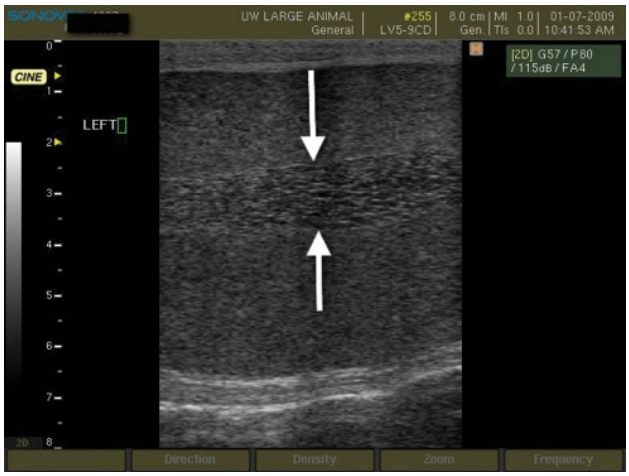

Figure 10.8 Sagittal view of the left testis of a mature Holstein bull that presented with a complaint of low semen volume and oligospermia. Note the hypoechoic distension of the rete testis (dark linear area between arrows). The distension was secondary to a complete outflow obstruction resulting from the absence of the epididymal body on this side.

affected testis confirmed a diagnosis of agenesis of the body of the epididymis and fluid distension of the rete testis. The distension can also affect the efferent ducts. In our experience, extensive and uniform hypoechoic distension of the rete testis as seen in Figure 10.8 is pathognomonic for sperm outflow obstruction, most often congenital. In unilateral cases, the presenting complaint is usually low sperm numbers and semen volume in an otherwise normal young bull. Congenital cases may be associated with aplasia affecting the epididymis, deferent duct, ampulla, or seminal vesicle.

The head of the epididymis is best seen in a sagittal view and is found on the dorsocranial aspect of the testis. It is usually less echoic than the parenchyma of the testis. The

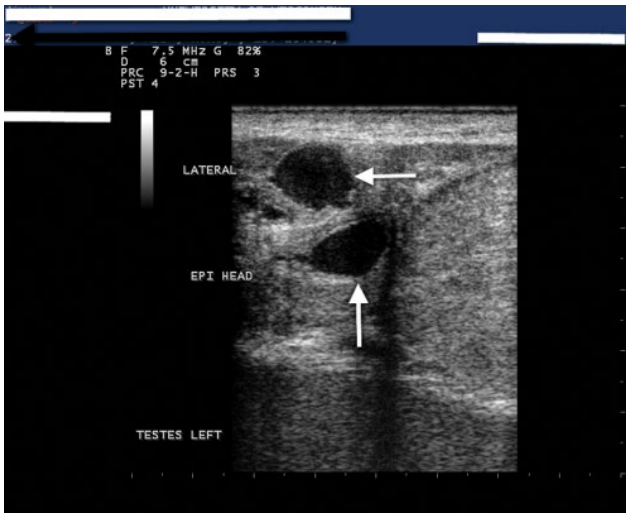

Figure 10.9 Sagittal view of the testis. Note the hypoechoic dilations (arrows) in or near the head of the epididymis. Normal testis parenchyma is seen to the right of the cysts.

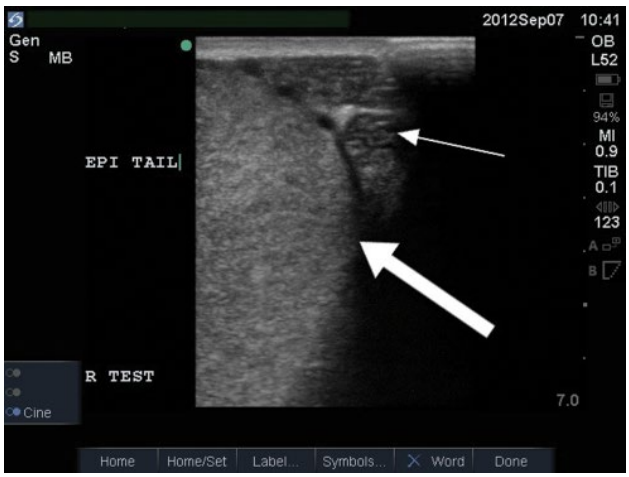

Figure 10.10 Sagittal view of the ventral testis (large arrow) and tail of the epididymis (small arrow) of a normal bull.

tail of the epididymis can be readily located by palpation and is found on the ventral aspect of the testis. Acquired lesions of the epididymides can lead to outflow obstruction. A cystic distension of the head of the epididymis is shown in Figure 10.9. It is worth noting that cysts of the appendix epididymis (proximal mesonephric duct remnant) are also found in this area and even those as large as a few centimeters in diameter usually do not interfere with normal epididymal function [6]. The epididymal tail (Figure 10.10) can be difficult to image with a transrectal probe and for fine detail one should consider using a higher-frequency probe with a smaller footprint. Congenital, traumatic, and inflammatory lesions can be seen here, with sperm stasis and granuloma formation as possible sequelae. Alterations

of size and echogenicity are characteristic of disease in this tissue. Multiple small sperm granulomas are visible as focal hyperechoic lesions in the tail of the epididymis (Figure 10.11).

Ultrasonography can provide more specific information about the extent, location, and resolution of scrotal pathology. Examples include scrotal hydrocele (Figure 10.12), inflammation, sperm granuloma, spermatocele, fibrosis, mineralization, herniation, tumors, abscesses, trauma, hemorrhage, outflow obstruction, and lesions of the scrotal wall and vasculature. The echogenic pattern seen is variable and often quite heterogeneous. In cases of testicular trauma (Figure 10.12), ultrasound can confirm the actual degree of damage to the testis and provide a more accurate prognosis for recovery. Ultrasound can be used in cases of scrotal hernia to confirm the presence of herniated bowel as well its viability as assessed by the presence or absence of peristalsis.

The final element of the scrotal ultrasound evaluation is an assessment of the scrotal neck and spermatic cord (Figure 10.13). While herniation, trauma, hemorrhage, and scrotal hydrocele can affect this region, they are usually more evident in the scrotum proper. The vas deferens cannot be reliably imaged in normal bulls. The primary ultrasonic feature of this region is the vascular cone consisting of the prominent tortuous testicular artery overlain by a fine network of very small veins called the pampiniform plexus. Brito et al. [21] reported an increase in vascular cone diameter up to 13.5 months of age in beef bulls and increased vascular cone diameter was positively correlated with an increased percentage of normal sperm.

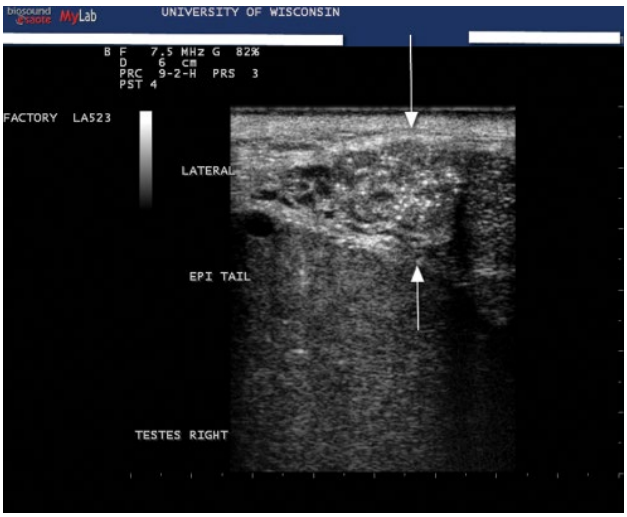

Figure 10.11 Transverse view of the ventral aspect of the right testis of an aged beef bull. The tail of the epididymis is seen between the arrows. The small white foci seen in the epididymal tissue between the arrows are sperm granulomas.

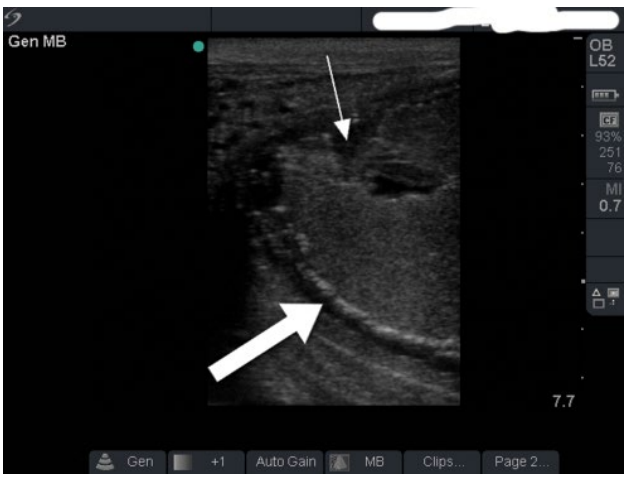

Figure 10.12 Sagittal view of the dorsal testis. The small arrow points to a traumatic lesion of the testis capsule and visceral vaginal tunic. The hypoechoic fluid surrounding the testicle is a persistent scrotal hydrocele (large arrow).

Examination of the Pelvic Organs

The anatomy of the pelvic accessory sex organs is reviewed in Chapter 1. Ultrasonic assessment of the accessory glands of the bull was first described in 1987 by Weber et al. [22] Transrectal ultrasound images are generally sagittal but may also be oblique to the long axis. An ultrasonic evaluation of the tissues is performed after first evacuating fecal material and manually palpating the reproductive tract. The transverse band of prostatic tissue on the dorsal aspect of the cranial extent of the pelvic urethra is a convenient landmark (Figure 10.14). The pelvic urethra is then imaged in a caudal direction (Figure 10.15) until the paired

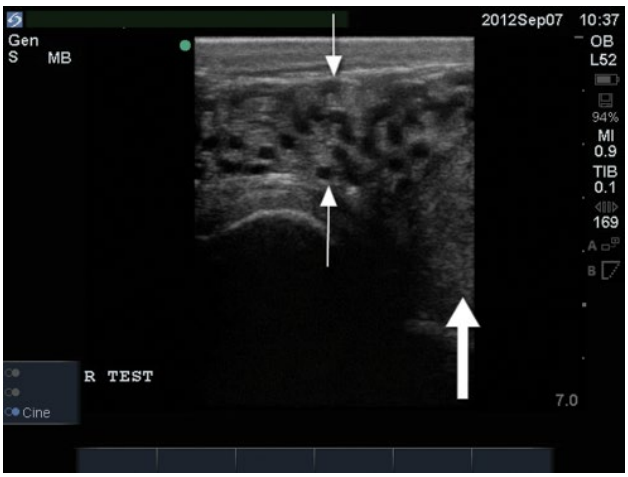

Figure 10.13 Sagittal view of the vascular cone (between small arrows) just dorsal to the testis (large arrow). The lumen of the testicular artery is represented by the black irregular areas in the vascular cone. The network of veins forming the pampiniform plexus is not usually visible due to their small size.

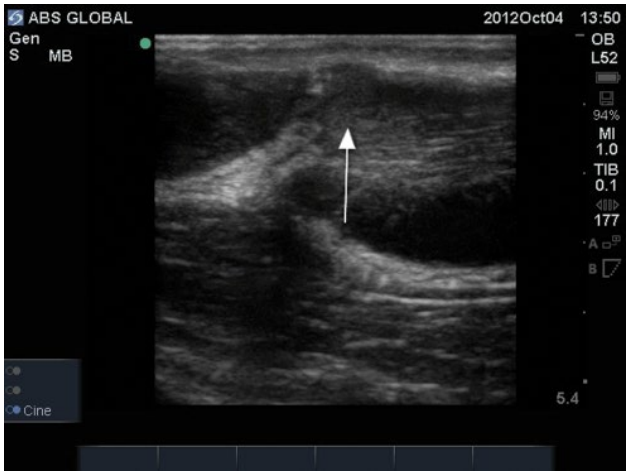

Figure 10.14 Midline sagittal view of the body of the prostate gland (ovoid tissue above arrow). Dorsal is on top, ventral on the bottom, cranial to the left, and caudal to the right.

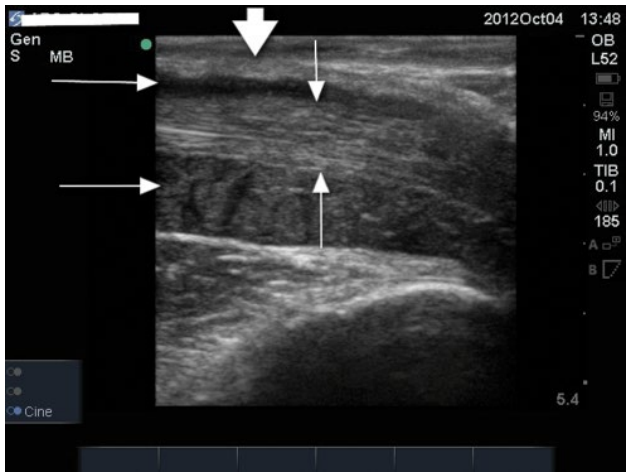

Figure 10.15 Sagittal view of the urethralis just caudal to the body of the prostate. The horizontal arrows on the left point to the more hypoechoic urethral muscle above and below the urethra. The more hyperechoic tissue between the vertical arrows is the cavernous tissue immediately surrounding the pelvic urethra. The disseminated prostate is seen as a hyperechoic linear structure on the dorsum of the urethralis (large vertical arrow). Dorsal is on top, ventral on the bottom, cranial to the left, and caudal to the right.

bulbourethral glands are detected (Figure 10.16). Moving cranially, the urethralis is followed until the prostate is encountered again. The paired ampullae are found just cranial to the prostate, on or near the midline (Figure 10.17). The paired vesicular glands are found just lateral to the ampullae (Figure 10.18). An ultrasonic assessment of the bladder should also be done at this time to check for anomalies, cystitis, or calculi.

Pathology of the bulbourethral glands and prostate is uncommon. Aplasia [6] and sperm accumulation [23] have

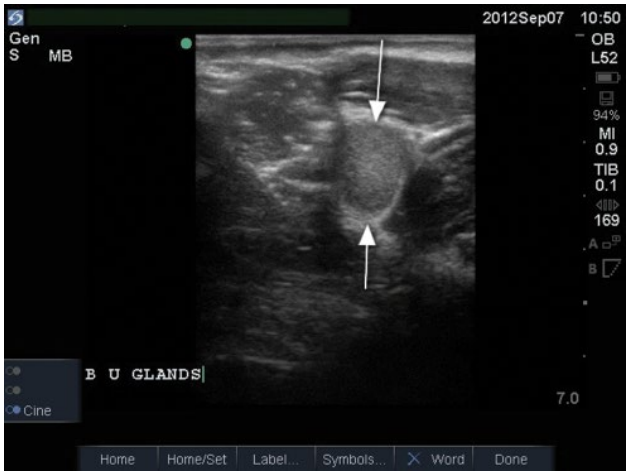

Figure 10.16 Sagittal view of the bulbourethral (Cowper's) gland (between arrows). Dorsal is on top, ventral on the bottom, cranial to the left, and caudal to the right.

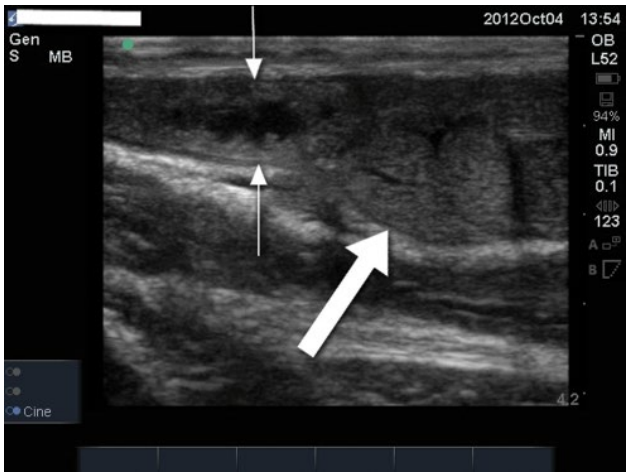

Figure 10.17 Sagittal view of the ampulla (between small arrows). Note the distended hypoechoic lumen surrounded by gland tissue. Luminal contents may or may not be seen during examination of normal bulls. The lobar tissue above and to the right of the large arrow is an adjacent seminal vesicle. Dorsal is on top, ventral on the bottom, cranial to the left, and caudal to the right.

been reported in the ampullae. Inflammation of the vesicular glands is relatively common in bulls and should be suspected whenever an asymmetry in size or echotexture is encountered. Inflamed glands are larger and often have a mixed echogenicity, while abscessed glands show a loss of lobar architecture and often have a globoid area of variable echogenicity [24]. A bacterial infection is most commonly incriminated as the cause of seminal vesiculitis, but sterile inflammation resulting from urine or sperm leaking into the glands is also a potential etiology. Figure 10.19 is an ultrasonogram from a two-year-old beef bull with segmental aplasia of the right vesicular gland. Note the cystic dilation

Figure 10.18 Oblique view of the seminal vesicle (horizontal tissue between arrows). Note the lobar architecture. A short segment of the hypoechoic central duct is seen in the center of the gland between the two arrows.

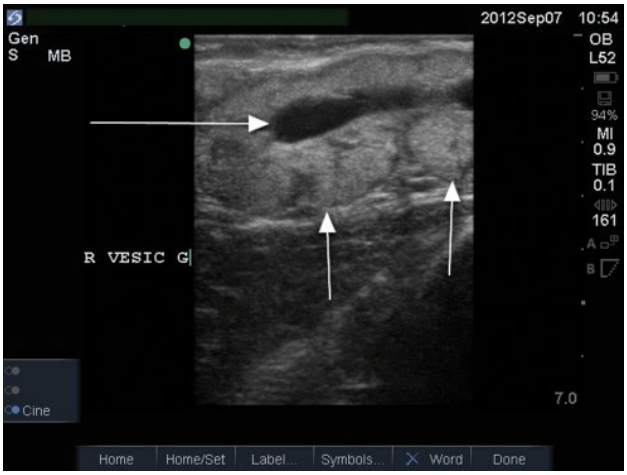

Figure 10.19 Oblique view of the seminal vesicle (above vertical arrows). This bull had a segmental aplasia of the seminal vesicle on this side resulting in the cystic distension of the central duct (horizontal arrow).

of the occluded central duct. The gland was much larger compared with the gland on the left. This bull also had aplasia of the right epididymal tail and a grossly distended hypoechoic right rete testis.

Examination of the Penis and Prepuce

Ultrasound can be used to examine the penis, prepuce, and penile urethra. Ultrasonography of the perineal area caudal and dorsal to the scrotum will generally require shaving the hair to obtain good images. The risks associated with ultrasound examination of the penis and prepuce cranial to the scrotum should be balanced with the lower probability of the examination providing valuable diagnostic and prognostic information beyond that obtained by visual inspection and palpation. Direct observation of the penis and prepuce during mating or semen collection is necessary to detect many conditions, such as penile hypoplasia, genital warts, persistent frenulum, hair rings, or balanoposthitis. Ultrasonically relevant lesions affecting the penis and prepuce include trauma, neoplasia, hematoma, abscess, calculi, urethral dilation and rupture, and vascular shunts.

Alternative Ultrasound Modalities

While B-mode ultrasonography is currently the most commonly employed modality for examination of reproductive tissue, other ultrasound-based diagnostic methods exist. Color Doppler, contrast-enhanced ultrasonography and tissue elastography are adjunct imaging modalities used to investigate lesions in human testes [25] as well as other tissues.

The direction, relative velocity, and volume of blood flow in arteries can be assessed by use of Doppler ultrasonography [4]. A color Doppler ultrasonogram of the testicular artery dorsal to the testis within the vascular cone is shown in Figure 10.20. In a recent report using Doppler ultrasound, the resistive index in both the marginal and intratesticular portions (Figure 10.21) of the testicular artery of the bull were correlated with the total sperm in the ejaculate, immature sperm, abnormal sperm, and presence of the Dag defect [26]. Because of the relative ease of marginal testicular artery imaging (located medial to the testis), the

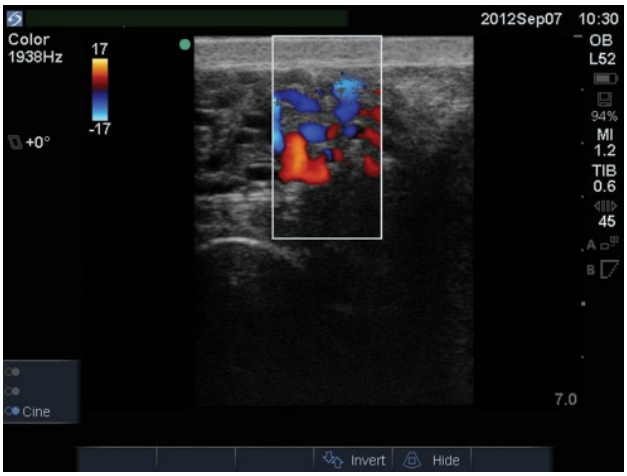

Figure 10.20 Sagittal view of the vascular cone using color Doppler mode. The direction of blood flow in the supratesticular portion of the testicular artery is indicated by color and the velocity by shade within color.

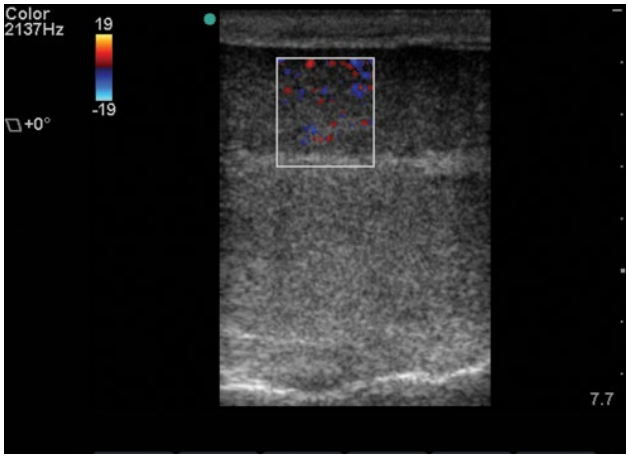

Figure 10.21 Sagittal color Doppler image of the testis illustrating blood flow (colored areas) in the intratesticular portion of the testicular artery.

authors conclude that this could be an "easy-to-perform parameter to evaluate the spermatogenesis quality" in bulls. And while the correlations in this report were significant, there was no evidence that they could be used to establish cut-off values to distinguish between satisfactory and unsatisfactory breeding bulls.

Tissue elastography measures the stiffness of tissue in response to an applied force. This force can be applied either mechanically or by the ultrasound waves themselves. A soft consistency of the testis is present in cases of testicular degeneration [27], but manual assessment of testis consistency is limited by both its subjective nature and the presence of intervening scrotal wall with varied skin texture and fat deposits. Mechanical systems that compress the scrotal surface have been proposed [28], but they still have limitations as they must be applied to the scrotal surface and do not directly measure the consistency of the testis. Tissue elastography offers the advantage of both more objective assessment of tissue stiffness and the ability to focus on the tissue of interest within the testis. Most focal lesions of the testes will differ in consistency in comparison to the surrounding normal parenchyma.

It is important to note that most inexpensive portable bovine ultrasound systems lack a color Doppler function and even much more expensive systems do not routinely offer elastography. Given the cost and limited clinical application in bulls, these modalities will be of more interest to researchers than to clinicians for the foreseeable future.

Summary

Diagnostic ultrasound is a safe, non-invasive method for acquiring additional diagnostic and prognostic information in cases of infertility in the bull. Clinical competence with bull genital ultrasonography can be readily achieved by routinely imaging the genital tract of normal healthy bulls. This will provide the frame of reference necessary to identify and interpret pathologic changes as they are encountered. The common lesions are seldom subtle and are readily detected by systems providing average or better image quality. We recommend ultrasonography as an adjunct to the BBSE for all cases of subfertility in artificial insemination (AI) sires and valuable natural service sires. Routine screening of young sires as part of a pre-purchase evaluation should be done with caution as the most common ultrasound change encountered is a fibrotic lesion or foci in the testes. These lesions have been shown to have little or no effect on semen quality in young bulls. Advances in ultrasound diagnostic capability, especially as it relates to assessment of blood flow in the scrotum or tissue density measurement, may enhance our ability to discriminate between fertile and infertile bulls in the future.

Management of Breeding Bull Batteries

E. Heath King

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

The purchase and maintenance cost of the bull battery represents a significant expense to the cow calf producer. Improper management of this investment can have negative economic consequences through both a reduction in herd productivity and the loss of bulls due to injury or death. A reduction in the size of the calf crop or loss of the calf crop is easily noticed by the producer, but many subfertile bulls are capable of inefficiently producing offspring and this may go unnoticed in some herds. This inefficiency leads to delayed conception, which has been estimated to cost 23–27 kg of weaning weight for every 21 days a cow remains open during the breeding season [1]. In an attempt to compensate for poor bull management, producers will often increase the stocking density of bulls within their herd. The expense of purchasing and maintaining excess bulls can also limit the profitability of a herd.

The management of breeding bulls will vary somewhat between herds, but the overall goal should be to provide a group of disease-free, structurally sound, and physically fit fertile bulls with good libido. Achievement of this goal requires an understanding of both the general and reproductive health requirements of breeding bulls and how these requirements change during the production phase of the bull. The production phase of a breeding bull can be divided into three time periods: the pre-breeding period, breeding period, and non-breeding period.

Pre-Breeding Period

The pre-breeding period begins 60–90 days prior to the start of the breeding season. Breeding soundness evaluations, vaccinations, and diagnostic testing for reproductive pathogens should all occur at the beginning of this period. Performing these procedures early gives the producer time to find replacements if necessary. Vaccination prior to the start of the breeding season should provide protection to the bull while reducing or eliminating his significance as a disease reservoir or vector. Vaccinating bulls at least 60 days prior to the breeding season should allow any viral shedding or transient negative effects on spermatogenesis to subside before breeding. Body condition can also be assessed at this time and minor adjustments to the diet made if necessary.

Breeding Soundness Evaluation

Breeding soundness evaluations should be performed by a veterinarian on all bulls prior to the breeding season. Any bulls deemed unsatisfactory potential breeders, by the standards for breeding soundness of the Society for Theriogenology, should not be used for breeding and bulls placed in the deferred category should be reevaluated prior to use. Herds with two breeding seasons should have their bulls examined before each season. The complete breeding soundness evaluation of breeding bulls is covered in Chapters 7, 8, and 9. Lameness and other foot problems are often first identified during the breeding soundness evaluation. Performing these examinations early will allow for treatment and corrective trimming prior to breeding, possibly salvaging bulls that may have been culled otherwise.

Vaccination

As a general recommendation, breeding bulls should be vaccinated for the same pathogens as the mature cow herd. Vaccination should include protection against clostridial diseases, leptospirosis, campylobacteriosis, bovine viral

Companion website: www.wiley.com/go/hopper/bovine

diarrhea virus (BVDV), and bovine herpesvirus 1. Vaccine efficacy and safety varies between vaccine types and products. The goal of this section is not to endorse specific products but to demonstrate the role vaccination plays in control of these pathogens and to address any negative impacts vaccination may have on bull fertility.

Clostridial Diseases

Clostridial diseases are not transmitted directly between cattle and are not considered reproductive pathogens, but they are invariably fatal. Therefore vaccination is solely aimed at protection of the bull. All clostridial vaccines are killed products and should be boostered according to the label directions. Annual revaccination is recommended especially in all cattle two years of age and younger [2].

Leptospirosis

Leptospirosis is a common cause of abortion and infertility of cattle worldwide. More than 200 serovars of *Leptospira* have been identified, each of which is supported within its own maintenance host. The severity and chronicity of disease caused by organisms of the genus *Leptospira* depends on whether infection is taking place in the maintenance host (host-adapted) for that specific serovar or an incidental host (non-host-adapted) [3]. Cattle are the maintenance host for serovar *hardjo*, which contains two genetically distinct types: *Leptospira interrogans* serovar *hardjo* type *hardjoprajitno* found primarily in the British Isles and *Leptospira borgpetersenii* serovar *hardjo* type *hardjo-bovis* found throughout the world including North America [4, 5]. Infection of cattle with a non-host-adapted serovar is characterized by acute disease, late-term abortion, and transient renal shedding of the organism. Infection with the serovar *hardjo* is characterized by chronic infections, prolonged renal shedding, abortion, and infertility [4]. *Leptospira* species are primarily shed in the urine of infected cattle. Transmission is possible via semen, and venereal transmission of serovar *hardjo* is thought to be common [3, 6].

Vaccination of cattle against leptospirosis is a complex and controversial subject. Many pentavalent vaccines marked for prevention and control of leptospirosis contain antigens for *hardjoprajitno* not *hardjo-bovis*, the type most commonly isolated in North America [5]. Challenge studies evaluating the efficacy of pentavalent vaccines for protection against *hardjo-bovis* have yielded conflicting data; however, these studies utilized different products and the time period from initial vaccination until administration of the booster differed greatly [7, 8]. Administration of a commercial monovalent *hardjo-bovis* vaccine has been shown to prevent renal colonization and shedding of *hardjo-bovis* following challenge [9]. The subject is further complicated by the true incidence of infertility that can be attributed to *hardjo-bovis*. A study in California involving 207 first-lactation cows found that cows seropositive for serovar *hardjo* had a mean time from calving to conception 34 days longer than seronegative cattle [10]. However, when beef cattle were vaccinated with a commercially available monovalent *hardjo-bovis* vaccine and administered oxytetracycline to eliminate the carrier state of *hardjo-bovis*, no improvements in pregnancy and calving rates were observed [11]. The decision to vaccinate and the product used should be based on the prevalence of leptospirosis in the area and its potential impact on reproductive performance in the herd. All the commercial vaccines currently available are killed products which should be boostered according to the label and revaccination annually is recommended.

Campylobacteriosis

Bovine venereal campylobacteriosis caused by *Campylobacter fetus* subsp. *venerealis* results in transient infertility in cattle and occasional abortion. The bull serves as an asymptomatic carrier transmitting the organism to cows during coitus. Vaccination of bulls with an oil-adjuvanted killed bacterin can be both protective and curative [12–14]. Exposure of 4- and 5-year-old vaccinated bulls to *C. fetus*-infected heifers resulted in transmission to only 1 of 17 unvaccinated naive heifers and carrier status was not established in any of the five bulls exposed [12]. Therapeutic vaccination of experimentally infected 5-year-old bulls with a two-dose series of an oil adjuvanted killed bacterin was curative in 8 of 10 bulls [13]. While prophylactic vaccination will not clear infection in all bulls, it is an important and inexpensive method of control. The efficacy of vaccines containing an aluminum hydroxide adjuvant is questionable [14, 15]. All bulls should be vaccinated and boostered according to the vaccine label and annual revaccination is recommended.

Bovine Viral Diarrhea

Clinical manifestation of BVDV infection in cattle can vary from subclinical to fatal [16]. BVDV is transmitted primarily by direct contact with bodily fluids of infected cattle. Venereal transmission via semen from acutely and persistently infected bulls is also well documented [17, 18]. Cattle that are born persistently infected with BVDV shed large amounts of the virus and are considered the major reservoir. Control of BVDV centers around elimination of these persistently infected individuals combined with vaccination and biosecurity measures to prevent exposure to BVDV [16].

The bull is also capable of maintaining a prolonged testicular infection that persists beyond the initial viremia [19, 20]. These localized prolonged testicular infections can persist for at least 2.75 years and have been induced by vaccination of seronegative peripubertal bulls with a modified live vaccine containing non-cytopathic BVDV [20, 21]. Semen from one bull with prolonged testicular BVDV infection was capable of infecting heifers through artificial insemination (AI); however, others studies evaluating transmission from bulls with prolonged testicular infection have not resulted in transmission [20, 22]. While the exact risk of transmission from these bulls appears to be low, further studies are needed before the use of vaccines containing non-cytopathic BVDV can be recommended in breeding bulls [14, 20]. Current recommendation are to vaccinate all bulls with a vaccine containing cytopathic modified live BVDV at least 28 days prior to breeding and booster according to the product label recommendations [14].

Infectious Bovine Rhinotracheitis

Bovine herpesvirus (BHV)-1 is a common cause of abortion, conjunctivitis, and respiratory disease of cattle. Genital infections also occur, resulting in balanoposthitis of bulls and pustular vulvovaginitis of cows. Cattle that become infected often develop latent infection that can reactivate later, complicating BHV-1 control in the herd. The virus is shed by the mucous membranes of the respiratory tract, conjunctiva, and genital tract and transmission occurs primarily through direct contact. Venereal transmission occurs during natural mating and through AI with contaminated semen [23].

Vaccine products containing killed or modified live BHV-1 are available for cattle. In general, the protection induced by modified live viral products is more rapid and of longer duration than killed viral products. However, modified live BHV-1 vaccine products are capable of establishing latency that can be reactivated under stress and have been reported to cause abortion if used inappropriately in pregnant cows [24–26]. Most modified live products available for use in pregnant cows carry a label which states that the vaccine may be used in pregnant cows and calves nursing pregnant cows only if those cattle were vaccinated with the same product within the last 12 months. In order to err on the side of caution, it is my opinion that bulls should be vaccinated with the same BHV-1 vaccine product as the mature cow herd. Vaccine products containing modified live BHV-1 should not be administered to bulls unless the cow herd received the same vaccine product in the previous 12 months.

Trichomoniasis

Trichomoniasis caused by the protozoan *Tritrichomonas foetus* subsp. *venerealis* is a venereal disease resulting in endometritis, embryonic death, abortion, and pyometra in infected cattle. The bull serves as an asymptomatic carrier [27]. Prevention of bovine trichomoniasis is centered on biosecurity practices to avoid introduction of infected individuals into the herd. Only one *T. foetus* vaccine is currently available in the USA. Administration of this killed vaccine to bulls aged 55–72 months prevented colonization of the preputial epithelium following intrapreputial challenge [28]. Within affected herds, vaccination of bulls and cows may reduce the economic impact of this pathogen [14].

Breeding Period

The length of the breeding period is generally determined by the producer and can vary from 65 to 365 days. A controlled calving/breeding season has obvious economic advantages and simplifies the overall health management of the herd; however, in many herds especially in the southern USA the bull is housed with the cow herd year round. The following discussion on the stocking rate of bulls will assume that the herd has a controlled breeding season of 65–90 days.

Stocking Rate

The correct stocking rate of bulls, or more specifically the bull to cow ratio that will result in the most efficient and successful servicing of females, is not known. Typical bull to cow ratios in the USA ranges from 1 : 20 to 1 : 30 for mature bulls [29]. Young bulls less than 3 years of age can be placed with one cow per month of age; for example, a 15-month-old bull can be expected to service 15 cows during the breeding season [30]. Assuming that a bull is fertile and has passed a breeding soundness examination, other factors that will influence the number of females he can successfully service during the breeding season include his libido or "sex drive" and his social ranking, both of which are difficult to quantify and predict. The assessment and measurement of bull libido can be attempted by performing a servicing capacity test; however, no standardized testing method exists and results vary depending on age of the bulls tested, breed, and the methodology of the test [31]. An Australian trial of 1100 servicing capacity tests found that measurements of sexual behavior were not consistently correlated to the calf output of the tested bulls and that the main value of a servicing capacity test may be to identify bulls that are unable to mount and/or gain intromission [32].

Social dominance occurs in multisire herds where the presence of a dominant bull suppresses mating activity of other bulls. Dominance is generally expressed by older, more senior bulls and the effects may become more pronounced as the number of females assigned to each bull is reduced [29, 33]. The impact of social dominance on individual bull performance was demonstrated by a series of trials from northern Australia which examined the effect of the bull to cow ratio in multisire breeding groups on reproductive performance. Reducing the percentage of bulls to cows from 6 to 2.5% had no impact on conception patterns between groups. Variation in calf output between bulls was noted in both groups but was significantly reduced when fewer bulls were utilized. The area of movement of individual bulls within the pasture expanded as the percentage of bulls to cows decreased, suggesting that the effects of social dominance were reduced by increasing the breeding pressure on the bull battery. Interestingly, bull attrition due to injury was also reduced [33].

Recently, workers from Auburn University published the following formula for bull to cow ratio:

$$B = 1 + \left[\left(T - N \right) / 1 / 2N \right]$$

where B is number of bulls required to breed the given number (T) of cows in the breeding group and N is the individual bull's fair complement of cows as a single-sire breeding group. N is calculated for bulls less than three years of age by assigning one cow per month of age. Scrotal circumference is used to calculate N for bulls greater than three years of age, where one cow is assigned for each centimeter of scrotal circumference.

This formula assumes that after the first bull each additional bull added to a multisire herd can only be expected to reliably service half the number of females that he would service in a single-sire breeding group [30]. Utilizing this formula for a 200-cow breeding group will demonstrate the inefficiency that many people believe exists in a multisire breeding group. The calculated requirements for this group would be nine adult bulls with 40-cm scrotal circumferences; however, if this same group was divided into single-sire breeding groups of 40 cows each, only five bulls would be needed to service the entire herd. Clearly, single-sire breeding groups would be a more efficient use of bulls in this situation, but the added expense of fencing required for single-sire breeding groups and the risk of bull injury/illness going unnoticed make producers hesitant to adopt this management strategy.

Scientific recommendations on bull stocking rates are difficult because variations in libido exist between bulls but are hard to predict and the effects social dominance on breeding performance are not well understood. While the effects of social dominance and breeding overlap may reduce the efficiency of multisire breeding groups in terms of the number of bulls needed compared with single-sire breeding groups, these effects have been reportedly reduced by increasing the breeding pressure on the bulls [33]. Clearly, more research is needed in this area so that more accurate recommendations can be made to producers, allowing them to avoid purchasing and maintaining excess bulls. Until further research is published, the Auburn formula provides a good guide when making recommendations to producers and is not likely to result in inadequate bull power.

Producer Observation

Libido is not assessed during the routine breeding soundness examinations of bulls, so it is up to the producer to ensure that the bull is actively servicing cows. Producers should take care to observe that intromission is achieved when a female is mounted and make note of the date when the individual was serviced. Breeding injuries and lameness are best identified early so that treatment can be initiated and adjustments made before the herd's reproductive performance is reduced. Routine observation of the herd and documentation of breeding activity during the breeding season is especially important in the single-sire breeding group to prevent loss or reduction in the calf crop.

Non-Breeding Period

The non-breeding period provides an opportunity for the bulls to rest and replace any weight that was lost during the breeding season. Body condition scoring or weighing bulls at this time will allow producers to make the necessary dietary changes to ensure that the bull battery enters the next breeding season at an appropriate body condition. The effect of body condition on breeding performance of mature bulls is not well documented; however, logic would suggest that avoiding overconditioning will reduce the effort to mount and the force on the hindlimbs during mating. Commonly, breeding bulls are fed to reach a body condition score of 6–7 prior to entering the breeding season [34]. Dietary energy excess has been shown to have detrimental effects on semen quality in yearling bulls. These effects are thought to be related to impaired thermoregulation of the testes due to increased scrotal fat deposition [35].

Housing during the Non-Breeding Period

Group housing is generally recommended for bulls used in multisire breeding groups to reduce bull attrition due to injury during the breeding season by allowing the social hierarchy to be established and maintained in the absence

of females. Some separation of bulls may be necessary depending on the uniformity of the bull battery. Young bulls less than two years of age may need to be grouped separately to avoid competition for feedstuffs and allow for continued growth and development. Bulls finishing the breeding season in poor body condition may likewise be grouped together or fed separately until their body condition improves. Housing recommendations in cold climates with significant snowfall may also include the addition of a shelter with bedding to avoid scrotal frostbite.

Parasite Control

Specific recommendations on parasite control will vary depending on the geographical region. Most bulls are dewormed once yearly prior to the breeding season. In warmer more humid climates, twice-yearly deworming may be necessary, especially in younger bulls. Yearling bulls are at the highest risk for internal parasitism and may need to be dewormed immediately following the breeding season to remove the parasite burden accumulated while in the cow herd. Fly control is also important in bulls to eliminate fly strike in the scrotal region, which can lead to inflammation and impaired thermoregulation of the testes [34].

Biosecurity Concerns for Replacement Bulls

The introduction of replacement bulls into the cow herd represents a significant risk for disease introduction. The primary pathogens of interest in the USA include *Brucella abortus*, *Campylobacter fetus* subsp. *venerealis*, *Tritrichomonas foetus* subsp. *venerealis*, *Leptospira* species, *Mycobacterium avium* subsp. *paratuberculosis*, *Mycobacterium bovis*, BVDV, and BHV-1.

In addition to diagnostic screening for potential pathogens, all replacement bulls should be quarantined for a minimum of 30 days before exposure to the cow herd. This period will allow viral shedding to cease in bulls with acute BVDV and BHV-1. Producers should also be aware that no diagnostic test is 100% sensitive and therefore bulls should be purchased from herds with good health programs. Purchasing bulls from herds that are certified free for a specific pathogen provides additional security. Likewise, purchasing virgin bulls eliminates the risk for *C. fetus* and *T. foetus*.

Recommendations for Dairies Utilizing Natural Service

The genetic improvements associated with AI and their impact on production and profitability in the dairy industry are well established. However, utilization of natural service (NS) is still widespread for a variety of reasons [36]. Bulls may be utilized to improve estrus detection, resulting in increased conception rates, as a management tool to prevent dystocia in heifers, for the production of dairy beef, and to decrease the cost and labor associated with AI [36, 37]. The use of NS to improve reproductive efficiency in dairy herds with poor reproductive performance can improve profitability by decreasing the calving to conception interval, resulting in increased milk production per cow and reducing culling. These improvements may not be economically significant in herds with acceptable reproductive performance [37]. The most obvious disadvantages of NS are reduced genetic improvement, cost associated with bull purchase and replacement of bulls, disease introduction and transmission, and safety. The extent of the reduction in genetic improvement by utilizing NS depends on the quality of bulls utilized. Some dairies offset this loss by utilizing a combination of one or multiple attempts of AI followed by NS. Only heifers produced from AI are then retained for replacements.

The typical stocking rate of bulls on dairies ranges from 1 : 20 to 1 : 30 bulls to cows [38, 39]. This stocking rate can vary significantly between dairies, especially those that utilize AI followed by NS. In herds that utilize this combination, the bulls needed should be based on the actual number of cows that are eligible to become pregnant at the time of bull turnout. The length of the bull breeding season is also quite variable between dairies and is commonly impacted by seasonal breeding. Dairy bull attrition due to lameness is a common problem resulting from a combination of diet, housing and flooring, and injury from fighting. Lactating cow rations are higher in energy, protein, and calcium, which exceed the needs for bull maintenance. The excess energy leads to laminitis, while excessive calcium has been shown to induce skeletal lesions [38]. Rest and rotation of bulls during the breeding period is recommended to reduce the impact of diet and hard-surface flooring on lameness. Whether bulls are rotated or not, the length of rest periods varies greatly among dairies. One report from California dairies utilizing NS found that bulls are never removed from the breeding group after initial introduction in 47% of the dairies surveyed [40]. Reports from Australia found that bulls are left in the breeding group from 1 to 14 days and then are rested for an average of 7 days before returning to the breeding group. The Australian dairies surveyed used bulls on average for 56 days following multiple attempts at AI [41]. Using young bulls, less than 2.5 years of age, is recommended to reduce the impact of social dominance on breeding and fighting and to improve human safety. Social dominance is thought to be less dramatic if bulls of similar age and size are utilized [36].

Other management considerations of paramount importance include the fertility of the bulls used and their potential to introduce disease into the herd. Lameness is common in dairy bulls, as discussed above, and it can impact fertility by reducing bull libido and physical ability to seek out and service cows. Chronic lameness will also reduce semen quality. Dairy bulls should be assessed frequently for lameness and should have breeding soundness examinations performed before introduction and, at least, annually thereafter [36]. The biosecurity risk that the dairy bull represents is similar to the concerns discussed above regarding beef bulls. Special considerations should be given for sexually transmitted diseases like trichomoniasis, campylobacteriosis, and host-adapted leptospirosis when NS is utilized. The diagnosis, treatment, and prevention of these conditions is covered in their respective chapters. Likewise, a complete overview of biosecurity measures for the beef and dairy herds is covered in Chapter 28.

Management of Bulls at Custom Collection Studs

Gary Warner

Elgin Veterinary Hospital, Elgin, TX, USA

Veterinary Services for the Commercial Bull Stud

The semen collection – or "custom bull stud" – industry has markedly evolved during the time it has been in existence. Initially, a large majority of semen product was provided by large cooperatives or studs that maintained a large resident bull herd, catering primarily to the dairy industry and its needs. Most bulls in these studs were either purchased outright by stud management or secured by a long-term lease, and thus breeders/owners very rarely realized the full rewards of their production successes. Beef cattle were processed as an aside, as the beef industry's use of frozen semen products was not widespread. As technology and breeding synchronization systems have evolved, the demand for semen in the beef industry has skyrocketed and custom bull studs have developed throughout the USA. These custom studs allow bull owners the opportunity to present herd sires with proven genetic merit, process and store these quality genetics, and retain ownership and possession of the bull. Also it gives bull owners the option to access the international marketplace by allowing them to transport the frozen semen product anywhere in the world.

To assure health quality of the frozen semen products, any semen produced for export must meet standards set by Certified Semen Services, Inc. (CSS). Recommendations for housing, collection, handling, and health testing are made and supervised by administrators within this organization. Recommendations for health standards for residents at the bull studs are taken from guidelines published by the World Organization for Animal Health (OIE). This group concerns itself with advising importing and exporting countries on protecting themselves from introducing disease into their countries from foreign sources. Many countries will take the guidelines of the OIE and formulate entry requirements for cattle as well as bovine germplasm, both semen and embryos. Guidelines are specific and must be followed, as entry is forbidden unless standards are met.

The Veterinarian's Role in the Bull Stud

The primary role of a veterinarian in an artificial insemination center (AIC) is to ensure biosecurity and animal welfare for the bovine population housed there. Standards for testing protocols are established and readily available on the website of the National Association of Animal Breeders (NAAB) (www.naab-css.org). These are standard recommendations for the industry that are accepted by the United States Department of Agriculture (USDA)/Animal and Plant Health Inspection Service (APHIS) but certainly may be augmented by any further testing considered appropriate by the center's veterinarian.

The ultimate responsibility of the veterinarian is to assure the welfare of the animals under his or her care. Since the stud is usually compensated by the units of semen provided, it is in the stud's best interest to ensure that the cattle in its charge are adequately cared for. This means that feed, water, forage, and facilities meet the best of standards for quality. Although some facilities may retain the services of a nutritionist, others may rely on their veterinarian for suggestions on ration formulation or forage sampling and testing. Supplementation of minerals should not be forgotten for long-term resident herd members. Quality control of commercial feed rations should be observed and the resident veterinarian should periodically check feed and storage facilities to ensure proper care and quality.

Since the focus of this chapter is the private veterinarian consulting for the bull stud, we should concentrate on the start of the process: entry into the bull stud. There are three periods at which health testing requirements must

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

be performed: pre-isolation, isolation, and routine testing that will take place at regular intervals after entry into the resident herd.

The first round of testing, pre-isolation testing, may be done at the farm of origin by the resident veterinarian. Pre-entry requirements should be met within 30 days prior to entering the isolation facility. If bull owners do not wish to trouble themselves with testing, many custom studs offer pre-isolation facilities to house the bull while testing is conducted. These pre-entry requirements also apply to any mount or jump animals to be used in isolation or the resident herd. The isolation and resident testing requirements will be conducted upon arrival at the collection facility and at prescribed intervals thereafter. All testing phases require a complete physical examination, a negative intradermal test for tuberculosis, a negative test for bovine brucellosis, and a negative test for bovine leptospirosis. Those with titers of 1:100 or greater for leptospirosis may be reevaluated in two to four weeks. Those with titer no greater than 1:400 will be considered stabilized and allowed entry into isolation. Testing for bovine viral diarrhea virus (BVDV) should be performed before entry and a negative result obtained; the testing must only be conducted by virus isolation from whole blood or serum performed in cell culture, followed by evaluation of cell cultures with immunoperoxidase (IP), fluorescent antibody (FA), enzyme-linked immunosorbent assay (ELISA), or polymerase chain reaction (PCR). Lastly, testing for campylobacteriosis and trichomoniasis is required during the isolation period and at six-month intervals thereafter. For both diseases, bulls are required to undergo a series of weekly tests, with the required number varying depending on the age of the bull. Table 12.1 outlines a basic AIC testing protocol. Please refer to http://www.naab-css.org

Table 12.1 Basic AIC testing protocol per CSS testing requirements.

	Testing environment		
	Pre-entry to isolation	**Isolation**	**Resident herd**
Physical examination	Conducted by accredited veterinarian	Conducted by accredited veterinarian	Conducted by accredited veterinarian
Tuberculosis	Negative intradermal tuberculin test (within 60 days prior to entry)	Negative intradermal tuberculin test at least 60 days after pre-entry test	Negative intradermal tuberculin test at 6-month intervals
Brucellosis	Official test of state where bull is located. Blood serum test (CF, BAPA, or Card)	CF and one BAPA or Card test at least 30 days after pre-entry testing	CF and one BAPA or Card test at 6-month intervals
BVDV	One negative virus isolation test performed on either whole blood (animals less than 6 months of age) or serum	Virus isolation and serologic testing at least 10 days after entry into the isolation facility. If seropositive, virus isolation of semen required	Not required
Leptospirosis	Blood test for five serotypes important in the USA[a]	Blood test for five serotypes important in the USA[a] at least 30 days after pre-entry test	Blood test for five serotypes important in the USA[a] at 6-month intervals
Campylobacteriosis	Not required	Series of negative culture tests of preputial material or screening by FA, with any positive FA tested by culture for final determination; 1, 3, or 6 consecutive weekly tests; number of necessary tests dependent on age	Negative single culture test of preputial material or FA for screening test at 6-month intervals
Trichomoniasis	Not required	Series of negative microscopic examinations of cultured preputial material; 1, 3, or 6 consecutive weekly tests; number of necessary tests dependent on age	Negative single microscopic test of cultured preputial material at 6-month intervals

for complete details and the most recent updates regarding testing requirements.

Examination of entry-level animals should be conducted as soon as possible after admission to pre-isolation. A good physical should include observation of ambulation on a surface that provides good footing, preferably loose soil or grass. At this time all physical features should be assessed from the muzzle to the tail, paying particular attention to the feet (Figure 12.1). After this initial examination, the bull should be properly restrained in a squeeze chute, head gate, or lock stanchion. For beef bulls, a squeeze chute would be most desirable for restraint. Starting at the head, the oral cavity should be examined, making sure that all teeth are present and showing even wear (particularly important in more aged herd sires). The eyes should be evaluated for clarity, any presence of neoplasia, or previous injury. Make sure both eyes respond to movement and function normally. The ears are checked for any unusual discharge; in some areas of the country they should also be checked for ear ticks. The bull's chest should be auscultated and any abnormalities noted, as should the entire abdominal cavity. Particular attention should be paid to rumenal contractions, both in strength and number. Several peripheral regional lymph nodes are palpated for any evidence of lymphadenitis. Next, the underline of the bull should be evaluated from the bottom of the chute. The preputial orifice is palpated and examined as well as the scrotum, with palpation of the testes and all epididymal structures. Record the scrotal circumference with a scrotal measuring tape. Evaluation of the lower limb joints and hooves is performed at this time as well. Lastly, rectal palpation should be performed to evaluate abdominal structure, with a rectal temperature being taken and recorded. It is vital to pay attention to accessory reproductive organs, with specific interest in the health of the seminal vesicles. During the rectal examination, it is a good idea to massage the crus of the penis to allow an assistant the opportunity to fully extend the penis. Both vaginal rings are palpated and any abnormalities noted. After examination and pre-entry testing, follow the recommendation of the NAAB/CSS for entry into isolation after presentation at the stud. Some producers may not be interested in submitting a bull for further testing as they have no desire to export semen. It is always recommended to follow CSS guidelines on any mature bull that has been breeding cows before presentation for collection.

At the time of entry into isolation at the bull stud, or AIC as some like to be called, the bull is assigned a unique sire code number per the NAAB uniform coding system, if the stud is an NAAB participant. This code is separate and apart from any tattoo or brand used in a breed registry. The bull may display this code in a number of ways but most AIC's use ear tags with the code plainly marked. This code can be used by the center to identify product produced by the bull, although other permanent identification is used for health testing purposes (i.e. hide brands or tattoos).

After admission the bull entering the isolation facility must go into a pen that has been properly cleaned of any residual organic material deposited by the former occupant and disinfected (Figure 12.2). For stalls with dirt floors, a disinfectant applied as a mist over the area should be sufficient to meet NAAB standards. The veterinarian should be aware of the facilities and any damaged portions of housing that could injure an animal. The isolation facility must be separate and apart from the resident housing. All equipment used for cleaning, feeding, watering, and semen collection of the isolation bulls must remain separate from the resident herd. This includes feed storage and any mechanical means of transport. Workers must change

Figure 12.1 Bulls going into a chute.

Figure 12.2 Ideal conditions for housing bulls in central Texas, Elgin Breeding Service.

boots or protective cover before entering or leaving an isolation area and going to other quarantine areas. Testing on the isolation bulls starts with an intradermal test for tuberculosis performed at least 60 days after the pre-entry test; a test for bovine brucellosis not sooner than 30 days after the pre-entry test, with negative result; and a test for bovine leptospirosis not sooner than 30 days after the pre-entry test, with negative result or subject to stabilized titer of less than 1 : 400. Bovine campylobacteriosis requires up to six cultures and examination of preputial wash material collected at weekly intervals. Bovine trichomoniasis has the same weekly culture requirement during the isolation period. Testing for BVDV is performed no longer than 10 days after entry via whole blood or serum, with evaluation by FA, IP, or PCR on cell culture. All bulls having semen collected will have future testing for BVDV before semen is released. Semen testing by PCR is preferred, with at least one passage through cell line culture.

Veterinarians should also familiarize themselves with the diagnostic laboratory they will be working with, particularly with regard to sample submission requirements, the intricacies of testing procedures, and especially testing protocols and the reporting of test results, as understanding results is very important. Any positive test results, particularly on pre-entry tests, should be evaluated in conjunction with previous vaccination history. Frequently, certain vaccines produce a prolonged immune response that may interfere later on with attempts to approve semen for export. Leptospirosis vaccination produces a persistent titer for prolonged periods in certain cases.

Once the bull meets all the requirements of the isolation protocol, he is allowed to enter the resident herd, where testing is continued to assure compliance with international protocols. The required testing is preformed semi-annually on each bull occupying the resident herd. Previous testing is continued at a less frequent pace (every six months), with tuberculosis, brucellosis, leptospirosis, trichomoniasis, and campylobacteriosis all evaluated using the same testing protocols as discussed earlier. Bulls must be restricted from any contact with any other cloven hoofed animal; if such contact occurs, the bull must be returned to isolation and the testing protocol for isolated bulls must be followed once again.

Facility overview is another responsibility of the veterinarian. Supervision of the artificial vagina (AV) preparation room, collection area, bull housing, and semen lab and processing area should all be evaluated for cleanliness, absence of any cross-contamination, and ability to disinfect contact surface areas. Semen processing equipment should be clean and serviceable and packing and shipping areas clean and organized (Figure 12.3). The veterinarian is responsible for all these areas, as noted when signing off on any federal export certificate. Accuracy is the goal of the veterinarian to assure that standards set by the OIE and NAAB/CSS are met to ensure continued access to all markets.

Figure 12.3 Semen canisters for storage of frozen semen and embryos. Note the cleanliness and organization of the facility.

The Collection Process

The collection of semen for cryopreservation is a fairly simple and straightforward process, except for those with no experience. Therefore the procedures should only be administered by someone who is competent and experienced at handling bulls and very familiar with the collection process. Good facilities are paramount to a successful collection attempt, particularly when dealing with beef bulls that have primarily had pasture breeding experience. Collection of semen from bulls with an AV is not for the faint of heart. The procedure basically involves allowing the donor bull to mount or "jump" another steer, bull, or cow and diverting the penis laterally in order to introduce the extended penis into the AV. Usually, once bulls are familiar with the technique, they will readily mount and serve the AV. Training them to do this is an art, particularly when dealing with less docile mature beef bulls and bucking bulls.

CSS mandates guidelines to be followed for bull health and cleanliness. Steers are the most common mount animal unless the facility prefers the use of a phantom (dummy structure designed for supporting a mounting bull). Using cows as mount animals is discouraged because of the potential for penetration and contamination by the bull. Mount animals should have their hair closely clipped from the hindquarters, allowing for ease of cleaning and disinfection, which should be accomplished after every use. The process usually requires at least two people and

preferably three. One person is assigned the mount animal, which is usually haltered or handled by nose ring. This person's responsibility is to position the mount animal for mounting and to assist in keeping it in position during collection. In large facilities there is also a bull handler who may have the bull haltered or tethered to control him during the mounting process. Most beef bulls in custom studs are free to mount the jump animal. Lastly, the semen collector manages the AV and is in charge of the entire collection area (Figure 12.4). It is this person who ensures the sample is properly identified and collected hygienically and is responsible for the safety and welfare of the team as well as the animals.

The procedure of semen collection is rather straightforward. Several bulls are usually penned separately along a "bull alley" facing the collection area. Mount animals are allowed to move along in front of the bulls in order to initiate some arousal. The bulls are allowed to observe other bulls mounting and being collected from this vantage point. It can be very evident that bulls in the bull gallery are aroused by the amount of vocalization that occurs as a bull is being collected.

Once it is time for a bull to be collected, he is allowed to leave his pen and enter the mount area. At this time, the mount handler will move the mount animal to prevent the bull from mounting. This may continue for several minutes until such a time as the semen collector is satisfied the bull is properly aroused. The semen collector may further determine that the bull needs to "false mount" to further his arousal and thus increase the quality and quantity of semen he produces. This is accomplished by the bull handler allowing the bull to mount but the semen handler diverting the penis away from the mount animal as the mount is withdrawn from under the bull. As discussed previously, when the semen collector believes the bull is properly stimulated, the bull is allowed to mount for collection (Figure 12.5). After collection the bull is either returned to housing or is placed back in the bull alley for another collection attempt.

The preparation of the AV is important as the tactile sensation received by the bull is paramount to his semen production. It should simulate the natural breeding act as closely as possible. The AV is constricted, with a ridged tube that has a port allowing water to be added between the rigid structure and a latex liner. Within this liner another is placed to facilitate collection of the semen from the bull. This liner has a tapered end that allows the inclusion of a glass or plastic receptacle that will serve to hold the collected semen sample. Water added to the water jacket should be in the temperature range 40–60 °C and varies according to the preference of the bull; this has to be determined by the semen collector. Also, the amount of water within the jacket determines the rigidity of the liner, which can impact the bull's reaction to the AV. It is very important that a sterile non-spermicidal lubricant be applied to the upper one-third of the AV. This improves sensation and reduces the possibility of abrasive injury to the bull's penis.

For those bulls that are too fractious or are incapacitated and unable to jump a mount animal, the collector has the option to use an electroejaculator. Although it is discouraged in the semen production industry, it may be used when all else fails. Usually the bull will produce a slightly less concentrated ejaculate and with the potential for a somewhat higher abnormal sperm count. However, with proper stimulus (rectal massage of the ampulla and seminal vesicles) adequate semen may be collected for processing. Massage of the pelvic genitalia alone usually does not produce adequate semen product for processing and is discouraged in the industry.

Figure 12.4 Collection area.

Figure 12.5 Proper technique for collection of bull semen.

Common Problems of Bulls at Stud

Lameness

Lameness is the most common problem in bulls at stud. The primary complaint from the stud manager will be lameness of acute onset. Some of the more common insults are hoof or foot rot, hairy heel wart (bovine dermatitis), hoof abscess, hoof lacerations, broken toes, and overgrown toes. Hoof abscesses due to wall separations ("white line disease") are most often identified as the problem in these lame bulls. Most white line disease can be traced back to subclinical laminitis occurring some time in the bull's yearling development. The best curative approach is to access a hydraulic tilt table and to place the bull in lateral recumbency in order to remove the damaged sole and/or wall (Figures 12.6 and 12.7). Feed and water are withheld for 24 hours before table placement to reduce the chance of rumenal tympany while in lateral recumbency. If over 1 cm of sole or hoof wall is removed, it is recommended that an elevated block be placed on the opposing toe in order to reduce contact with the ground by the injured toe. Postprocedure antibiotics and analgesics are necessary to prevent infection and pain due to the lesion. Other injuries causing lameness are usually accidents that can occur in the collection areas, for example shoulder "sprains" when bulls get their forelimb hung up on the back of the mount animal and stifle injuries when mounting or dismounting the mount animal. Sometimes the only method available to properly diagnose the problem is diagnostic anesthesia, which often requires the use of a tilt table. Superficial injuries may be treated with a few days of non-steroidal anti-inflammatory drugs. The more serious may require more aggressive measures.

Figure 12.6 A well-designed work area for performing lameness examinations at a custom stud. Note the hydraulic tilt table and footbath in foreground.

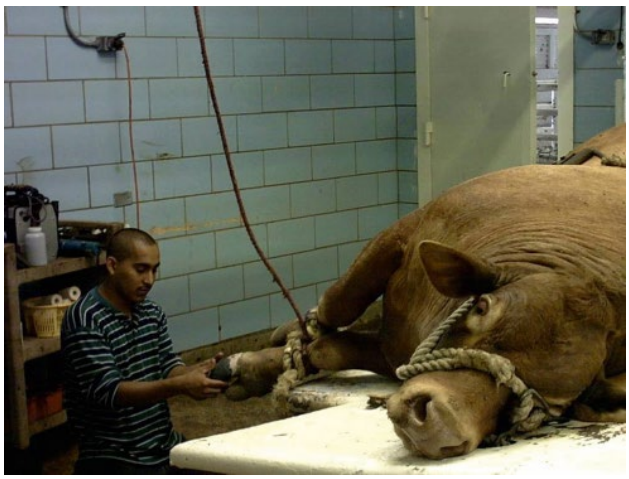

Figure 12.7 Assisting in preparation of hoof block application.

Treatment of issues such as foot rot or hairy heel wart may best be treated via footbath or topical therapy. The more stubborn infections may require antibiotics and periodic topical antibiotic bandages. If lameness persists after a few days of therapy, it is always recommended to question the original diagnosis and reinvestigate the problem.

Occasionally, a diffusely swollen limb is observed associated with a joint (most often a tarsus) with accompanying pyrexia, which can signal initiation of septic arthritis secondary to a generalized bacteremia. These are usually consequences of some kind of stress, most often change of feed or feeding methods. Any bull presenting with generalized cellulitis in a limb should be considered a medical emergency. Most bulls are not weight-bearing and can be difficult to deal with in local settings, so it is often better to refer these cases to a facility capable of handling this kind of care.

Penile Injuries

One of the more common penile injuries observed in the bull stud is preputial laceration/avulsion at the site of the preputial reflection. This injury occurs as a friction "tear" due to misapplication of the AV as it is placed on the bull to collect the semen sample. Most often, the only evidence of injury initially will be drops of blood in the AV or in the ejaculate, or by blood dripping from the preputial orifice. This is to be considered a medical emergency and should be addressed as soon as possible after injury. After a pudendal nerve block and/or local anesthesia, the wound should be debrided with copious lavage of the site. Debridement should be followed by suturing with simple interrupted sutures or by surgical stapling. Bandaging of the orifice to maintain the penis in the sheath, with antibiotics and anti-inflammatory drugs, will be required for several days. After recovery, the bull

should only be collected with an electroejaculator or rested from sexual activity for about four weeks.

Occasional preputial lacerations from self-trauma may occur. It is not uncommon to see bulls "catch" the prepuce with a dew claw as they start to rise. These may only require antibiotics and topical medication instead of debridement and surgery. Each case should be independently assessed. Occasionally, the injury may scar sufficiently to reduce the diameter of the prepuce and impede full extension of the penis. If this occurs a penile reefing or circumcision may be required in the future.

Gastrointestinal Tract Problems

AICs will need veterinary services to treat a wide variety of gastrointestinal problems. Most are simple ruminal tympanies or bloat, followed by non-specific and transient diarrheas. Most are thought to be due to mistakes in feeding protocols but on occasion may be caused by changes in gastrointestinal motility brought on by a host of other primary problems. These incidents will respond to systemic treatment of laxatives, oral fluids, and analgesics if warranted. More serious gastrointestinal problems encountered include hemorrhagic bowel disease, perforating abomasal ulcers, intestinal intussusception, and intestinal volvulus. Once diagnosed, these are best referred to those most experienced in dealing with such problems as these bulls will need surgery and intensive aftercare.

Occasionally, an acute disease due to a foreign body may occur in a bull at an AIC. Of course, the penetrating foreign body could have been present for years; such subtle problems should not be overlooked when making a differential list. Advising a custom stud owner on per-os administration of rumen magnets should be considered when creating entry requirements.

Urinary Tract Problems

Urinary tract problems are rare at stud but do occasionally occur. Initial presentation of a bull with urinary obstruction is much like any other abdominal problem: colic-like symptoms, kicking at abdomen, elevated heart rate, increased salivation, straining attempts to defecate and urinate, etc. Most often bulls may respond to analgesic therapy along with smooth muscle relaxants and urinary acidification. It is to be remembered that if the urinary obstruction is relieved, there are probably still many calculi left in the bladder. When urinary calculi are involved it is wise to diagnose the type of calculi present and adjust therapy accordingly, maintaining the bull on acidification until the calculi significantly decrease in a urine sample. In some areas, calculi do not respond to urinary acidification, presenting the clinician with a whole new set of problems. Most bulls that have calculi problems also have an ongoing cystitis requiring bacterial culture and sensitivity testing and prolonged antibiotic therapy.

Summary

Consulting for an AIC can be rewarding both financially and professionally. Many breeders working with an AIC are the elite within their breed and by exposure to the veterinarian through association with the bull stud new client relationships can develop. Consultation services, from disease prevention to improving reproductive efficiency and development, can occur through contacts made with the AIC.

Acknowledgment

The author wishes to acknowledge his mentor Dr. Wallace Cardwell for his countless contributions to the information found in this chapter.

Testicular Degeneration

Albert Barth[1] *and John P. Kastelic*[2]

[1] *Department of Large Animal Clinical Sciences, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Saskatchewan, Canada*
[2] *Department of Production Animal Health, Faculty of Veterinary Medicine, University of Calgary, Calgary, Alberta, Canada*

Introduction

Testicular degeneration may be temporary or permanent; temporary degeneration is much more common and, with removal of underlying cause, testis structure and function often recover. It may be difficult to distinguish between degeneration and a severe disturbance of spermatogenesis, with a marked decline in semen quality. The term "degeneration" is somewhat arbitrary, but usually implies reduction in scrotal circumference, testes may be soft, and sperm quality is poor (usually <20% morphologically normal). With temporary degeneration, there is loss of germinal cell layers near the lumen in many or all seminiferous tubules. Sertoli cells and spermatogonia, which are more resistant to damage, are likely to be retained and if the cause of degeneration is removed, tubules are repopulated with spermatocytes and spermatids, restoring testis size and semen quality. Advanced degenerative changes causing permanent damage include spermiostasis, tubular mineralization, granuloma formation, thickened basement membranes, and fibrosis in focal or diffuse areas of testicular parenchyma.

Pathogenesis

Factors involved in pathogenesis of testicular degeneration include abnormal testicular thermoregulation, nutritional excess or deficiency, toxicity, inheritance, congenital blockage of sperm outflow from testes, infectious disease, severe trauma, and senile atrophy.

Testes of scrotal mammals function normally when testis temperature is 2–6 °C below body temperature [1]. Scrotal insulation is a classic model to induce temporary testicular degeneration [2, 3]. In one study, the scrotum was insulated for 10 days; there were reductions in semen quality, but no fibrotic lesions within 6 months after insulation [4]. Therefore abnormal testicular thermoregulation that is reversible (e.g. obesity) may not be a common cause of permanent damage. Other less common causes of chronic abnormal thermoregulation that may lead to temporary or permanent testicular degeneration include severe chronic scrotal dermatitis, heat and swelling due to orchitis, trauma, chronic illness with prolonged fever, endotoxins (potent gonadotropin inhibitors), a congenitally short scrotum, severe scrotal frostbite leading to adhesions, and incomplete descent of a testis into the scrotum.

Obesity is a leading cause of testicular degeneration in bulls. It is common to fatten bulls for livestock shows and sales. Many bulls become obese and fat accumulates in the scrotum, chronically increasing testicular temperatures [2]. However, after a reduction in body condition, including loss of fat from the scrotum, regeneration of seminiferous tubules may occur with return to normal sperm production [5].

Nutritional deficiencies seldom cause testicular degeneration in bulls. Naturally occurring deficiencies are usually multiple and deficiency of any single nutrient as a cause of bull infertility is rare. Similarly, vitamin deficiencies are also rare as a cause of infertility in larger male domestic animals if forages are normal in quality and quantity. However, reductions in feed quality and/or quantity causing weight loss may depress spermatogenesis via an endocrine effect on developing germ cells rather than by vitamin or mineral deficiencies. In one study, protein supplementation of bulls on poor-quality forage significantly increased dry matter intake, enabling maintenance of live weight, whereas in control (unsupplemented) bulls, weight loss was accompanied by a significant decrease in scrotal circumference and daily sperm production per gram of testis. However, histologically, seminiferous tubule activity was apparently not different between bulls

Companion website: www.wiley.com/go/hopper/bovine

with or without protein supplementation [6]. Vitamin A deficiency can cause testicular degeneration in laboratory rats [7], but in bulls under practical feeding conditions, diets that result in long-term marginal vitamin A deficiency or a relatively short-term absence of vitamin A intake probably have minimal effects on spermatogenesis [8]. There is little evidence that deficiencies of vitamins B, C, D, or E cause infertility in domestic animals [9]. Although vitamin E is essential for reproduction in rats, naturally occurring deficiencies resulting in testicular degeneration in livestock have apparently not been reported. Mineral deficiencies may affect male reproduction, but reports are rare. Deficiencies of calcium, manganese, zinc, iodine, potassium, and selenium have not been proven to cause testicular degeneration. Deficiencies of phosphorus, cobalt, iron, zinc, and copper may cause anemia, lack of appetite, and weight loss, with adverse effects on reproduction. Deficiencies of these minerals are often associated with inadequate protein and vitamin A.

Although experimental exposure to various drugs, chemicals, and heavy metals causes testicular degeneration (mainly in rats and mice), there are very few reports of naturally occurring cases in bulls [9, 10]. Ingestion of plant toxins may cause testicular degeneration. *Fusarium* mold in grain crops is common; one of the toxins produced is zearalenone. It has an estrogenic effect, with potential to reduce semen quality and cause testicular degeneration. In one report [11], 23 young rams became infertile after eating grain containing zearalenone (5–20 mg/kg) for several months. Furthermore, two bulls fed maize containing zearalenone (20 mg/kg) for 72 days had poor semen quality after 21 days [11]. Histologically, rams' testes had complete destruction of germinal epithelium and aspermia, whereas in bulls, degeneration of the germinal epithelium was marked only in certain areas of the testes, although >75% of sperm were degenerate [11]. Cottonseed meal may cause gossypol toxicity; it alters mitochondrial structure and function and causes abnormalities of spermatocytes, spermatids, and mature sperm [12], although it did not appear to cause testicular degeneration [13, 14]. Locoweed (*Astragalus lentiginosus*) may cause temporary testicular degeneration, as reported in mature rams [15]. Growth-promoting implants have potential to impair testicular development [16, 17]. When bulls were implanted with zeranol (Ralgro^{TM}) at birth and at 3 and 6 months of age, or every 3 months from birth to 18 months of age, scrotal circumference was reduced but tended to recover with increasing age. However, implanting bulls with zeranol after 7 months of age had limited effects on reproductive organs.

Congenital and inherited disorders of testes and epididymis may be involved in testicular degeneration. Young bulls with testicular hypoplasia may produce semen with satisfactory quality, but are more prone to develop testicular degeneration at two to three years of age [10]. In young bulls, small scrotal circumference has been associated with a lack of germinal epithelium within seminiferous tubules [18, 19]. Hypoplasia may be unilateral or bilateral, although most cases are unilateral and the left side is more frequently affected [10]. There appears to be no clear definition for testicular hypoplasia based on physical measurement. Histologically, testicular hypoplasia is defined based on cell populations in seminiferous tubules. Testicular hypoplasia is congenital and possibly hereditary. For example, in Swedish Highland cattle, it appears to be caused by an autosomal recessive gene with incomplete penetrance [20]. This condition occurs in many breeds, albeit at very low frequency [21]. Double muscling (myofiber hyperplasia), inherited as an autosomal recessive, is associated with a high incidence of bilateral testicular hypoplasia [22].

The embryo needs to connect its gonads with the mesonephric urinary system to develop its excurrent duct system. The connection comes via the rete tubules that develop between the fetal gonad and mesonephros. The ureter for the mesonephros, the mesonephric duct, will become the epididymis. Efferent ductules develop from the mesonephric tubules and join to the mesonephric duct via rete tubules during embryonic development. Failure of some efferent ductules to join with the rete may later (at puberty) result in sperm impaction of blind-ending ductules; their subsequent rupture causes sperm granulomas. If all efferent ductules are obstructed, seminiferous tubule fluid and sperm cannot leave the testes, resulting in testicular enlargement, edema, and degeneration.

Infectious organisms may be involved in testicular degeneration. *Eperythrozoon* infection caused anemia, scrotal and hindlimb edema, and soft testes in young bulls. Loss of scrotal thermoregulation was likely the main cause of testicular degeneration and poor semen quality [23]. In another report, testicular degeneration and loss of libido occurred in beef bulls experimentally inoculated with *Anaplasma marginale* [24]. Testicular degeneration was confirmed by histopathology and semen evaluation. Picornavirus and bovine enterovirus isolated from semen and feces of a bull were implicated as a cause of orchitis, testicular degeneration, aspermatogenesis, and loss of libido [25].

Diagnosis

During clinical evaluations, it may be difficult to distinguish between disturbances of testis function that reduce sperm output and increase sperm abnormalities compared to more severe disturbances of testis function that cause degeneration. Therefore a clinical diagnosis of degeneration is arbitrary. Degeneration does not necessarily reduce sperm concentration in the ejaculate, due to sperm accumulation in ampullae during sexual rest.

Ultrasonography is not necessarily clinically useful for distinguishing between normal testis tissue and tissue that has lost germinal epithelium [26]. When considerable fibrous tissue is present, testes may become more firm; however, a diagnosis of fibrosis is best accomplished with ultrasonography. Echographic anatomy of abattoir-derived bull testes has been reported [27] and ultrasonography of testes does not affect semen quality [28]. Ultrasonography has been used to examine effects of testicular degeneration induced by scrotal insulation in bulls [4, 29, 30]; however, there were no evident visible changes in ultrasonograms after induced testicular degeneration. Furthermore, some studies failed to demonstrate significant correlations between computer analysis of ultrasonogram pixel intensity and semen quality, either during breeding soundness evaluations or after scrotal insulation [29, 31]. In other studies, echogenic changes induced by scrotal insulation preceded increased sperm abnormalities [4]; changes in pixel intensity accounted for 13–25% of variation in semen quality of ejaculates collected two to four weeks after ultrasonographic examination.

Prognosis

Recovery of normal testis tone and spermatogenesis is possible in most cases of testicular degeneration if the cause can be removed. Obese bulls may be fed restricted diets or put on pasture for weight loss, although it often takes three to four months for sufficient weight loss and seminiferous epithelium regeneration to restore semen production. When breeding seasons are short and bull to female ratio is ~1 : 35, there is sufficient breeding overlap to prevent an infertile dominant bull from making a significant impact on herd fertility [32, 33].

Testicular Fibrosis

Focal testicular fibrosis is common in some groups of bulls after weaning. Diffuse fibrosis is much less common and in aged bulls it occurs more commonly in ventral parts of testes [10]. Routine ultrasonography of the testes of bulls may reveal presence of a few to many foci of fibrosis, with or without production of elevated percentages of abnormal sperm. In one study [34], ultrasonography of the testes was done in bulls at three locations in western Canada ($n = 325$) and one in Argentina ($n = 387$) to determine prevalence of fibrotic lesions and relationships between fibrotic lesions and location, age, breed, testis size, and semen quality. Bulls in western Canada are typically fed forage and grain-based rations after weaning, whereas in Argentina, weaned calves did not receive grain supplementation until 18 months of age. Bulls used in the study ranged in age from 3 to 20 months and ultrasonography was done at varying ages.

Bulls in all groups in Canada and Argentina had been vaccinated at weaning with clostridial vaccines and vaccines for bovine viral diarrhea virus (BVDV), infectious bovine rhinotracheitis, and parainfluenza 3 (some bulls also received *Mannheimia* and *Histophilus somni* vaccines). In all groups, there were no unexpected health issues except in Group 1 in Argentina. In that group, there was a severe outbreak of respiratory disease with high morbidity and 6% mortality, attributed to bovine respiratory syncytial virus (BRSV). In the following year, bulls at this location were vaccinated for BRSV, preventing problems with this disease.

Ultrasonographic examinations in some groups of bulls in western Canada were done monthly from 3 to 15 months of age. In other groups in Canada and Argentina, ultrasonography was done after weaning at 5–8 months of age and repeated at 12–14 months of age in Canada and 18–20 months of age in Argentina. Testis assessment was done by orienting the transducer vertically on the scrotum and moving it 180° around the testis (both dorsal and ventral portions). Testes were scored for fibrosis from none to very severe, based on number and size of fibrotic lesions (Figures 13.1 and 13.2).

Immunohistochemistry was performed on testis tissues of 10 bulls from the group affected by BRSV. Only one of these bulls had fibrotic lesions in testes. Testis tissue was submitted to a diagnostic laboratory for immunohistochemistry for BVDV and BRSV.

Fibrotic lesions scored as slight or mild were very common (31.3%) in testes of a group of bulls raised under intensive rearing conditions in western Canada. Only 2.5% had moderate scores and none had severe scores for fibrosis. In the more extensive management in Argentina, in a group not affected by respiratory disease associated with BRSV, fibrotic lesions were also mainly slight or mild, but incidence was higher (48.6%). In that group, 1.9% were scored moderate and 0.95% severe. In the Argentine group affected by BRSV, fibrotic lesion scores were higher and more frequent. Scores for slight to mild, moderate, and severe to very severe were 58.3, 17.1, and 5.7%, respectively.

Fibrotic lesions appeared as early as 5–6 months of age and number of cases continued to increase until at least 12–14 months. Lesion severity increased in some cases during this period, although it appears that lesion development occurred during a finite interval. There were indications that during fibrosis formation, spermatogenesis was adversely affected; however, presence of a large number of fibrotic lesions that may occupy as much as approximately half of testis parenchyma did not preclude

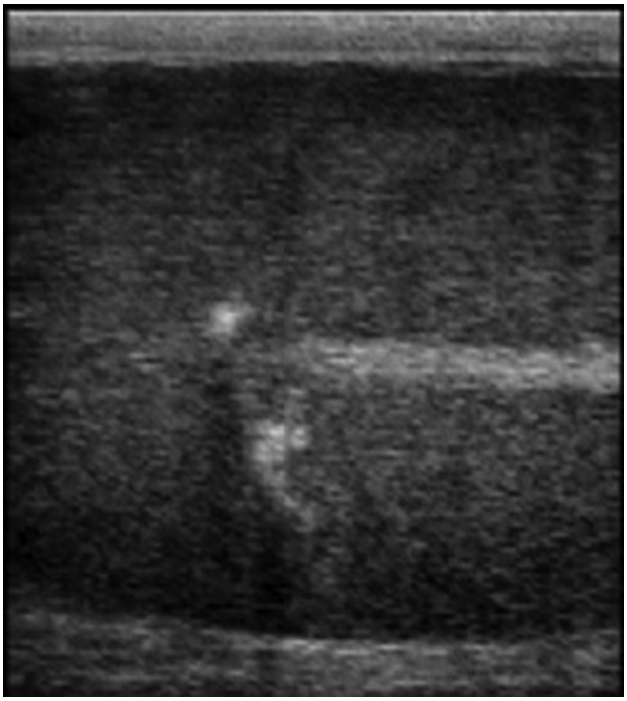

Figure 13.1 An ultrasonogram of testis scored as having mild fibrosis.

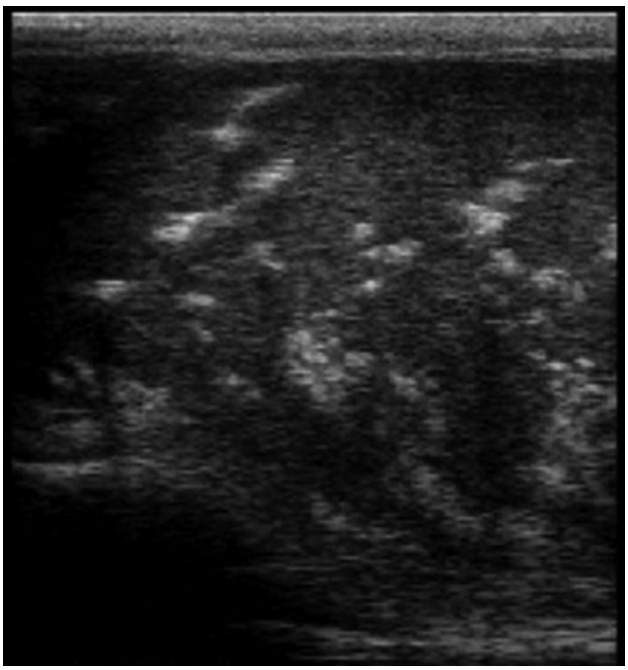

Figure 13.2 An ultrasonogram of testis scored as having very severe fibrosis.

production of a high percentage of morphologically normal sperm. In bulls with no, mild, moderate, or severe testis fibrosis, median percentages of normal sperm were 88, 87, 86, and 90% respectively. Lesion prevalence was not influenced by breed or testis size.

Histologically, lesions consisted of masses of fibrous tissue with fine fibrillation, or heavy bundles of wavy tissue seminiferous tubules. Usually there were fewer germinal cells in seminiferous tubules within masses of fibrous tissue. In some tubules, germinal cells and Sertoli cells were missing entirely and hyaline material was present in the lumen. Similar abnormalities were evident in seminiferous tubules adjacent to fibrous tissue masses; however, completely normal tubules were often beside or very close to fibrous tissue masses. Inflammatory cells were consistently absent. Therefore we inferred that neither the insult that caused fibrosis nor proximity of fibrous tissue to seminiferous tubules affected function of adjacent tubules.

With real-time ultrasonography, many lesions appeared to extend from the rete testis toward the periphery of the testis and appeared to involve the entirety of one or more tubules at specific sites within the testis. This pattern was apparent in both gross sections (Figure 13.3) and in ultrasonograms (Figure 13.4). It appeared that entire tubules may be destroyed with replacement by fibrotic tissue. In other cases, there were isolated lesions in central or peripheral parts of testis parenchyma without extension to rete testis, implying tubular destruction occurred only at a specific site.

The cause of the testicular fibrosis is uncertain. Potential causes are disrupted development of embryonic tubule-to-rete connections, an infectious disease process affecting tubule health and development, abnormal testes thermoregulation, and trauma.

Developmental changes of testes may be involved in development of fibrotic lesions. Tubularization of seminiferous cords within the testis tissue begins at ~4 months of age and is complete in nearly all bulls by 6 months [35].

Figure 13.3 Cross-section of a bull testis with fibrotic lesions that appeared to radiate from rete testis toward the periphery, suggesting individual tubules were destroyed and replaced by scar tissue.

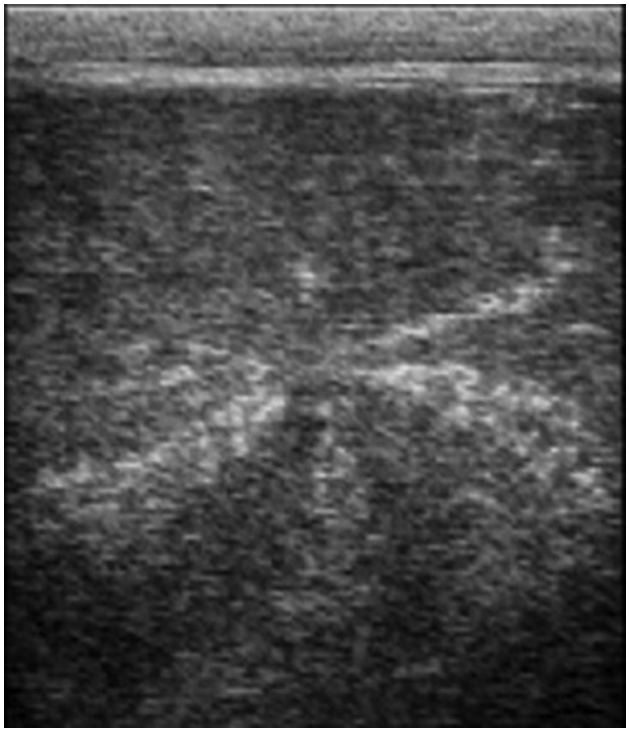

Figure 13.4 Ultrasonogram of a testis with fibrotic lesions radiating from the rete testis toward the periphery.

Sperm release into tubules starts as early as 8 months and occurs in most bulls by 10 months. Therefore tubule impaction with sperm and tubule rupture with escape of sperm into the peritubular space of the testis tissue would not be expected to occur much before 8 months. Because sperm are antigenically foreign, a tissue reaction against escaped sperm could cause fibrosis. Impaction of seminiferous tubules might be due to congenital failure to develop a tubular connection to the rete tubules. Tubule rupture and a tissue reaction against sperm should not occur until testes produce sperm; as production increases, testes lesions would be expected to increase in number and severity.

Bacterial and viral infections are common in early postweaning period when maternal immunity has waned and animals of multiple origins intermingle [36]. Thus an infectious process, as a cause of fibrotic lesions, would fit the time period when testis lesions appear in young bulls. Although bacterial or viral infections would be expected to cause testicular swelling and pain, perhaps inflammation is mild and not apparent. Infectious agents could cause inflammation of arterioles and capillaries in the testes, leading to local tissue necrosis and formation of foci of fibrosis [10]. Viral infections may also target specific cells within seminiferous tubules, e.g. Sertoli cells or individual germinal cells, resulting in tubule damage and fibrous tissue infiltration [37, 38].

Two common viral diseases of cattle, bovine herpesvirus (BHV)-1 and BVDV, have been investigated for their role in male reproductive infections. Both viruses have been isolated from semen [39, 40] and BHV-1 has been associated with degenerative changes in the seminiferous epithelium, perhaps due to illness and fever [41]; however, there are no reports that associate BHV-1 or BVDV with lesions in bovine testes.

The association of a greater prevalence of testis fibrosis with occurrence of a severe outbreak of BRSV respiratory disease in the Group 1 bulls in Argentina, combined with a lesser prevalence of testis lesions in Group 2 (vaccinated against BRSV), suggests that BRSV may be involved in etiology of testis fibrosis. However, immunohistochemistry of testis tissues from 10 bulls that were culled and slaughtered from Group 1 failed to detect BRSV antigen. Failure to find evidence of BRSV antigen may indicate that this virus does not multiply in testis tissue or it might be due to the lack of fibrotic lesions in 9 of 10 of the testes from which samples were submitted and because samples were obtained ~12 months after BRSV incident.

Viral agents multiply within the testes of several species. For example, mature male domestic European rabbits were infected with an attenuated strain of myxoma virus. The animals developed symptoms of myxomatosis 7–10 days after infection and had high viral titers in testes. After 20–30 days, testes were 50% of normal size and affected animals had interstitial orchitis and epididymitis [42]. Protein and genomic studies of a porcine paramyxovirus had a close relationship to human mumps virus [43, 44], known to multiply in human testis, causing orchitis in postpubertal men [45]. Furthermore, when 9-month-old boars were experimentally infected with porcine paramyxovirus, histopathological epididymal alterations and testicular atrophy associated with degeneration of seminiferous tubules occurred [38]. In another study, colostrum-deprived pigs were inoculated with porcine circovirus type 2 alone, porcine parvovirus alone, or with both viruses. All pigs that received both viruses became ill; at necropsy (21–26 days after infection), many had hepatomegaly and enlarged kidneys, with granulomatous lesions apparent in many tissues, including testis [46].

Obesity is associated with testicular degeneration and scrotal insulation has been used to produce testicular degeneration; however, scrotal insulation did not induce fibrotic lesions [4]. In one study, deficient, normal, and excessive dietary intakes did not affect prevalence of fibrotic lesions. However, with prolonged abnormal thermoregulation, especially when semen quantity and quality are very severely reduced, with loss of testis tone and size and with severe seminiferous tubular degeneration, scar tissue infiltration and testis fibrosis are plausible.

Trauma to the testes has also been proposed as a cause of testis fibrosis [10]. Trauma caused by a blow to the testes from kicking or butting could occur at any age, but may be

more frequent during crowding in pens or handling in chute systems. Therefore appearance of fibrosis in conjunction with postweaning penning and feeding could be considered in the etiology of testis fibrosis. However, one of the authors observed a bull receive an acute blow to the testes with a metal pipe. Ultrasonography the following day and several times over the course of a month did not reveal any damage to the testes. Perhaps testis trauma, although common in penned bulls, does not cause fibrotic lesions.

Interestingly, fibrotic lesions in the testes were not associated with poor semen quality. Even bulls with very severe fibrosis produced semen with up to 94% morphologically normal sperm. Therefore presence of relatively large amounts of scar tissue within testis parenchyma did not prevent remaining unaffected parenchyma from producing normal sperm. Although large amounts of scar tissue would be expected to reduce sperm production, this has apparently not been reported.

Vesicular Adenitis

Mike Thompson

Willow Bend Animal Clinic, Holly Springs, MS, USA

The vesicular glands are paired glands located on the floor of the cranial pelvic cavity situated laterally and craniodorsal to the prostate and the origin of the paired ampullae. They have also been described as lateral to the ampullae and dorsal to the neck of the bladder. The size of the vesicles is age related. These glands have a lobar structure and each is normally 2–4 cm wide and 10–15 cm long (Figure 14.1). As bulls age, non-infected glands may have considerable variation in size. The vesicular glands are easily palpated per rectum; hence an appreciation of the normal variation is important. As the major accessory sex glands in the bull, infection and inflammation of the vesicular glands has a significant impact on bull fertility. The glands secrete a clear fluid containing nutrients and buffers, which is discharged immediately before and during ejaculation through ducts that open into the urethra adjacent to the colliculus seminalis [1].

The overall prevalence of vesicular adenitis has been reported to be between 1 and 10%, with the highest incidence occurring in yearling and peripubertal bulls and bulls over nine years old [2]. The prevalence is also higher in bulls that are intensively housed and/or fed high energy diets [3]. The actual prevalence of vesicular adenitis in premortem bulls is difficult to establish due to the variance in diagnostic criteria.

Multiple microorganisms have been associated with vesicular adenitis. These include bacteria, chlamydia, mycoplasma, and ureaplasma [2, 3]. Bacteria are considered the most common cause with the most common isolates, including *Trueperella pyogenes*, *Histophilus somni*, and *Brucella abortus* (in areas where brucellosis has not been eradicated). Multiple other pathogens have been isolated from infected vesicular glands [4]. Although the precise mechanism and route of infection is not known, suggested routes of infection include ascending, descending, direct invasion from local sources, and hematogenous routes [2, 4, 5]. Association with congenital defects, particularly involving the development of the colliculus seminalis, as well as naval abscesses in calves have been suggested to predispose bulls to vesicular adenitis [6]. Congenital defects leading to retrograde ejaculation or urine reflux can be a source of infection or sterile inflammation [7]. High energy diets that predispose young bulls to rumen acidosis and rumenitis with subsequent bacteremia may lead to hematogenous vesicular gland infection [2, 3, 7, 8].

Although most bulls diagnosed with vesicular adenitis are found during routine breeding soundness examinations without any history suggestive of vesicular adenitis, occasionally bulls will present with a history of subfertility [3]. Rarely, these bulls may present with acute signs mimicking peritonitis, gastritis, tenesmus, or hindlimb lameness [4].

Physical examination findings, with the exception of those identified through transrectal palpation, are usually normal. Transrectal palpation can reveal a range of findings. Some bulls with vesicular adenitis have no palpable abnormalities with either vesicular gland. Abnormal findings can include any or all of the following: loss of symmetry, bilateral enlargement, loss of lobulation, increase in firmness, heat, and pain (Figure 14.2) [2, 3]. In chronically infected bulls, fibrin and adhesions may be palpable [2, 4].

Bulls suspected of vesicular adenitis should have a thorough examination of the entire reproductive tract. These physical examination findings should be corroborated with semen evaluation. Large numbers of leukocytes with or without flocculi of pus can be found without palpable evidence of vesicular adenitis. Conversely, bulls with palpable signs of vesicular adenitis may have no evidence of infection during semen evaluation. Bulls with transrectal signs of vesicular adenitis but no leukocytes in semen should be further massaged and recollected to ensure

proper evaluation and classification of the presence of disease [2–4, 7]. Transrectal ultrasonography can be revealing in subclinical cases. The normal vesicular gland has homogeneously echogenic lobes with small anechoic vesicles and a distinct anechoic collecting duct all surrounded by a distinct capsule. Vesicular adenitis leads to varying degrees of enlargement, loss of lobular structure, thickened walls, and increased echogenicity with fluid-filled cavities in the gland [9].

Due to likely contamination of samples with environmental microorganisms and normal flora, Parsonson et al. described a technique to obtain vesicular gland secretions for microbiologic examination [10]. After clipping preputial hair, the penis is extended by transrectal massage of the urethralis muscle. The glans penis is restrained by grasping it manually with sterile gauze sponges and wearing sterile gloves. After washing and disinfecting the end of the penis, the urethra is irrigated with sterile saline utilizing a sterile teat cannula. A 25- to 30-cm sterile Silastic tube is passed up the urethra to a point leaving 2.5–5 cm protruding from the penis. The vesicular glands are then massaged and the secretions are collected into a sterile container.

Several treatment modalities for vesicular adenitis have been utilized. These include multiple systemic antimicrobials given at several different dosages and frequencies. Intraglandular antibiotics and intraglandular chemical ablation have shown some success. Surgical removal of chronically infected glands has been described.

Many systemic, parenteral antibiotics have been used in the past to attempt treatment of vesicular adenitis. Since spontaneous recovery commonly occurs in younger bulls, evaluation of treatment methods is complicated [4]. Earlier antimicrobials utilized include penicillin, oxytetracycline, chloramphenicol (no longer legal), sulfamethazine, florfenicol, and cetiofur [2]. These medications all produced poor treatment success rates, even though the bacterial isolates from the vesicular glands are usually sensitive to most antibiotics [2, 11]. Success was improved when increased dosages of these agents was used. Unfortunately, even at twice the recommended dose, these antibiotics often do not reach inhibitory concentrations in vesicular gland tissue [2]. Antibiotics that are highly lipid soluble and low protein binding possess a pH higher than vesicular gland fluid along with a favorable pKa, and should be chosen [4, 12]. Due to the varying clinical signs of vesicular adenitis, establishing whether treatment is successful can be difficult. Treatment can be considered successful when the ejaculate contains less than one neutrophil per five high-powered fields (1000×) [4].

More recently, tilmicosin and tulathromycin have shown efficacy for treatment of vesicular adenitis [13]. The author has treated multiple older bulls successfully using subcutaneous tulathromycin. There is evidence these antimicrobials accumulate in macrophages and neutrophils, which carry the antibiotics into sites of infection to be released slowly [14, 15]. Recovery rates were higher for bulls treated with tulathromycin

than tilmicosin in all age groups; thus tulathromycin at this time appears to be the drug of choice [2].

Intraglandular injection of antimicrobials or chemical ablation agents is another option for treatment of refractory vesicular adenitis. Multiple antimicrobial agents have been utilized in this technique, all with varying results. Success has been achieved in some cases utilizing a single intraglandular injection of ceftiofur or penicillin. In one study, bulls were treated with intraglandular penicillin or intraglandular ceftiofur. Bulls that did not recover were treated with whichever antibiotic was not used initially. Approximately half of the bulls receiving the second treatment responded. Bulls that did not recover after intraglandular treatment with ceftiofur and penicillin recovered after three treatments of tilmicosin [13].

Chemical ablation of chronically infected vesicular glands utilizing 4% formalin has been described [16]. The success of parenteral tulathromycin as an initial treatment has substantially reduced the usage of chemical ablation in the author's practice. Resolution of vesicular adenitis after intraglandular formalin ablation approached 100% when utilized by the author. The procedure requires the bull to be restrained in a chute with epidural anesthesia. After clipping and prepping an area lateral to the anus, a 14-gauge needle is placed through the skin directly caudal to the affected vesicular gland (Figure 14.3). The affected gland is grasped transrectally to stabilize it for injection and a 30-cm, 18-gauge needle is introduced through the 14-gauge needle (Figure 14.4). This needle is advanced pararectally to achieve penetration of the affected vesicular gland. When sure the needle is within the gland, inject 10–15 ml of saline to ensure proper needle placement. Gland enlargement verifies proper needle placement. At this point, inject 4% formalin to a volume where the gland is enlarged with a smooth surface (Figure 14.5). In the author's experience, this will be approximately 50 ml. After injection, the bull should be treated with flunixin meglumine for three days, as most bulls show signs of abdominal discomfort. The proper authorities should be consulted regarding current legal use and withdrawal time prior to the extra label use of formalin for chemical ablation.

Surgical removal of the vesicular glands may be considered in bulls that do not spontaneously recover or do not respond to antimicrobial treatment or ablation. A subrectal approach has been described that provides better visualization of the vesicular glands and improved postsurgical fertility than traditional pararectal approaches. None of the described techniques for surgical gland removal has provided uniform success in returning a bull to function [1].

Any specific plan for prevention of vesicular adenitis is limited by the lack of a definitive pathogenesis. Proper herd health and husbandry may play an important role in reducing the prevalence of vesicular adenitis. Proper

vaccination and deworming help support the overall health and general disease resistance of bulls. Proper nutrition and bunk management to reduce the incidence of rumen acidosis may reduce the possibility of hematogenous bacteria reaching the vesicular gland. Monitoring the genetic lines of bulls with vesicular adenitis may reveal a genetic basis for the disease. Although early detection, with or without medical intervention, has not shown a significant reduction in the incidence of clinical vesicular adenitis [17], herds with a high prevalence of adenitis may benefit from early transrectal palpation and treatment [2].

Inability to Breed Due to Injury or Abnormality of the External Genitalia of Bulls

Herris Maxwell

Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

The inability to sire offspring is referred to as impotence and may result from abnormalities in sperm production and/or inability to copulate. Inability to copulate (impotentia coeundi) is further divided into inability to perform the copulatory act due to physical limitations and inability to copulate due to erection failure (impotentia erigendi). This chapter reviews important causes of impotence due to abnormalities of the genitalia of the bull. Abnormal spermatogenesis is covered in Chapters 3 and 5.

Impact of Impotence

Natural service typically utilizes bull to cow ratios of 1 : 15 to 1 : 50 [1]. The inability of the bull to breed in a single sire unit will always have a devastating effect on reproductive efficiency. Similarly, when a socially dominant bull in a multisire unit is unable to complete the copulatory act, the decrease in breeding efficiency may not be masked by the presence of additional subservient bulls. Although artificial insemination eliminates the requirement for coitus, most semen processed for the artificial insemination industry is collected by methods that mimic the copulatory act utilizing an artificial vagina (AV) as the bull mounts a teaser or phantom. While some impediments to the copulatory act may be overcome by the collection of semen using electroejaculation, others may not be easily managed.

Physiology of Erection in the Ruminant

The unique and interesting features contributing to extension and erection of the penis of the bull are well described [2, 3]. A brief summary of the process follows.

The fibroelastic ruminant penis is encased in the rigid tunica albuginea which encloses the erectile tissues of the corpus cavernosum penis (CCP). In the non-erect state the penis is maintained within the prepuce and sheath by the traction of the retractor penis muscles, which insert on the ventral surface of the mid-shaft of the penis at the distal bend of the sigmoid flexure. The proximal terminus of the CCP is the bulb of the penis, which divides laterally into two crura which are covered by the ischiocavernosus muscles at they attach to the bony pelvis at the ischiatic arch.

At the initiation of sexual arousal, the retractor penis muscles relax in synchrony with increased blood flow from the deep arteries of the penis into the crura, and the CCP fills with blood. The loss of muscle tension from the retractor muscles coupled with complete filling of the CCP initiates partial straightening of the sigmoid flexure. Contractions of the ischiocavernosus muscles compress the blood-filled penile crura against the pelvis and occlude all vascular flow to and from the CCP, resulting in a closed hydraulic system. Further rhythmic contractions of the ischiocavernosus muscles increase the pressure of the blood contained within the crura and the CCP to produce the force necessary for full erection and extension of the penis. The pressure generated in the CCP far exceeds the arterial pressure of the circulatory

system, reaching 14 000 mmHg (1.87 MPa) or higher at the time of peak erection in the bull [4].

Coitus

The breeding act requires orchestration of interrelated simple and complex events. The bull must identify the female in estrus, approach, extend the penis, mount appropriately, achieve full erection, adjust his stance and posture, blindly search for the vulva with the penis, achieve intromission, make the breeding lunge, ejaculate, and dismount. The physical requirements are obvious and structural soundness is a necessary component of the successful breeding act.

In cattle the coital act occurs rapidly, with time from mounting to intromission and ejaculation generally less than 10 seconds and the time from intromission to ejaculation 1–2 seconds [5, 6]. Some non-productive false mounts are expected, but excessive numbers may be associated with pathology of the axial or appendicular skeleton, problems with the erection process, impediments to penile protrusion and extension, or lack of innervation of the glans penis.

Following a successful breeding attempt the bull has a brief refractory period, the length of which varies among bulls and is likely affected by age, physical condition, and the presence of other bulls and females exhibiting estrus. For young physically sound bulls the refractory period may be only a few minutes and most bulls can be expected to copulate multiple times per day.

Abnormalities of the Prepuce

The prepuce is an invagination of abdominal skin that contains the free portion of the non-erect penis and covers the body of the penis behind the glans. The preputial orifice is located caudal to the umbilicus and is surrounded by a tuft of long hair that serves to divert urine away from the skin surrounding the orifice following micturition.

The penile attachment of this invagination of skin occurs caudal to the glans penis and in the non-aroused state penile retraction results in the presence of a fornix in the preputial cavity adjacent to the free portion of the penis. When erect, the free portion of the penis extends beyond the preputial orifice and the hairless reflection of skin within the preputial cavity extends with the penis and covers the shaft. The subcutaneous tissues of the prepuce must be freely moveable to allow extension and retraction of the penis and the preputial reflection. The specialized connective surrounding the tunica albuginea are referred to as the elastic layers of the prepuce.

Congenital and Developmental Anomalies

Congenital Preputial Stenosis

Congenital preputial stenosis will prevent extension of the penis, but stenosis secondary to injury or laceration of the preputial tissues is more common.

Incomplete Separation of the Penile and Preputial Epithelium

Prior to puberty, the epithelium of the free portion of the juvenile penis and the integumentary epithelium of the penile portion of internal lamina of the prepuce are joined by an interdigitating attachment [7–9]. Exposure to the trophic effects of androgens as bulls approach puberty leads to an increase in penile size and to development of the sigmoid flexure characteristic of ruminants. Simultaneous with the increase in penile size, the epithelial attachments between the preputial skin and the epithelial surface of the free portion of the penis weaken and begin separating. Separation may be facilitated by mounting activity and early attempts at erection during sexual role playing by young bulls. Until the separation is complete at 8–11 months of age, extension of the penis is not possible [7, 8, 10].

Normal separation is sometimes delayed and may result in an inability to fully extend the penis at the time of a breeding soundness examination or during an observed breeding attempt (Figure 15.1a). The attachment will often spontaneously regress in affected bulls if allowed adequate time to mature, but assisted separation by gentle application of manual traction to the penis is sometimes advocated in cases where partial separation has already occurred (Figure 15.1b and c).

Young bulls at times tear the epithelial attachment prematurely, and hemorrhage into the space between the penile and preputial epithelium results in a localized hematoma. Such injuries may go unnoticed and are often self-limiting [10]. If bacteria gain access to the damaged tissues and associated hematoma, abscess formation and fibrosis may compromise the ability to extend the penis. Case management should emphasize isolation from other animals to discourage sexual role-playing during the healing period, accompanied by broad-spectrum antibiotic treatment to minimize complications. Drainage of an abscess in this location is difficult and must be done with care to minimize loss of the elastic layers of the prepuce.

Persistent Frenulum

The frenulum is a thin band of tissue found in juvenile bulls that extends from the midline of the ventrum of the tip of the penis to the attachment of the preputial epithelium near the base of the free portion. Like the epithelial connection between the penis and prepuce, this band of tissue normally separates under the influence of androgen

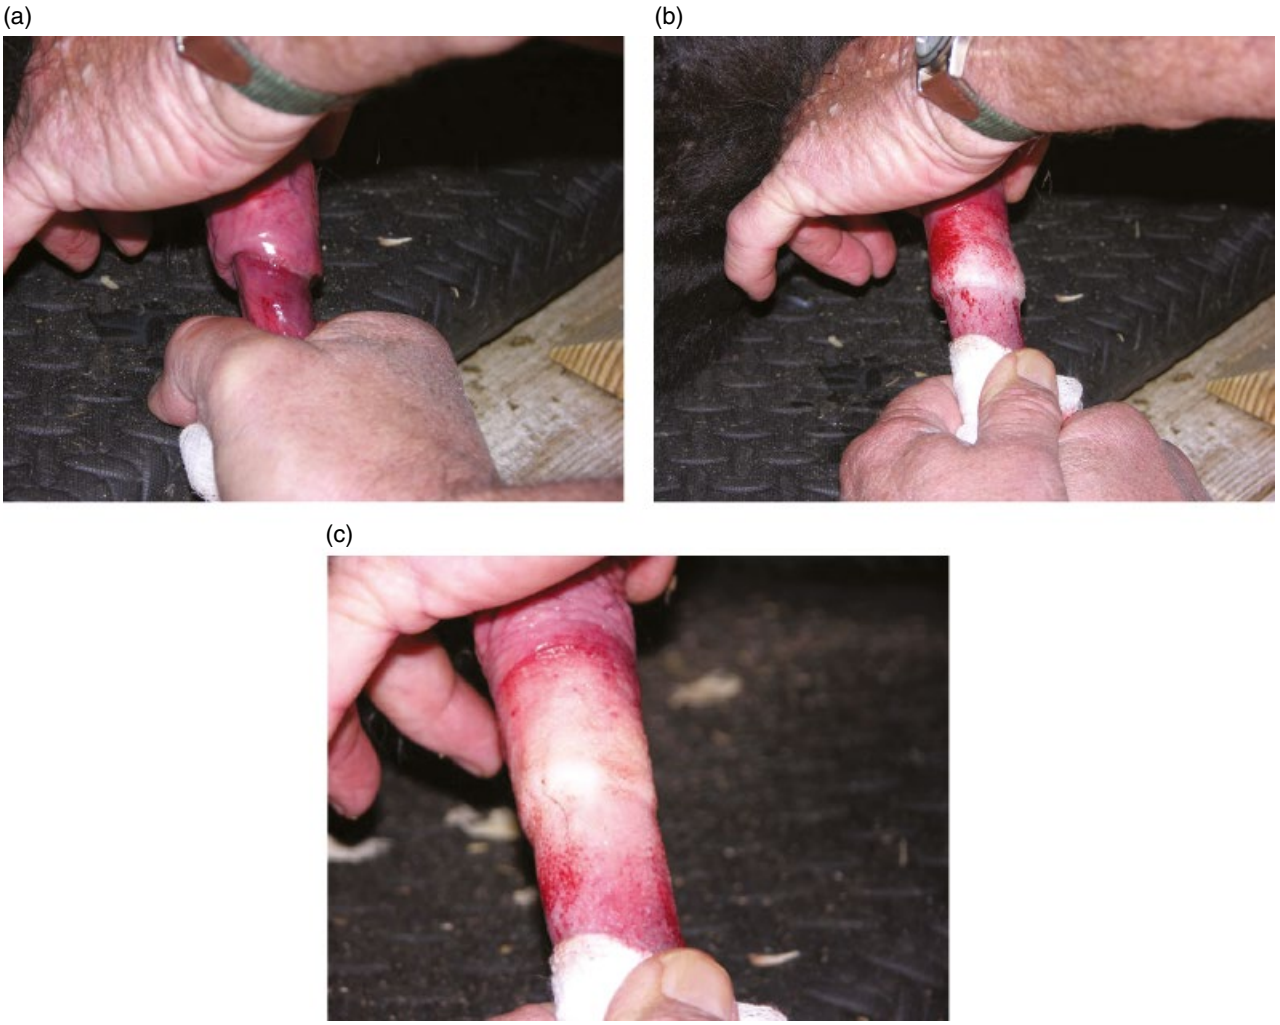

Figure 15.1 (a) Failure of separation of the epithelium of the free portion of the penis and the penile portion of the prepuce. (b) Note the adherence between the preputial and penile skin. Application of gentle traction to the penis to facilitate adherence breakdown. (c) Penile and preputial epithelium following breakdown of the epithelial adherence. *Source:* Courtesy of Robert L. Carson and Dwight Wolfe.

exposure as the bull matures. Unlike the epithelial tissues joining the penis and prepuce, the frenulum often contains a large vein. When the process of normal separation fails, the frenulum may persist after breakdown of the other epithelial attachments and result in a band of epithelium and connective tissue joining the tip of the penis with the preputial epithelium at the junction of the prepuce and free portion of the penis (Figure 15.2). A persistent frenulum results in a sharp ventral bend of the distal penis as it becomes erect. Persistent frenulum is often detected in young bulls during a routine preservice breeding soundness examination [11], but occasionally is not detected until bulls attempt natural service.

The cause or causes of failure of separation of the preputial epithelium and/or frenulum are unknown. An unproven genetic association is suspected [12, 13]. Surgical transection of the frenulum is curative [13, 14], but limiting affected animals to use as terminal sires is recommended.

Injuries to the Prepuce

Bulls sometimes sustain injuries to the prepuce severe enough to interfere with breeding. Bulls from breeds with substantial *Bos indicus* influence have a pendulous sheath, excessive preputial skin, and a large preputial orifice, and bulls of this phenotype are predisposed to preputial trauma at the time of breeding. While *Bos taurus* breeds have less redundant skin in the area of the prepuce and are less likely to sustain breeding-associated preputial trauma, preputial injury at the time of the ejaculatory lunge may occur in any breed.

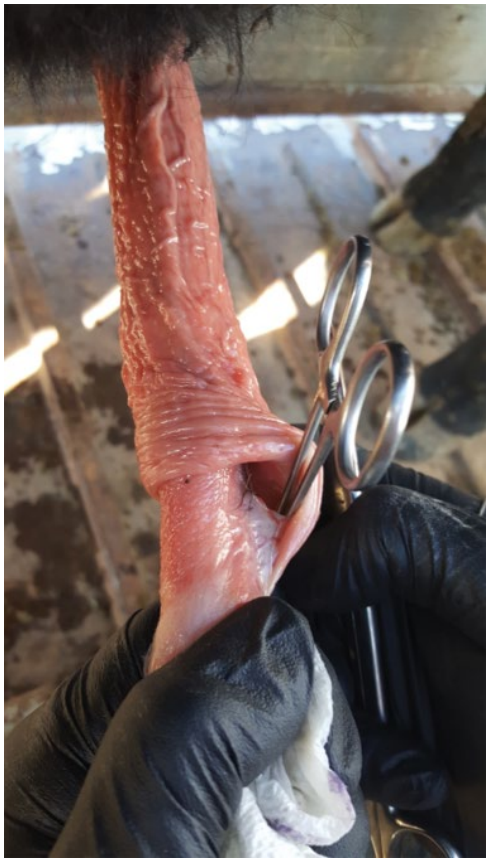

Figure 15.2 Persistent frenulum. The presence of the persistent frenulum was noted at the time of a post-purchase breeding soundness examination. A satisfactory pre-purchase "semen test" had been provided at the time of sale, emphasizing the importance of examination of the external genitalia during a bull breeding soundness examination. *Source:* Image courtesy of Dr. Clint Hilt.

Preputial Laceration

Bulls with a pendulous sheath and excessive preputial skin may traumatize the preputial tissues independent of the breeding act, but most serious preputial injuries occur at the time of the ejaculatory lunge. As the free portion of the penis enters the vagina during coitus, preputial skin slides caudally, up the shaft of the penis, toward the abdomen of the bull, and folds of redundant skin gather at the preputial orifice. This "bunching" of preputial skin usually occurs without incident, but when preputial tissue is inadvertently trapped between the abdomen of the bull and the bony pelvis of the female at the time of intromission, compressive forces generated at the time of the ejaculatory lunge can injure the entrapped tissues. With mild injury, the preputial epithelium remains intact and the accumulation of edema in the damaged tissues results in an uncomplicated preputial prolapse. More serious injuries result when compression of the entrapped prepuce disrupts the epithelium, with subsequent exposure and damage of the underlying elastic tissues. Commonly referred to as preputial laceration, the injury is in reality the result of bursting of preputial tissues in response to compressive force [15].

Preputial lacerations initiated during the breeding act are predictably located on the ventrum of the prepuce, with the initial disruption of the preputial tissues oriented longitudinally, parallel to the long axis of the bull's body. Following the injury, the disrupted tissues at the site of the injury become oriented transversely as the penis is retracted and the damaged preputial tissues are drawn toward the preputial orifice. As a result, the defect becomes oriented transversely (Figure 15.3). When the damaged preputial tissues cannot be retracted through the preputial orifice, the transverse orientation of the lacerated tissues results in shortening of the caudal aspect of the exposed prepuce and a characteristic "elephant trunk" appearance of the prolapsed tissues (Figure 15.4).

Trauma and disruption of the preputial epithelium and underlying elastic tissues is accompanied by inflammation and edema and the open wound inevitably becomes septic. As dependent edema accumulates, the prolapsed tissue increases in size and weight, and traction on the prepuce results in greater amounts of preputial tissue becoming exposed. Additional trauma, mutilation, and desiccation of the unprotected preputial tissues occur and wound contracture at the site of the injury distorts the tissues as the reoriented wound undergoes fibrosis and cicatrix formation (Figure 15.5).

Preputial retractor muscles serve to elevate the prepuce and this elevation can minimize edema formation in damaged tissues. Many polled bulls lack retractor prepuce muscles and preputial prolapse following laceration in naturally

Figure 15.3 Preputial laceration in a breeding bull. The laceration assumed a transverse orientation as the preputial tissues were retracted toward the preputial orifice.

Figure 15.4 Preputial laceration with prolapse of the damaged preputial tissues. Reorientation of the wound results in the elephant trunk appearance of the prolapsed preputial tissue.

Figure 15.5 Wound contracture and fibrosis at the site of a preputial laceration. *Source:* Courtesy of Richard Hopper.

hornless bulls tends to become more severe than similar injuries in horned animals [16].

Wolfe and Carson constructed a four-point classification scheme that incorporates the severity of the preputial injury to estimate the prognosis for return to function and guide treatment decisions (Table 15.1) [17].

Medical management of preputial laceration and prolapse is aimed at control of tissue sepsis, reduction of edema, and the eventual return of the damaged tissues to the preputial cavity. Application of emollients to prevent desiccation and topical antibiotics should be combined with light bandaging. Careful cleansing and flushing of the wound with dilute antiseptic solutions and debridement of devitalized tissues is necessary. Topical antibiotic therapy is sufficient if wound management is adequate, and systemic antibiotic therapy is not often required.

Table 15.1 Classification of preputial prolapse.

Category	Description	Treatment and prognosis
I	Simple preputial prolapse with slight to moderate edema without laceration, necrosis, or fibrosis	Either conservative or surgical treatment with good prognosis
II	The prolapsed prepuce has moderate to severe edema, may have superficial lacerations or slight necrosis, but has no evidence of fibrosis	Surgery is the usual course of therapy with a good to guarded prognosis
III	There is severe edema of the prolapsed prepuce with deep lacerations, moderate necrosis, and slight fibrosis	Surgery is indicated and the prognosis is guarded
IV	The prolapsed prepuce has been exposed for quite some time and has severe edema, deep lacerations, deep necrosis, fibrosis, and often abscess	Surgery and salvage by slaughter are the only options, and a guarded to poor prognosis follows surgery

Source: Modified from [17], p. 258, © 1998, Wolters Kluwer.

Application of a circumferential bandage to protect the wound, prevent desiccation, and apply mild compression of the damaged tissues is useful. To apply a bandage following cleansing and application of an emollient antibiotic ointment, first place a short length of latex tubing into the preputial orifice and position it with one end in the preputial cavity proximal to the torn epithelial tissues and the other end exiting the preputial orifice to allow urine egress from the prepuce. Then place a piece of clean 5-cm orthopedic stockinette over the exposed preputial tissues and snugly apply an elastic tape bandage over the stockinette, prepuce, and urine egress tube beginning at the distal end of the prolapsed tissue, overlapping the tape as it advances up the prepuce to the preputial orifice, where it can be secured to the haired skin of the sheath (Figure 15.6). Following bandaging, the edematous prepuce may sometimes need to be suspended by application of a bib or sling made of net material or burlap supported by straps encircling the bull's abdomen (Figure 15.7). Frequent bandage changes are necessary, and the wound should be treated locally each time it is exposed. Cold water hosing for 10–15 minutes at each bandage change will reduce edema and remove necrotic debris. With diligent treatment many bulls may be returned to service without surgery [18] but repeat injury is common.

Surgical treatment following preputial laceration can improve outcome [19] and is indicated when the bull's

value and remaining breeding life justify the expense [19, 20]. Surgery must always be preceded by preoperative wound management. Excellent descriptions of the surgical options appear elsewhere in this book (see Chapter 19).

Retropreputial Abscess

Preputial injury and laceration are not limited to *B. indicus* influenced breeds. In *B. taurus* bulls, preputial injury may occur at the time of breeding in a manner identical to that described for *B. indicus* bulls, but the outcome is often altered by phenotype. *B. taurus* breeds are more likely to retract all the damaged tissues into the preputial cavity following injury and as a result the wound is less likely to be noticed early. The visible preputial swelling may be confined to a well-defined area adjacent to the bull's sheath, or may be more diffuse and occasionally extend from the preputial orifice caudally toward the scrotum. Because the compromised elastic tissues within the preputial cavity are contaminated with bacteria, cellulitis and phlegmon develop rapidly, often progressing to abscess formation.

Retropreputial abscess formation is more likely in bulls of *B. taurus* than *B. indicus* influenced breeds due to lack of redundant skin and generally tighter sheath conformation. Affected bulls present with an obvious swelling visible through the overlying skin of the sheath that may be accompanied by the presence of pus or blood at the preputial orifice. Diagnosis is based on physical examination and palpation, sometimes augmented by ultrasound imaging of the tissues. The differential diagnosis for preputial inflammation with visible disruption of the normal contour of the sheath must include the enlargement of the elastic tissues seen following rupture of the tunica albuginea of the penis. In contrast to the lesion seen with rupture of the tunica albuginea, retro preputial abscesses are usually non-symmetrical and located distal to the sigmoid flexure nearer the level of the preputial fornix (Figure 15.8). Retropreputial abscess formation is associated with poor prognosis for future breeding. Destruction and impairment of the elastic tissues frequently result in adhesion formation within the elastic tissues of the prepuce and the overlying skin, or in compromise of the diameter of the preputial lumen, either of which may prevent extension of the penis [17].

Figure 15.8 Retropreputial abscess following preputial laceration in a young bull. Note location of the swollen tissues in the distal sheath.

Therapy for retropreputial cellulitis, phlegmon, and abscessation relies on systemic antibiotic administration and local wound management. Daily flushing of the preputial tissues with dilute antiseptic solutions and cold water hosing of the sheath aid in resolution of cellulitis. Drainage of a retropreputial abscess into the preputial lumen at the site of the original injury may facilitate recovery but is difficult to accomplish. No attempt should be made to drain a retropreputial abscess through the overlying skin of the sheath as inflammation and sepsis of the underlying elastic tissues are inevitable and subsequent formation of peripenile adhesions will decrease the chance of a successful outcome [17, 18]. Even with aggressive therapy the prognosis is guarded to poor and many affected bulls never return to service [17].

Phimosis

Phimosis, the inability to extend the penis, effectively prevents the bull from breeding and may be diagnosed at the time of an observed breeding or by induction of erection with an electroejaculator. Phimosis may be due to stenosis of the preputial opening or lumen, adhesions within the elastic layers of the prepuce and surrounding skin, or occasionally abnormalities of the distal penis including the presence of large penile fibropapillomas.

Stenosis or stricture of the preputial lumen can occur following preputial injury despite appropriate and apparently successful medical or surgical management. Scar tissue replaces damaged elastic tissues, and contracture and cicatrix formation may constrict the preputial lumen and result in preputial stenosis sufficient to prevent extension of the penis (Figure 15.9). If circumferential constriction of the preputial cavity occurs distal to the end of the tip of the non-erect penis, sexual arousal and engorgement of the penis will force the distal portion of the penis down the prepuce until the restriction is encountered and the preputial lamina will then be forced out the preputial orifice without exposure of the free portion of the penis. Strictures sometimes interfere with the evacuation of urine from the preputial cavity. Non-circumferential scar formation at the site of a healed preputial laceration may also compromise the preputial lumen and prevent penile extension.

Extension of the penis requires appropriate function of the elastic tissues and severe damage prevents the gliding action that permits the free portion of the penis and internal lamina of the prepuce to exit the preputial orifice. Formation of adhesions between the penis, the elastic tissues, and overlying skin following trauma may effectively limit the movement of the penis and result in partial or complete failure of extension. The site of the adhesions may sometimes be identified by a visible deformation of the contour of the overlying skin at the time of attempted erection.

Phimosis may also result due to the presence of a penile wart (papilloma) larger than the external opening of the preputial orifice. Incision of the internal lamina of the prepuce to allow extension of the penis and removal of the wart followed by primary closure of the incised preputial tissue can be curative if the value of the bull is sufficient to

Figure 15.9 Phimosis due to circumferential stricture of the preputial cavity following preputial laceration. *Source:* Courtesy of Craig Easley.

justify the expense of surgery (Figure 15.10). Restraint on a tilt table and administration of local analgesia by blocking the dorsal nerves of the penis or administration of an internal pudendal nerve block facilitate this procedure.

Many bulls with phimosis are culled. In cases of preputial stenosis, restoration of the preputial lumen may be accomplished by resection of the compromised tissues and anastomosis of the remaining prepuce if sufficient healthy preputial tissues remain. Similarly, surgical scar revision can be useful for restoring the integrity of the preputial lumen when the amount of healthy preputial skin is insufficient for preputial resection. Both techniques are described in Chapter 19. No treatment is effective if adhesions of the elastic tissues are severe.

Avulsion of the Prepuce

The attachment of the reflection of preputial skin to the free portion of the penis is susceptible to avulsion injury at the time of breeding, but this injury occurs more commonly when semen is collected with an AV. If the AV is inappropriately sized or not properly lubricated, preputial skin will not easily slide down the interior of the latex liner and can be avulsed or torn from its attachment to the penis at the time of the ejaculatory lunge. This injury can often be recognized immediately following service with the AV when blood is seen at the external preputial orifice. Extension of the penis allows visual observation of the avulsion injury, typically located on the ventrum of the penis (Figure 15.11) [21]. Unlike preputial lacerations which occur at the time of breeding, the underlying tissues are not severely traumatized and immediate repair by direct suture of the avulsed tissues is recommended. Prognosis following early detection and repair is good [21]. If not noticed early and repaired immediately, hemorrhage and wound sepsis may complicate management but careful dissection and reattachment of the avulsed tissue can still be successful.

When collecting semen with an AV the person collecting the semen should be appropriately trained, a suitable AV and liner should be selected and properly prepared, and bulls should always be observed closely following collection [21].

Abnormalities of the Penis

Congenital Abnormalities

Congenital abnormalities of the penis occur sporadically and are sometimes associated with other disorders of sexual development.

Hypospadias

Hypospadias, an abnormal opening in the urethra that occurs when the embryonic urethral groove fails to close or closes incompletely anywhere along its length, has been reported in bulls and other species. In some cases the entire length of the penile urethra may be involved and may be easily observed at birth [22]. Cases that involve only the distal urethra may go unobserved until the bull is examined during a breeding soundness examination [23]. Slight caudal relocation of the urethral meatus may not significantly affect fertility.

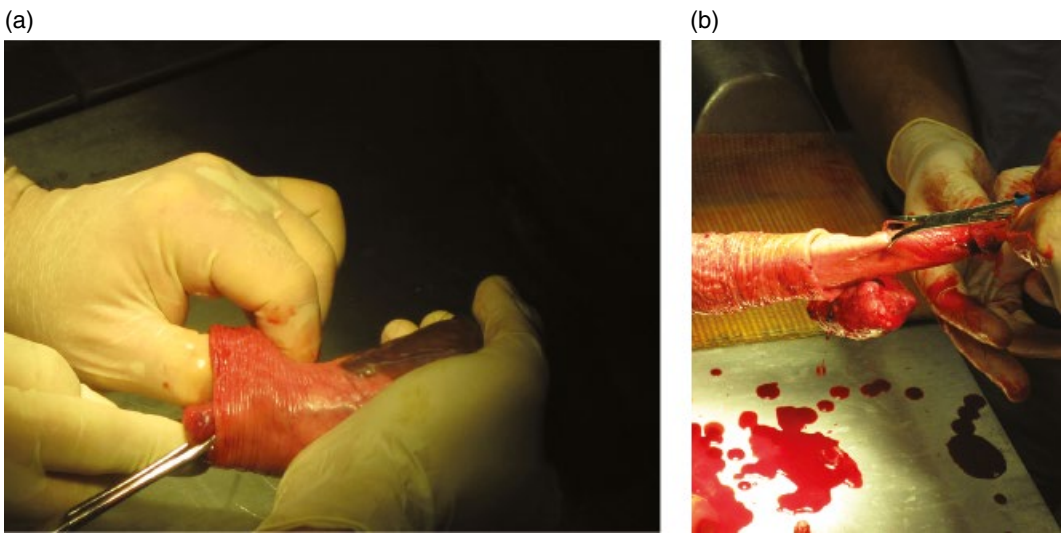

Figure 15.10 Phimosis due to the presence of a penile fibropapilloma larger than the preputial orifice. The tip of the free portion of the penis has been grasped with sponge forceps (a). Following incision of the internal lamina of the prepuce to enlarge the preputial orifice, the penis was extended and the fibropapilloma surgically excised (b).

Figure 15.11 Preputial avulsion. Notice the separation of the attachment of the preputial skin from its attachment at the base of the glans penis. Such injuries most commonly occur during collection of semen in a poorly prepared AV but sometimes, as in this case, occur during natural breeding. *Source:* Image courtesy Jessica Rush.

Congenital Short Penis

Congenital short penis is seen uncommonly and must be differentiated from a partial phimosis secondary to preputial injury or fibrosis of the retractor penis muscles. Some affected bulls may sire calves by natural service during their first or second breeding season, but copulation becomes impossible as they reach mature body size. Diagnosis is made by observation of breeding and measurement of the distance from the preputial orifice to the tip of the extended penis. The etiology of congenital short penis is unknown [24]. Affected bulls are unable to breed naturally and should be culled.

Diphallus

Diphallus, or duplication of the penis, is reported sporadically [25, 26]. Duplication may involve only the glans penis, or the free portion of the penis may be involved.

Congenital Vascular Shunts

Anomalous vascular anastomoses between the peripenile circulation and the erectile tissues of the CCP result in shunts that allow blood from the CCP to exit the erectile tissues and destroy the integrity of the closed hydraulic system necessary for complete erection [27]. Vascular shunts may occur as a congenital anomaly or form following an injury that disrupts the integrity of the tunica albuginea of the penis. Regardless of etiology, when erection is stimulated at a test breeding or with an electroejaculator, partial erection and protrusion of the glans penis is initiated followed by loss of intrapenile pressure and failure to achieve full erection.

Vascular anastomoses between the CCP and extracorporeal vasculature found in the distal free portion of the penis are usually multiple and result from congenital flaws in the integrity of the tunica albuginea [28]. As blood escapes through these distally located shunts at the time of sexual stimulation, "blushing" of the preputial tissues may be observed as blood from the CCP enters the venous circulation beneath the preputial skin. A presumptive diagnosis may be made following observation of a test mating or attempts to induce erection with an electroejaculator. Confirmation requires demonstration of the shunts with radiographic contrast studies in which radiopaque contrast media are injected directly into the CCP as serial radiographs are taken. In the normal penis the contrast media remain within the CCP until eventually exiting at the crura of the penis (Figure 15.12). Visualization of the contrast media within the peripenile vasculature outside the CCP is diagnostic (Figure 15.13). Demonstration of anomalous vessels in the distal portion of the penis may be enhanced by occlusion of the distal peripenile vessels by application of a tourniquet to the penis proximal to the location of the shunt(s) [29]. Unlike acquired vascular shunts of the CCP, congenital shunts are seldom amenable to surgical correction.

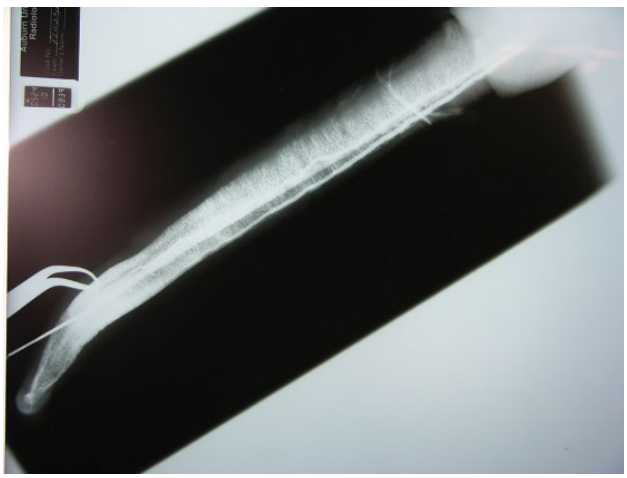

Figure 15.12 Normal cavernosogram. Contrast media injected into the CCP at the level of the free portion of the penis remain within the CCP. The ventral canals and cavernous spaces are clearly outlined.

Anatomic and Developmental Abnormalities

At the time of puberty androgens initiate growth of the juvenile penis and initiate separation of the penile and preputial epithelium [7], as discussed in the section "Abnormalities of the Prepuce." The sigmoid flexure develops as the penis enlarges and the retractor penis muscles attached to the proximal flexure of the sigmoid maintain the non-erect penis within the sheath. The rigid tunica albuginea has sufficient strength to effectively contain the pressures generated at the time of erection and gives the erect penis its tubular shape. Uniform filling of the cavernous spaces of the CCP is required for complete erection. The dorsal apical ligament of the penis must elevate the free portion of the erect penis to allow successful intromission.

Penile Deviation

Deviation of the penis results in inability to copulate. Affected bulls may have a history of one or more successful breeding seasons and there is often no history of trauma or penile injury. In the bull the dorsal apical ligament of the penis originates from the tunica albuginea proximal to the free portion of the penis, runs along the dorsum of the free portion beneath the penile skin, and rejoins the tunica albuginea near the distal end of the CCP. The ligament inserts on the distal penis centrally with a broad set of fibers and on the left lateral aspect of the free portion of the penis with a narrower and better defined set of fibers [9, 30]. This ligament gives support to the erect penis and maintains the normal alignment of the penis as the bull positions himself for coitus and utilizes the tip of the penis to search for the vulva. Following intromission and achievement of peak erectile pressure the ligament may "slip" to the left and the distal penis will often assume a corkscrew shape and spiral within the vagina at the time of the ejaculatory lunge [6]. When erection is induced with the artificial stimulus of an electroejaculator, the penis will frequently assume this same spiral orientation, often prior to ejaculation.

Spiral Deviation

Pathologic spiral deviation of the penis occurs when the dorsal apical ligament slips laterally prior to intromission (Figure 15.14a). The role of the dorsal apical ligament in the development of spiral deviation is well described, but the factor or factors leading to the premature occurrence of this otherwise normal phenomenon are poorly understood [9, 30, 31]. Malfunction of the dorsal apical ligament due to a shortening of the ligament or lengthening of the penis as the bull ages was once commonly felt to be the cause but remains unproven. More recent speculation suggests that intravaginal spiral deviation occurs normally in many bulls, associated with peak erectile pressure, and that pathologic spiral formation occurs prematurely in bulls in which peak erectile pressure occurs prior to intromission. In either case, bulls with premature spiral deviation of the penis are unable to complete the copulatory act.

A diagnosis of spiral deviation is suspected based on history and a description of the penis during the breeding attempt, but diagnosis can only be confirmed by an observed test mating. Because the penis of many normal bulls will spiral under the artificial stimulus of electroejaculation, diagnosis following observation of spiraling during stimulation with an electroejaculator is insufficient (Figure 15.14b). Deviation may be intermittent, especially early in the development of the condition, and repeated observations of test matings may be required to confirm the diagnosis.

No medical therapy is available to correct spiral deviation of the penis. Surgical correction of spiral deviation relies on induction of fibrous tissue to strengthen the attachments of the dorsal apical ligament to the penis. The available surgical techniques are described in Chapter 19. Spiral deviation is sometimes seen in association with damage to the dorsal nerves of the penis and careful observation at the time of test mating to rule out penile denervation should precede any attempted surgical correction.

Ventral Deviation

Ventral deviation of the penis is less common than spiral deviation and the etiology is uncertain. The penis assumes a ventral curvature as erection progresses and has been described as a "rainbow" due to the arc formed by the erect penis. Like spiral deviation, ventral deviation is best diagnosed with an observed test mating, but observation under

Figure 15.14 (a) Spiral deviation of the penis demonstrated during a test mating. (b) Spiral deviation of the penis induced with an electroejaculator during semen collection. Spiraling of the penis during electroejaculation is common and should not be confused with the pathologic deviation prior to achieving intromission shown in (a). *Source:* Image courtesy of Clint Hilt.

stimulation with an electroejaculator is useful because, unlike spiral deviation, ventral deviation is not a normal phenomenon. The area of ventral deviation usually originates in the shaft of the penis proximal to the origin of the dorsal apical ligament (Figure 15.15), meaning that surgical correction of ventral deviation with techniques to supplement the ligament are unlikely to be successful. The occasional reports of successful correction by pexy of the dorsal apical ligament are limited to cases in which the deviation is restricted to the free portion of the penis [32] (Figure 15.16).

S-Shaped Deviation

S-shaped deviation of the penis is the least common type of penile deviation. It develops in mature bulls and the serpentine curvature of the penis appears to result from a mismatch of the length of the penis and dorsal apical ligament. The penis may appear excessively long or the apical ligament may have undergone contracture following repeated injury. The dorsal apical ligament prevents the fully erect penis from assuming its normal straight orientation and the bull may be unable to control the penis sufficiently to locate the vulva of the cow. Semen from affected bulls

Figure 15.15 Ventral deviation of the penis demonstrated during stimulation with an electroejaculator. Note that the deviation begins proximal to the origin of the dorsal apical ligament of the penis. Surgical repair has been unsuccessful in such cases. *Source:* Courtesy of Robert L. Carson and Dwight Wolfe.

Figure 15.16 Ventral deviation of the penis demonstrated during a test mating. Note that in this case the deviation begins distal to the origin of the dorsal apical ligament of the penis. could be collected for use in artificial insemination, but no effective treatment for the condition exists.

Persistent Frenulum

Persistent frenulum has been described under "Abnormalities of the Prepuce." Diagnosis by observation is obvious but may sometimes be confused with phimosis in bulls with excessive redundant preputial skin when the ventral bending of the prepuce prevents extension of the glans beyond the preputial orifice (Robert L. Carson, personal communication).

Penile Injury

Urethral Fistula

A urethral fistula may develop following laceration of the urethra, constrictive injury from a penile hair ring, or urethral necrosis associated with the presence of a urethral calculus (Figure 15.17). The bull's ability to deposit semen properly in the cranial vagina may be compromised depending on the location of the fistula [33].

Paraphimosis

Paraphimosis, the inability to retract the penis into the preputial cavity, may occur following penile laceration or preputial trauma. Edema effectively reduces the diameter of the preputial orifice and the non-erect penis remains exposed beyond the preputial orifice. The exposed preputial and penile epithelium desiccates rapidly and the superficial layers become necrotic and slough. The exposed penis is typically discolored and assumes a mild corkscrew orientation (Figure 15.18). Paraphimosis resulting from breeding injuries warrants a grave prognosis and treatment must be initiated early to be successful. Apply emollient ointments and humectants to protect the exposed skin and cover the damaged tissues with a length of orthopedic stockinette or other light bandage material. Frequent bandage changes and fresh application of dressings combined with daily cold water hosing should continue until the penis can be retracted into the prepuce. Continue preputial lavage with antiseptics and application of antibiotic ointments or emollients for at least a week after the penis is returned to the sheath. Even with aggressive early treatment, return to service is unlikely and the chance for a successful outcome decreases the longer treatment is delayed following injury.

Paraphimosis may sometimes be associated with the presence of a penile papilloma on the distal penis large enough to prohibit retraction through the preputial orifice. Surgical removal of the wart can be curative.

Penile Hematoma (Rupture of the Tunica Albuginea of the Penis)

While any extravascular accumulation of blood in the vicinity of the penis could technically be termed a penile hematoma, in the bull the terms "hematoma of the penis" and "penile hematoma" are usually reserved to describe the breeding injury that results in rupture of the tunica albuginea of the CCP. The penis of ruminants is well equipped to withstand high intrapenile pressure created within the CCP. At the time of erection, venous outflow to the CCP is obstructed and contraction of the ischiocavern-

osus muscles increases pressure within the penis to 14 000 mmHg (1.87 MPa) or greater [3]. Pressures of this magnitude are easily contained by the thick fibrous tunica albuginea of the penis which encompasses the CCP. However, if a cow or heifer collapses during coitus or if an ill-timed breeding lunge accidently forces the erect penis against the escutcheon, sudden angulation of the penile shaft may increase intrapenile pressure to greater than the 70 000 mmHg (9.3 MPa) required to rupture the tunica albuginea [34]. Although occasionally seen at other sites [35, 36], rupture of the tunica albuginea almost inevitably occurs on the dorsum of the penis opposite the attachment of the retractor penis muscles on the distal bend of the sigmoid flexure.

Rupture of the tunica albuginea is accompanied by extravasation of the blood contained in the CCP and formation of a hematoma which is visible as a symmetrical enlargement at the site of the rupture. While the erect penis contains a relatively small quantity of blood (about 150–250 ml), the hematoma may grow from comparatively small to quite large if repeated sexual stimulation results in additional attempts at erection and continued leakage of blood through the rent. In some cases several liters of blood may accumulate in the peripenile tissues and form a large symmetrical swelling dorsal to the penis near the neck of the scrotum (Figure 15.19). Hematoma of the penis is diagnosed based on physical examination findings, occasionally supplemented by ultrasound, and may be differentiated from retropreputial abscess by the typical location and symmetry of the swelling.

Following rupture of the tunica albuginea, ventral migration of blood and edema within the peripenile elastic tissues often results in a secondary prolapse of preputial tissues through the preputial orifice. These mild to moderate preputial prolapses may have a distinct bluish tinge as a result of subcutaneous blood and may be the first sign noticed by the owner or manager of the bull (Figure 15.20).

Rupture of the tunica albuginea is seldom life-threatening, but the injury and the complications that follow can result in permanent loss of reproductive function. Potential complications following penile hematoma include abscess formation at the site of the hematoma, formation of adhesions between the penis and peripenile tissues, development of vascular shunts between the CCP and the surrounding vasculature, injury to the prolapsed preputial tissues, and destruction of the dorsal nerves of the penis. Injury to the dorsal nerves of the penis at the time of injury or by entrapment injury as scar tissues remodel can result in loss of sensation to the distal penis, rendering the bull unable to breed by natural service. Even following apparently successful management and resolution, recurrence of injury may occur during subsequent attempts at breeding [17].

Case management options following rupture of the tunica albuginea include salvage for slaughter, surgical removal of the blood clot coupled with repair of the rent, or medical management. If the injury is recognized early, surgical removal of the hematoma and closure of the rent increases the likelihood for restoration of breeding ability and decreases the incidence of other post-injury sequelae. Surgical repair of hematoma of the penis and postoperative care is covered in Chapter 19. Medical management is advocated when diagnosis has been delayed or when the economic value of the bull will not justify the expense of surgery and aftercare. Non-surgical management includes

Figure 15.19 Hematoma of the penis (rupture of tunica albuginea). Note the location of the swelling, dorsal to the penis and cranial to the scrotal neck. *Source:* Courtesy of Richard Hopper.

Figure 15.20 Preputial prolapse associated with penile hematoma due to rupture of tunica albuginea of the penis.

broad-spectrum antibiotic coverage to decrease the likelihood of abscess formation, twice-daily cold water hydrotherapy of the affected area, local treatment of the secondary preputial prolapse, and strict enforcement of sexual rest for 60–90 days.

Erection Failure

Inability to achieve or maintain penile erection (*impotentia erigendi*) precludes natural service. A history of failure to impregnate females in the breeding pasture or observation of unsuccessful breeding is often the presenting complaint. A well-taken history including previous breeding performance, breeding injuries, and the owner's description of the appearance of the bull at the time of attempted coitus are valuable, but observation of the penis during an attempt at erection is a required element for diagnostic evaluation. Use of the electroejaculator to induce erection may be useful but a controlled test mating is preferred.

Because painful stimuli from the spine, rear limbs, or pelvis may interfere with the willingness or ability of the bull to achieve erection and complete the breeding act, a physical examination of the bull at rest and in motion is mandatory. Appropriate management or correction of painful musculoskeletal and spinal conditions may be useful and return some bulls to breeding soundness.

True erection failure may involve disruption of vascular components of the erection mechanism or failure of the corpus cavernosum to fill completely.

Erection Failure Due to Vascular Shunts

Sexual stimulation of the bull is followed by increased blood flow through the crura of the penis and into the CCP. This mechanism may be mimicked by stimulation with an electroejaculator. As discussed previously, the tunica albuginea encases the erectile tissues in the CCP and there are normally no functional venous outlets along the body or shaft of the penis at the time of erection, allowing the intact tunica albuginea to effectively maintain a closed hydraulic system to contain the extraordinary pressures generated as the ischiocavernosus muscles rhythmically contract against the blood-filled crura of the penis [2, 4]. If the integrity of the fibrous tunica albuginea is compromised, anastomoses between the CCP and the surrounding peripenile vasculature may form and provide an escape route for blood contained in the CCP. Should this occur, pressure sufficient to achieve or maintain erection cannot develop [28, 37]. Communication of the CCP with the corpus spongiosum penis will produce a similar result because venous drainage of the CSP is not occluded during erection [29, 38]. Formation of vascular shunts may follow traumatic disruption of the tunica albuginea or be associated with a congenital weakness of the tissues of the tunica albuginea.

The presence of vascular shunts as a cause of erection failure can be suspected based on findings of an observed test mating, and confirmation depends on demonstration of the vascular communication of the CCP and surrounding vasculature or CSP using radiographic contrast studies. Cavernosography (Figure 15.12) utilizes water-soluble radiographic contrast media (Renografin 76, Squibb Diagnostics, New Brunswick, NJ). Best results are obtained with the bull restrained in lateral recumbency on a tilt table. Extend the penis and place towel clamps under the dorsal apical ligament and apply sufficient traction on the towel clamps to maintain extension of the penis. A length of suture or umbilical tape should be attached to the towel clamps to keep the hands of the assistant out of the radiograph beam. At the same time, place a 30-cm loop of suture through the skin under the retractor penis muscles and apply traction to pull the more proximal portion of the penis away from the abdomen for better radiographic visualization. Make an initial scout film without contrast media to establish appropriate radiographic settings. While utilizing the towel clamps to extend the penis and the loop of suture under the retractor penis muscles to pull the penis from the abdomen, insert a 16-gauge needle into the CCP on the dorsum of the free portion of the penis and attach an infusion set of sufficient length to keep the operator's hands out of the radiographic field (Figure 15.21). Inject saline into the CCP to ensure proper placement, and once proper needle placement is ascertained, inject 15 ml of the radiographic contrast media and begin the radiographic series. Have the assistant slowly inject additional contrast media over the next 60 seconds as serial radiographs are taken of as much of the penis as possible. Take enough exposures to allow visualization of the free portion of the penis and penile shaft to the level of the distal sigmoid flexure [39].

Formation of vascular shunts is recognized as a potential complication following rupture of the tunica albuginea as described under the section on penile hematoma. Anastomoses which develop following disruption of the integrity of the tunica albuginea and subsequent penile hematoma formation are located at the site of injury, the dorsum of the penis at the level of the distal bend of the sigmoid flexure (Figure 15.22). Penetrating injury to the tunica albuginea at sites other than the location of a penile hematoma may also be followed by shunt formation. Surgical correction of vascular shunts that occur following either type of trauma may be successful.

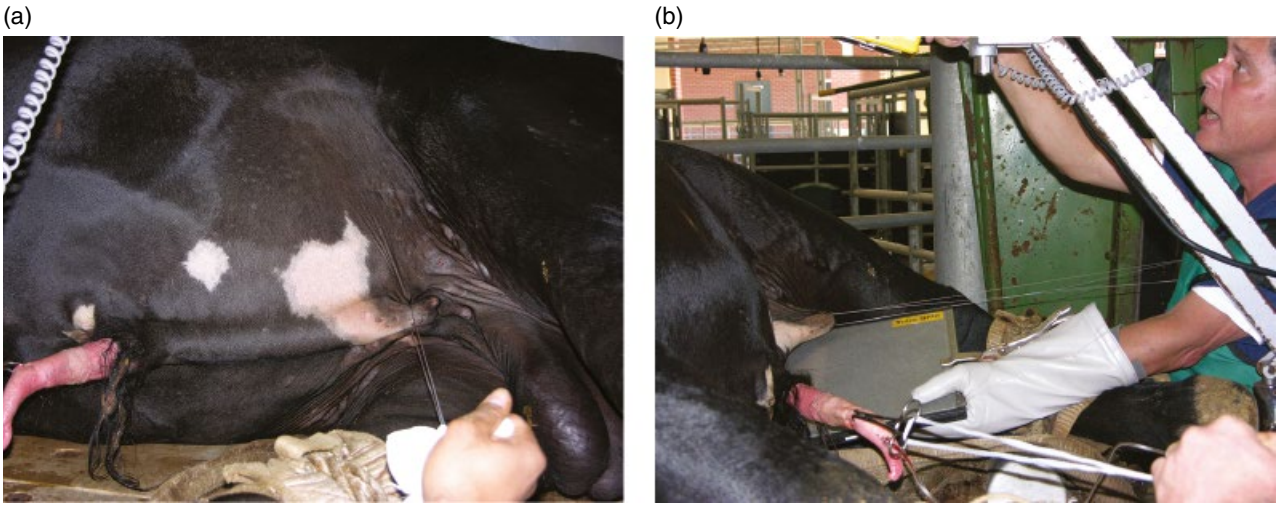

Figure 15.21 Bull prepared for cavernosography. Note suture placed through the abdominal skin and under retractor penis muscles to pull the penis away from the abdomen (a). As the bull is positioned, an extension set is attached to a hypodermic needle placed into the CCP of the free portion of the penis, the penis is held in extension with a towel clamp placed under the dorsal apical ligament, and traction is applied to the preplaced sutures under the retractor penis muscles (b).

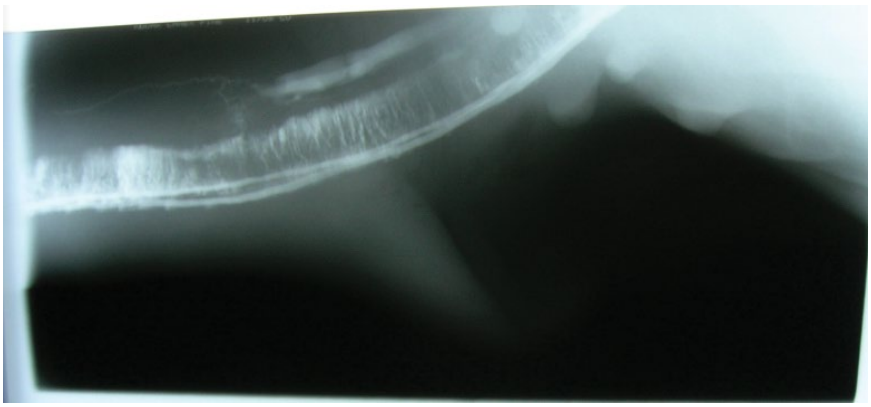

Figure 15.22 Cavernosogram of the penis of a bull demonstrating escape of contrast media into the peripenile circulation at the level of the distal sigmoid flexure. *Source:* Courtesy of Dwight Wolfe.

Cases of erection failure due to multiple vascular shunts involving defects in the tunica albuginea of the free portion of the penis are thought to be the result of a congenital weakness in the structural integrity of the tunica. In such cases there is no history of penile trauma or injury. Affected bulls fail to achieve erection following sexual stimulation and may have bluish discoloration of the penile or preputial skin when attempting to breed or when attempts are made to induce erection with an electroejaculator. Discoloration is the result of blood exiting the CCP through the peripenile vasculature. Multiple distal vascular shunts are most often diagnosed in bulls during the first breeding season. Vascular shunts in the distal penis are readily demonstrable with cavernosography (see Figure 15.13). Unlike vascular shunts that form secondary to traumatic disruption of the tunica albuginea, surgical correction of multiple congenital shunts is unsuccessful.

Filling Defects of the CCP

Erection and maintenance of the normal penile form is dependent on complete distension of the unobstructed cavernous spaces with blood under pressure. If the cavernous spaces are blocked sufficiently to prevent blood from completely filling the CCP, engorgement of the penis can only progress from the proximal portion of the penis to the area of the filling defect [40]. The clinical presentation depends on the location of the obstruction. Complete obstruction of portions of the CCP may result in extension of the penis without erection of the portions distal to the blockage (Figure 15.23). Partial blockade of the cavernous spaces in the distal free portion of the penis may sometimes cause the erect penis to deviate ventrally or laterally.

Cavernosography can demonstrate filling defects in portions of the penis located distal to the sigmoid flexure.

Figure 15.23 Failure of the distal portion of the penis to become erect due to occlusion of the cavernous spaces of the corpus cavernosum penis.

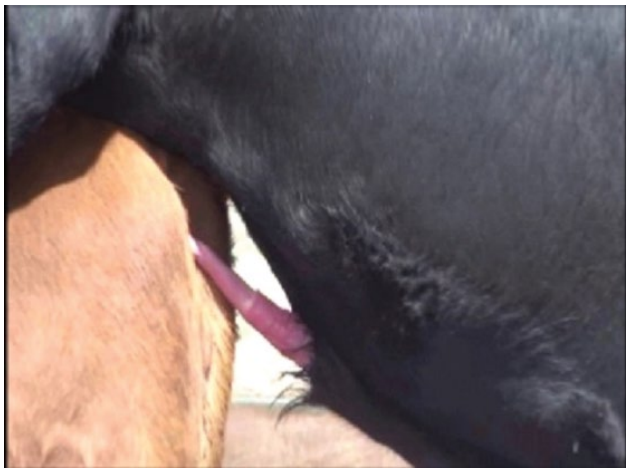

Figure 15.24 Failed attempt at copulation due to denervation injury of the penis. During repeated breeding attempts during test mating, the bull was unsuccessful in locating the vulva with the penis. Note the location of the penis beside the tail head of the cow.

Filling defects may be congenital, secondary to fibrosis following trauma, or subsequent to cavernositis.

Denervation Injury

When mounting an estrus female the bull must position himself to make searching motions and use the penis to locate the vulva in order to make intromission. Sensory innervation to the glans and free portion of the penis is necessary for the bull to align the penis, achieve intromission, and successfully complete the breeding act. Without sufficient sensory innervation of the distal penis the bull is unable to locate the vagina and the coital act cannot be completed [41].

Sensory input from the distal penis is transmitted by branches of the paired dorsal nerves of the penis through the pudendal nerves to reach the spinal cord and brain. Although disruption of any portion of the neurologic pathway could result in loss of sensation, damage to the dorsal nerves of the penis is the most likely etiology of penile desensitization. Denervation injury does not interfere with erection, but affected bulls are unable to breed by natural service and usually cannot be successfully collected with an AV. Semen collection with an electroejaculator for artificial insemination is possible.

An observed test mating utilizing an estrus female in a confined area with adequate footing remains the best method to evaluate function of the dorsal nerves of the penis. Successful intromission and ejaculation definitively demonstrate normal nerve function [17]. In bulls with impairment of sensation to the distal penis, erection is not impaired but the searching motions made with the penis are ineffective and the bull will be unable to achieve intromission and complete the breeding act. Affected bulls often place the penis to the side of the tail head, on the cow's hip, or below the vulva near the udder (Figure 15.24). Observation of typical signs at the time of test mating coupled with a history of reproductive failure is usually sufficient for diagnosis, but definitive electrodiagnostic testing of nerve function [39, 42] is available at some veterinary teaching hospitals (Figure 15.25).

Figure 15.25 Electrodes and stimulator in place for nerve conduction study of dorsal penile nerves. Electrical stimulation applied through the electrode on the free portion of the penis is recorded as the signal passes the proximally placed electrodes.

Management of Lameness in Breeding Bulls

Gary Warner[1] *and Jacob L. Warner*[2]

[1] *Elgin Veterinary Hospital, Elgin, TX, USA*
[2] *College of Veterinary Medicine, Texas A&M University, College Station, TX, USA*

Introduction

The following discussion of lameness issues in cattle is not intended to be a recipe for how to resolve a particular problem associated with lameness. It is a compilation of knowledge gained from 40 years of serving the beef cattle industry. Lameness evaluation is an analytical process, to be taken one step at a time, giving consideration to history, age, breed, sex, environment, intended use, and nutritional state. Conducting a proper examination on the bovine animal is no different from what is done in the equine species, though the examination of cattle takes more time and requires better restraint. Bovine lameness examination requires a pen or alley with a hard surface and a tilt table or tilt squeeze chute. Proper restraint reduces the chance of injury for both the patient and the examiner. In practices that do not have proper facilities or methods of restraint, often the diagnosis of lameness comes down to a good guess (Figure 16.1).

Most of the literature available is derived from treatment of dairy cow lameness; very little has been reported dealing with beef cattle. By the end of the chapter, the reader should have a better appreciation of lameness conditions in beef cattle and their expected response to treatment.

Bovine lameness examinations must begin with a good history that considers duration of lameness, observation of irregularities, and the production parameters involved. During visual examination, the whole body and every limb must be evaluated before focusing on the affected limb. For instance, while examining an animal for a suspected subsolar abscess in a back hoof, do not miss the laceration on the pastern of the supporting limb and subsequent swelling indicating a septic flexor tendon sheath. Watching the animal in motion may help in ruling out proximal versus distal limb problems. Observing the entire animal is important as sometimes other limbs may be affected by the primary lameness or may contribute further to it (Figure 16.2).

Getting Back to Basics in a Lameness Examination

Unfortunately, economics dictate what practitioners are able to offer the client and the patient. Additionally, some clinical options available to other species are just not practical in bovine practice. If the problem is not obvious after visual examination, the next step is to properly restrain the patient on a hydraulic tilt table or tilt chute. Casting the animal is another option, but it is difficult without an abundance of labor and may not allow for an accurate examination. It is possible to cause harm or even create a new injury by tying a leg in a squeeze chute with the good intention to examine a lesion more closely. Since approximately 70% of bovine lameness is in the hoof, hoof testing while the patient is in lateral recumbency is an important part of the examination. If hoof testing reveals a painful area, explore the area by paring the hoof and examine any cracks, crevices, or wall separations. Often aggressive trimming of the sole will provide evidence of a puncture, laceration, or developing crack that can lead to an abscess. If no pain is elicited on hoof testing and no direct visual abnormalities are noted, attention should be directed further up the limb. Each joint should be palpated and individually flexed and extended, including the shoulder or hip. Most often, lameness caused by a joint in the lower limb can be identified by flexion or extension of the joint, eliciting a painful withdrawal of the limb by the animal. The flexor and extensor tendons must be evaluated for evidence of sepsis or rupture. If the examination at this

point has still not revealed the cause for the lameness, the animal may have to undergo local anesthetic nerve or tissue infiltration in order to isolate the painful area.

Facilities for Performing the Lameness Examination

Diagnosis of lameness in the field is not ideal, and the practitioner must consider possible risks to themselves, the client or caretaker, and the animal. Having a proper facility to diagnose and provide treatment to lame individuals makes the opportunity much more appealing. Let us consider what would be the ideal setting for evaluation of bovine lameness.

The most desirable area to evaluate a bovine animal in motion is on a hard-surfaced alley, free of rocks or other irregular debris, with access on either end to stimulate the animal to travel back and forth (Figure 16.3). Additionally, an alley or chute leading to a tilt table or a tilt chute allows the practitioner to get a closer look at all limbs, hooves, and back while preparing to place the animal in lateral recumbency (Figure 16.4).

A hydraulic tilt table is preferred as it allows full access to the upper part of the limbs and allows the animal to be positioned in either left or right recumbency (Figures 16.5 and 16.6). Most hydraulic tilt chutes only allow the animal to be placed in a single position. Animal restraint on a tilt table is also easier due to the application of belly bands for support and leg ropes used to restrain limbs on the table. Leg ropes should also be used with a tilt chute, especially the down forelimb (Figure 16.7).

Placement of the animal on a tilt table is an orchestrated team effort, usually requiring at least two people. There is inherent risk in releasing the restraints at the end of the examination or procedure. Any bovid that is expected to be in lateral recumbency for longer than 15 minutes should be fasted for at least 24 hours before the procedure to reduce possible development of rumen tympany. Also, during lateral recumbency, the animal should be continually observed for any evidence of regurgitation, especially if sedation is used. If regurgitation occurs, the animal should be immediately returned to an upright position (Figure 16.8).

Local/Regional Anesthesia

The use of local anesthetics is helpful in isolating pain in the lameness examination, but proper restraint in lateral

Figure 16.4 Crowd alley leading to hydraulic table that enables practitioner to fully evaluate lameness up close.

recumbency is required for administration. The application of anesthetics should only be done after local examination of the affected area and any other diagnostics (including hoof testing, radiography, and ultrasound) have been performed. Lidocaine is used because of its rapid onset of action (3–5 minutes) and short duration (20–30 minutes) (Figure 16.9).

Most often the first anesthetic administered will be a vascular perfusion of all structures distal to and including the

fetlock. For regional limb perfusion, place a tourniquet (using IV tubing or bicycle inner tube) proximal to the fetlock. In a limb free of edema, wrap tightly enough to identify the dorsal digital vein and administer 15–25 ml of lidocaine. Maintain the tourniquet for 10 minutes before releasing the animal to observe for lameness. If no improvement in gait occurs, the animal is restrained again. Regional whole limb perfusion or a four-point block may be used to isolate lameness below the elbow or stifle. To perfuse the whole limb, 30 ml of lidocaine in 50 ml of saline is administered with a tourniquet above the carpus or tarsus. This can be performed standing in a squeeze chute. The practitioner may also consider the use of intra-articular anesthesia for individual joints; 10 ml of lidocaine is sufficient for each joint except the stifle, which usually requires a larger volume.

In beef cattle with forelimb lameness, if the cause does not appear to be in the hoof, it is often in the shoulder. This is suspected to be due to inadvertent abduction during mounting or due to falls and displacement of the limb laterally. Rear limbs can be difficult to evaluate and require more patience and effort to examine. The coxofemoral joint must not be overlooked as a cause of lameness in the rear limb. These too can be injected with anesthetics to rule in or out lameness.

Back Injuries

The back is often forgotten as a cause or contributor to lameness, particularly in the bull. Close evaluation may lead to subtle findings such as a shuffling of the rear limbs or muscle atrophy of the lumbar muscles. Pelvic injuries can happen in both sexes of cattle, and sacroiliac injuries supporting ligamentous injuries and fractures to the ilium and ischium are possible [1]. Diagnostic anesthesia in the lower back is rarely effective due to the involvement of multiple structures in most back injuries. Acupuncture and chiropractic examinations may be of value in isolating the problem. Since most radiographic equipment available in practice cannot penetrate the body mass of most mature cattle, radiographs of the spine are of little value. Sometimes, all we can do is make an educated guess and come up with a conservative therapeutic plan.

Advanced Diagnostics

Many practices now have digital radiography and digitally enhanced imaging to allow the practitioner the opportunity to clearly identify problems that could only be guessed at a few years ago. It can be a bit challenging to position the animal to get a good image of some areas, but with experience and sometimes sedation of the patient, a good study can be performed.

Ultrasound is used to evaluate soft tissue injury of ligaments, menisci, and tendon sheaths. Proper technique and an experienced skill set are necessary to fully appreciate

abnormalities associated with lameness. An inexperienced operator or one with less than optimal knowledge of bovine anatomy may lead to misdiagnosis of some conditions.

Arthrocentesis is another valuable diagnostic tool for evaluation of lameness directly associated with a joint. Color, viscosity, protein content, and cellularity are used to diagnose the health of the joint and can offer a reasonable prognosis. This procedure can be performed in most practices with laboratory access. Evaluation of cell types and protein level found within the synovial fluid is most important. Cellularity should be less than 1000 cells/μl, and protein should be less than 2.5 g/dl in the normal joint.

Laminitis

Seventy percent of the lameness cases observed in beef cattle practice are associated with the hoof. Fifty percent of these cases are diagnosed with chronic laminitis, the vast majority of which are the chronic subclinical form. Acute laminitis is caused by an acute metabolic or systemic illness and is characterized by reluctance to stand, arched back, and the appearance of walking as if they were on a very hot surface (Figure 16.10).

There are no outward lesions expressed or seen on the soles of the hoof, although inflammation may be observed in the coronary band and a digital pulse may be present. Subacute laminitis doesn't usually express itself until several weeks after the insult, and the symptoms observed are sole hemorrhage and discoloration of the white line and sole tissue.

Subclinical laminitis is due to periodic upsets in normal body function. A few scenarios that can predispose to chronic laminitis include:

- Mismanagement of the young growing calf
- Bulls on gain test
- Cattle being prepped for sale
- Cattle breeds involved with progressive genetic improvement
- Cattle being fitted for show
- Dairy cows being fed for maximum milk production

The general appearance of a hoof with subclinical laminitis is one that flares out at the wall with a flattened sole. Closer examination reveals white line separation with abscessation, vertical and horizontal wall fissures, heel erosion, and subsolar ulcers [2]. Horizontal lines (known as hardship lines) may be observed in a portion or the entire hoof wall. Over time, more than one hoof can be affected. Since hoof overgrowth is the number one initiator of lameness, cattle with chronic laminitis should have regular hoof trimming to maintain proper hoof health [3]. The vascular damage that occurs during episodes of subclinical laminitis can lead to a cascade of hoof problems, discussed in the following sections [4] (Figures 16.11 and 16.12).

Treatment of Solar Injuries

Many predisposing factors have been mentioned that lead to laminitis and play a part in subsolar injuries. The metabolic effects of subclinical acidosis and laminitis can affect normal hoof growth and lead to white line separation, toe ulcers, heel erosion or ulceration, and sole ulceration. Puncture wounds and traumatic concussive injury are other contributing factors to subsolar abscess formation. Without proper treatment, these conditions may lead to damage of deeper structures including pedal osteitis, infection of the navicular bursa, sepsis of the distal interphalangeal (DIP) joint, and septic tenosynovitis of the digital flexor tendon sheath.

Figure 16.10 Acute laminitis in a Hereford bull on self-feeder.

Figure 16.11 Severe white line disease and hoof crack as a result of chronic subclinical laminitis.

Figure 16.12 Subclinical laminitis with hardship lines present as horizontal grooves in hoof wall.

Figure 16.13 Vertical fissure in hoof wall due to subclinical laminitis.

Treatment of complicated subsolar abscesses and white line disease involves complete and total curettage of the overlying sole or hoof wall and removing all necrotic debris from the affected area. Exploration of all tracts is necessary to evaluate if deeper structures are involved. If sepsis of the pedal bone or coffin joint is suspected, radiographs should be performed at this time. Parenteral antibiotics and bandaging with astringent antiseptic compounds should be incorporated into a treatment plan when possible. While some practitioners elect to leave sole abscess lesions exposed, it is my opinion that these wounds heal better in beef cattle when protected. The application of a hoof block to the supporting claw prevents the affected claw from bearing weight and allows quicker healing due to the lack of contact with sole surface.

Vertical Hoof Cracks

The prevalence of hoof cracks appears to be increasing, most likely related to genetics and intensive management. Subclinical laminitis has been suspected as an underlying cause in many of these cases. These cracks can affect one or multiple claws (Figure 16.13).

Lameness is caused by instability in the hoof wall as weight is shifted to the wall. Debris and soil may be packed into the crack, inducing abscessation with encroachment on the sensitive lamina. Remove all debris through careful curettage. If any debris is left before immobilization, it can lead to sepsis of the laminae. If debridement of the crack results in penetration of the laminae, antibiotic bandages should be applied until the wound completely heals and the crack is dry and hard.

To stabilize a hoof crack, drill horizontally across the crack and place stainless-steel wire across the defect in a bootlace pattern. Application of an acrylic compound into the crack and around the wire will bond the hoof. Alternatively, the crack can be filled with fiberglass cloth and acrylic compound that bonds to the hoof wall. This will bridge the crack and stabilize it, allowing new normal hoof wall to be produced at the coronary band. Newer products are now available that come with an applicator that allows direct application to the affected area without the need for any other material to support the repair.

If there is radiographic evidence of abscessation or osteomyelitis, open and debride the area to allow for healing. Curettage of the coffin bone and removal of bony fragments may have to be performed. To alleviate pain during

movement, apply a hoof block to the healthy claw or consider using a splint. Systemic antibiotics are always indicated in situations involving deep sepsis of the hoof, and localized vascular perfusion can aid in increasing antibiotic concentrations within the area. Potassium penicillin, ampicillin, and tulathromycin are commonly used for vascular perfusion. Common side effects of tulathromycin include vasculitis and localized tissue edema. Medicated bandages, analgesics, and support bandaging of the contralateral limb should also be considered.

Septic Arthritis of the Distal Interphalangeal Joint

Septic arthritis of the DIP joint is a common sequela to chronic infectious processes involving the hoof and/or interdigital space. Examination findings include a swollen coronary band with a draining tract occurring at the dorsal aspect of the extensor process, diffuse swelling of the pastern area, and partial or complete non-weight-bearing lameness. Radiographs will reveal osteomyelitis of the coffin joint and increased joint space, with osteolysis of the second and third phalanx (Figure 16.14).

To block the hoof and provide postsurgical analgesia, perform regional limb perfusion using a long-acting local anesthetic, such as mepivacaine or bupivacaine. The following surgical approach to the DIP joint is preferred over the abaxial approach because it allows better exposure of the joint [5]. Closely trim the sole and heel area and disinfect with surgical scrub and alcohol. A full-thickness incision is made through the heel and continuing through the deep flexor tendon to expose the intra-articular area between the navicular bone and the proximal extent of the caudal portion of the coffin bone. It is recommended that the navicular bone be removed. A half-inch drill is used to facilitate curettage of the joint surface, drilling from the heel incision toward the extensor process and following the surface of the joint [6]. Further debridement of the joint is necessary using a large bone curette. Curettage is complete when you can't remove any more necrotic bone. Use a squeeze bulb to lavage the surgical site with a broad-spectrum antibiotic or antiseptic saline solution. Place a wooden block on the healthy claw, pack the joint with medical-grade honey, and bandage the hoof [7] (Figure 16.15).

Parenteral antibiotics are administered daily, and bandage changes and joint lavage are performed every other day up to four times. Beads of bone cement mixed with an antibiotic can be placed in the joint space to facilitate healing, but they should not be placed until there is a healthy granulation bed and no more purulent discharge. When the surgical wound has closed with granulation tissue, the limb is casted above the fetlock for five to six weeks. After the cast and hoof block are removed, the animal should have a recuperative period. The patient should show at least 80% improvement in lameness over the initial presentation after the convalescent period; some lameness is to be expected.

Figure 16.14 Sepsis of the DIP joint with sequestrum formation.

Figure 16.15 Dressing change post DIP joint currretage. Notice the gauze packing ingress at location of the extensor process of the third phalanx and eggress at the heel bulb.

Corkscrew Claw

Corkscrew claw (CSC) is observed in the young adult beef animal and usually involves the lateral claw of both hindlimbs. In some breeds, such as Brahman and Brahman crosses, it can occur on the medial claw of both forelimbs. Because CSC can be seen in calves and yearlings, some practitioners believe that this is a heritable condition. However, it appears that this is a management-induced problem, in our opinion, even in younger animals. Offering overabundant feed can lead to rapid skeletal growth and subsequent epiphysitis and rotational limb deformity. This results in abnormal load bearing and compensatory changes in the hoof. Therefore rapidly growing animals may express CSC. To prevent structural changes to the phalanges secondary to CSC, corrective hoof trimming must occur during the active growth phase. In the fully grown adult, CSC cannot be cured, only managed [8] (Figure 16.16).

It is unknown whether bone remodeling in the distal phalanx is the cause or effect of CSC. In some patients with CSC, the second and third phalanges become misaligned and the third phalanx becomes narrower with an abaxial curvature. This leads to abnormal load bearing, which affects the white line and leads to separation. In other patients with CSC, the growth rate of the middle to caudal portion of the wall is faster than the fore portion of the toe, which causes the animal to bear weight on the abaxial wall, predisposing to bruising, abscessation, and sole ulcers.

Figure 16.16 Corkscrew claw on the lateral claw of a Brahman bull.

Correction of CSC involves balancing the weight-bearing surface of both claws. It is best to trim excess from the medial claw just until the white line is apparent. Next shorten the affected claw to the same length as the normal claw. Remove the upward deviation and rotation of the wall with a grinder or nippers. The heel is often higher in the CSC and it should not be lowered. Bevel the sole to encourage wall contact with the sole surface. At this point, there may not be very much area for bearing weight, but it will encourage more favorable wear for the hoof wall. Corrective hoof trimming should occur every four to six months.

Interdigital Dermatitis, Digital Dermatitis, and Interdigital Pododermatitis

The hoof problems of interdigital dermatitis, digital dermatitis, and interdigital pododermatitis are often lumped together, but each condition has its own etiology, tissue involvement, and disease progression. Interdigital and digital dermatitis are often not serious problems unless left to become chronic. Interdigital pododermatitis can progress rapidly and cause serious economic loss if left untreated.

Interdigital dermatitis is a localized inflammatory process involving the interdigital space. In the early stages, the skin has a greasy appearance and some erosion can occur, particularly in the heel bulb area. Digital dermatitis (hairy heel wart) is another low-grade inflammatory process with pronounced change when allowed to become chronic. The epidermal layer becomes overproductive, at first producing excessive hair growth that stands out from the skin, and progressing to small papillary projections giving the appearance of wart-like growths. As the condition becomes chronic, the dermis can become very proliferative [9], making for an unsightly lesion. These conditions respond well to treatment via footbath. Care should be taken in the choices of medications recommended in footbath treatments as some products may cause environmental contamination with improper disposal [10]. A copper sulfate solution is considered environmentally safe. In chronic lesions that are extremely proliferative, surgical resection and topical treatment may have to be provided before resolution can occur.

Interdigital pododermatitis, commonly called foot rot, can be an acute, aggressive infection that progresses to deeper structures quickly. While systemic antibiotics are rarely indicated in the treatment of digital or interdigital

dermatitis, they should always be administered in patients with foot rot. Bandaging with a broad-spectrum antiseptic or antibiotic is recommended when treating each of these three conditions.

Interdigital Fibroma

Interdigital fibroma is a condition most often observed in heavier weight beef breeds, particularly older bulls with widely placed claws. Occasionally, cows will develop fibromas as well. If the condition is allowed to persist, the "corn" can become ulcerated and infected due to continued contact with the ground (Figures 16.17, 16.18 and 16.19).

Surgical removal is necessary to resolve the fibroma. Anesthesia of the interdigital area can be provided by four-point block or the use of a tourniquet and intravascular anesthesia. Removal of the prolapsed tissue is accomplished by sharp dissection followed by extraction of the fat pad. Cautery of the vascular bed is sometimes required to control excessive hemorrhage. A bandage is applied with a sterile gauze pack and changed after three days. As an aid to healing, especially in the individual with splayed toes, it is helpful to wire the toes together to reduce swelling and decrease granulation bed formation. The second bandage can be removed in 4 days, with complete healing expected within 10 days of surgery.

Figure 16.17 Digital dermatitis (hairy heel wart).

Figure 16.18 Interdigital fibroma can be misleading; this one does not appear to be significant until observed from the solar surface.

Distal Limb

Lameness involving the distal limb usually has a traumatic origin. Most often, acute and severe lameness can be attributed to a severe concussive force, entanglement or entrapment of the lower limb within a fence or handling device, or foreign body penetration of the skin with invasion of deeper structures. Young cattle are predisposed to joint sepsis due to hematogenous spread of bacteria from the umbilicus, digestive tract, or lungs in times of general immune compromise [11].

Joint sepsis often presents as severe lameness of several days' duration. Many cases will not respond to broad-spectrum antibiotics administered by the owner. The animal will have an elevated heart rate and usually an elevated rectal temperature. Thorough examination should be performed under appropriate restraint, preferably on a hydraulic tilt table. Radiographs should be performed to detect any concurrent fractures. Both systemic and local antibiotics via vascular perfusion should be administered. In severe cases, joint lavage must be considered. In these cases, it may be difficult to lavage the joint space due to fibrin accumulation within the joint. Fibrin deposition seems to increase with subsequent flushes, and in those cases that are slow to respond to treatment, arthrotomy or arthroscopic surgery may be the only option to remove the fibrin deposits from the joint. Surgical drain placement is not advised due to the risk of contamination even with proper bandaging. In cases where there are financial constraints and osteomyelitis is already present, aggressive curettage of the area may be the only alternative. Active lavage can be incorporated with sterile bandaging to provide continued protection, although compression bandaging may suppress desired drainage [12]. When there is marked reduction in exudate coming from surgical wounds, polymethyl methacrylate (PMMA) beads impregnated with an appropriate antibiotic might be considered for placement in the remaining joint space. When the beads are used, the goal is joint ankylosis, which cattle seem to take well. When wounds no longer need attention,

it is best to immobilize the limb in a cast, with consideration to using transfixation pins. Cattle tolerate the process well as long as a support bandage protects the contralateral limb. Due to the expense of these procedures, clients may only elect to have these procedures done for cattle with high economic or emotional value.

Sequestra should be surgically removed. Most often, these occur on the lateral aspect of the metatarsus and are directly related to trauma from kicking a hard object like a gate or post or entrapment of the limb within a confined space (Figure 16.20). On presentation, most cattle with a sequestrum will have an associated draining tract. Surgical removal can be performed under vascular anesthesia and sedation while the animal is restrained in lateral recumbency unless there is extensive bony proliferation that should also be removed, in which case general anesthesia should be considered. A surgical drain should always be incorporated in the closure, as there is virtually no way to close the entire dead space after removal of the sequestrum. The drain should be removed four to five days after surgery and recovery may take up to two weeks.

Sepsis of the superficial and/or deep digital flexor tendon is usually due to traumatic injury (laceration of the caudal pastern or heel bulb area) or due to extension of deep infection from a chronic hoof rot lesion. Parenteral antibiotics alone will not resolve this problem; surgical drainage is performed and a drain placed from the pastern, through the tendon sheath and above the dewclaw. Extensive and chronic sepsis may require complete resection of the superficial and deep flexor tendons, after which partial closure with packing and drain placement is a must. Active or passive lavage may be provided, with several bandage changes required to resolve the issue. The drain should be removed in five to seven days. Apply a hoof block to the non-affected claw and cast the limb to the carpus or tarsus to alleviate pain and allow better ambulation. After four weeks the cast may be removed. Some deep digital flexor tendons may spontaneously rupture after treatment, which will cause the patient to walk on the heel bulb.

Figure 16.19 Sole view of interdigital fibroma. Notice the ulceration that has occurred due to contact with the ground.

Figure 16.20 Sequestrum formation of the lateral cortex of MTIII in a yearling.

Proximal Limb

Lameness involving the femorotibial joint usually involves a traumatic episode such as a bullfight, breeding injury, or restraint accident. Suspected stifle injuries should be addressed immediately, and treatment should be aimed at decreasing inflammation and reducing the development of degenerative joint disease. Diagnostics often include observation of ambulation and weight bearing, amount of joint effusion present, joint laxity and the direction of laxity, radiographs, and ultrasound (which may not be possible in larger individuals) [13]. Arthrocentesis is used to rule out sepsis, and total cell count should be less than 2500 WBC/μl and protein less than 4.5 g/dl. Ideally, positive pressure joint lavage should be performed with a sterile isotonic fluid solution containing antibiotics and anti-inflammatories [14]. Follow-up therapies may include repeated lavage and regenerative medicine modalities such as plasma-rich protein or stem cell therapy. Strict stall confinement is necessary for healing. Some injuries take up to six months to heal, and severe cranial cruciate or collateral ligament tears may require strict immobilization with a Thomas

splint. These cases should be treated with long-term non-steroidal anti-inflammatory drugs (NSAIDs). Of course, such injuries carry a very guarded prognosis when considering pasture soundness and return to breeding. If only the medial meniscus is involved, arthroscopic surgery may be of benefit in valuable individuals [15].

Lameness associated with the shoulder or elbow joint is often caused by trauma and can have a significant impact on ambulation. Non-weight-bearing lameness usually equates to serious injury such as a fractured scapula or fracture of the olecranon. A lesser degree of lameness may be observed with subchondral cysts or ligamentous injuries to supportive structures. Intra-articular anesthetics may temporarily improve lameness but rarely resolve all of the pain during examination. Treatment of these joints is usually relegated to the use of intra-articular injections unless surgical repair is financially feasible, for example compression plating of a fractured olecranon.

The carpus is probably the least affected large joint in beef cattle. Most lameness associated with this joint occurs in bucking bulls. Degenerative joint disease is observed in older bucking stock due to chronic hyperextension of the carpus when the bull "goes vertical." This condition responds fairly well for a time to intra-articular injections of anti-inflammatories and the administration of NSAIDs.

Upward Fixation of the Patella

Upward fixation of the patella is a fairly easily diagnosed problem in the bovid. Cattle will have a hyperextended hindlimb (extension of tarsus with flexion of fetlock and all distal structure) that appears "locked" and causes the animal to drag the toe while walking. Those that have had the problem for a while will have worn down the toe on the affected limb. Occasionally an animal will exhibit the problem in both limbs, although one limb is often more severe. The condition most often affects females in the last trimester of pregnancy but is also observed in bucking bulls [16] (Figure 16.21).

This condition occurs when the patella is dislocated mediodorsally on the distal femoral trochlea and is treated with a medial patellar desmotomy. It is easier to identify the medial patellar tendon in the standing position. If there is a danger to the surgeon due to temperament, short-acting anesthetics should be used. An appropriate anesthetic would be K-stun (butorphanol, xylazine, ketamine) (Figure 16.22).

The animal is restrained in dorsal recumbency, with the rear limb fully extended and pressure applied to the hoof with forceful downward motion. This will allow for identification of the ligament. For standing procedures, mild

sedation with xylazine and a tail hold should be sufficient for restraint. Infuse a local anesthetic, starting approximately 2 cm medial to the tibial tuberosity and include the area of the medial patellar ligament that will be transected. A rib-back scalpel blade or teat bistory is used to transect the ligament. The ligament should be transected in both legs since it is likely that the other limb will be affected. Relief is immediate and little aftercare is required; cattle can be returned to their normal environment.

Rupture of the Gastrocnemius

In commercial cattle, rupture of the gastrocnemius tendon is induced by aggressive mounting behavior by an oversized herd sire or slipping in an already unhealthy individual. It can also be seen in cows undergoing reproductive procedures. If an epidural goes too high, the motor control to the hindlimbs can be affected. As the cow comes out of the chute, she can get her legs caught in a brisket bar or slip on concrete. The injury most often occurs at the junction of muscle and tendon and is quite obvious in the standing

animal. The hock is markedly flexed and may even drop to the ground; the fetlock is simultaneously flexed. The diagnosis can be confirmed with ultrasonography. The condition is usually unilateral, but if the patient continues to struggle the contralateral tendon can also be damaged. Complete rupture of one or both tendons has a grave prognosis. Partial rupture of one or both tendons has a better prognosis but is rarely observed in cattle since most occur in fractious patients and quickly proceeds to complete rupture. Treatment involves a full limb cast or Thomas/Walker splint. Healing usually involves six weeks of immobilization and four weeks of stall confinement. NSAIDs should be used during recovery (Figure 16.23).

Osteochondrosis Dissecans

Osteochondrosis dissecans (OCD) is a common cause of lameness in cattle, particularly those being fitted for show, fed for sale, or being pushed for performance. It is often management induced in cattle with a genetic predisposition, particularly in club calves. Factors leading to OCD development include:

Figure 16.23 Bilateral partial rupture of the gastrocmenius tendon from its associated muscle.

- Excessive feeding with subsequent excessive weight gain
- Lack of proper mineral supplementation leading to mineral imbalance, complicated by increased mineral requirements due to breed variances
- Feeding of distillate products with high sulfur content
- Lack of opportunity for skeletal maturity.

The most common location for OCD in the hindlimb is in the tarsus and the medial malleolus of the tibia; it develops less commonly on the lateral femoral condyle, the tibial plateau, and the medial and lateral trochlear ridges of the talus. In the forelimb, the primary site is the medial surface of the humeral condyle, though osteochondrosis can appear in any joint [17, 18] (Figures 16.24 and 16.25).

Surgical management of OCD and OCD fragments is preferred to slow down or stop the progression of inflammation and subsequent degeneration occurring within the affected joint. When anatomically possible, the OCD lesion should be debrided by curettage and overdrilling or implantation of a compression screw above the lesion (Figure 16.26).

Medical management of cattle with OCD fragments is generally palliative in nature and often does not resolve the lameness, particularly in the growing animal. NSAIDs, stall rest, and intra-articular injection of long-acting anti-inflammatories are utilized. However, as cattle get heavier and more weight is placed on the affected joint, clinical lameness may become worse.

Bone Fractures

Fractures in the bovine often occur due to inappropriate management, such as mishandling, crowding, or improper handling facilities. The duty of the practitioner is to evaluate the fracture and determine whether economical repair or salvage is most appropriate. Fractures of the rear limbs often occur due to trauma from other cattle; the tibia is the most commonly affected of the long bones when this occurs.

Physical examination and palpation with manual manipulation of the limb can be helpful to assess the extent of the injury. Radiographs are necessary to determine if the fracture is comminuted or involves a joint that may not be readily apparent on physical examination. Attention should also be given to soft tissue injuries that may have damaged the vascular supply. Damage to the dermis may result in sloughing tissue and exposure of the fracture. Crushing injuries of the digital vasculature and metacarpus can happen after forced fetal extraction during dystocia. Consideration should be given to sepsis at the fracture site, particularly in older fractures, as hematogenous spread of bacteria in the bovine can occur.

Cattle with fractures of the distal limb, forelimb, or hindlimb heal extremely well. Even comminuted and compound fractures can resolve if proper immobilization and therapy are provided. The most common method of repair in simple fractures is passive fixation with a cast. A half-limb cast is used for fractures below the carpus or tarsus.

Comminuted or compound fractures of the digits usually require a more rigid immobilization in order to get adequate healing in a reasonable amount of time. Of great value in complete immobilization is the traction/pin cast, which involves incorporation of wires passing through holes drilled in the rear abaxial walls of the hoof. This also serves to allow the assistant to properly position/align the limb for casting. Transfixation or transcortical pins are usually placed at some point in the lower to mid-third of metacarpal (MCIII) or metatarsal III (MTIII) to provide for weight transfer to the cast. Predrilling of a slightly smaller hole (0.5 m or less than the pin diameter) will reduce thermal injury to the bone during pin placement. Oftentimes, only one pin is needed to properly provide for weight transfer in younger animals. Threaded transcortical pin systems are preferred in older, heavier cattle, usually requiring placement of two pins at least 1.5 inches apart from each other. During casting, the pins are incorporated into the cast, with the pin ends cut even with the cast and protected by an acrylic compound placed over them, as well as acrylic applied to the bottom of

the cast to protect it. The wires placed in the hoof wall are incorporated into the wall of the cast under tension before completion of the procedure. Most of these casts can be removed at four to six weeks post casting.

Full Limb Casting

When dealing with fractures below the carpus/tarsus, it is always best served to apply a full limb cast. Single or multiple transcortical pins can be of value when incorporated with the cast as a complete fixation. This system provides complete immobilization and can even allow for "windows" to be placed in the casting to allow for local wound treatment in compound fractures. Single cortical fixators may be made with polyvinyl tubing. The one drawback to a large window in a cast is the local tissue edema that can occur at the site of tissue exposure at the opening. This can be controlled somewhat with pressure dressing at the wound site. The more complicated the fracture, the longer the cast may be required to stay in place. Be aware that young animals incurring extended time with a cast on are more predisposed to developing joint stiffness post removal. Fractured limbs that present with a large amount of edema should have the cast replaced 2–3 weeks after initial casting, at this time evaluating bone configuration and examining for any loose pins that may need to be replaced. Be aware if the animal's performance has been good in using the limb; if it becomes reluctant to use the casted limb there may be a problem with the transcortical device (pin fracture or osteomyelitis or both), which is commonly seen in the fourth to fifth week after application. If this is observed, removal of the pin should occur with lavage of the pin site after removal and possibly a course of antibiotics administered. This problem can specifically occur when too much heat is generated as the transcortical device is inserted in the bone. Occasionally a sequestrum may form within one or both cortices at the pin site, requiring aggressive curettage and lavage of the area. These areas will heal quickly. Once again, young animals heal rapidly and four weeks may be ample time for cast placement, yearlings usually require six weeks, and grown cattle require eight weeks of immobilization before cast removal.

Fractures of MCIII and MTIII respond very well to the use of transfixation pinning and casting or external skeleton fixation. In valuable individuals where cosmetic appearance is important, transfixation pinning/external skeletal fixation provides more complete immobilization and improved fracture healing, along with better overall alignment of the fracture fragments.

Special approaches are needed for fractures of the tibia and radius/ulna because external immobilization is difficult. Internal fixation with dynamic compression plates and screws should be considered in the extremely valuable individual, although clinical outcomes have not been very rewarding due to implant failure and postoperative sepsis. Success is more often seen with several different external coadaptations, along with skeletal fixators. In animals of lower genetic and economic value, the modified Thomas splint and a cast can be used to immobilize the limb. This system works well for fractures at the mid-shaft or the lower one-third of the affected bone and can be adapted as needed to allow for treatment of open wounds associated with the fractures. External skeletal fixation should be considered in the fractious individual since they seem prone to continually casting themselves on the splinted side, and therefore unable to rise on their own. This form of repair is especially desired when dealing with rough stock [19].

The Walker splint is another versatile splint device used for immobilization of the entire limb and is particularly valuable in tibial or radial fractures involving the proximal one-third of the bone. It is nearly always combined with casting of the distal limb. The design of the support structure as it relates to the groin area helps to protect the proximal limb from damage caused by abduction. It provides lateral support by cradling the gluteal muscles and keeping the stifle and upper limb more upright as opposed to being abducted. It is amazing how well calm cattle will handle these devices and heal the long bone fractures without additional coadaptation (Figures 16.27–16.29).

Fractures of the Proximal Limb

Fractures of the humerus usually occur after a fall or during a traumatic episode such as a bullfight or breeding injury. These fractures are best treated with stall rest,

Figure 16.27 Excellent treatment for transport of a comminuted fracture of MCIII. Notice a rebar stirrup support for the Robert Jones applied bandage. Stabilized fracture for an 800-mile ride.

Figure 16.28 Use of a pin cast and external fixators to stabilize a comminuted fracture of the Hereford heifer.

Figure 16.29 Thomas splint/cast and external fixators to immobilize severely comminuted fractures in a mature Longhorn steer.

supportive bandaging of the weight-bearing limb, and NSAIDs. Concurrent damage to the radial nerve can occur with fractures of the humerus, and supportive care with acupuncture and electrical stimulation has proven helpful. If tendon contracture of the affected limb starts to occur, the limb should be bandaged and splinted (Figure 16.30).

Figure 16.30 Fractured humerus with mild radial nerve involvement in a mature cow. Splintage of the lower leg was required to reduce deep digital flexor (DDF) contracture.

Surgical repair of femoral fractures using dynamic compression plates is not often successful in adults because of the difficulty in attaining alignment and compression with fixation screws, and only marginally successful in neonates. Salter-Harris fractures of the distal femur may be seen in calves delivered by forced extraction during dystocia. If attempted in the calf, it must receive appropriate colostrum supplementation and its health status should be thoroughly evaluated. Use of dynamic compression plates is difficult in neonates because the cortices of the femur are not strong enough to offer good purchase for the fixation screws. Stacked intramedullary pins or locking nail devices may be a better choice for the repair of the neonatal bovine [20].

Fracture Recovery

Immobilization times vary due to fracture configuration, age, and disposition of the animal. Young calves may heal a fracture within 3 weeks, whereas adult cattle with comminuted tibial fractures may require 10 weeks to heal. Radiographic evidence of fracture healing may not be

evident at the time of splint removal. A guideline to follow is to remove the splint if the limb feels stable and there is evidence some callus is being formed radiographically. Some form of continued splintage of the limb may be considered to lend support as active mineralization takes place. Weight transfer to the limb seems to increase mineralization of the callus, and within two weeks of removal, radiographic mineralization will be readily apparent. Activity after removal should be restricted for four to six weeks. Further time may be needed to completely rehabilitate the leg.

Hoof Trimming for Beef Cattle

Hoof trimming services are a great practice builder. Much of the literature available discusses hoof trimming in dairy cows, but the same basic principles can be applied to beef cattle as well. The Dutch five-step hoof trimming method is a good protocol to follow; however, any method of hoof trimming will certainly do as long as the animal has an even weight-bearing surface with proper hoof angles to ensure balance and symmetry of the hooves.

Most beef cattle presented for hoof trimming have grossly overgrown hooves, often due to issues with subclinical acidosis and multiple events of subclinical laminitis during their development. After restraint of the individual, either in a hoof-trimming chute or on a tilt table, the animal's hooves should be cleared of any excess organic debris. Evaluate the length and angulation of the hoof and identify the amount of wall and sole to be removed (Figure 16.31).

This process is almost automatic for the seasoned trimmer; less experienced practitioners should take their time and assess all four hooves before beginning the process.

Figure 16.31 Trimming the overgrown claw resulting from chronic subclinical laminitis.

Starting with the front hooves, use hoof nippers on the lateral claw to shorten the toe to 3.25–3.5 inches (Figure 16.32).

Proceed to trim the sole, leaving approximately 0.25 inches of sole; when the white line is apparent, you have removed enough sole. As sole is removed, make sure that the remaining sole surface is level and even, front to back. Next, the medial claw is shortened, and the solar surface is trimmed

Figure 16.32 First step in trimming of the hoof is shortening the claw to an acceptable length.

Figure 16.33 Completed trimming of a grossly overgrown hoof.

to match the lateral claw. When complete, both toes should be evaluated with a flat surface (a small board works well) to ensure that both hooves are level [21] (Figure 16.33).

Lastly, the sole should be modeled, scooping the axial portion of the claw to create a dish-like effect on the sole, which reduces the opportunity for mud or manure to build up between the toes and gives a more natural appearance to the hoof. After the claws have been properly shaped, address any solar defects and questionable wall areas.

Once the front hooves have been taken care of, the rear claws can be assessed and approached in reverse order, starting with the medial claw. Completion of the procedure should be followed by overall visualization of all four hooves, paying particular attention to the interdigital space. If any evidence of disease is observed in this region, it should be addressed before removing the animal from restraints. The animal should also be examined as it leaves the trimming area to ensure no lameness has developed.

Summary

Lameness evaluation and treatment can be a very rewarding portion of beef cattle practice. Economics sometimes play a role in what services can be provided, and the majority of patients may be limited to the economically valuable herd sires. At the end of the day, we have the opportunity to advance diagnostics and provide treatment options that will fit any scale of production, we just have to get past the mindset that it is "just a cow."

Regional Anesthesia for Urogenital Procedures

Darcie R. Sidelinger

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

When performing urogenital surgery in cattle, local and regional anesthesia are routinely utilized. They are a safe and effective alternative to general anesthesia in the large animal patient. Some benefits to using local and regional anesthesia include the need for minimal supplies to administer the necessary medications (anesthetic of choice, needles, and syringes), decreased risk of toxic effects, and minimizing bloat, regurgitation, and temporary or permanent nerve or muscle damage associated with positioning animals in recumbency. Many of the urogenital surgeries can be performed safely, rapidly, and humanely using physical restraint, sedation, and local or regional anesthesia. These techniques are easy to perform, the drug cost is minimal, and the effects are temporary and fairly well localized to the site of administration. This eliminates the widespread effects of general anesthesia on the entire body. The most common techniques used in bovine reproduction include infiltration anesthesia, nerve block anesthesia, and epidural anesthesia (Table 17.1).

Local Anesthetics

Many local or regional anesthetic drugs are available that can produce reversible loss of autonomic, motor, and sensory function with acceptable onset times and predictable duration [1]. These drugs vary in their potency, toxicity, and cost [2]. Lidocaine hydrochloride 2% and mepivacaine hydrochloride 2% have become two of the most widely used local anesthetic agents in cattle due to limited toxicity and low cost. Lidocaine hydrochloride has a duration of 90–180 minutes, is three times more potent than procaine, and diffuses into tissues more widely [1, 3]. Mepivacaine has a duration of 120–180 minutes, which is longer than lidocaine; however, the time to onset of anesthesia is similar. Although, bupivacaine has an even longer duration of action (up to 360 minutes), it is not recommended for routine use in cattle due to risk of inadvertent intravenous administration which could lead to toxic effects [4].

The addition of a vasoconstrictor such as epinephrine (5 μg/ml) to the local anesthetic solution (0.1 ml epinephrine 1 in 1000 added to 20 ml of local anesthetic) increases the potency and duration of activity of both regional and epidural anesthesia. However, local anesthetics containing epinephrine 1 in 200 000 should not be used in wound edges or in the subarachnoid space due to the risk of causing tissue necrosis and spinal cord ischemia [1].

Anesthesia for Laparotomy

Anesthesia of the paralumbar fossa and abdominal wall can be achieved by several techniques, including infusion of the incision or line block, the inverted L block, the proximal paravertebral nerve block, and the distal paravertebral nerve block. These anesthetic techniques are commonly used for reproductive procedures such as cesarean section, ovariectomy, and cervicopexy.

Line Block

Infusion of local anesthetic into the incision site or a line block may be used to desensitize a selected area of the paralumbar fossa. An 18-gauge, 3.8-cm needle is used to infuse multiple injections of 10 ml of local anesthetic solution subcutaneously and into the deep muscle layers and peritoneum. Pain of successive injections may be alleviated by placing the edge of the needle into the edge of the previously desensitized area at an angle of approximately 20–30° [2]. In heavily muscled or overweight cattle, it may be necessary to

Table 17.1 Common nerve blocks with landmarks and volume of lidocaine for reference.

Nerve block	Landmark(s)	Volume of lidocaine
Proximal paravertebral	T13, L1, L2	6–8 ml ventral and dorsal to the transverse processes
Distal paravertebral	L1, L2, L4	10 ml dorsal and ventral to the transverse processes
Caudal epidural	S5–Co1, Co1–Co2	0.5 ml /45 kg
High-volume caudal epidural	S5–Co1, Co1–Co2	1 ml/5 kg
Sacral paravertebral	S3, S4, S5	2–3 ml per foramina
Internal pudendal	Lesser sacrosciatic foramen	20–75 ml per side
Castration	Skin and testicle	5–10 ml subcutaneous; 10–15 ml/200 kg into testicle

use an 18-gauge, 7.5-cm needle to penetrate through the large amount of subcutaneous fat to reach the deep muscle layers. The amount of local anesthetic needed to acquire adequate anesthesia depends on the size of the area to be desensitized. Adult cattle weighing 450 kg can safely tolerate 250 ml of a 2% lidocaine hydrochloride solution [2]. Delayed healing of the incision site is a possible complication of infiltration of local anesthetic at the surgical site.

Inverted L

The inverted L block is a non-specific regional block that locally blocks the tissue bordering the caudal aspect of the thirteenth rib and the ventral aspect of the transverse processes of the lumbar vertebrae [5]. An 18-gauge, 3.8-cm needle is used to inject up to a total of 100 ml of local anesthetic solution in multiple small injection sites into the tissues bordering the dorsocaudal aspect of the thirteenth rib and ventrolateral aspect of the transverse processes of the lumbar vertebrae (Figure 17.1). This creates an area of anesthesia under the inverted L block. Advantages of the inverted L block are that it is simple to perform, it does not interfere with ambulation, and deposition of anesthetic away from the incision site minimizes incisional edema and hematoma [1]. Disadvantages include incomplete analgesia and muscle relaxation of the deeper layers of the abdominal wall (particularly in obese animals), possible toxicity after larger doses of anesthetic, and increased cost because of larger doses of local anesthetic [1].

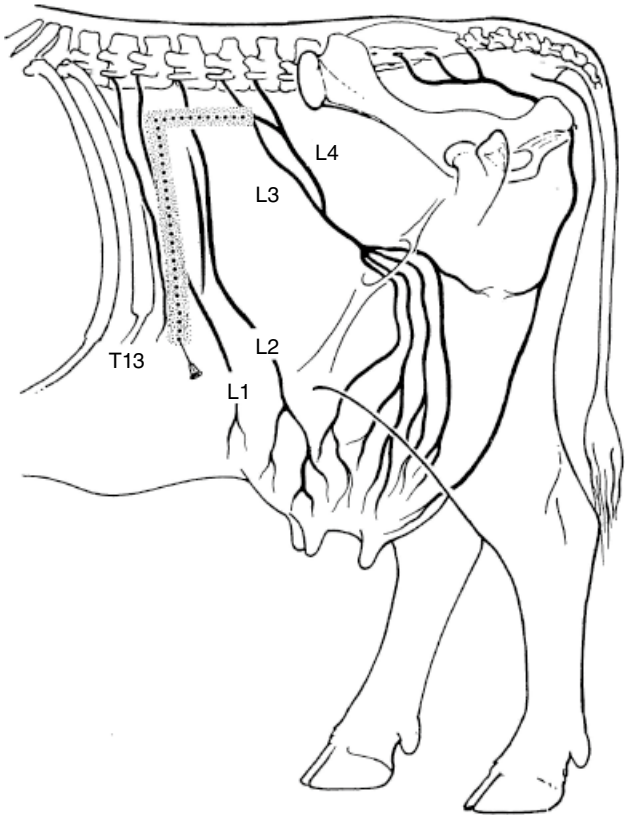

Figure 17.1 Inverted L. Ventral branches of labeled T13 and L1 to L4 are desensitized by this block. T13, Last thoracic nerve; L1–4, first to fourth lumbar spinal nerves. *Source:* From [1], © 2007, John Wiley & Sons.

Proximal Paravertebral

The proximal paravertebral nerve block desensitizes the dorsal and ventral nerve roots of the last thoracic (T13) and first and second lumbar (L1 and L2) spinal nerves as they emerge from the intervertebral foramina. To facilitate proper needle placement of anesthetic, the skin at the cranial edges of the transverse processes of L1, L2, and L3 and at a point 2.5–5 cm off the dorsal midline is desensitized by injecting 2–3 ml of local anesthetic using an 18-gauge, 2.5-cm needle. A 14-gauge, 2.5-cm needle is used as a cannula or guide needle to minimize skin resistance during insertion of an 18-gauge, 10- to 15-cm spinal needle. Approximately 5 ml of local anesthetic is placed through the cannula to anesthetize the needle tract for further needle placement.

To desensitize T13, the cannula needle is placed through the skin at the anterior edge of the transverse process of L1

at approximately 4–5 cm lateral to the dorsal midline. The 18-gauge, 10- to 15-cm spinal needle is passed ventrally until it contacts the transverse process of L1. The needle is then walked off the cranial edge of the transverse process of L1 and advanced approximately 1 cm to pass slightly ventral to the process and into the intertransverse ligament. A total of 6–8 ml of local anesthetic is injected with little resistance to desensitize the ventral branch of T13. The needle is then withdrawn 1–2.5 cm above the fascia or just dorsal to the transverse process and 6–8 ml of local anesthetic is infused to desensitize the dorsal branch of the nerve.

To desensitize L1 and L2, the needle is inserted just caudal to the transverse processes of L1 and L2. The needle is walked off the caudal edges of the transverse processes of L1 and L2, at a depth similar to the injection site for T13, and advanced approximately 1 cm to pass slightly ventral to the process and into the intertransverse ligament. A total of 6–8 ml of local anesthetic is injected with little resistance to desensitize the ventral branches of the nerves. The needle is then withdrawn 1–2.5 cm above the fascia or just dorsal to the transverse processes and 6–8 ml of local anesthetic is infused to desensitize the dorsal branch of the nerves (Figure 17.2).

Evidence of a successful proximal paravertebral nerve block includes increased temperature of the skin; analgesia of the skin, muscles, and peritoneum of the abdominal wall of the paralumbar fossa; and scoliosis of the spine toward the desensitized side. Advantages of the proximal paravertebral nerve block include small doses of anesthetic, wide and uniform area of analgesia and muscle relaxation, decreased intra-abdominal pressure, and absence of local anesthetic at the margins of the surgical site. Disadvantages of the proximal paravertebral nerve block include scoliosis of the spine, which may make closure of the incision more difficult, difficulty in identifying landmarks in obese and heavily muscled animals, and more skill or practice required for consistent results [2, 3, 5].

Distal Paravertebral

The distal paravertebral nerve block desensitizes the dorsal and ventral rami of the spinal nerves T13, L1, and L2 at the distal ends of the transverse processes of L1, L2, and L4, respectively. An 18-gauge, 3.5- to 5.5-cm needle is inserted ventral to the transverse process and 10 ml of local anesthetic is infused in a fan-shaped pattern. The needle can then be removed completely and reinserted or redirected dorsal to the transverse process, in a caudal direction, where 10 ml of local anesthetic is again infused in a fan-shaped pattern. This procedure is repeated for the transverse processes of the second and fourth lumbar vertebrae (Figure 17.3). Advantages of the distal paravertebral nerve block compared with the proximal paravertebral nerve block include lack of scoliosis, easier performance, and more consistent results. Disadvantages of the distal paravertebral nerve block compared with the proximal paravertebral nerve block include larger doses of anesthetic and variations in efficiency caused by differences in anatomic pathways of the nerves [2, 3, 5].

Anesthesia of the Perineum

Anesthesia of the perineum is routinely performed for obstetric procedures and for relief of rectal tenesmus in the cow. Many urogenital surgeries in cows (i.e. replacement

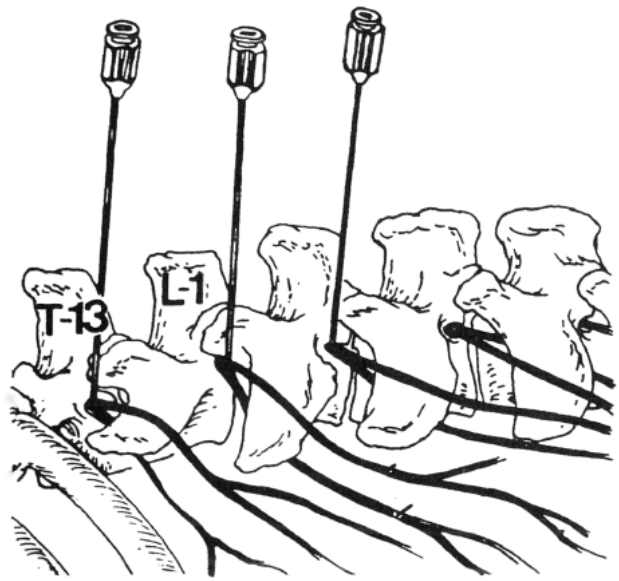

Figure 17.2 Proximal paravertebral. *Source:* From [2], © 1986, Elsevier.

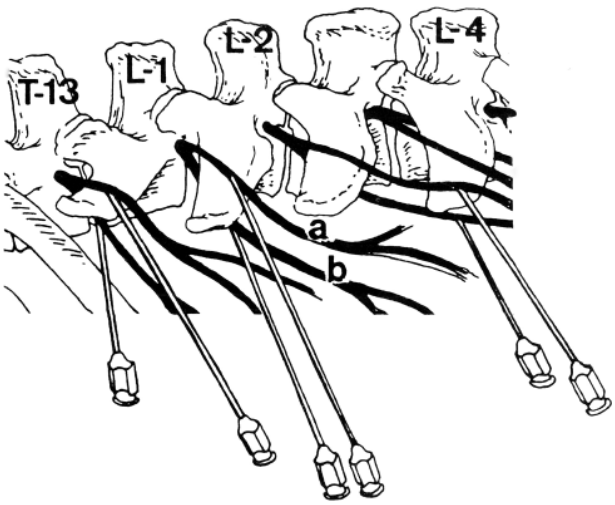

Figure 17.3 Distal paravertebral. *Source:* From [2], © 1986, Elsevier.

of vaginal/cervical prolapse) and bulls/steers (ischial urethrostomy, penile amputation) also require anesthesia of the perineum.

Caudal Epidural Anesthesia

Caudal epidural anesthesia is an easy and inexpensive method of analgesia that is commonly used in cattle. A high caudal epidural at the sacrococcygeal space (S5–Co1) desensitizes sacral nerves S2, S3, S4, and S5. The low caudal epidural at first coccygeal space (Co1–Co2) desensitizes sacral nerves S3, S4, and S5; as the anesthetic dose increases, nerves cranial to S2 may also become affected [6]. If possible, the hair should be clipped and the skin scrubbed and disinfected.

Standing alongside the cow, the tail should be moved up and down to locate the fossa between the last sacral vertebra and the first coccygeal vertebra (first freely moveable space) or between the first and second coccygeal vertebrae. An 18-gauge, 3.8-cm needle (with no syringe attached) is directed perpendicular to the skin surface. Once the skin is penetrated, place a drop of local anesthetic solution in the hub of the needle (hanging drop technique). The needle should then be advanced slowly until the anesthetic solution is drawn into the epidural space by negative pressure. The syringe may then be attached to the needle and anesthetic solution slowly injected with no resistance (Figure 17.4a). The dose of local anesthetic to be used is 0.5 ml per 45 kg body weight.

An increased dose of local anesthetic can be used to facilitate other urogenital procedures including teaser bull preparation and ventral midline cesarean section. This is referred to as high-volume caudal epidural anesthesia and is performed in the same way as the standard caudal epidural, only increasing the volume of local anesthetic used. The recommended dose is 1 ml per 5 kg body weight; however, volumes up to 0.5 ml/kg have been used without adverse effects. The patient will lose control of the hindlimbs, so recumbency is a must when using this technique. The effects on the hindlimbs may last up to four to six hours after administration. It is recommended that hobbles be placed on the hindlimbs and the patient be recovered in an area with good footing and left alone until they are able to stand unassisted [4, 7].

Continuous Caudal Epidural Anesthesia

Continuous caudal epidural anesthesia is used in cattle with chronic rectal and vaginal prolapse that experience continuous straining after the initial epidural. This procedure is performed by placing a catheter into the epidural space for intermittent administration of local anesthetic. A 17-gauge, 5-cm spinal needle (Tuohy needle) with stylet in place is inserted into the epidural space at Co1 to Co2 with the bevel directed craniad. The stylet is removed, and 2 ml of local anesthetic is injected to determine if the needle is in the epidural space. A catheter is inserted into the needle and advanced cranially for 2–4 cm beyond the needle tip. The needle is then withdrawn while the catheter remains in place (Figure 17.4b). An adapter is placed on the end of the catheter and the catheter secured to the skin on the dorsum. Local anesthetic solution may then be administered as needed [2].

Additives or Alternatives to Local Anesthetic Epidural Anesthesia

More recently, α_2-adrenergic agonists and opioids either alone or in combination with local anesthetic solutions have been used for epidural anesthesia. Epidural administration of the

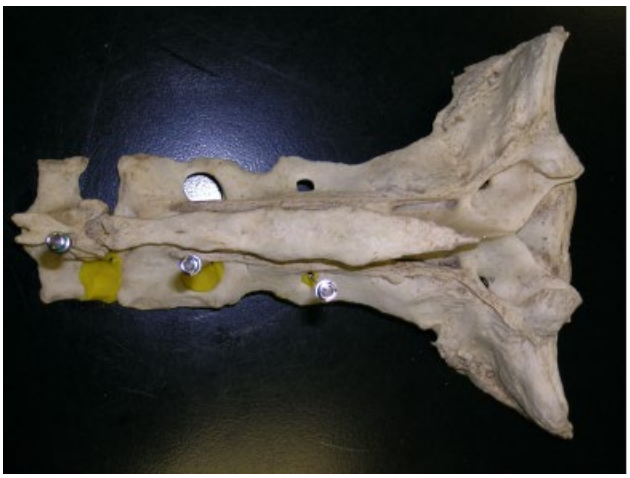
α_2-agonist xylazine hydrochloride (0.05 mg/kg) diluted in 5–12 ml of sterile saline or xylazine hydrochloride (0.3 mg/kg) added to 5 ml of 2% lidocaine hydrochloride offer similar anesthesia to lidocaine. Although the duration of anesthesia is prolonged (four to five hours) using these combinations, systemic effects (sedation, salivation, ataxia) may also occur [1]. Epidural administration of opioids, such as morphine (0.1 mg/kg) diluted in 20 ml of sterile saline, is used to provide analgesia for a prolonged period (approximately 12 hours) without interfering with motor function. Disadvantages of using opioids for epidural anesthesia are that the analgesia is not as potent as lidocaine and the maximum effect of a morphine epidural may not occur for two to three hours. Caudal epidural administration of morphine may be used to help alleviate pain in the perineal area and straining [8].

Alcohol has been used previously to desensitize the perineum for a prolonged period and in some cases permanently. Alcohol administered by this route can lead to demyelination of nerves. This can result in damage more cranial than the perineum and could effectively paralyze the patient if it were to travel up the nerve root and into the sciatic nerve. Therefore its use in epidural anesthesia is not recommended [9].

Sacral Paravertebral Anesthesia



Sacral paravertebral anesthesia is used to relieve rectal tenesmus associated with rectal prolapse without affecting the sciatic nerve and function of the tail or the animal's ability to stand. The sacral paravertebral nerve block is used to provide analgesia to the pudendal nerve (pudic nerve), medial hemorrhoidal nerve (pelvic splanchnic nerve), and caudal hemorrhoidal nerve (caudal rectal nerve) by blocking S3, S4, and S5 as they branch off the spinal cord, thereby providing analgesia to the anus, vulva, and vagina [1, 10]. In bulls, S3 supplies motor function to the retractor penis muscles. Physical restraint in a squeeze chute and/or sedation may be beneficial in order to prevent lateral movement of the animal during the procedure. In addition, a caudal epidural may be helpful if the animal is fractious. The skin over the dorsal sacrum should be clipped of hair and surgically prepared for the procedure. The paired S5 foramina are 1–2 cm lateral to the sacral coccygeal joint. The S4 foramina are about 3–4 cm cranial and more lateral to the S5 foramina. The S3 foramina are an additional 3–4 cm cranial to the S4 foramina (Figure 17.5a and b). A stab incision can be made dorsal to each foramen to aid in the introduction of an 18-gauge, 5- to 7-cm needle. The foramina can be palpated rectally with a finger placed in or over the ring which allows for identification of the foramen and ensures correct needle placement (Figure 17.6). Once the needle has entered the osseous ring, inject 2–3 ml of lidocaine hydrochloride; this should be repeated for each foramen [10]. The use of a lidocaine/alcohol mixture has also been described to manage tenesmus following chronic cervicovaginal prolapse or rectal prolapse. A mixture of 1 ml of 2% lidocaine hydrochloride and 2 ml of 95% ethyl alcohol has been used effectively [10].

Anesthesia of the Penis and Prepuce

Desensitization of the Internal Pudendal Nerve Block

The procedure for bilateral internal pudendal (pudic) nerve block was first described by Larson [11] to facilitate relaxation of the bull's penis without causing locomotor impairment.

(a)

(b)

Figure 17.7 Injection of 2 ml local anesthetic in the skin at the ischiorectal fossa.

Figure 17.8 Needle placement for pudendal nerve block. *Source:* Image courtesy of Douglas Hostetler.

The internal pudendal nerve block can be used in the standing bull for penile relaxation and analgesia distal to the sigmoid flexure and examination of the penis. In the standing female, the internal pudendal nerve block can be used to relieve straining caused by chronic vaginal prolapse. This technique may also be used for surgical procedures of the penis, such as repair of prolapses, removal of peripenile tumors, removal of penile papillomas or warts, and other minor surgeries of the penis and prepuce.

This procedure involves desensitizing the internal pudendal nerve and the anastomotic branch of the middle hemorrhoidal nerve using an ischiorectal approach. The internal pudendal nerve consists of fibers originating from the ventral branches of the third and fourth sacral nerves (S3 and S4) and the pelvic splanchnic nerves. The skin at the ischiorectal fossa on both sides is clipped, disinfected, and desensitized with approximately 2 ml of local anesthetic (Figure 17.7). A 14-gauge, 1.25-cm needle is inserted through the desensitized skin at the ischiorectal fossa to serve as a cannula. An 18-gauge, 10- to 15-cm spinal needle is then directed through the cannula to the pudendal nerve. The operator's left hand is placed into the rectum to the level of the wrist and the fingers directed laterally and ventrally to identify the lesser sacrosciatic foramen. The lesser sciatic foramen is first identified by rectal palpation as a soft depression in the sacrosciatic ligament. The internal pudendal nerve can be readily identified lying on the ligament immediately cranial and dorsal to the foramen and approximately one finger's width dorsal to the pudendal artery passing through the foramen. The internal pudendal artery can be readily palpated a finger's width ventral to the nerve. The spinal needle is held in the operator's right hand and introduced through the cannula in the ischiorectal fossa. The spinal needle is directed medial to the sacrosciatic ligament and directed cranioventrally (Figure 17.8). The needle is not felt until it has been introduced approximately 5–7 cm and can then be repositioned to the nerve. Once at the pudendal nerve, 20–75 ml of local anesthetic is deposited at the nerve (Figure 17.9). The needle is then removed and the site of deposition is massaged to aid in dispersal of the local anesthetic. This procedure is repeated on the opposite side of the pelvis. Relaxation of the penis varies and may take as long as 30–40 minutes for full effect. Effectiveness of the block can be assessed by firmly squeezing the tail of the epididymis of each testicle. The bull's inability to lift or retract the testicle signifies adequate analgesia. The duration of the internal pudendal nerve block lasts two to four hours [10].

Desensitization of the Dorsal Nerve of the Penis

The dorsal nerve of the penis may be desensitized at a location just proximal to the surgical site. With the bull restrained, the penis should be manually extended and a towel clamp should then be placed under the dorsal apical ligament.

Figure 17.9 Pudendal nerve block.

Alternatively, a gauze tourniquet may be placed around the free portion of the penis to aid in penile extension. With the dorsal aspect of the penis thoroughly cleansed, 2–4 ml of 2% lidocaine hydrochloride should be infused subcutaneously across the dorsum of the penis proximal to the lesion [9].

Alternatively, the dorsal nerve of the penis may be desensitized as it passes over the ischial arch for penile anesthesia and relaxation. The skin associated with the penile body and located 10 cm ventral to the anus and 2.5 cm from midline is infiltrated with 2–4 ml of 2% lidocaine hydrochloride using a small-gauge needle (22–25 gauge). A 20-gauge, 4-cm needle is then inserted through the desensitized skin and advanced for 5–7 cm to contact the pelvic floor. Aspiration ensures that the needle is not in the dorsal artery of the penis. The needle is then withdrawn approximately 1 cm and the area infiltrated with 20–30 ml of 2% lidocaine hydrochloride. The procedure is repeated on the opposite side of the penis. Analgesia and paralysis of the penis will occur within 20 minutes and should last for one to two hours [1].

Anesthesia for Castration

Castration of bulls is a very common surgical procedure in general practice. Historically, castration was often performed with minimal or no anesthesia. However, anesthesia for castration is more commonly practiced because calves benefit from anesthesia with improved feed consumption and rate of gain. Depending on the age and size of the animal, the surgery is usually performed with chemical and/or regional anesthesia (scrotum and testicles). Depending on the size of the calf, the proposed line of incision for removal of the distal aspect of the scrotum should be subcutaneously infiltrated with 5–10 ml of 2% lidocaine hydrochloride. In bulls, an 18-gauge, 3.8-cm needle is inserted at an angle (30–45°) into the center of the testicle and 10–15 ml of local anesthetic per 200 kg body weight is injected into the parenchyma of each testicle. The anesthetic quickly enters the lymphatics and desensitizes the sensory fibers in the spermatic cord. For smaller animals or calves, a smaller needle (20 gauge, 2.5 cm) may be used to administer 2–10 ml of 2% lidocaine hydrochloride [1].

Surgery of the Scrotum and its Contents

E. Heath King

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

The scrotum of the bull is a dependent appendage of the ventral abdominal skin that supports and protects the testicles and helps regulate testicular temperature. The testis must be maintained at a temperature 4–6 °C cooler than body temperature for normal spermatogenesis to occur. Testicular thermoregulation is a complex process that involves a combination of evaporative cooling from scrotal sweat glands, relaxation and contracture of the tunica dartos muscle in response to scrotal temperature, and counter-current heat exchange between the pampiniform plexus and the testicular artery [1]. Trauma, inflammation, or swelling of the scrotum or testes can easily impair testicular thermoregulation, and studies utilizing scrotal insulations have shown that morphological abnormal sperm are produced within 6–14 days of the insult [2].

Physical Examination of the Scrotum and Testicles

Carefully examine the scrotum for dermatitis, edema, scar tissue, and symmetry [3]. Palpate the testicles for relative size, firmness, symmetry, evidence of pain or swelling, presence of fluid in the vaginal cavity, and the ability of the testicles to move freely within the vaginal cavity. There should be no more than 10% difference in the size of the testes and normal testicular tone approximates that of liver.

Ultrasound of the Testicles

Diagnosis of scrotal or testicular disease may be aided by B-mode real-time ultrasound using a 5-MHz probe. Normal testicles are homogeneous and moderately echogenic [4] (Figure 18.1). The mediastinum testis is a readily identifiable hyperechoic area in the center of the testicle when viewed in the transverse plane or a hyperechoic line when viewed in the sagittal plane (Figure 18.2). The head, body, and tail of the epididymis are less echogenic than the testicle and are readily identified as they course along the testicle. Thickness of the scrotal skin and vaginal tunics and the presence of fluid within the vaginal cavity are readily determined.

Thermography of the Scrotum

Testicular temperature must be below body temperature for normal spermatogenesis in bulls. Infrared thermography provides a non-invasive, non-contact imaging technique to determine normal and abnormal thermal patterns in bulls and other animals [5]. Thermography utilizes sensitive infrared imaging to produce a color photograph that portrays variations in surface temperature that reflect the temperature of tissues immediately beneath the skin. The normal thermogram of the scrotum in all species is a left and right symmetric pattern with a constant decrease in temperature gradient from the base to the apex (Figure 18.3). In bulls a temperature gradient of 4–6 °C from base to apex is considered normal. A gradual decrease from base to apex with concentric color

bands is consistent with normal function of the vascular counter-current heat-exchange mechanism of the testes. An excessively cool or excessively warm area as evidenced by thermographic color is consistent with testicular disease or injury [6, 7] (Figure 18.4).

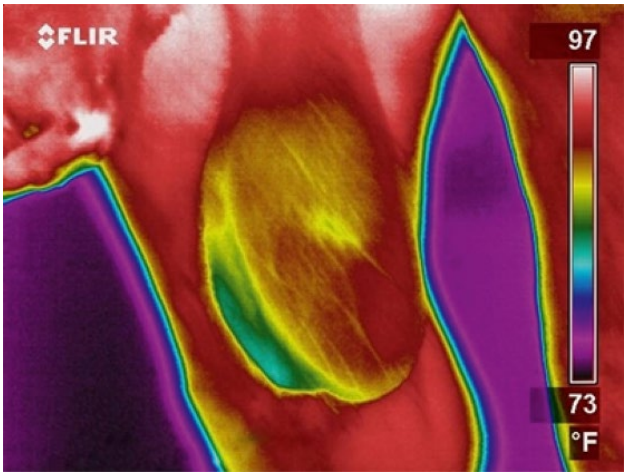

Figure 18.4 Thermograph of scrotum of bull with unilateral pathology. Note decreased temperature on left side of scrotum.

Semen Evaluation

Semen from bulls with significant scrotal or testicular pathology generally does not meet the minimum 70% morphologically normal sperm of which more than 30% are progressively motile, and these bulls are thus considered subfertile. The temporal appearance of sperm abnormalities following scrotal insulation has been established in bulls and may be useful in determining the chronicity of an insult [2, 8, 9]. Semen evaluation may also be used to determine when surgical intervention should be pursued in bulls with unilateral testicular disease.

Scrotal and Testicular Disease and Injury

Fluid Accumulation in the Vaginal Cavity

Fluid accumulation in the vaginal cavity is a common cause of scrotal enlargement in bulls. This accumulation can occur bilaterally, but unilateral enlargement is more common. The condition can be further defined by the type of fluid present. Hemorrhage in the vaginal cavity commonly results from trauma and is known as a hematocele. Injury or periochitis can cause the accumulation of an inflammatory exudate or transudate in the vaginal cavity which is referred to as a hydrocele [10]. Bilateral scrotal hydroceles have been reported in bulls secondary to ascites caused by gastrointestinal parasitism [11]. Fluid accumulation in the vaginal cavity causes distention of the parietal vaginal tunic, creating the appearance of testicular swelling. Depending on the nature of the fluid present and the degree of distension of the parietal

vaginal tunic, the affected side may palpate firm and the testicle itself may be hard to identify. The presence of fluid in the vaginal cavity can easily be confirmed with ultrasound (Figure 18.5). Fibrinous and fibrous adhesions between the testicle and the parietal tunic may also be visible on ultrasound.

Orchitis, Periorchitis, and Epididymitis

Orchitis is uncommon in bulls and usually unilateral. Infection is often subclinical but rarely may range to severe and perhaps suppurative [12, 13]. The route of infection is primarily hematogenous but penetrating wounds of the scrotum are also possible. The dense fibrous tunica albuginea surrounding the testicle limits this organ's potential for enlargement and therefore there is usually not significant testicular swelling. However, when infection involves the surrounding tunica vaginalis (periorhitis), significant scrotal enlargement can occur. The affected side may also be warm and painful to the touch, with pain significant enough to alter the gate of the bull [12].

Epididymitis occurs more commonly than orchitis in bulls and may be diagnosed by thorough examination of the testes and scrotal contents [14–16]. The condition is often unilateral in the bull and may present as a swollen painful epididymal tail in the acute phase of the disease. Chronic epididymitis usually results in epididymal tails that are small and firm, and infertility is often caused by their eventual obstruction.

Trauma

Trauma is a common cause of pathological changes in scrotal contents. As mentioned above, trauma often leads to the accumulation on fluid in the vaginal cavity in the form of a hematocele or hydrocele. Penetrating wounds of the scrotum can result in orchitis/periorchits with potential scrotal abscessation. Severe trauma can induce rupture of the tunica albuginea [10]. Leakage of sperm due to tubular damage of the testicle can invoke an autoimmune reaction leading to granulomatous reactions. Depending on the acuteness and severity of the trauma, significant scrotal enlargement and edema may be present (Figure 18.6).

Inguinal Hernia

Inguinal hernias can be classified as either congenital or acquired and direct or indirect. In mature bulls all inguinal hernias are considered acquired. Indirect hernias occur when bowel passes through an intact but dilated inguinal ring. This type of herniation occurs more frequently on the left side and rarely causes strangulation of bowel. Bulls with an indirect hernia will typically present clinically normal, other than swelling in the neck of the scrotum that gives the scrotum an hourglass appearance (Figure 18.7). Direct inguinal hernias occur through the inguinal ring, but disruption or tearing of the ring or vaginal tunic is present. Direct inguinal herniation is more likely to result in strangulation and obstruction of bowel with more pronounced and generalized scrotal swelling [17, 18].

The presence of an inguinal hernia can be confirmed with rectal palpation and scrotal ultrasound. Palpation should reveal a dilated or disrupted inguinal ring on the affected side and the presence of herniated bowel contained in the ring. Ultrasound of the neck of the scrotum can definitively confirm the presence of bowel. Bulls with intestinal obstruction will present with abdominal pain and distention and will require emergency surgery. Inguinal hernias in bulls that present clinically normal without any signs of obstruction can be managed with elective surgery [17, 18].

Figure 18.7 Inguinal hernia in a bull. Note characteristic swelling confined to neck of scrotum.

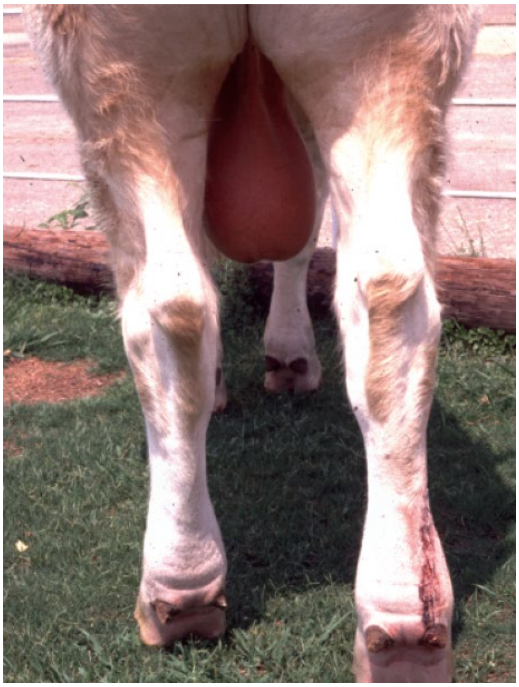

Figure 18.8 Generalized edema of scrotal wall due to *Mycoplasma weyenoii*.

Less Common Causes

Bilateral scrotal enlargement with pitting edema of the hind limbs has been reported in young bulls secondary to *Mycoplasma wenyonii* infection (Figure 18.8). Swelling subsided in these bulls following treatment with oxytetracycline [19, 20]. Scrotal edema can be differentiated from other causes of scrotal enlargement by palpation and ultrasound.

Primary testicular tumors are not common in bulls but unilateral or bilateral scrotal enlargement has been reported in bulls with mesothelioma [5, 12, 13, 19].

Unilateral Castration

Hemi- or unilateral castration should be considered in bulls with unilateral testicular disease. When one testicle is inflamed, the heat thus generated affects the contralateral testicle and the reversibility of degenerative change depends on the severity and duration of the insult [12]. Valuable animals with unilateral hematoceles, hyrdrocleles, orchitis, periorchitis, or testicular rupture may be able to resume breeding soundness with unilateral castration.

Although unilateral castration is not an emergency procedure, the prognosis for return to fertility improves if surgery is performed early in the disease process. Early intervention can reduce further insult to the contralateral testicle generated by inflammation, with less likelihood that the testicle will undergo irreversible degeneration. Most bulls will return to fertility following surgery if the remaining testicle is not severely compromised [10, 21, 22]. Compensatory hypertrophy in the normal testis should allow the bull to subsequently produce up to 75% of normal sperm capacity. Therefore, advise owners that restrictions may be necessary following surgery. Additionally, although a bull may be productive in a herd situation, a unilaterally castrated bull will not pass a standardized breeding soundness evaluation and is therefore ineligible for certain shows or sales [10].

In preparation for surgery the bull should be withheld from feed for 48 hours and water for 12 hours. Surgery is performed with the bull restrained in lateral recumbency under general anesthesia or heavy sedation and regional or local anesthesia. Regional anesthesia can be accomplished with the use of a pudendal nerve block, or local anesthetic can be injected into the neck of the scrotum and the spermatic cord. Antibiotics are administered prior to surgery and continued for at least five days post-surgery. Nonsteroidal anti-inflammatories should also be administered immediately prior to surgery. The scrotum is clipped and prepped for aseptic surgery [10, 23]. On the lateral aspect of the scrotum an elliptical skin incision is made approximately the length of the testicle, preserving the parietal vaginal tunic (Figure 18.9). The affected testicle within the parietal vaginal tunic is bluntly dissected away from the surrounding scrotal fascia (Figure 18.10). If the condition is chronic, variable amounts of fibrous tissue and adhesions of the parietal and visceral vaginal tunics may be

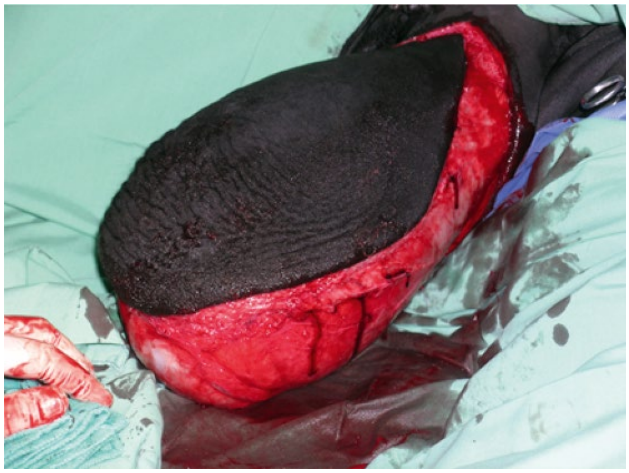

Figure 18.9 Elliptical skin incision on lateral aspect of scrotum. *Source:* Image courtesy of Richard Hopper and Heath King.

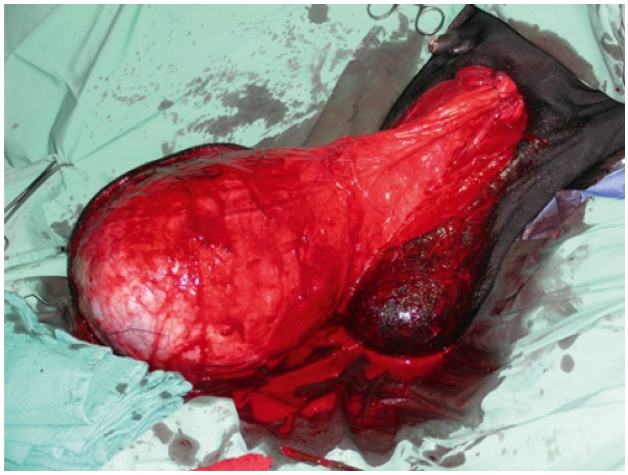

Figure 18.10 Testicle within parietal vaginal tunic bluntly dissected from scrotal fascia. *Source:* Image courtesy of Richard Hopper and Heath King.

encountered. At this point the decision is made whether an open or closed castration should be pursued. An open castration allows for more careful ligation of the vasculature but does expose the surgery site to potential contamination from the contents of the parietal tunic. A closed castration is typically performed by the author to limit contamination of the surgical site. Both techniques are described below.

To perform an open castration, a vertical incision is made through the parietal tunic sufficiently long to remove the testis and exteriorize the testicle and spermatic cord (Figures 18.11). The spermatic artery, vein, and ductus deferens are isolated and double ligated with #0 chromic gut 8 cm proximal to the pampiniform plexus and transected between the two ligatures (Figure 18.12). The vaginal tunic is then transected and the external cremaster muscle is ligated and transected distal to the stump of the spermatic

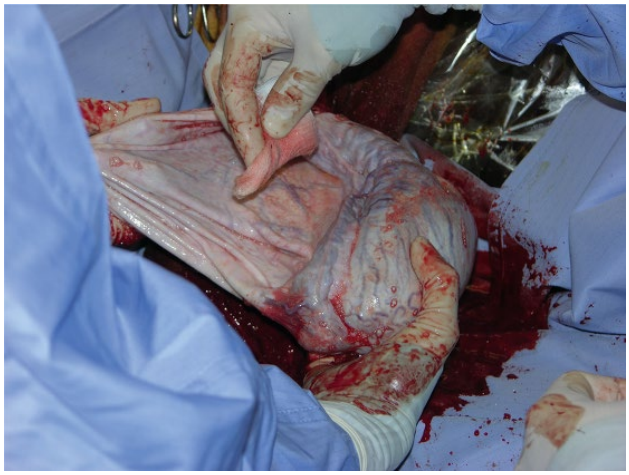

Figure 18.11 Parietal vaginal tunic incised and testicle exposed. *Source:* Image courtesy Darcie Sidelinger & Heath King.

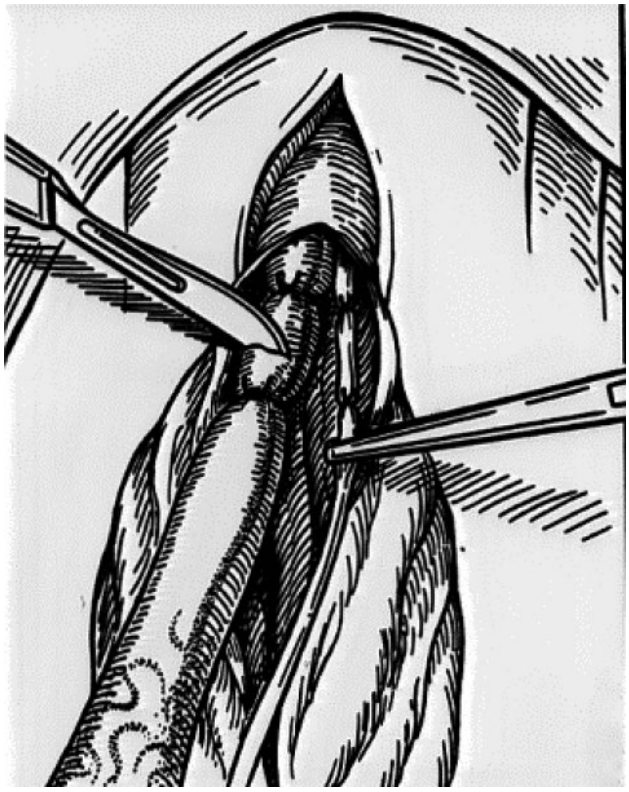

Figure 18.12 Schematic of double ligation and transection of spermatic cord and vessels.

cord (Figure 18.13). The vaginal tunic is closed with an inverting pattern such as a Connell or Parker–Kerr using #0 chromic gut (Figure 18.14). To perform the closed castration, the spermatic cord is ligated proximal to the pampiniform plexus with a combination of one transfixing ligature and two circumferential Miller's knot ligatures using #4 polyglactin suture (Figure 18.15). The spermatic cord is then transected distal to the ligatures with emasculators.

Figure 18.13 Transected stump of vaginal tunic following inverting suture closure. *Source:* Image courtesy Darcie Sidelinger & Heath King.

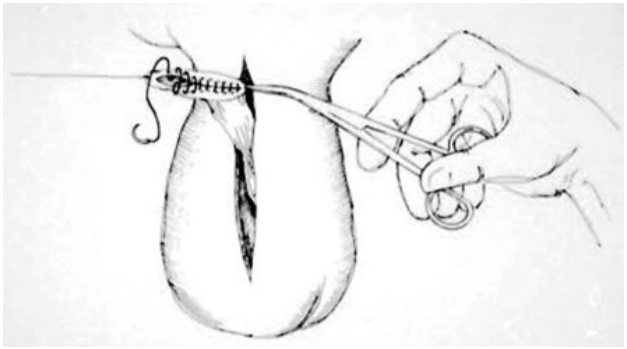

Figure 18.14 Schematic of inverting closure of vaginal tunic.

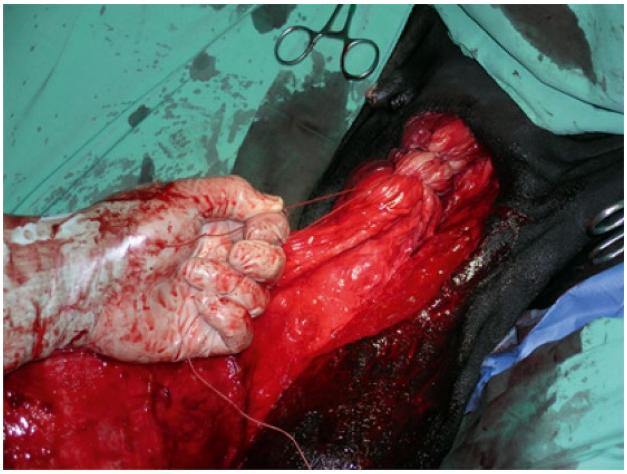

Figure 18.15 Ligation of spermatic cord for a closed castration. *Source:* Image courtesy of Richard Hopper and Heath King.

For either technique, the scrotal fascia and tunica dartos are closed with #0 or larger chromic gut in a simple continuous pattern being careful to eliminate dead space. The skin is then closed with non-absorbable suture in a continuous pattern of the surgeon's choice (Figure 18.16).

Postoperative swelling can be reduced by wrapping the scrotum in 4 inches of elastic adhesive tape (Figure 18.17). The bandage should be removed in 24–48 hours. Skin sutures are removed in 10–14 days and the bull can return to service when the spermiogram returns to normal. Normal bulls undergoing unilateral orchiectomy had normal spermiograms by 14 days after surgery [16]. Bulls with unilateral scrotal pathology and transient testicular degeneration of the remaining testicle should be expected to return to normal sperm production approximately 60 days after removal of the diseased or injured testicle [17].

Figure 18.16 Scrotal skin incision closed with continuous interlocking pattern. *Source:* Image courtesy of Richard Hopper and Heath King.

Figure 18.17 Postoperative bandaging of scrotum to minimize swelling. *Source:* Image courtesy of Richard Hopper.

However, if the surgery is performed during the warmer months of the year, normal testicular function may not resume until ambient temperatures moderate.

Inguinal Hernia Repair

The two approaches for inguinal hernia repair in bulls are the standing flank approach and the inguinal approach performed in lateral recumbency. The primary advantage of the flank approach is that it does not require general anesthesia. However, not all hernias can be reduced through the flank approach and closure of the inguinal ring must be performed blindly. Utilizing the inguinal approach requires general anesthesia but provides much better surgical exposure and simplifies closure of the inguinal ring. The improved exposure allows for the identification and transection of adhesions between the herniated bowel and parietal tunic and facilitates resection and anastomosis of injured and strangulated bowel. Therefore bulls that present with an inguinal hernia and evidence of abdominal pain should be repaired by the inguinal approach [18].

Standing Flank Approach

The ipsilateral paralumbar fossa is clipped and prepared for aseptic surgery. An inverted L or paralumbar block is used for local anesthesia. The abdomen is then entered in a routing manner and the inguinal ring is identified. The herniated bowel is grasped and traction is applied to reduce the hernia (Figure 18.18). Failure to reduce the hernia by traction at this stage will require transition to the inguinal approach described below. Once the hernia is reduced, closure of the inguinal ring is performed by blindly placing several interrupted sutures or by utilizing the continuous blind suture technique described in Chapter 55. Care must be taken during closure of the inguinal ring to avoid the vasculature entering and exiting the abdomen through the ring. The flank is then closed in a routing manner [17, 18].

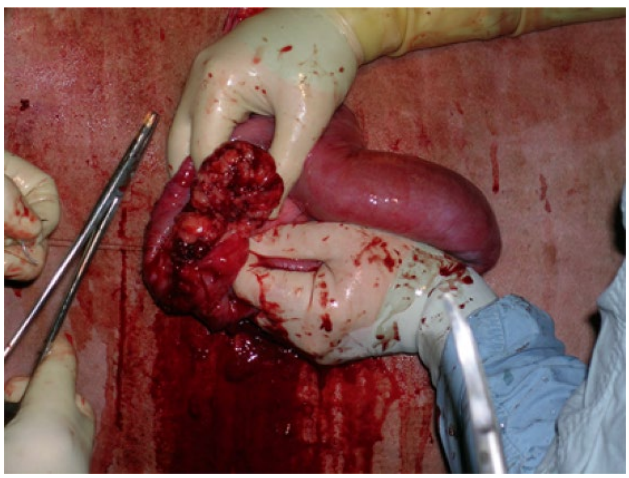

Figure 18.18 Resection and anastomosis of herniated bowel removed from inguinal ring by flank approach. *Source:* Image courtesy of Richard Hopper.

Inguinal Approach

For the inguinal approach, the bull is anesthetized and placed in lateral recumbency with the affected side up. The upper rear leg must be elevated to expose the inguinal area. The inguinal area is clipped and prepared for aseptic surgery. A 20- to 25-cm incision is made over the inguinal ring (Figure 18.19). The subcutaneous tissues are bluntly and sharply dissected to expose the spermatic cord. An incision is then made in the parietal tunic to expose the herniated tissues (Figure 18.20). The herniated bowel is examined for adhesions or evidence of strangulation. If encountered, strangulated or devitalized bowel should be removed by resection and anastomosis. Adhesions between the bowel and parietal tunic should be ligated before separation [17, 18]. The herniated bowel is then reduced. The decision is made as to whether the testicle on the affected side will be spared or removed. Removing the testicle will prevent postoperative complication that could impact testicular thermoregulation and allows for simplified and complete closure of the inguinal ring.

Closure of the inguinal ring, when the testicle is spared, is accomplished in two stages. The first stage pulls the internal

abdominal oblique muscle posteriorly to support and protect the spermatic cord (Figures 18.21 and 18.22). An atraumatic "hernia" needle loaded with #4 non-absorbable suture is used to take the first bite through the median border of the inguinal ring near the caudal apex of the ring. The suture is passed under the spermatic cord and the second bite is made through the internal abdominal oblique muscle. The suture is then passed back beneath the spermatic cord and through the border of the inguinal ring near the first bite. This procedure is repeated on the opposite side to the spermatic cord, with the initial bite going through the lateral border of the inguinal ring to engage the internal abdominal oblique muscle 3 cm

from the first site. Both sutures are then tightened and tied simultaneously, with care taken to not constrict the spermatic cord. An overlapping suture pattern with non-absorbable suture is used to close the external boarders to the inguinal ring (Figures 18.23 and 18.24). Enough room should be left adjacent to the spermatic cord for two fingers to pass through the inguinal ring. The parietal vaginal tunic is closed with a simple continuous pattern of absorbable suture, and the subcutaneous tissues of the inguinal area are closed to eliminate dead space. The skin is then apposed with a continuous interlocking pattern of non-absorbable suture [17, 18].

Closure of the inguinal ring following unilateral castration is less complicated. Following ligation and transection of the spermatic cord, the lateral borders of the inguinal ring are closed with a series of preplaced simple interrupted or cruciate sutures. Large non-absorbable suture can be used or the author has also utilized #4 braided polyglactin for closure. Regardless of the approach chosen, broad-spectrum antibiotics are administered on the day of surgery and continued for five days. Non-steroidal anti-inflammatory drugs are also useful to control postoperative pain and inflammation. Recovery in a small lot versus a stall provides exercise, which helps to reduce postoperative swelling and edema.

Restorative Surgery of the Prepuce and Penis

Richard M. Hopper and Dwight F. Wolfe

Department of Clinical Sciences, College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

Bulls commonly sustain injuries to the reproductive tract during natural breeding activity. Through close observation of their bull battery during the breeding season, cattle owners or managers can identify many reproductive tract maladies. Close observation of a cowherd during the breeding season can potentially reveal cows that are returning to estrus, a bull standing off to himself, or a swelling of and trauma to the external genitalia of a bull. All of these represent issues for further investigation or veterinary intervention, which in turn should lead to the identification of conditions such as penile hematoma, preputial prolapse, phimosis, paraphimosis, or an injury that has led to a denervation, vascular shunt, or deviation of the penis. Through the utilization of a bull breeding soundness examination (BBSE) prior to each breeding season, when properly performed as directed by the standards of the Society for Theriogenology, other problems such as fibropapillomas, hair rings, and minor preputial injuries can also be identified [1].

As all of the conditions that will be described in this chapter either hamper or potentially end the functional use of a bull, it is incumbent on our part to first correctly diagnose and then provide a reasonable prognosis for successful resolution. The prognosis obviously takes into consideration the severity of the injury or condition, but also the temperament of the bull, your facilities, and economics. The economic factors that must be considered include the replacement cost of the bull, his cull value, treatment costs, and service time lost for treatment and recovery.

Fibropapilloma

Fibropapilloma or warts are a common finding in young cattle under the age of 24 months. Caused by bovine papilloma virus, the virus is believed to enter the penile skin through wounds or abrasions sustained during homosexual activity among young bulls. The virus causes neoplastic growth of fibroblasts that is not locally invasive or metastatic. Often several bulls in a group will develop penile fibropapillomas and affected bulls frequently may not have obvious lesions on other parts of the body. Other neoplastic growth on the bovine penis is extremely rare [2]. Group housing of young bulls along with a predisposition for homosexual behavior both increase the incidence and add to the possibility that the penis will be among the affected locations. Penile warts (Figure 19.1) are usually identified at the time of a BBSE [3] or by an owner that notices a young bull that is reluctant or unable to breed. Bulls may present with either a phimosis or paraphimosis.

Fibropapillomas may be managed by careful surgical removal with the bull restrained on a tilt table or in a squeeze chute [4], whether it be by excision, cryotherapy, or use of a laser, alone or in conjunction with immunization. Some level of prevention can be accomplished with the use of a commercial wart vaccine and it is my recommendation (Hopper) to administer wart vaccine to bulls following weaning that will be developed in large groups, specifically those to be shipped to bull test stations or to other group bull development stations where they will be housed with multiple bulls from multiple sources. When this is a continuous herd problem, utilization of an autogenous vaccine is a useful management tool [5].

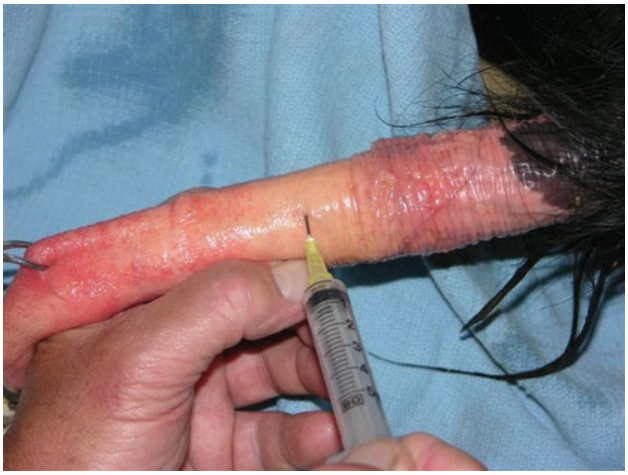

Figure 19.3 Subcutaneous injection of local anesthetic over dorsum of penis. This provides analgesia to distal penis.

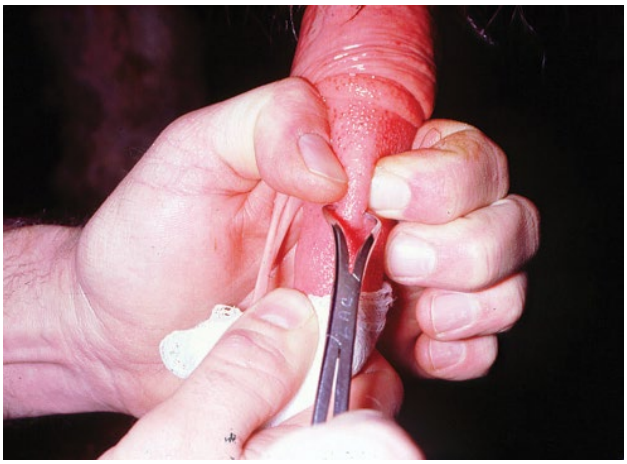

Figure 19.2 Proper placement of towel clamp under dorsal apical ligament to hold penis in extension.

Figure 19.4 Catheterization of urethra.

Surgical removal begins with manually extending the penis and placing either a towel clamp under the dorsal apical ligament (Figure 19.2) or a gauze tourniquet around the penis proximal to the growth to aid in holding the extended penis. Prepare the surgical field and infiltrate 2–4 ml of 2% lidocaine subcutaneously across the dorsum of the penis proximal to the lesion (Figure 19.3). Repeat the surgical preparation and carefully identify the urethra to avoid incising this tissue during excision of the growth. Catheterize the urethra with a 10-French male dog urinary catheter to help identify the urethra and thus avoid this structure (Figure 19.4). Then dissect the skin of the penis at the base of the lesion until the growth is completely removed. In lieu of sharp dissection with a scalpel, judicious dissection with a CO_2 laser may assist hemorrhage control. Large growths are more easily removed by gradually debulking the lesion until the entire mass is removed. Ligate any small vessels and close the skin with #0 absorbable suture. Very small growths may be excised without anesthesia or suture closure. Remove the towel clamp and return the penis to the preputial cavity. Application of topical or systemic antimicrobials is optional.

Penile fibropapilloma may recur if the bull is in an active state of the disease. Complete removal of the growth with an adjacent margin of unaffected penile surface epithelium lessens the likelihood of recurrence. In addition to the administration of a commercial or autogenous wart vaccine, anecdotal evidence suggests that the use of Immunoboost™ (Bioniche Animal Health, USA) may help prevent recurrence of penile lesions. Bulls treated for penile fibropapilloma should be examined for healing or regrowth four weeks following surgery before entering breeding service.

Hair Ring

Although far less common than warts, the presence of a hair ring also occurs due to homosexual behavior and group housing of young bulls. Accumulation of hair during riding and the continuous action of riding with extension and retraction of the penis serve to create a tight band of hair (Figure 19.5). Hair rings are typically identified during a BBSE and treatment is simply removal and application of a suitable ointment. Because the encircling ring may become sufficiently tight to cause pressure necrosis with damage to the urethra, careful examination to determine the depth of the lesion is warranted [6]. Small urethral fistulae will typically heal on their own, but those that are larger and more proximally located must be closed (Figure 19.6). In severe cases the constricting ring may cause avascular necrosis to the extent that damage to the dorsal nerves of the penis or sloughing of the entire glans penis can occur.

Persistent Frenulum: Delayed Preputial–Penile Separation

The penis of the bull calf cannot be extended prior to puberty due to the interdigitating attachment of the skin of the penis and prepuce and the lack of a sigmoid flexure. During puberty, androgen production shifts from androstenedione to testosterone, and the attachment of the penis and prepuce begins and should be complete between 8 and 11 months of age. Occasionally, young bulls between the age of 12 and 14 months will present with incomplete separation [4, 7]. In these bulls separation can be completed by pulling the prepuce back from the free portion of the penis. These tissues should separate easily and hemorrhage is seldom a problem.

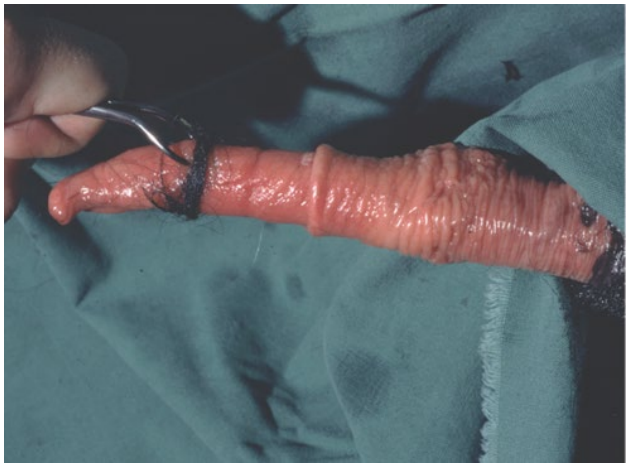

Figure 19.5 Penile hair ring.

Figure 19.6 Urethral fistula that is of a size and location to require repair.

The penile frenulum is a thin band of connective tissue on the ventral midline of the free portion of the penis, which adjoins the prepuce. Normally the frenulum ruptures during penile separation from the prepuce. When the frenulum does not rupture, the penis extends but the frenulum causes ventral bending of the distal penis during extension (Figures 19.7–19.9). Surgical repair is relatively simple. I recommend ligating each end of the frenulum and transecting the tissue to reduce the possibility of hemorrhage, although not all practitioners adhere to this practice (Figures 19.10–19.12). The owner should be advised that this condition is considered to be heritable and retaining the bull's sons as sires is not recommended.

Preputial Injury

Bulls most commonly sustain injuries to the prepuce during breeding. The extent of disruption of the surface epithelium and peri-penile elastic tissue determines the prognosis and therapeutic approach for returning the bull to breeding soundness. The veterinarian should understand the etiology of preputial injury and the therapeutic options for the animal [4, 6].

Primary preputial prolapse in the bull is usually a sequela to breeding injury, frostbite, or balanoposthitis caused by herpesvirus infection (infectious bovine rhinotracheitis/infectious

Figure 19.12 Completed excision of frenulum.

pustular vulvovaginitis, or IBR-IPV). Secondary preputial prolapse is often seen with penile hematoma or urethral rupture. Bulls suffering preputial frostbite may undergo considerable necrosis of the preputial epithelium and heal with mild to severe preputial stenosis (Figure 19.13). IBR-IPV most commonly affects young bulls and the prepuce may be extremely edematous, with vesicles or pustules on the preputial epithelium. These bulls usually respond well to sexual rest, application of emollient ointments, and conservative therapy, which may include hydrotherapy and support bandaging.

Laceration of the prepuce of *Bos taurus* breeds usually does not lead to preputial prolapse. The damaged prepuce is typically withdrawn into the sheath and swelling of the sheath may or may not be observable. Minor injuries are often unnoticed, heal without complication, and result in only minor superficial scarring [4, 6–9]. However, it should be noted that occasionally the resultant scar tissue will create pain during breeding [1]. In this case a scar revision procedure can be utilized. Some *B. taurus* bulls with preputial laceration develop paraphimosis, where the damaged tissues will not allow retraction of the penis into the sheath (Figure 19.14). Alternatively, some bulls that do retract the penis into the sheath develop phimosis due to stricture of the injured prepuce (Figures 19.13 and 19.15).

Laceration of the prepuce with subsequent preputial prolapse occurs more commonly in *Bos indicus* breeds due to their pendulous sheath, redundant preputial tissue, and larger preputial orifice [4, 6, 10]. Additionally, when combined with cattle that are polled, this condition is exacerbated due to the fact that polled cattle breeds typically lack the preputial retractor muscle. During breeding, the excess prepuce is forced caudally and forms a collar at the preputial orifice when intromission is achieved. This collar of prepuce becomes forcefully entrapped between the bull's abdomen and the vulva and pelvis of the cow during the ejaculatory lunge, with subsequent contusion and occasionally laceration or bursting of the skin on the longitudinal axis of the ventral aspect of the prepuce. Edema quickly develops in the traumatized skin and underlying elastic tissue, leading to prolapse of the prepuce. As the penis is withdrawn into the preputial cavity the longitudinal tear assumes a transverse orientation that effectively shortens the ventral aspect of the prepuce. As edema accumulates in the damaged tissues the prolapsed prepuce increases in size and assumes the appearance of an elephant's trunk, with the lumen of the prepuce directed caudally (Figure 19.16). The laceration is evident as a transverse wound on the caudal aspect of the prolapsed tissues (Figure 19.17), with the severity of preputial tissue

Figure 19.13 Severe preputial stenosis due to frostbite.

Figure 19.19 Preputial prolapse with severe laceration and minimal edema.

damage a result of both severity and duration of the injury (Figures 19.18–19.20).

Preputial Prolapse

Minor trauma with prolapse (Grade 1) can be treated with various medications and wrapped. More extensive trauma with swelling and the presence of necrotic tissue (Grades 2–4) requires a more aggressive approach and, because these cases result in fibrosis of the preputial tissue, surgical correction. In any case, medical treatment should be

Figure 19.20 Preputial prolapse with laceration and severe edema.

instituted as soon as possible either as the primary end of management or as a necessary precursor for surgery.

Prior to bandaging the prepuce, the wounds should be cleaned and an attempt should be made to replace the prolapse. This can be facilitated with hydrotherapy (water hose spray, showerhead spray, or soaking) (Figure 19.21). Soaking the prolapsed prepuce in a hypertonic solution with any povidone iodine solution also serves to aid in the debridement of the tissue. I (Hopper) add both salt and sugar so that solution will be very hypertonic without being too irritating. Then, after drying, an ointment is applied. I prefer a petrolatum, tetracycline, and scarlet red oil mixture for severely traumatized, necrotic wounds. I utilize less irritating ointments or mixtures for less affected tissue or after several days of treatment when the tissue is less swollen. Options for this are commercially available udder balms, human hemorrhoid ointment, intramammary infusion ointments, or "sugardine" (Betadine™ + sugar). A 6- to 10-inch rigid plastic tube (milk line or equine nasogastric tubes can be used) is then placed within the prepuce to allow urination and the prepuce is wrapped with Elasticon™. In addition to facilitating urination, the placement of the tube helps decrease the circumferential scarring of the preputial orifice, which results in phimosis. Bandage change intervals are dictated by the extent of damage, the bull's tolerance for the bandage, and whether or not you can completely replace the prepuce within the sheath. When the prepuce cannot be replaced, compression bandaging is utilized. In this case, apply the medicated ointment of your choice and cover with orthopedic stockinette prior to wrapping (Figures 19.22–19.24). In any case when the prepuce has been replaced, the use of a purse string suture to maintain retention is strongly discouraged due to the risk of abscess and an increased likelihood of stenosis. The one acceptable application for a purse string

Figure 19.21 Soaking injured prepuce.

Figure 19.22 Orthopedic stockinette applied over prolapsed prepuce.

Figure 19.23 Latex tube inserted into preputial lumen for urine drainage.

Figure 19.24 Prepuce bandage with Elasticon and with tube held in place.

retention suture would be to facilitate the safe transport to slaughter.

Bulls with a particularly pendulous preputial prolapse may benefit from a support sling to lift the sheath and prolapsed tissues close to the body. A sling fashioned by cradling the prepuce and sheath in a large piece of burlap or other loosely woven material may be held in place with bungee cords across the bull's back (Figure 19.25). The support sling may be preferred to avoid adhesive scald from repeated bandaging in bulls with especially pendulous sheath or severe prolapse with deep laceration where prolonged treatment is necessary. Alternatively, a reusable support wrap (bull diaper) also employing bungee cords over the back can be utilized (Figure 19.26). Following resolution of swelling (infection/inflammation) a decision is then made to return the bull to use or surgically correct.

Figure 19.25 Support sling fashioned from burlap material and bungee cords.

Figure 19.26 Reusable bull diaper canvass construction with eyelets for attachment to bungee cords and laundry mesh "window" for urine egress.

Surgical Management of Preputial Injury

Avulsion of the Prepuce

Avulsion of the distal prepuce from its attachment on the dorsum of the free portion of the penis occurs most commonly in bulls that serve an artificial vagina (AV) for semen collection for artificial insemination. This injury rarely occurs during natural breeding. The prepuce adheres to the latex liner of the AV and the prepuce is torn loose from the penis when the bull makes the ejaculatory lunge. Contrary to other types of lacerations, those that occur in an AV should be sutured immediately. The wounds are quickly diagnosed and comparatively clean and excellent healing is expected with immediate primary closure of the wound. If the injury is not immediately closed by suture, surgical repair should be delayed until the wound is completely covered by healthy granulation tissue. With local anesthesia of the penis, prepare the surgical field for aseptic surgery, undermine the retracted prepuce, and slide it distally to the normal position and appose the prepuce to the free portion of the penis with absorbable suture.

Ring Amputation

Often a client will choose to cull rather than allow treatment. Because these bulls are the victims of severe price discrimination, I will offer a salvage-type procedure. A large swine rectal (prolapse) ring or short length of PVC pipe is placed within the preputial lumen dorsal to the lesion and a band is placed around the prepuce over the pipe. This will amputate the damaged prepuce, but fibrosis and stenosis will likely occur. Alternatively, holes can be drilled in the PVC pipe prior to placement and, rather than a band, heavy (6-mm) Braunamid™ is utilized in an overlapping pattern. The overlapping suture serves to both fix the tube and provide for hemostasis when the end of the prepuce is amputated [3]. This is the "ring amputation" procedure and can be performed with the bull standing, utilizing local analgesia and chute restraint [1]. This procedure usually results in some degree of stricture. It should be noted that correction with the circumcision technique remains an option for bulls in which the ring amputation results in a stricture and thus it might be considered for the client that desires a more economical option than lengthy medical treatment prior to surgical correction by circumcision (Figures 19.27 and 19.28).

Circumcision (Reefing)

The surgical technique for repair that is advocated by the authors is the circumcision or "reefing" technique. The bull

Figure 19.27 PVC pipe prepared for use in "ring technique."

Figure 19.28 Ring sutured in place, inside prepuce.

must be tabled and is often anesthetized, but this procedure can be performed with regional analgesia and heavy sedation. Prior to surgery, the bull is fasted for 36–48 hours and water withheld overnight. The bull is placed in right lateral recumbency and the hair of the sheath is clipped. The penis is extended and maintained in extension with towel forceps that engage the apical ligament. The penis and prepuce are prepped (NO alcohol) and draped. A tourniquet is applied utilizing 1-inch Penrose tubing, proximal to the area to be transected. The amount of prepuce to be resected is then determined (the remaining prepuce must be a minimum length of 1.5× the free portion). Two marker sutures are placed on what will be the adjoining edges of the suture line to ensure that tissues are returned in the proper alignment. Two circumferential incisions are made with these representing the edges of the epithelial tissue to be removed. These incisions are then joined with a longitudinal incision. The incisions are to be very superficial so that with careful, sharp dissection, underlying tissue, blood vessels, and lymphatics will be spared. The area of fibrosis should be included in the tissue removed. Following dissection and tourniquet removal (the tourniquet can be maintained safely for up to 1 hour); hemorrhage is controlled by vessel ligation and/or cautery. When hemostasis is achieved, lavage the area with a warm solution of sterile saline with 50 ml Betadine Prep Solution added per liter of saline. The edges are sutured with a simple continuous subcuticular pattern using your choice of 2–0 absorbable suture material.

Do not use a single continuous pattern, but instead end the pattern and restart in three stages to avoid a constrictive (purse-string) effect. Do not close dead space. This can then be followed with a row of staples or closed with your choice of suture pattern with 0 chromic gut. Then suture in place Penrose tubing over the end of the penis. An antibiotic ointment is applied to the wound and, placing the free end of the Penrose tubing into a 6- to 10-inch rigid tube, the penis and prepuce are carefully returned into the sheath and bandaged. The bandage can stay on as long as a week; the staples can be removed in two weeks. A support wrap (Bull diaper) or sling as previously described can be employed to protect the bandage and prevent pendulant swelling (Figures 19.29–19.39).

Amputation of the Prepuce

Amputation of the prepuce is occasionally performed on young bulls of *B. indicus* breed to prophylactically shorten an excessively long prepuce to reduce the likelihood of

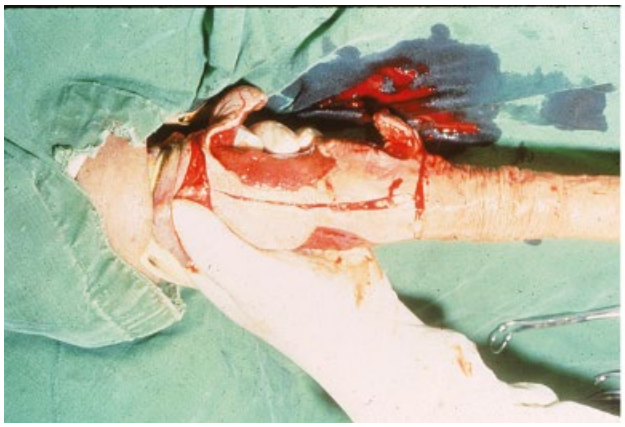
Figure 19.29 Penis extended in preparation for circumcision. Note loose excessive prepuce.

Figure 19.30 Determination of length of free portion of penis.

Figure 19.31 Proximal end of free portion indicated by surgeon's left forefinger.

Figure 19.32 Length of excess prepuce measured from end of sheath (surgeon's small finger) to preputial ring (surgeon's thumb).

preputial laceration when the bulls begin breeding. The advantage of this procedure is that it is quick to perform compared with circumcision. The disadvantage is that there is more elastic tissue removed, as well as underlying vasculature and lymphatics, and likely edge-to-edge apposition of skin, creating a higher incidence of preputial stenosis compared with circumcision. The surgeon should also keep in mind that the prepuce is a tubular structure and that with wound contracture stenosis is more likely.



With the bull adequately restrained for aseptic surgery, infiltrate local anesthetic in the skin of the sheath just proximal to the preputial orifice. Incise the prolapsed prepuce into the preputial lumen approximately one-third of its circumference and ligate bleeders. Suture the internal and external layers of skin with #0 absorbable suture using a simple continuous pattern. Repeat the procedure for the remaining two-thirds of the circumference of the preputial prolapse. Suture a Penrose drain over the glans penis as previously described and revert the prepuce into the preputial cavity. Place an elastic bandage over the sheath as previously described and manage postoperatively as for circumcision.

Preputial Reconstruction by Scar Revision

Following healing of a preputial laceration and when the length of the healthy prepuce is insufficient to allow circumcision, the bull may be returned to breeding soundness with scar revision and preputial reconstruction. Restrain the bull and prepare the prepuce for aseptic surgery. With the penis extended, excise only the superficial transverse scar tissue (Figures 19.40–19.43). Return the edges of the preputial laceration to their original longitudinal orientation. Loosely place an absorbable bootlace suture in a longitudinal plane such that the free ends are toward the sheath (Figure 19.44). Place a 2.5-cm Penrose drain over the free potion of the penis and revert the penis into the preputial cavity (Figure 19.38). Tighten the sutures to appose the skin edges as you allow the penis to return to within the prepuce (Figure 19.45). You will restrict retraction of the penis if you tighten and tie sutures prior to this.

The purpose of this procedure is to allow the surgical wound to heal in a longitudinal plane and to maintain normal elastic tissue function. Since no elastic tissue or preputial skin is removed with this procedure, first intention healing should reduce the risk of preputial stenosis and allow subsequent penile extension. Most bulls require 60–120 days for the penis to freely extend following this procedure. Do not forcefully extend the penis during the convalescent period as the potential trauma increases the likelihood of excessive scar formation. Most bulls begin to

masturbate within a few weeks following surgery and will stretch contracted tissues without permanent damage.

Phimosis

Preputial injuries that occur on *B. taurus* breeds typically result in phimosis rather than prolapse and therefore represent a different sort of challenge. If the penis is forcefully extended and then not repaired and replaced within the sheath at the same time, paraphimosis may result. The prepuce can be lavaged with an antiseptic solution. Then apply an ointment of your choice and allow second intention healing to occur. If there is extensive swelling, infection, and inflammation (phelgmon), it is usually best to allow the bull one to three months to heal as much as possible on its own before attempting surgical correction. Continued

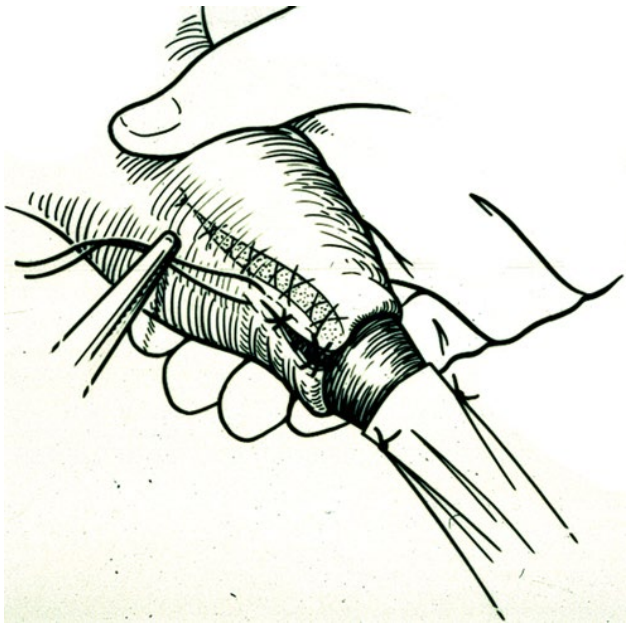

Figure 19.45 Schematic of closing incision with bootlace suture pattern when penis returned to retracted position.

treatment attempts in the face of extensive inflammation as described is virtually always unrewarding. Ascertain the extent of fibrosis and whether or not the penis can be extended (some bulls that can extend will still require surgery). In addition, it is common to encounter one or more abscesses. Scar tissue often must be removed to allow easy, painless, and full extension of the penis. Unlike *B. indicus* influenced bulls, these bulls rarely have enough preputial tissue to allow for a circumcision. A scar revision technique as previously described can usually be utilized.

Creation of Preputial Stoma

Occasionally bulls with preputial injury or frostbite develop extensive scar tissue such that there is insufficient length of healthy prepuce for scar revision and preputial reconstruction or circumcision. Creation of a stoma from the preputial cavity through the sheath may allow sufficient penile protrusion for semen collection. In my experience (Wolfe), two bulls were able to successfully complete coitus following this surgical procedure. With the bull adequately restrained and following preparation for aseptic surgery, make an elliptical incision through the skin. This incision is made on the ventral sheath sufficiently proximal to the scar tissue to penetrate the lumen of the preputial cavity (Figure 19.46). The diameter of the stoma should be sufficiently large to allow the free portion of the penis to extend, but not sufficiently large that the remaining prepuce may prolapse. Following removal of the elliptical skin, continue

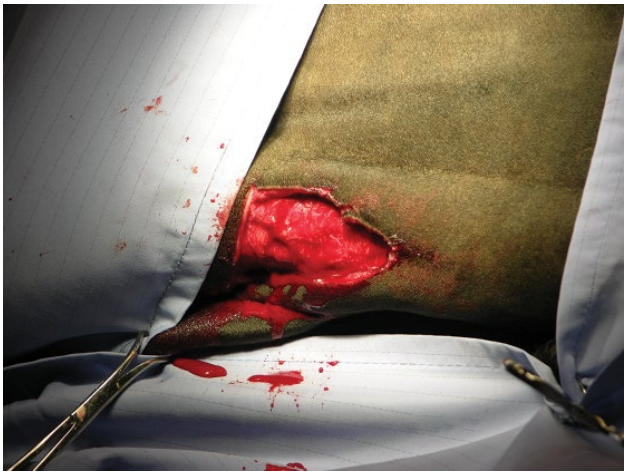

Figure 19.46 Triangular flap of skin removed from sheath (apex of triangle oriented toward scrotum).

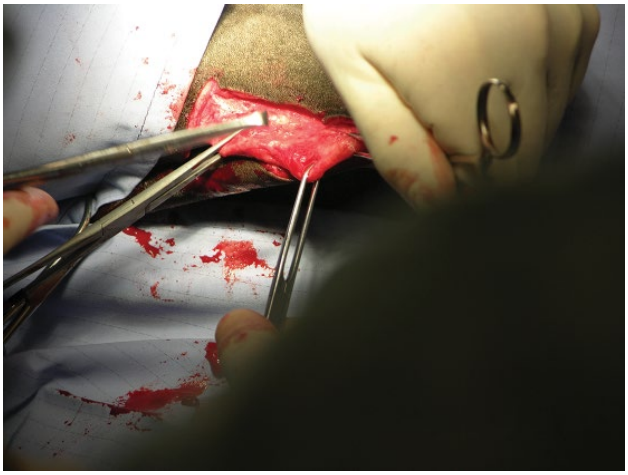

Figure 19.47 Prepuce elevated through incision in sheath.

dissection through the peri-penile elastic layers and elevate the prepuce through the opening in the sheath (Figure 19.47). Incise the prepuce (Figure 19.48) and exteriorize the free portion of the penile through the incision (Figure 19.49). Using #0 absorbable suture, appose the skin of the prepuce to the skin of the sheath with a simple interrupted pattern (Figure 19.50). Suture a 2.5-cm Penrose drain over the free portion of the penis to allow postoperative urine drainage away from the incision (Figures 19.51–19.53). Remove the Penrose drain 10 days postoperatively and allow 60 days' sexual rest prior to attempted semen collection (Figure 19.54).

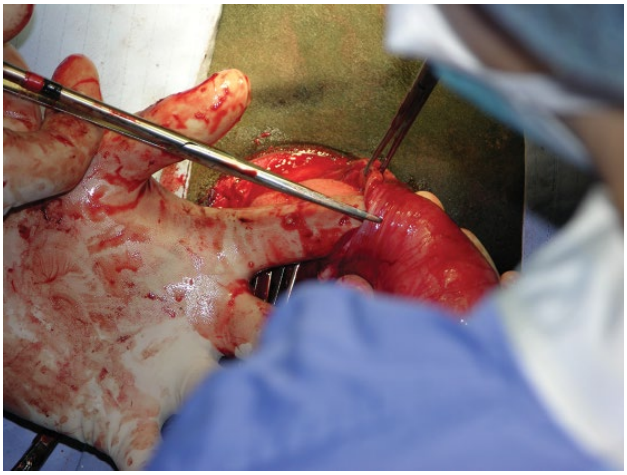

Figure 19.48 Incision into preputial cavity to create stoma.

Paraphimosis

Paraphimosis with resultant injury from penile exposure can be managed with a combination of medical and surgical therapy. Because of the inability to completely retract the penis, significant damage to the epithelial layers of the penis occurs (Figure 19.14).

Soaking the affected areas, as described previously for preputial prolapse, should occur immediately and be continued daily until there is a return to the normal appearance of the tissue. In between the therapeutic soaking the penis is covered with stockinette that has been coated in a suitable ointment (the authors' preference is one of the commercially available "bag balms"). Realize that three to four weeks of medical management is often required before the tissue is healed and surgery can be performed. Once the superficial layers are healed, a scar revision procedure as previously described to allow the penis normal retraction/extension can be performed.

Hematoma

Hematoma of the penis is probably the most common injury of the penis. This injury occurs when the penis misses the intended target, hits the cow's perineum, and bends. Although it usually occurs in young inexperienced bulls [4, 11–13] it can also occur in the older bull, which due to orthopedic injury or pain has altered his approach during mounting. From a seasonal standpoint, it usually occurs early in the breeding season when the bull is an aggressive breeder and a large number of females may be cycling, or conversely late in the breeding season when the bull may be fatigued and perhaps has lost body condition and is not as athletic or becomes awkward or clumsy during his breeding attempts. The hematoma results due to rupture of the tunica albuginea and subsequent hemorrhage from the corpus cavernosum. The initial volume of blood escaping is less than 250 ml [4], but the size of the

resultant hematoma varies as each subsequent erection results in further hemorrhage. Thus the hematoma may range in size from 15 to 30 cm. The resultant swelling occurs in the sheath over and cranial to the rudimentary teat (Figure 19.55). A prolapsed prepuce often results and this in fact may be the owner's reason for seeking help. Diagnosis may be aided with ultrasound, but, typically, a diagnosis is made from history and physical diagnosis. Do not attempt to aspirate the swelling, as inadvertent introduction of bacteria can convert a hematoma to an abscess.

Approximately 50% of bulls with rupture of the tunica albuginea return to breeding soundness without surgical repair of the injured penis. Conservative therapy consisting of absolute sexual rest for a minimum of 60 days (and avoiding extension of the penis) with systemic antibiotic therapy for the first 7–10 days is recommended. Daily hydrotherapy of the swollen sheath may stimulate circulation to the damaged tissues and assist with resorption of the edema and blood clot within the elastic tissues. If preputial prolapse is present, an emollient ointment should be applied and the protruding tissues protected with a support bandage or sling to prevent secondary trauma. The bull should have a complete BBSE prior to returning to service.

If surgery is to be performed, 5–7 days post occurrence has been shown to be the optimal timeframe [5]. Given that the owner or attendant typically may not notice this problem for 2–3 days and a 36- to 48-hour fast must occur prior to surgery, surgery must be scheduled immediately in an attempt to fit that best timeframe. Timely surgical correction avoids the clot organization and fibrosis that begins to occur 10 days post injury. Once the decision is made to attempt surgical correction, antibiotic therapy is instituted if not already begun and feed is removed. The bull is fasted for 36–48 hours and water withheld overnight. General anesthesia can be utilized or regional anesthesia with heavy sedation [14]. Either way, the bull is tabled in right lateral recumbency, with the left hind leg pulled back and up and fastened securely. The surgical area is prepped and a vertical incision 20–25 cm long is made just cranial to the rudimentary teat. Careful dissection, attention to hemostasis, and manual removal of the blood clot follow. Lavage with a warm saline + Betadine Prep Solution™ aids in the removal of additional clots and, coupled with blunt dissection, identification of the lesion (Figure 19.56). Careful blunt or manual dissection is not just preferred over scalpel or scissor dissection but mandatory, as injury to the area vasculature and nerves must be avoided. Specifically, the area near the dorsal nerve of the penis must be avoided. Since identification of this area can be confusing as penile manipulation changes the anatomical context, it is useful to identify the urethra which is on the ventral aspect of the penis and thus 180° from the dorsum.

After the tear or rent is identified, carefully lavage the area again and debride the often tattered edges of the rent. This must be minimal as excessive removal of tissue complicates closure and following healing there is the potential that the bull will have trouble extending his penis. Closure of the defect with No. 1 polyglycolic acid (PGA) in a bootlace pattern is the long-standing recommendation and justifiably so, as there is enough wound tension to make simple interrupted suture patterns problematic. The elastic layers over the penis can be closed with 3–0 chromic gut in a simple continuous pattern. The penis is then returned to its normal position within the sheath and the surgical field is irrigated with warm 3% povidone–iodine in saline. Gently remove remaining blood clots. The subcutaneous tissues are closed with 0 chromic gut and the skin can be closed with 6-mm Braunamid, typically with a Ford interlocking pattern. Antibiotics are continued for 5–7 days. The bull should have 60–90 days of sexual rest following

Figure 19.55 Hematoma location.

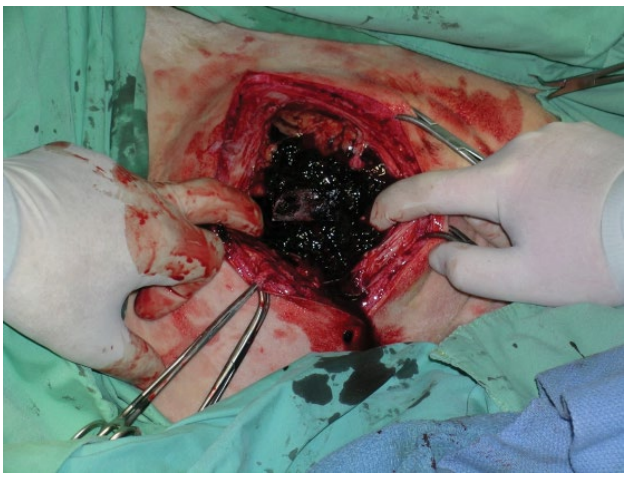

Figure 19.56 Rent in tunica albuginea.

surgery. Continue treatment of preputial prolapse as needed, but this condition usually resolves spontaneously within one week after surgery in *B. taurus* bulls. In *B. indicus* bulls the preputial prolapse may persist for longer than two weeks. In either case, it is wise to evaluate them for secondary damage to the prolapsed tissues. Seroma formation occurs often enough that it probably should not be considered a true complication. Complications include abscessation, suture dehiscence, shunts, permanent analgesia to the penis, and reoccurrence during the subsequent breeding seasons [2, 14]. Permanent analgesia may be the result of the original injury or an injury that occurs even following surgical resolution of the hematoma. In this later instance, the bull, having returned to service, sustains penile analgesia after breeding a few cows. Best evidence suggests that there are adhesions that surround portions of the nerves along the distal bend of the sigmoid flexure. These adhesions are not severe enough to restrict extension of the penis, but following repeated breeding they tear enough to damage the nerves [14].

Penile Deviations

Deviations of the penis may occasionally prevent intromission and coitus. Bovine penile deviations are classified as spiral (corkscrew), ventral, or S-shaped [4, 15–19]. Typically, bulls have had one or more successful breeding seasons prior to development of penile deviations with usually no known history of previous penile injury. Most bulls with these conditions are three or four years old and occasionally a bull over that age will develop penile deviation.

Spiral Deviation

Spiral deviation of the penis occurs more commonly than either ventral or S-shaped deviations. One potential etiology involves malfunction of the dorsal apical ligament. The apical ligament, a thick collagen band, arises from the dorsum of the tunica albuginea about 2.5 cm proximal to the distal end of the prepuce and inserts into the tunica albuginea near the distal end of the corpus cavernosum penis (CCP). The function of this structure is to help maintain the shape of the penis during erection [17]. Historically, spiral deviations were considered to result from a short or inadequate apical ligament that slipped off to the left side of the penis at peak erection, allowing the penis to spiral and therefore preventing intromission [16–18].

However, the rapidly coordinated events leading to erection and the high maximum pressures within the CCP at ejaculation suggest that affected bulls may prematurely achieve maximum erection pressures prior to intromission. This suggestion may be supported by the fact that the penis of many normal bulls likely develops a spiral orientation in a cow's vagina during ejaculation [19]. Although the definitive cause of spiral deviations remains uncertain, apical ligament malfunction and premature achievement of high CCP pressure may be involved.

Many bulls develop spiraling of the distal penis during electroejaculation and masturbation [20]. Therefore spiral deviation should only be diagnosed as a pathologic condition when it consistently develops during natural mating (Figure 19.57) [4, 17, 21].

Bulls with spiral deviation of the penis are most often three years old and have had a successful previous breeding season. Development of this condition may be insidious, occurring intermittently at first, then more consistently as breeding efforts continue. Therefore several test matings may be necessary to confirm the diagnosis. In *B. indicus* bulls the deviation may occur prior to penile extension such that the deviation remains hidden within the bull's pendulous sheath and excessive prepuce. For bulls with this sheath conformation, manual retraction of the prepuce during attempted breeding may be necessary to differentiate from erection or other causes of penile extension failure.

Ventral Penile Deviation

Ventral penile deviation occurs much less commonly than spiral deviation and the etiology is uncertain. Ventral deviations may occur as a result of altered blood flow through the ventral portion of the CCP or due to stretching or injury of the apical ligament, both of which probably result from chronic traumatic injury [1, 17, 18].

Figure 19.57 Spiral deviation.

Ventral penis deviation is obvious as long gradual curvatures of the erect penis (Figure 19.58). The curvature frequently originates proximal to the junction of the sheath and prepuce [17, 18]. These conditions become more apparent as erection pressure increases. Because ventral penile deviation can be induced during electroejaculation, observation during natural breeding is recommended, especially for less obvious cases. These conditions are only considered to be pathologic when they consistently prevent intromission.

Repair of Spiral and Ventral Penile Deviations

The prognosis for return to breeding soundness is greater following surgical repair of spiral than of ventral deviations. I recommend only attempting surgical repair of ventral deviations when the deviation is limited to the free portion of the penis. Spiral and ventral penile deviations are both repaired with a fascia lata graft. A narrow strip of fascia lata is sutured between the dorsal apical ligament and the dorsum of the tunica albuginea to serve as a fibroblast lattice to strengthen adjacent structures and stabilize the apical ligament on the dorsum of the penis [22].

Fascia Lata Graft Technique

This deviation as with those of a developmental etiology can be repaired with a fascia lata implant technique described by Walker and Young [22]. A rectangular strip of fascia is harvested from the bull, cleaned (areolar tissue removed), and placed between the apical ligament and the tunica albuginea. Alternatively, synthetic surgical mesh material can be used to substitute for the fascia implant. Utilization of the mesh has the obvious advantage of removing the time-consuming fascia harvesting step. However, problems with postoperative infection with the mesh materials of the day along with dissatisfaction with the apical ligament "strip" technique were the impetus stated by Walker for the development of this technique [22]. Thus, the fascia lata technique will be described and those that prefer to can easily modify the technique to utilize surgical mesh.

The bull is fasted for 48 hours and water withheld overnight. Depending on his nature, the bull can be sedated with 10–20 mg xylazine and 10 mg acepromazine IV. With the bull restrained and standing, the surgical site, an area on the upper left hindlimb, is prepped, since the bull will later be placed in lateral recumbency on his right side. A local block utilizing an inverted L injection pattern is administered. A 15- to 20-cm incision is then made utilizing the patella and greater trochanter as anatomical guides, with the incision being midway between. When the fascia lata is exposed, remove a rectangle-shaped section. Removing a 3-cm-wide by 15-cm-long section will provide more than enough tissue for your graft (Figure 19.59). Place the tissue in saline, maintaining sterility, and suture the edges of the fascia with a continuous pattern utilizing any No. 1 or 2 dissolvable suture. Failure to do so will result in painful muscle herniation. The skin can be closed with No. 3 Braunamid utilizing a Ford interlocking pattern. The harvested tissue is prepared by rinsing in saline and removing any attached tissue (Figure 19.60).

The bull is then prepared for the placing of this graft material. As with the other surgeries described, general anesthesia can be utilized or regional anesthesia with heavy sedation. The bull is tabled in right lateral recumbency and the preputial area is clipped and prepped. The penis is extended and the apical ligament identified and grasped

Figure 19.58 Ventral deviation.

Figure 19.59 Harvest of fascia.

Figure 19.60 Prepared fascia graft.

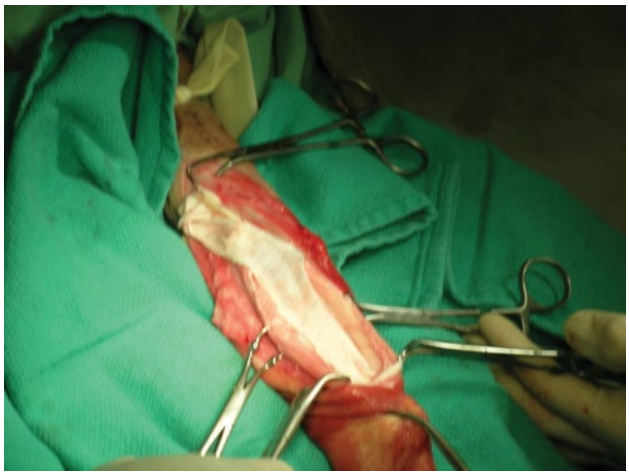

Figure 19.61 Placement of fascia graft.

with towel forceps. The penis is prepared with Betadine Surgical Scrub™, rinsed with sterile water or saline, and dried. Unlike when performing a circumcision, a tourniquet need not be utilized, as you will want to be able to easily visualize the area vasculature. An incision is made on the central dorsal aspect of the penis from a point 3 cm from the tip and extending 20 cm proximally. With careful dissection, identify the apical ligament and incise through it for its entire length. This incision will expose the tunica albuginea, and this is where the fascia or alternatively the synthetic mesh implant will be placed (Figure 19.61). The proximal aspect is placed first and sutures (2–0 chromic gut) are placed in the corners attaching the implant material to the tunic. Interrupted sutures are then placed on the lateral sides of the implant, stretching the implant so as to avoid crumpling of the tissue (Figure 19.62). Care is taken to not penetrate too deeply into the tunic and to avoid suture placement that impinges on the dorsal vasculature.

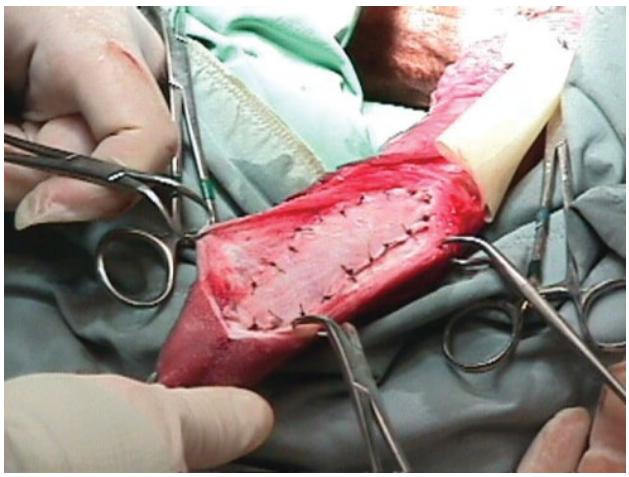

Figure 19.62 Suturing graft to tunic.

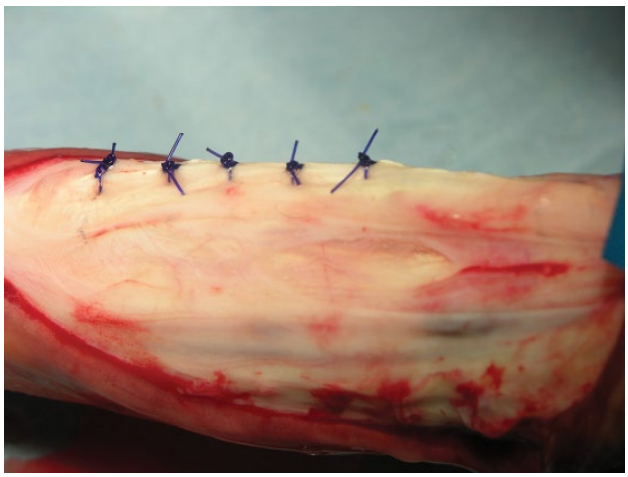

Figure 19.63 Closure of apical ligament.

Figure 19.64 Closure of penile and preputial epithelium.

The distal end of the implant is trimmed if necessary and the distal end is sutured as previously described.

The edges of the apical ligament are closed utilizing 0 chromic gut, with every other or every third suture engaging the implant (Figure 19.63). This suture will keep the apical ligament from slipping to the side, which is crucial if correcting a spiral deviation. The elastic tissues and dead space are closed with a continuous suture pattern (3–0 or 4–0 chromic gut) and the skin can be closed with 0 chromic gut or other dissolvable suture using an interrupted pattern (Figure 19.64). The incision site is gently rinsed with dilute Betadine solution, an antibiotic ointment (bovine intramammary infusion medication) is liberally applied, and the penis is returned to the prepuce. Systemic antibiotics are administered for 4–5 days and the penis can be manually extended for examination in 7–10 days. Three months of sexual rest is recommended.

Management of Urolithiasis

Gretchen Grissett

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

Urolithiasis is an economically significant disease of ruminants. In cattle, fatal urolithiasis is reported anywhere from 3 to 10% [1, 2]. Treatment and prevention of urolithiasis is a continual challenge for bovine practitioners and producers. The morbidity and mortality is devastating for not only steers in feedlots, but also breeding soundness for bulls.

Urolithiasis is a multifactorial disease involving diet, urine pH, and body water balance. Contributing factors include ruminant anatomy, factors favoring nidus development, factors precipitating solutes, and factors favoring cementing of stones. Uroliths occur when minerals precipitate from the urine and bind to an organic matrix or nidus [3]. The organic matrix is a mixture of urinary peptides, proteins, and mucopolysaccharides [3]. The proteinaceous aspect of the matrix can consist of desquamated epithelial cells, casts, or other urinary tract debris for infection or inflammation; however, this is uncommon in ruminants [3].

In cattle, urolithiasis typically falls into two categories: animals consuming high concentrate rations and pastured animals consuming grasses high in silica [4]. High concentrate rations usually fed with feedlot and show animals contain a low calcium to phosphorus ratio. High phosphorus rations typically create phosphate calculi (calcium, ammonium, and magnesium), with struvite being the most common [4, 5]. Ruminants afflicted with phosphate urolithiasis typically have multiple offending calculi that are smooth, soft, and sandy in appearance. These are the uroliths typically associated with calculi on the preputial hairs. Cattle grazing pastures in the western USA high in silica are most at risk of developing silicate uroliths. Silicate uroliths can even occur after removal of the offending forage [4]. Oat grain and oat straw are also high in silica and can be the etiology of silica urolith in the absence of grazing a pasture high in silica [4]. Cattle afflicted with silica urolithiasis typically obstruct with a single urolith that is rough, hard, and white measuring approximately 4–7 mm in diameter. One retrospective study reported 6.6% of cases afflicted with two distinct calculi [5]. Carbonate and oxalate uroliths are uncommonly encountered in cattle [4]. Carbonate uroliths are associated with consumption of legumes and oxalate uroliths are associated with consumption of oxalate-containing plants such as clover, halogeton, greasewood, soursob, and sorrel [6].

Uroliths tend to form in alkaline urine in ruminants with normal pH ranging from 7 to 9.5. Increasing urine pH results in increasing likelihood that urinary colloids will precipitate [7]. Uroliths that precipitate in alkaline urine include struvite, calcium phosphate, and calcium carbonate [4]. Urine pH has no effect on the calculogenesis of silica uroliths [3, 4].

Inadequate body water balance is a significant risk factor in the occurrence of urolithiasis. Dehydration results in increased solute concentration in the urine, providing more scaffold and calculogenesis opportunities. Seasonality can occur, with an increase of cases seen when decreased water consumption occurs. During the summer, palatable water sources and drought can result in decreased water intake. During times of extreme cold, voluntary decreased intake may occur. Herd outbreaks of urolithiasis can even occur if available palatable water sources are extreme.

The narrow, long, and tortuous male ruminant urethral anatomy contributes to the occurrence of urinary obstruction in cattle. The most common site for urethral obstruction in bulls and steers is the distal sigmoid flexure. Occurrence at the ischial arch is less commonly reported [8]. While urolithiasis is seen in castrated and intact males, obstruction tends to be most common in steers due to the narrower urethral diameter from the absence of testosterone. Early castration

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.
© 2021 John Wiley & Sons, Inc. Published 2021 by John Wiley & Sons, Inc.
Companion website: www.wiley.com/go/hopper/bovine

has been shown to result in decreased urethral diameter and increased incidence of urolithiasis [9, 10]. Steers greater than eight months of age are the most commonly presented for disease [9]. Because of the effect of castration on urethral diameter, some authors suggest delaying castration until six months of age [1]; however, ethical considerations and castration complications at this weight should be considered before implementation of this recommendation.

Other commonly cited implications for urolith formation include hypovitaminosis A, hypervitaminosis D, and estrogenic intake [1, 4, 8]. However, true evidentiary support in the literature is lacking. Hypovitaminosis A occurs when cattle are fed poor quality hay and silage stored for prolonged periods. Hypervitaminosis D is commonly a result of feeding error during ration mixing. Diethylstilbestrol implantation and estrogen intake are hypothesized to result in hypertrophic effect on seminal vesicles, urethras, and bulbourethral glands, thus increasing the risk for urolithiasis [1, 8, 10].

Clinical Signs

Clinical signs associated with urolithiasis vary based on the location and duration of the obstruction. Common clinical signs include listlessness, anorexia, colic, tail switching, posturing, vocalization (more common in goats), and dehydration. Less common signs include rectal prolapse associated with tenesmus. For urolithiasis associated with phosphate calculi, stones can be appreciated on the preputial hairs (Figure 20.1). For cases with a single obstructive urolith, careful palpation of the urethra along the length of the penis might assist with location of the urolith.

Figure 20.1 Urethral calculi visible on preputial hairs.

Acute urethral obstruction is commonly associated with acute colic symptoms such as bruxism, repeated stretching, treading of feet, and kicking of the abdomen in bulls and steers. In addition to the previously mentioned clinical signs, palpation of the preputial orifice and preputial hairs is dry, indicating no urine passage. Upon rectal palpation, affected individuals will have an enlarged urinary bladder and palpable urethral pulsations. Individuals with a partial urethral obstruction show signs of discomfort as well as dribbling of urine, stranguria, and hematuria. If a complete obstruction is left untreated for 48 hours or longer, a urethral rupture or bladder rupture will occur and signs of colic typically cease. If a urethral rupture occurs, subcutaneous edema develops along the ventral abdomen that can extend from the scrotum to the sternum, but especially in the preputial region (Figure 20.2). Severe necrosis and sloughing of these tissues can occur if left untreated. With bladder rupture, bilaterally symmetric ventral abdominal distention will occur ("waterbelly"). With bladder rupture, a palpable fluid wave will also be present. Upon rectal palpation, free abdominal fluid will be appreciable and a small partially filled urinary bladder. Bulls with uroabdomen may also develop a hydrocele. Owners typically report the colic associated with a complete urethral obstruction, then improvement for 24–48 hours, after which they notice the abdominal distention and worsening depression again. Dehydration is also severe (≥10%) with bladder rupture, due to osmotic pull of fluid from the vascular space into the abdomen. Individuals afflicted with ureteroliths and nephroliths will experience similar clinical signs as those listed above. A ureterolith and hydroureter may be palpable per

Figure 20.2 Subcutaneous peripenile swelling typically extends from the base of the scrotum cranially and involves the entire ventrum.

rectum, but often definitive diagnosis of ureteroliths and nephroliths does not occur antemortem.

Diagnosis

Urolithiasis can typically be diagnosed utilizing historical data and clinical signs. Additionally, rectal palpation and careful palpation of the penis can typically locate the site of obstruction and the presence or absence of a urethral or bladder rupture. For feedlot steers or economically constrained cases, treatment is implemented based on physical examination. However, for valuable individuals a complete diagnostic picture includes a complete blood count (CBC), biochemistry profile, and ultrasound.

The abnormalities observed with a CBC will typically coincide with the severity and duration of disease. Typical findings include a neutrophilia and possible hemoconcentration depending on the degree of dehydration. Cases with urethral rupture may have increased fibrinogen with excessive subcutaneous tissue necrosis. Common biochemical abnormalities include azotemia, hyponatremia, and hypochloremia. In ruminants, potassium can be normal or elevated in individuals with obstructive urolithiasis. When hyperkalemia is present, the degree of elevation is typically mild. One study experimentally induced uroabdomen and demonstrated increased salivary potassium excretion, possibly explaining the less severe hyperkalemia observed in ruminants with urolithiasis [11]. In small ruminants, Ewoldt et al. found individuals with no free abdominal fluid and a serum potassium less than 5.2 meq/l more likely to survive [12]. Individuals with urolithiasis may have a metabolic alkalosis, acidosis, or normal blood pH. When acidosis occurs, individuals are often severely dehydrated and suffering from lactic acidosis [13]. With prolonged obstructions, hyperphosphatemia and hypomagnesemia can occur and concerns of secondary renal failure should be considered. One study stated the best prognostic indicator was excessive serum phosphate being associated with increased likelihood of death [14]. In absence of hydronephrosis, 48 hours of fluid diuresis should be administered before diagnosing an individual in secondary renal failure. In individuals with uroabdomen, the degree of azotemia, hyponatremia, hypochloremia, and hyperkalemia can be severe due to the osmotic gradient across the abdominal wall pulling sodium and chloride into the abdomen, potassium and blood urea nitrogen intravascularly, with creatinine staying mostly intra-abdominally, since it diffuses at a slower rate being a larger molecule.

If available, ultrasound can be used to assist with assessment of the urinary tract. Ultrasonography can be used transcutaneously or transrectally to assess the integrity and location of uroliths. Additionally, ultrasonography can assist with diagnosing the presence of cystoliths, ureteroliths, or nephroliths. Cystoliths usually have a sandy debris appearance that is hyperechoic with a rough, irregular surface that casts acoustic shadows [15]. Ureteroliths and nephroliths are often difficult to diagnose antemortem, but are hyperechoic half-moon-shaped or round calculi that cast acoustic shadows through deeper tissues [15]. Ureteroliths may also be diagnosed via rectal examination if hydroureter is associated with the condition. Prior to surgical intervention, presence of hydronephrosis and/or hydroureter should be investigated. The right kidney extends from the 13th rib to the third lumbar vertebrae with the cranial pole in the renal impression of the liver in the 12tth intercostal space [15]. The left kidney can be imaged from the right paralumbar fossa caudal and is found slightly ventral to the right kidney from the 2nd to 5th lumbar vertebrae [15]. The left kidney can also be evaluated with transrectal ultrasound. If severe hydronephrosis is present, humane euthanasia is recommended (Figure 20.3). Presence of peripenile subcutaneous edema is suggestive of a urethral rupture and poor prognosis for returning to breeding soundness. Significant diffuse hypoechoic free fluid in the abdominal area is generally suggestive of uroabdomen. However, definitive diagnosis of uroabdomen is done by performing an abdominocentesis in either the flank fold of the abdomen or at the location of the fluid found ultrasonographically with an 18-gauge, 3.8-cm (1.5-inch) needle after surgical prep. An abdominal fluid creatinine to serum creatinine ratio of 2:1 or greater confirms the diagnosis of uroabdomen [11, 16].

A baseline urinalysis can be performed. Common abnormalities include hematuria, proteinuria, and alkalinuria. Diagnosis of bacteriuria is beneficial to ensure a primary urinary tract infection is not the etiology of the urolithiasis.

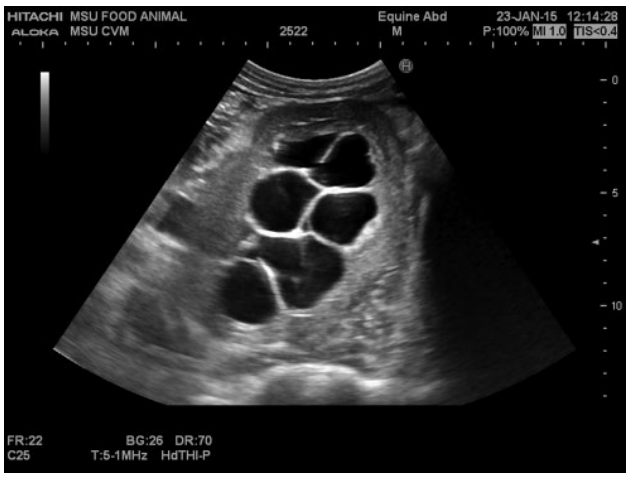

Figure 20.3 Severe hydronephrosis in a mature bull.

Baseline pH knowledge is important if urinary acidification is implemented. Ideally, if uroliths are obtained during surgery, the uroliths should analyzed to determine type. This information will help determine the best prevention strategy for the individual and herd. If urolith analysis is not feasible or delayed, a urolith can be placed in an acidifying solution to determine if urinary acidification would be a useful adjunct therapy. If available, urethroscopy can be utilized to assess location of the obstruction, extent of urothelial damage, and presence of strictures, or provide possible avenues for utilization of a laser or basket retrieval method.

Treatment

Immediate Care

Prior to initiating treatment for urolithiasis, the intended use of the animal, economics, site of obstruction, and integrity of the urinary tract should be considered. For acute cases, medical management can be attempted or immediate slaughter if uremia is not present. Most cases of urolithiasis will require surgical intervention. For breeding bulls, maintaining a patent urethra is paramount for successful outcome and breeding career. Surgical procedures utilized in breeding individuals include tube cystostomy, cystotomy, ischial urethrostomy, and urethrotomy. Surgical procedures utilized in salvage bulls and steers include ischial urethrostomy, perineal urethrostomy, and urethrotomy.

Before sedation or anesthesia, any severe electrolyte derangement should be corrected. For severe hyperkalemia, a bolus of 50% dextrose can be administered for an endogenous release of insulin to drive potassium intracellularly. Exogenous insulin can also be administered; however, this should be used with caution to avoid iatrogenic hypoglycemia. A bolus of hypertonic bicarbonate (8.4%) can also be administered to drive potassium intracellularly in individuals without metabolic alkalosis. For individuals with bradycardia caused by severe hyperkalemia, calcium borogluconate and atropine can be administered.

Saline (0.9%) is a good empirical choice for fluid therapy in treatment of urolithiasis. Saline will help correct the hyponatremia and hypochloremia often present in individuals with urolithiasis and will not exacerbate the hyperkalemia. However, if metabolic acidosis is present, saline should be avoided. For individuals greater than 8% dehydrated, intravenous fluid therapy is ideal. However, in field circumstances or economic constraints, hypertonic saline and oral fluids provide a reasonable alternative. In severe hypovolemia, fluid therapy should be instituted prior to sedation or tranquilization. Due to the diuretic effect, alpha 2-adrenergic agonists should never be used for tranquilization in cattle with urethral obstruction unless administered for sedation immediately prior to surgical relief.

Urethral rupture is diagnosed during physical examination. If present, this often will dictate the outcome and treatment plan for the individual. Generally, once a urethra has reached the point of rupture, severe urethral necrosis has occurred and attempting primary closure is futile. Typically, a perineal urethrostomy and salvage is the treatment recommendation with urethral rupture due to the high occurrence of urethral stricture at the site of rupture. If breeding soundness is desired, a urinary diversion technique such as a tube cystostomy or ischial urethrostomy should be performed to allow the site of urethral rupture to heal by second intention. However, prognosis for natural breeding soundness is poor due to the likelihood of peripenile adhesions from subcutaneous urine accumulation, as well as the possibility of urethral stricture and fistula formation. In cases with severe subcutaneous urine accumulation, skin incisions should be performed as needed to facilitate drainage to help reduce the degree of tissue necrosis, infection, and abscessation that occurs caused by the caustic nature of urine.

For cases with bladder rupture and uroabdomen, stabilization is required prior to pursuing surgical intervention. Ideally, intravenous fluids should be administered to correct severe dehydration and electrolyte disturbances prior to general anesthesia. For feedlot steers, hypertonic saline and oral fluids are a more economical choice. Drainage of urine from the abdomen should be performed with all cases of uroabdomen, but it is especially important to perform prior to placing any individual in dorsal recumbency. The drainage site should be surgically prepped and infiltrated with 2% lidocaine. A rumen trocar and cannula or thoracic catheter can be used to tap the abdominal cavity just medial to the caudal superficial epigastric vein [4]. The fluid should be drained slowly over 30 minutes or more preferably with intravenous fluid support to prevent circulatory shock. Rapid removal of uroabdomen at surgery should also be avoided because hypotensive crisis and death can occur. Ideally, the abdomen should be lavaged during surgery. However, cattle with uroabdomens do not develop peritonitis in experimentally created uroadodomen, so removal of urine is typically sufficient [11]. For valuable breeding animals, a cystorrhaphy is ideally performed via a standing laparotomy or ventral paramedian incision. However, access to the bladder can be difficult with a standing approach and often uroabdomen is the result of multiple small holes secondary to chronic overdistension and necrosis rather than a single rent. Often a ruptured bladder will heal without primary surgical repair. As long as the urinary bladder remains decompressed via a

tube cystotomy, ischial urethrostomy, or indwelling urinary catheter, the rent in the bladder will form a fibrin seal and heal. A ruptured bladder can also heal with a perineal urethrostomy if urethral patency is established. Ventral tears are less likely to heal without primary surgical repair. Spontaneous healing of the bladder occurs in approximately 50% of animals following urethrotomy and drainage of the abdomen [17]. Cases of experimentally induced uroabdomen survived an average of 14 days until death [11]. The survival rate in steers with urinary bladder rupture is reportedly 90% in animals treated with tube cystostomy [18] compared with 55% [19] and 86% [20] in animals treated with cystorrhaphy, with or without urethrotomy and transurethral catheterization, respectively.

Unless an individual is to be immediately slaughtered, antibiotic therapy should be administered in preparation for any surgical intervention. Additionally, antimicrobials should be considered in cases managed with retrograde catheterization or where a urinary tract infection is suspected. Generally, beta-lactams are appropriate due to their renal excretion. Antibiotics should be administered five to seven days postoperatively. For cases treated with an indwelling urinary tube or catheter, antibiotics should be administered for the duration of catheter or tube placement and continued for three to five days after removal.

Pain management should be administered to individuals treated medically and surgically. For postoperative pain, inflammation, and urethral swelling, non-steroidal anti-inflammatory drugs (NSAIDs) are recommended. Flunixin meglumine (1.1 mg/kg intravenous [IV]) is administered perioperatively for pain and inflammation. Caution should be used when administering flunixin meglumine to extremely dehydrated patients if immediate rehydration is not performed. Meloxicam (0.5–1 mg/kg per os [PO]) can be administered as needed postoperatively for pain. In cases where NSAIDs are insufficient for pain management, butorphanol (0.025–0.05 mg/kg intramuscularly [IM] or subcutaneously [(SC]) can be administered every six to eight hours in conjunction with NSAID therapy. Typically, the addition of opioids is only required for the first 24–48 hours postoperatively.

For cases with phosphatic calculi, urinary acidification is usually essential for treatment success. Ammonium chloride is recommended at 200 mg/kg orally every 24 hours for urine acidification. Due to the risk of causing metabolic acidosis, it is acceptable to start at 50 mg/kg orally every 24 hours and increase by 50 mg/kg until desired urinary pH is achieved. Phosphatic calculi will dissolve at a urinary pH range of 6–6.5, so the dose of ammonium chloride should be increased until this is achieved. Daily urinary pH should be monitored until a pH of 6–6.5 is reached. Feeding a dietary cation–anion difference (DCAD) ration is also an option to cause urinary acidification, but this is often difficult to implement for a single individual. In our clinic, we will often feed Soychlor®. Soychlor is utilized for DCAD rations in dairy cattle to aid in the prevention of hypocalcemia. For the cases in our clinics, we often feed 0.1–0.2 kg (0.25–0.5 lb) mixed with grain to create acidified urine. Soychlor eliminates the need for forced PO administration of ammonium chloride utilizing a balling gun to a patient and is easier than DCAD ration formulation. Urine acidification only needs to be performed until the clinician feels the stones dissolve due to the ruminant's ability for renal compensation and realkalization of urine. Further, long-term use of ammonium chloride can result in osteopenia.

Medical Management

Medical management is often unrewarding in the treatment of urolithiasis unless instituted early in the disease course. If the obstruction is recognized early, conservative therapy can be attempted with spasmolytic drugs and tranquilizers [2, 21, 22]. Phenothiazine tranquilizers are typically utilized which decrease urethral spasm and induce relaxation of the retractor penis muscles and straightening of the sigmoid flexure [2, 22]. In early cases, straightening of the sigmoid flexure and decreased urethral spasms may help urethral calculi to pass. However, if unsuccessful, retrograde urethral catheterization with hydropulsion can be attempted.

Retrograde catheterization is most easily performed in mature bulls versus castrated or prepubertal males due to the presence of persistent frenulum. Once exteriorization of the glans penis is accomplished, retrograde catheterization can be attempted with 8- to 10-French polypropylene tubing. Infusion of lidocaine may assist with urethral spasm prior to attempting hydropulsion with saline. If significant resistance occurs, further attempts should be abandoned to prevent further urothelial trauma, and surgical intervention is necessary. Catheterization and hydropulsion are typically unsuccessful in cattle due to the presence of the urethral diverticulum and the chronicity in which most individuals present.

Surgical Management

Tube Cystostomy

A tube cystostomy is associated with the best long-term prognosis in small ruminants for survival and breeding [12, 23–25]. This method provides urinary diversion, allowing the relief of urethral spasm and swelling and allows the urothelium time to heal. A tube cystotomy can be performed in dorsal recumbency via a paramedian incision or standing (Figure 20.4) via a left flank laparotomy (Figure 20.5) [26].

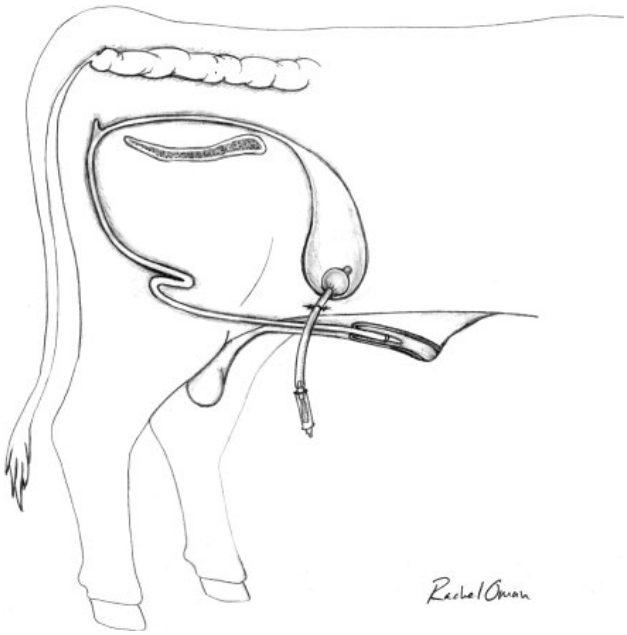

Figure 20.4 Placement of a Foley catheter in the tube cystotomy procedure. *Source:* Courtesy of Rachel Oman.

Figure 20.5 Placement of a Foley catheter in the flank tube cystotomy procedure.

For a paramedian tube cystostomy, general anesthesia is preferred, but a lumbosacral epidural and/or local anesthesia can also be utilized. The individual should be placed in dorsal recumbency and surgically prepped from sternum to pubis. If a uroabdomen exists, fluid stabilization and abdominal drainage should be performed prior to placement in dorsal recumbency. A 10- to 15-cm paramedian skin incision is performed approximately 2 cm lateral to the sheath approximately midway between the preputial orifice and pubis. A left-sided paramedian approach is preferred, so the rumen can assist with keeping abdominal viscera in the abdomen. If bladder rupture is suspected, the incision should be more caudal to assist with access to the smaller bladder often residing in the pelvis. Sharp and blunt dissection is used to access the linea alba and a routine celiotomy is performed. A paramedian celiotomy can be performed instead if preferred by the surgeon.

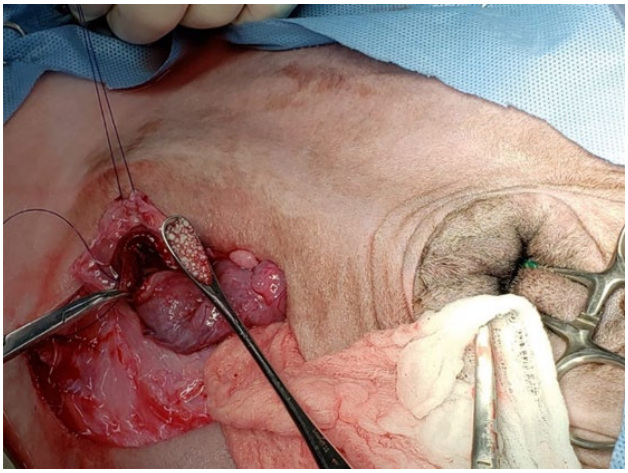

Figure 20.6 Utilization of stay sutures to assist with bladder manipulation and cystotomy. Utilization of a surgical spoon to assist with urolith removal.

Once the urinary bladder is localized, stay sutures with 2–0 or 0 monofilament can be placed in the bladder to assist with the cystotomy (Figure 20.6). A routine cystotomy is performed with aspiration of urine. Removal of uroliths from the bladder trigone and proximal urethra can be assisted with the use of a surgical spoon (Figure 20.6), as well as copious lavage and aspiration of sterile saline. An 8- to 10-French polypropylene catheter is then passed in a normograde fashion with hydropulsion to attempt resolution of the urethral obstruction. If the obstruction is not relieved or there is significant resistance, hydropulsion attempts should cease and the catheter should be removed. A stab incision is made 2 cm lateral to the paramedian skin through the skin and abdominal wall. A curved hemostat can be used intra-abdominally and directed toward the skin and incised over while placing pressure on the hemostat. The hemostat is used to grab the balloon end of a 20- to 30-French Foley catheter to assist with placement through the skin and abdominal wall. The balloon integrity of the Foley catheter should always be ensured prior to placement. Once the Foley catheter is in the abdomen, a separate stab incision is performed lateral to the primary cystotomy incision. A hemostat is placed through the stab incision of the bladder and the balloon end of the Foley is placed into the lumen of the bladder. The balloon is filled with the appropriate volume of saline.

Once filled, the balloon is directed toward the trigone of the bladder while the cystotomy incision is made and is sutured. A single- or double-layer continuous inverting pattern using absorbable monofilament 0 or 2–0 suture is used for the cystotomy and, if needed, cystorrhaphy. The balloon of the Foley catheter is pulled flush against the bladder and abdominal wall. Some surgeons choose to place a purse string suture around the Foley catheter [27]. The celiotomy, subcutaneous tissues, and skin are closed in a routine fashion. During closure, copious lavage with saline into the Foley catheter is important to prevent occlusion from any blood clots. A Chinese finger cuff ligature is used to secure the Foley to the ventral abdomen. After placement of the Chinese finger cuff ligature, saline should be flushed through the Foley catheter to ensure patency and confirm the ligature is not too tight.

A left flank tube cystotomy provides an economic alternative to tube cystotomy placement and avoids the risks associated with general anesthesia and dorsal recumbency. However, optimal access to the bladder is obtained through a ventral celiotomy. The left paralumbar fossa is aseptically prepped and flank anesthesia is performed. A 10- to 15-cm vertical skin incision is made with a routine celiotomy. Care should be taken to make the paralumbar fossa incision somewhat caudal to allow adequate access to the bladder. A needle and extension set can be used to drain excess urine from the bladder in particularly painful individuals attempting recumbency during surgery. The Foley catheter is placed through a stab incision through the skin and abdominal wall as described above on the caudoventral aspect of the incision. The balloon end of the Foley catheter is then placed through the apex of the bladder wall using a hemostat and bluntly forcing through the bladder wall. The balloon is inflated. If access is possible, a cystotomy should be performed on the dorsal aspect of the bladder to remove as many cystoliths as possible. Often a cystotomy is difficult with a standing procedure, so tube cystotomy alone can be performed, but recovery time will often be prolonged without removal of cystoliths. Closure of cystotomy or cystorrhaphy should be performed with 0 or 2–0 monofilament absorbable suture in an inverting pattern. The balloon of the Foley catheter is then pulled flush against the bladder and abdominal wall. A Chinese finger cuff ligature is used to secure the Foley catheter to the ventral flank. The abdomen and skin are closed in a routine fashion.

A one-way valve should be affixed to the Foley catheter to prevent air aspiration and minimize bacterial contamination. The fingertip of an examination glove with the tip slit affixed to the Foley catheter is a cheap, convenient one-way valve. After placement, a tube cystotomy must remain in place for a minimum of 7–10 days before removal to prevent any urine leakage from the defect created by the catheter. Urinary acidification should be implemented postoperatively for uroliths amenable to dissolution. Cystic acidification can also be administered with an acidifying solution seven days postoperatively with commercially available buffered acetic acid solution (Walpole's) or hemiacidrin (Renacidin®) [28]. A less expensive alternative for cystic irrigation is diluted acetic acid or 5% ammonium chloride solution [29]. Once urine dribbling from the preputial orifice or urination is observed, the Foley catheter can be occluded to more safely assess urethral patency prior to removal. One study reported dribbling of urine six to seven days postoperatively and free urine flow from the urethra nine days postoperatively [26]. The Foley catheter should be occluded for 48–72 hours with observed normal voiding before the Foley balloon is deflated and catheter removed. An average of 10–12 days postoperatively is required for small ruminants before successful voiding and Foley catheter removal [12, 23]. However, normal voiding can take as long as four to six weeks, especially if removal of cystoliths is not performed.

Complications of tube cystostomy include occlusion of the tube with blood clots, debris, uroliths, tube kinking, dislodgement or loss of catheter [26], balloon deflation, cystitis, uroperitoneum after catheter removal, adhesions to the urinary bladder, bladder atony, and failure to resolve urethral obstruction. Minimally invasive tube cystotomy [30] and laparoscopic-assisted placement [31] of cystic catheters have been described in small ruminants. Prognosis for survival in cattle treated with tube cystotomy is reported to be as high as 90% [18]. In cases without urethral rupture, utilization of a tube cystotomy provides a good treatment option for bulls to maintain breeding function.

Cystotomy

A cystotomy is ideally performed under general anesthesia with the individual in dorsal recumbency. Prior to creating the incision, the penis should be exteriorized and secured by clamping the apical ligament of the penis. A paramedian skin incision is performed lateral to the prepuce. The incision should be positioned relatively caudally to ensure adequate access and exteriorization of the bladder [27]. A paramedian or midline celiotomy can be performed. Once the urinary bladder is localized, stay sutures with 2–0 or 0 monofilament can be placed in the bladder to assist with the cystotomy. A routine cystotomy is performed with aspiration of urine. Removal of uroliths from the bladder trigone and proximal urethra can be assisted with the use of a surgical spoon, as well as copious lavage and aspiration of sterile saline. An 8- to 10-French polypropylene catheter is then passed in both a normograde and retrograde direction. Hydropulsion is performed with saline and may relieve the urethral obstruction. However, excessive force

and effort are contraindicated due to the risk of damaging the urothelium or causing a urethral rupture. The urethra is considered free of calculi when saline can easily be flushed normograde and retrograde [27]. If urethral patency is not obtained, a tube cystostomy should be performed. The bladder is closed with 2–0 or 3–0 monofilament suture in a single- or double-layer inverting suture pattern. In cases of bladder rupture, the defect should be repaired and/or any necrotic tissue removed. In cases of bladder rupture, aspiration and lavage of the abdomen should be performed. The celiotomy, subcutaneous tissues, and skin should be closed in a routine fashion. Disadvantages of this procedure include the expense and duration of the procedure, potential for urethral rupture, and extensive postoperative urethral swelling resulting in significant stranguria or postoperative obstruction.

Ischial Urethrostomy

Ischial urethrostomy is a viable treatment option for feedlot steers (≥318 kg) and breeding bulls [4, 32]. This procedure is performed under standing epidural anesthesia. The perineal region from the anus to the base of the scrotum is aseptically prepared. A 10-cm midline skin incision is performed starting over the ischial arch approximately 5 cm ventral to the anus [4]. The dense layer of fascia between the skin and retractor penis muscle is incised to expose the retractor penis muscle [4]. Blunt dissection between the retractor penis muscles reveals the bulbospongiosus muscle [4]. The urethrotomy incision is made through the bulbospongiosus muscle or just distal to its attachment [33]. Excessive hemorrhage is common during this procedure if the urethra incision is off midline and the corpus spongiosum is nicked. A 20- to 28-French Foley catheter is advanced into the bladder. Entrance into the bladder can be assisted with the use of a rigid stylet or curved hemostats to direct the tip over the ischial arch [4]. The Foley balloon is distended with saline and retracted until it is seated into the trigone of the bladder and sutured in place where it exits the skin. A one-way valve utilizing the fingertip of a glove with a slit should be taped onto the external end of the Foley catheter to prevent air aspiration into the bladder and minimize bacterial contamination. Ideally, impervious plastic should be adhered to the skin just ventral to the anus to prevent fecal contamination of the surgical site. For breeding bulls in which urethral patency is desired, a sterile bandage over the incision with stay sutures and surgical towels is recommended (Figure 20.7).

For feedlot steers, the catheter can remain in place until desired slaughter weight is reached or the uremia is resolved (~30 days) [32]. Additionally, this procedure can be used when a previous lower perineal urethrostomy site has strictured or reobstructed. In general, the prognosis is greatly reduced for individuals with bladder rupture. However, this technique allows the bladder to remain empty and heal by second intention.

Figure 20.7 Placement of a plastic or rubber (source-automobile inner tube) strip sutured to the perineum dorsal to the surgery site is recommended. *Source:* Image courtesy Dwight Wolfe and Misty Edmondson.

This technique can be a good option of urinary diversion for breeding bulls (without urethral rupture) because the urethral diameter is larger in this region, thus decreasing the risk of urethral stricture. If urethral patency is immediately obtained after the procedure, the Foley catheter can be removed and 3 mm polyethylene tubing is inserted through the urethrotomy incision into the bladder and exiting the distal urethra [4]. A primary urethral closure should be performed and the catheter exiting the distal urethra should be sutured to the ventral abdomen with a Chinese finger cuff ligature [4]. If urethra patency is not immediately obtained, the Foley catheter should remain in place to allow for relief of urethral spasm and swelling. If the obstruction fails to resolve after three to five days, alternative methods of calculi removal should be implemented. Other methods include retrograde catherization and hydropulsion, urethroscopy and possible basket retrieval, chemolysis (Walpole's solution, acetic acid, or hemiacidrin) for phosphatic uroliths (struvite or apatite), or urethrotomy. Long-term outcome and complication rates for breeding bulls have not been evaluated. However, there is one report of a goat with a strictured perineal urethrostomy being reversed with a buccal mucosal graft urethroplasty successfully [34].

Urethrotomy

Urethrotomy can remove individual uroliths or uroliths unamenable to dissolution with urinary acidification. This procedure is most utilized in breeding bulls since the urethra is not altered from its natural course. Additionally, this procedure is only a via option for individuals without urethral rupture. To perform the procedure, the urolith must be identified via palpation, catherization, or ultrasound. Depending on the location of the urolith, this can be performed under epidural anesthesia, general anesthesia, or sedation with casting harnesses. The individual is placed in dorsal recumbency, the urolith is located, and 2% lidocaine is infiltrated over the site of obstruction. The penis is grasped and a skin incision is performed. The penis is then exteriorized through the skin incision. A towel clamp or tissue forceps can be used to crush the stone and allow the fragments passage [4]. However, if this fails after two attempts, a urethrotomy should be performed directly over the urolith and the urolith(s) should be removed [4]. Some authors recommend bidirectional urethral flushing to ensure patency [21]. Urethral closure is then performed with 3–0 or 4–0 monofilament suture in a simple interrupted pattern. Suturing over a urethral catheter facilitates closure. The subcutaneous tissues and skin are closed in a routine fashion. Concurrent treatment with a urinary diversion technique such as tube cystostomy or ischial urethrostomy is ideal to allow adequate healing of the urethrotomy site. Urinary diversion allows resolution of inflammation at the urethra and thus prevents the risk of dehiscence or fistulation at the urethrotomy site. Alternatively, urethral catheterization can be used 24–48 hours postoperatively. Complication of urethrotomy includes urethral dehiscence and stricture especially if the urethral mucosa is devitalized. Peripenile adhesion is also a common complication that ultimate prevents a bull from reaching an erection and extension for breeding.

Perineal Urethrostomy

A perineal urethrostomy with penile amputation is a common salvage technique used for lightweight feedlot steers. This procedure is not intended for breeding individuals. Urethral stricture is an eventual complication of this technique; therefore it should be reserved for feedlot steers to resolve their azotemia and finish growth prior to slaughter. This technique is relatively quick and can easily be performed in the field.

It can be performed with the individual restrained in a chute under epidural anesthesia or in dorsal recumbency with heavy sedation and epidural anesthesia. The perineal area from the anus to the scrotum is clipped and aseptically prepped. A 10- to 15-cm midline incision is made immediately caudal to the scrotum. The incision is extended through the subcutaneous tissues and semitendinosus muscles. Blunt dissection is used until the penis can be grasped. The retractor penis muscles can often be confused for the penis. The retractor penis muscles are pink, soft, and identifiable as two separate components versus the firm penis which is covered in white tunica albuginea [21]. Once the penis is grasped, firm traction is used to pull the penis caudodorsally toward the skin incision, while the retractor penis muscles can be reflected or sharply dissected. Caudal traction and dissection are performed until a 6-cm segment of penis can be exteriorized without tension [21]. If substantial subcutaneous urine accumulation has occurred, the penis can separate from the preputial attachments, allowing exteriorization of the entire penis [4]. The dorsal penile artery and vein are identified and ligated approximately 5 cm distal to the dorsal aspect of the skin incision [21]. The penis is transected distal to this ligature. However, removal of the distal penis requires substantial dissection of the preputial attachments in cases with urethral obstruction but absence of urethral rupture. In these cases, the dorsal penile vasculature should remain intact and be blunted dissected and reflected from the penis.

Once the penis is transected, it is turned over 180° with the urethra now oriented dorsally. A horizontal mattress pattern using a monofilament non-absorbable suture is made through the corpus cavernosum to secure the penile stump to the skin [4, 21]. Caution should be used to not incorporate the urethra; a retrograde polypropylene catheter may be placed to ensure inadvertent urethral involvement is avoided (Figure 20.8). To assist with prevention of urine scald, the stump should extend 2–3-cm from the skin incision [21]. Spatulation of the urethra is optional (Figure 20.8). If performed, the urethra is incised from the distal aspect of the penile stump to the proximal aspect of the incision. The urethral mucosa and tunica albuginea are sutured to the skin using an absorbable 2–0 monofilament suture in a simple continuous or interrupted pattern. Spatulation of the urethra is performed to decrease the rapidity of urethral stricture formation [21]. The skin remaining proximal and distal to the urethrostomy site is closed in a routine fashion.

For individuals with a urethral rupture, subcutaneous skin incisions should be made as/if needed to drain any subcutaneous urine accumulation. Individuals with uroabdomen should have abdominal drainage of urine performed.

Potential complications from this procedure include postoperative hemorrhage from the corpus cavernosum of the penile stump and hemorrhage from repeated trauma to the penile stump. A securely fitted urethral catheter can be placed to put pressure on the corpus spongiosum to assist with hemorrhaging. Other common complications include urine scald, urethral stricture, and reobstruction with blood or calculi.

Figure 20.8 Perineal urethrostomy showing spatulation of the urethra and use of polypropylene catheter to assist with urethra location during suturing.

Other Procedures

Other treatment methods include laser lithotripsy, basket catheter urolith retrieval, and bladder marsupialization. Laser lithotripsy and basket catheter urolith retrieval will only be briefly mentioned here due to their limited use at referral institutions. Bladder marsupialization is only briefly mentioned due to the high complication rate in bovines.

Removal of urethroliths via laser lithotripsy has been reported in the literature for steers, goats, and pot-bellied pigs [35, 36]. An endoscope and laser fiber can be passed retrograde or normograde through an ischial urethrotomy [35]. Once the urethrolith is identified, the fiber is fired in a pulsatile fashion on the stone until fragmented enough to clear the urethra.

Basket catherization involves inserting a basket catheter into the urethral orifice and manipulating the instrument past the urethrolith. The instrument is opened, the urethrolith is maneuvered within the basket, and the catheter is removed. One report states a 55% successful urethrolith removal in calves [37] and another report successfully treated a bull with basket catherization while maintaining fertility [38].

Bladder marsupialization is often used in small ruminants as a last resort procedure with recurrent episodes of urethral obstruction. This procedure can also be utilized for detrusor muscle atony of the bladder. The apex of the bladder mucosa is sutured to the skin, allowing constant drainage of urine from the bladder. Numerous complications associated with this procedure include urine scald, bladder mucosa prolapse, stoma stricture, cystitis, and ascending pyelonephritis [12, 24, 25, 39]. It is not recommended for cattle. One study reported a mortality rate of 77% within two weeks of surgery [2]. Another study performed bladder marsupialization 12 hours after experimental induction of the urethral obstruction; of the six calves included in the study, one calf died and the remaining five calves had stoma stricture within three weeks postoperatively [40]. A novel procedure involving vesiculopreputial anastomosis has been described in small ruminants with a 50% success rate at six months postoperatively [41].

Prevention

The most important aspect of urolithiasis prevention is dietary modification. Ideally, the urolith(s) should be submitted to a laboratory for urolith analysis to determine composition. In the absence of this information, gross appearance of the urolith and ration evaluation should assist in figuring out the likely calculi involved. For phosphate calculi, excessive dietary phosphorus should be avoided, and rations should be adjusted to contain a calcium to phosphorus ratio of 1.5–2:1 and dietary magnesium should be less than 0.2%. Grain and alfalfa feeding should be reduced. For individuals fed a total mixed ration, roughage content should be evaluated. The primary excretion of phosphorus in ruminants is saliva, not urine. Therefore, if roughage is increased in the ration, rumination increases and salivary excretion of phosphorus is increased while solute in the urine is decreased. For silica uroliths, avoidance of at-risk pastures and feedstuffs is recommended. High-risk pastures can be used to graze female cattle instead of bulls and steers.

Adequate water consumption is critical in the prevention of urolithiasis. Ensuring access and availability to good quality water sources should be evaluated. If quality water sources are available, addition of sodium chloride to the ration should be considered to increase water consumption, ultimately creating dilute urine. According to Hawkins, sodium chloride has an effect of displacing magnesium and phosphorus from nucleation centers and thus preventing crystal development and urolith formation [1]. Silica uroliths form predominantly in the last 60 days before weaning; therefore a heavily salted creep feed is recommended for calves in the prevention of siliceous uroliths [4, 27, 42]. Sodium chloride can be fed up to 3–5% of the daily dry matter intake; this level of salt should be gradually increased to this level [4, 27].

Alternatively, reduction in urine pH can be attempted by feeding ammonium chloride at 0.5–1% of dry matter intake in a ration, which may help prevent apatite, struvite, and carbonate uroliths [27]. Feeding a DCAD ration can also be used to lower urinary pH in cattle. Silica urolith formation is not affected by urine pH. Caution should be used with long-term use; reduced bone mineral density has been reported in mature ewes fed anionic salts long term [43].

As previously discussed, urethral diameter is testosterone dependent. Delaying castration would result in a larger urethral diameter. According to Hawkins [1], a calf castrated at seven months of age could pass a urolith 13% greater in diameter and a bull could pass a urolith 44% greater in diameter than a calf castrated when one month old. While the evidence exists that delaying castration increases urethral diameter, the welfare consequences of delaying castration should be considered prior to implementation. Dietary modification and water consumption would be better areas of focus for prevention.

Preparation of Teaser Bulls

Gretchen Grissett

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

Historically, a key to a successful artificial insemination (AI) program has been accurate detection of estrus. Even with utilization of currently available estrus synchronization programs and timed AI, estrus detection is important as a tool to evaluate the efficacy of the protocol, troubleshoot problems in real time, and identify outliers that can be bred outside the prescribed "AI window."

Several estrus detection methods exist, including tailhead paint, mount detectors, self-adhesive heat detection patches, and visual observation. All these methods depend on female cattle standing for mounting during estrus. Thus these methods might miss females with weak or short estrus behavior [1]. By far the most efficient estrus detector is the bull, with the caveat that there is the benefit of male presence [2]. Therefore utilization of a teaser bull (intact sterilized male) is the most reliable method of estrus detection in the utilization of an AI program.

Several factors need to be considered when choosing a teaser bull procedure and each producer will have different needs and expectations. Besides the obvious need to render the bull sterile, other considerations would include herd status (open or closed herd). If an open herd, venereal disease transmission is an important factor to consider and prevention of intromission during mounting will be an important factor when choosing a teaser bull surgical procedure. Additionally, expected longevity needs to be discussed with the producer. On average, teaser bulls will last one to three years within a herd [1]. Decreased libido is the most common reason for culling, with excessive size and aggression being the next most common culling reasons [3]. To summarize, the main goals of surgical preparation of teaser bulls are to render him sterile, prevent intromission and therefore the transmission of venereal disease, and avoid excessive libido reduction [4, 5].

Proper bull selection is also an important aspect of teaser bull preparation. The ideal bull needs to be of moderate size, mild temperament, and easily handled. This bull also needs to be free of transmissible diseases. Of course, the bull also needs strong libido, but this can be difficult to assess in yearling bulls [4]. Teaser bull surgery should be performed well before the breeding season to allot time for healing and recovery from surgery. Ideally, the procedure should be performed on bulls less than 272 kg, primarily for ease of handling and decreased hemorrhage during surgery [4].

Teaser bull procedures can be divided into two categories: those that block semen flow and deliver sterility (vasectomy, epididymectomy) and those that prevent penile penetration (penile–prepuce translocation, penopexy, preputial pouch). Depending on the needs and expectations of the producer, any one or a combination of these procedures can be used for preparation of a teaser bull.

Vasectomy

As previously mentioned, vasectomy will render a bull sterile but does not prevent normal mating and copulation behavior. This procedure can be performed with the bull in standing restraint or recumbency, or a tilt chute may be used if available. The typical surgical approach is an anterior approach on the neck of the scrotum. However, if standing restraint is chosen, then the approach would be the posterior aspect of the neck of the scrotum. Figure 21.1 shows the procedure.

The neck of the scrotum should be clipped and aseptically prepared for surgery. Lidocaine 2% should be infused over the proposed incision site over each spermatic cord. A 3-cm incision should be made through the skin and tunica dartos over each spermatic cord. The spermatic cord is isolated by placing a hemostat underneath the entire spermatic cord.

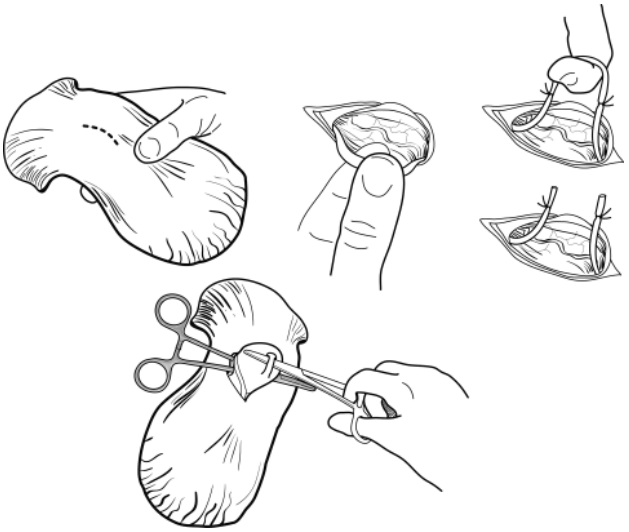

Figure 21.1 Procedure for vasectomy. *Source:* Illustration by Mal Hoover.

The ductus deferens is then identified via palpation. The ductus deferens is a firm structure that runs medially along the spermatic cord and is approximately 2–3 mm in diameter. Once identified, the tunica vaginalis is carefully incised, utilizing extreme caution so as not to damage the cremaster muscle or pampiniform plexus resulting in excessive hemorrhage. After the tunica vaginalis is incised, the ductus deferens is isolated with another hemostat.

Two ligatures are placed approximately 3–5 mm apart using #0 absorbable suture [4, 5]. The ductus deferens is removed between the two ligatures. The skin is closed with a cruciate pattern using nonabsorbable suture. Antibiotics can be administered to prevent any postoperative infection, especially if surgical contamination has occurred. It is recommended to wait 30 days prior to using the bull as a teaser animal, since sperm can be present in the reproductive tract up to 30 days postoperatively [4, 5]. Additionally, it is recommended to perform yearly evaluations of the teaser animal's ejaculate to ensure sterility of the animal.

Epididymectomy

An epididymectomy is similar to a vasectomy with regard to restraint options and copulation behavior [6]. For this procedure, the base of the scrotum is clipped and aseptically prepared. Lidocaine 2% is infused over the tail of the epididymis. Once prepared, the surgeon grasps the neck of the scrotum and pushes the testicle ventrally. A 3-cm incision is made over the tail of the epididymis through the skin and common vaginal tunic until the epididymis is exteriorized. The tail of the epididymis is carefully dissected from the testicle, and towel clamps or Allis tissue forceps can be used to assist in handling and manipulation of the epididymis. A hemostat is placed on the ductus deferens and the body of the epididymis. Ligatures with #0 absorbable suture are placed proximal to the hemostats. The tail of the epididymis is removed by transection distal to the hemostats. Figure 21.2 shows the procedure.

The common vaginal tunic is closed using #0 absorbable suture. The skin can be closed with non-absorbable cruciate sutures or the incisions can be left open to allow ventral drainage. Antibiotics can be administered to prevent postoperative infections. Postoperative resting recommendations and yearly ejaculate examinations are the same as previously stated for vasectomy aftercare.

Penile–Prepuce Translocation

Penile–prepuce translocation ("sidewinder") is the surgical transposition of the penis and prepuce from the ventral midline to the right or left flank of a bull. This procedure allows normal protrusion and erection but does not permit intromission. In general, "sidewinders" are preferred by producers due to longevity and herd retention of the teaser animal. Bulls with a penile–prepuce translocation maintain better and longer libido since this procedure allows normal protrusion and does not cause pain during erection. Some bulls are able to compensate and learn how to breed females despite the translocation of the penis and prepuce. Therefore it is recommended that a vasectomy or epididymectomy is performed to ensure sterility of the bull.

Penile–prepuce translocation is performed in lateral recumbency, so general anesthesia is the preferred method of restraint. If general anesthesia is not possible, heavy sedation with rope restraints and local infiltration of 2% lidocaine can be used. Ideally, food should be withheld for 24 hours and water for 12 hours before performing the procedure.

Prior to placing the bull in recumbency, the translocation site for the preputial orifice should be identified. The translocation site should be just outside the flank fold and lateral to the original preputial orifice site [3]. An 18-gauge needle can be used to abrade the epidermis so the location is not altered after placing the animal in recumbency and skin stretching occurs. The ventral abdomen from the umbilicus to just cranial to the scrotum and the site of translocation of the flank should be clipped and aseptically prepared. Flush the prepuce with dilute iodine solution.

Before making the initial incision, place one simple interrupted suture at the dorsal aspect of the preputial orifice to serve as a marker and prevent twisting of the prepuce during translocation. A circumferential skin incision around the preputial orifice is made 4 cm from the orifice or a total diameter of 8–10 cm (Figure 21.3) [3, 4]. Extend

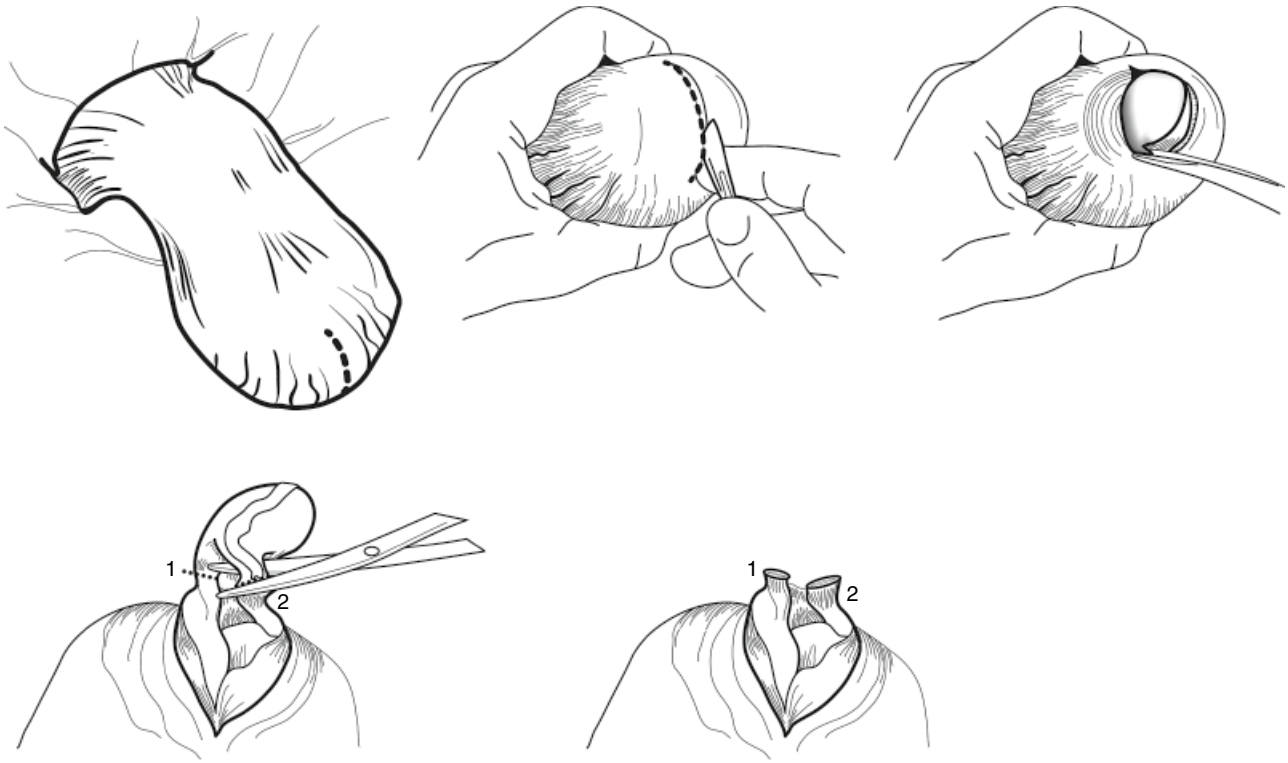

Figure 21.2 Procedure for epididymectomy. *Source:* Illustration by Mal Hoover.

Figure 21.3 Circumferential incision 4 cm from the preputial orifice is performed with an interrupted suture placed at the dorsal aspect of the preputial orifice to prevent twisting during translocation. *Source:* Photo courtesy of Tom Thompson.

the skin incision on the ventral midline from the preputial orifice to just cranial to the scrotum (Figure 21.4). Carefully dissect the penis and prepuce from the ventral abdomen. Avoid lacerating the prepuce; packing or tubing can be placed in the prepuce to aid with proper identification. While dissecting the penis and prepuce, avoid incising the dorsal penile vessels and control hemorrhage as it is encountered. Once the penis and prepuce are dissected, make a circular skin incision equivalent to the diameter of the preputial orifice at the desired translocation site (Figure 21.4). Use a sponge forceps to create a tunnel toward the flank incision. As the forceps is retracted, open it slightly to help facilitate penile translocation. This tunnel can also be accomplished with a cold sterilized polyvinyl chloride (PVC) pipe (Figure 21.5).

Place a sterile glove or sleeve over the preputial orifice to minimize contamination of the subcutaneous tissues. Then run a sponge forceps from the flank incision to the ventral midline incision and grasp the preputial orifice.

Figure 21.5 Use of a cold sterilized PVC pipe to facilitate tunneling of penile translocation and skin incision for the translocation site. *Source:* Photo courtesy of Tom Thompson.

Figure 21.6 Closure of new preputial orifice with interrupted sutures and ventral midline with Ford interlocking pattern. *Source:* Photo courtesy of Tom Thompson.

Manipulate the preputial orifice to the flank incision, taking care not to twist the prepuce (use a stay suture to ensure proper alignment). Suture the skin around the preputial orifice using #3 non-absorbable sutures with a cruciate or horizontal mattress pattern (Figure 21.6) [1]. Close the subcutaneous layer of the ventral midline incision with #3 absorbable suture, closing as much dead space as possible to prevent seroma formation. Close the skin with #3 non-absorbable suture in a Ford interlocking pattern. Place a cruciate suture at the cranial aspect of the incision to be removed for drainage if a seroma does occur.

The teaser bull should be monitored closely for 24 hours postoperatively to ensure he is able to urinate properly. Antibiotics should be administered for three to five days postoperatively to prevent infection. Allow four to six weeks of recovery time before using the teaser bull [3–5]. Penile–prepuce translocation is not a technically difficult procedure, but it is more invasive and can result in more postoperative complications. The most common complications are obviously seroma and abscess formation from the excessive dead space created. Another complication would be not translocating the preputial orifice high enough on the flank and thus the bull would still be capable of breeding a female animal. There is also one case report of a teaser bull developing paraphimosis with a penile–prepuce translocation [7].

Penopexy

Penopexy is the iatrogenic creation of phimosis by surgically creating an adhesion of the penis to the ventral body wall. This procedure prevents protrusion of the penis, thus preventing normal intromission or copulation. Penopexy is a relatively quick procedure and can typically be performed with sedation and local infiltration of 2% lidocaine. Tilt chute restraint or general anesthesia can also be utilized. Lateral recumbency is the preferred positioning.

The bull's ventral abdomen is clipped and surgically prepared from the preputial orifice to the scrotum. A skin incision is made 2–3 cm lateral of the midline and half the distance between the preputial orifice and scrotum approximately 10 cm in length. Carefully dissect the subcutaneous tissues until the penis is identified and exteriorized (Figure 21.7). Once the penis is exteriorized through the incision, identify the caudal reflection of the penis (fornix) and dissect the subcutaneous tissues on the dorsal aspect of the penis until the tunica albuginea is exposed for approximately 10 cm caudal to the fornix [4, 5]. Remove the subcutaneous tissue on the linea alba in conjunction with the dorsal aspect of the penis. The tunica albuginea and corresponding linea alba are scarified to promote strong adhesion formation. After preparation of both sites, the urethral groove is identified on the ventral aspect of the penis. Beginning 6–8 cm caudal to the fornix of the penis, pre-place four to six simple interrupted sutures approximately 2 cm apart using a heavy non-absorbable suture [4, 5]. The suture is placed through the dorsal third of the penis using care to not enter the urethra. The suture is then placed through a corresponding area of the linea alba (Figure 21.8) [4, 5]. Once all the sutures are pre-placed, return the penis to the normal anatomical position and ensure it is not protruding from the preputial orifice prior to securing all the sutures (Figure 21.9). Close the subcutaneous tissue with absorbable sutures and the skin with #3 non-absorbable suture in a Ford interlocking pattern. A vasectomy or epididymectomy is usually performed in conjunction with a penopexy to ensure sterility of the bull in case of procedure failure.

Allow three to four weeks of recovery to ensure proper formation of adhesions. The drawback of penopexy is the

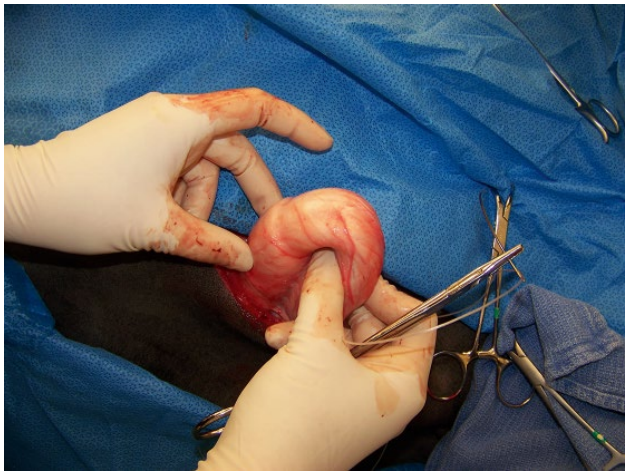

Figure 21.7 Exteriorization of the penis through the incision and identification of the caudal reflection of the penis.

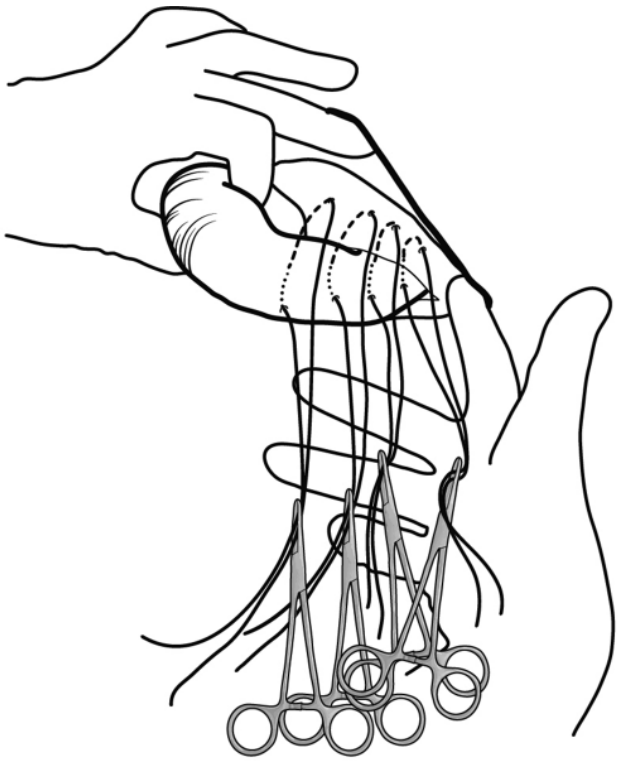

Figure 21.8 Preplacement of sutures through the dorsal third of the penis and linea alba. *Source:* Illustration by Mal Hoover.

risk of entering the urethra and decreased longevity in the herd since the bull will experience pain during attempted erection, thus decreasing libido. A follow-up study of 37 bulls found that 15% of bulls maintained good libido for one breeding, 30% for 1–1.5 years, and 42% for more than 1.5 years [5, 8].

A standing perineal penopexy approach has been described using light sedation and a caudal epidural. The

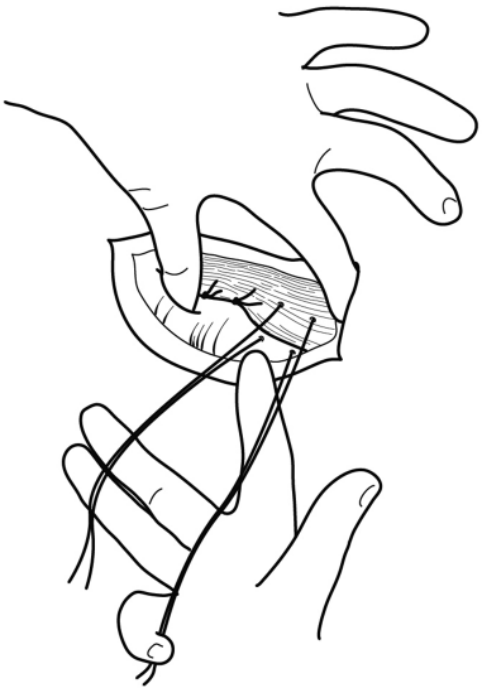

Figure 21.9 Securing the stay sutures for penopexy. *Source:* Illustration by Mal Hoover.

approach is over the distal loop of the sigmoid flexure [4]. A 4- to 5-cm incision is made through the skin and the tunica albuginea is exposed as mentioned previously. However, the stay sutures are placed on the lateral aspects of the penis and secured to the fibrous connective tissue in the perineal region of the bull [4, 5].

Preputial Pouch Technique (Ventral Slot with Preputial Orifice Obliteration)

The preputial pouch technique creates a fistula on the ventral prepuce and closes the normal preputial orifice. This technique prevents penile extension but allows for passage of urine through the ventral fistula. Teaser bulls with a preputial pouch are typically retained in the herd longer because libido is maintained for longer due to the lack of pain during attempted breeding [5]. This procedure is performed in lateral recumbency and can be accomplished with tilt chute restraint or sedation with local infiltration of 2% lidocaine. The ventral abdomen is clipped and prepared from the umbilicus to the midsheath region of the bull.

Prior to initiating surgery, the penis is extended and a Penrose drain is sutured around the glans penis with 2–0 polydioxanone (PDS). An approximately 1-cm-diameter elliptical incision is made through the skin 7 cm caudal to

the preputial orifice (Figure 21.10). The skin incision is extended through the preputial mucosa. The excised skin and mucosa are discarded. Then the internal mucosa of the prepuce is sutured to the skin of the sheath to create the fistula. An interrupted non-absorbable suture pattern is recommended (Figure 21.11a and b) [5]. Once suturing is complete, the free end of the Penrose drain is placed through the fistula. The Penrose drain will facilitate urine divergence while the primary incision sites heal.

The preputial orifice obliteration is accomplished by removing approximately 5 mm of the sheath skin and prepuce mucosal junction around the entire preputial orifice (Figure 21.12). This incision is closed in three layers: preputial epithelium, subcutaneous layer, and skin. The Penrose drain and sutures can be removed in two weeks. Allow three weeks of postoperative recovery time prior to utilizing the teaser bull [5].

The critical step in the preputial pouch technique is the size of the fistula. If the fistula is too small, proper urine flow is obstructed. If the fistula is too large, penile extension can occur with potential breeding. Therefore it is recommended to perform a vasectomy or epididymectomy to ensure sterility of the bull. Some bulls may pool urine in their preputial pouch and require postoperative flushing of the pouch. Thus this technique is not recommended for *Bos indicus* breeds since their pendulous sheath would predispose them to urine pooling and calculi formation [5].

Other Procedures

Other teaser bull procedures include iatrogenic preputial stenosis, artificial corpus cavernosal thrombosis, transection of the apical ligament, and penectomy. These procedures are briefly discussed, since their use has fallen out of favor due to high risk of failure, complication rates, and diminished libido.

Iatrogenic preputial stenosis involves a ventral mid-sheath approach to the prepuce and penis. The prepuce is identified and a stainless-steel rod or Steinmann pin is secured and tightened around the prepuce. Care must be taken to tighten the ring sufficiently to prevent penile extension, but loose enough to prevent urine pooling and balanoposthitis [5, 9]. Mixed success rates accompany this procedure. Complications associated with this procedure include excessive ring closure resulting in urine retention and balanoposthitis, complete stenosis resulting in subcutaneous urine accumulation, lack of stenosis resulting in penile extension and intromission, and excessive tissue reaction to the stainless-steel ring.

Corpus cavernosal thrombosis involves injection of an acrylic material into the corpus cavernosum of the penis [10]. The acrylic material results in thrombus formation that prevents erection. This method is performed with standing restraint under a caudal epidural. A midline incision is made over the penis. The distal sigmoid flexure is identified by locating the retractor penis muscle, with the proximal sigmoid flexure being approximately 15 cm proxi-

mally. A 14-gauge needle is inserted at the dorsolateral aspect of the penis at the proximal sigmoid flexure and the acrylic is injected. Non-absorbable stay sutures are placed at the lateral aspect of the penis at the level of the retractor penis muscle to prevent penile prolapse. Potential complications of this procedure include inadequate injection of acrylic into the corpus cavernosum resulting in procedure failure, or accidental injection into the corpus spongiosum or urethra resulting in urethral obstruction [5].

Transection of the apical ligament involves intentional transection of the apical ligament of the penis creating a ventral penile deviation and preventing intromission. The bull is restrained in lateral recumbency, either with heavy sedation and rope restraint or utilization of a tilt table. The penis is extended and a towel clamp is placed around the apical ligament of the penis to maintain penile extension. Prepare the penis and prepuce aseptically. Just proximal to the clamp, 2% lidocaine is infused subcutaneously under the epidermis of the penis. An approximately 2-cm skin incision is made longitudinally along the dorsum of the penis. Once the apical ligament of the penis is isolated, the ligament is transected extending to the tunica albuginea. The skin incision is closed with interrupted absorbable suture. Possible complications of this procedure include excessive hemorrhage with secondary seroma or abscess formation. Additionally, inadequate transection of the apical ligament could occur or healing of the ligament could allow breeding occurrence, so a vasectomy or epididymectomy is recommended in conjunction with this procedure.

Penectomy involves amputation of the penis. This can be performed by amputation of the glans penis at the fornix and suturing of the prepuce to the urethral mucosa [11]; alternatively this can be performed at the perineal region, suturing urethral mucosa to the skin [5, 11]. Amputation of the glans penis at the fornix results in teaser bulls that experience pain during breeding attempts, thus decreasing libido and herd retention time [5]. With penectomy via the perineal approach, bulls often lose interest and experience decreased libido due to the lack of coitus [11]. With either approach, urethral stricture is a risk factor.

Summary

Accurate heat detection is essential to any AI or embryo transfer program and teaser bulls are the best at detecting heat. There are multiple procedures for creating a teaser bull, with no single procedure being perfect. Each procedure has its advantages and disadvantages. Ultimately, the decision of which procedure to perform depends on the needs and expectations of the client (longevity of bull, postoperative complications, assured sterility). Additional factors that may impact procedural choice include facilities, veterinarian preference, cost, and herd status.

Anatomy of the Reproductive System of the Cow

Ben Nabors

Department of Clinical Sciences, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

The anatomy of the reproductive system in the cow is functionally grouped into the components associated with oocyte production and transport and those involved with gestation and copulation.

Production

The cellular machinery for oogenesis and steroid production is found in the ovary (Figure 22.1). The ovary consists of a cortex and medulla. The medulla is composed of connective tissue, lymphatic vessels, blood vessels, and nerves. Surrounding the medulla is the cortex. The cortex contains the ova surrounded by follicular cells within the connective tissue stroma [1]. Exterior to the cortex, the ovary is covered by the dense fibrous tunica albuginea and a superficial epithelium [2].

Because the ovary in the cow descends further from its embryologic origin near the kidney than other species, it is positioned closer to the pelvis. The consequence of this ovarian location and the attachment of the short mesovarium is that the uterine horns bend ventrally and caudally [3] (Figure 22.2). (Editor's note: for additional histological images of the ovary see Chapter 25.)

Transport and Gestation

The reproductive system of the cow is designed to transport spermatozoa toward the ovary and to transport an ovum toward the spermatozoa (Figure 22.3). The parts of this tubular system include the vestibule, vagina, cervix, uterine horns, and uterine tubes (oviduct).

Uterine Tube

The uterine tube is arranged like a funnel near the ovary. The funnel-shaped end, or infundibulum, contains processes, the fimbriae, which collect the ovum on ovulation (Figure 22.4). The ovum is then transported through the abdominal opening of the uterine tube located at the base of the infundibulum [4]. The ampulla of the uterine tube is the region adjacent to the infundibulum where fertilization takes place. The isthmus, the continuation of the uterine tube from the ampulla toward the uterus, is relatively long due to the meandering course it takes before ending at the uterine opening where it releases the ovum into the uterine horn [4].

Uterus

The uterus consists of a body and two horns (Figure 22.5). The body is short, beginning immediately after the cervix ends. The horns branch from the body but are joined together by the peritoneum, giving the appearance that the body is longer than it truly is. As the horns progress craniad they divide at the intercornual ligaments, each turning abruptly ventrally, then proceeding caudally, and finally ending dorsal to the ovary [3] (Figure 22.6).

From external to internal, the uterus can be divided into three layers: the perimetrium, the myometrium, and the endometrium [3]. The perimetrium is the continuation of the abdominal peritoneum onto the uterus. The myometrium constitutes the muscular layers, which can undergo substantial hypertrophy [5]. The endometrium is the internal epithelial lining of the uterus and is arranged into two distinct regions, caruncular and intercaruncular [6]. The caruncles are raised mucosal regions of the endometrium that are highly vascularized (Figure 22.7). The caruncles of the uterus join with the cotyledons of the fetal placental membranes to form the placentomes of a cotyledonary placenta [4].

Cervix

The cervix is located between the body of the uterus cranially and the vagina caudally (Figure 22.8). It is a firm, muscular, sphincter-like structure that acts as a barrier separating the external genitalia from the internal genitalia [5]. Characteristic of the cervix are the three to four circular folds projecting into its lumen.

The arrangement of the cervical musculature and mucosa is responsible for this characteristic architecture (Figure 22.9). The superficial mucosa is arranged in longitudinal folds punctuated by circular folds that interdigitate to form a series of ridges and interlocking notches when the cervix is closed [4]. This arrangement effectively seals the external environment from the internal uterine environment.

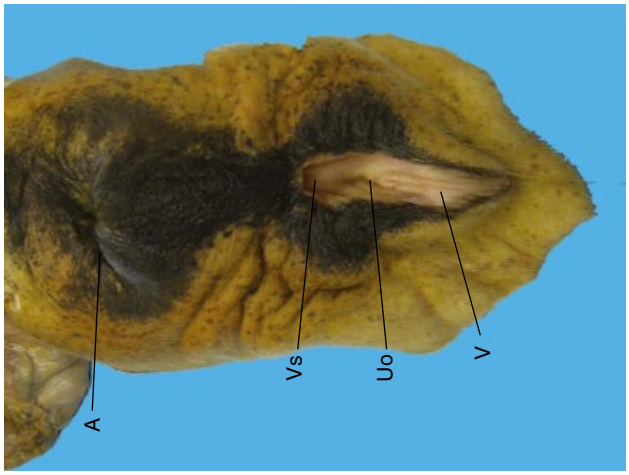

Figure 22.10 External view of perineum. A, Anus; Vs, vestibule; Uo, urethral orifice; V, vulva.

Vagina

The vagina is positioned between the caudal extent of the cervix and border of the vestibule at the external urethral orifice. The cervix projects into the lumen of the vagina caudoventrally, causing the dorsal vaginal fornix to form a deeper recess than the ventral fornix [4].

Vestibule

The vestibule is a small area in the cow that originates at the urethral opening and ends caudally to blend with the labia of the vulva.

Vulva

The labia of the vulva are located on either side of the labial fissure [3] (Figure 22.10). The labia meet dorsally, forming the dorsal commissure, and again ventrally to form the ventral commissure. The clitoris is found just cranial to the ventral commissure [3].

Blood Supply

The arterial supply to the reproductive system of the cow is provided by the ovarian, umbilical, vaginal, and internal pudendal arteries with their associated branches (Figure 22.11). The ovarian artery leaves the abdominal aorta, passing within the mesovarium to perfuse the ovary. The ovarian artery gives off branches to the uterine tube and the uterine horn [4]. The umbilical artery arises from the internal iliac artery near the pelvic inlet and sends out a uterine branch that supplies the cervix, body, and horns of the uterus. The vaginal artery arises directly from the internal iliac artery. The vaginal artery gives off a uterine branch that anastomoses with the uterine branch of the umbilical artery. The uterine artery formed by this anastomosis in turn anastomoses with the uterine branch of the ovarian artery, completing an arterial loop that supplies all the internal components of the reproductive system [4]. The internal pudendal artery is a direct continuation of the internal iliac artery. It courses caudally after the vaginal artery branches off within the ischiorectal fossa. The internal pudendal artery terminates as ventral perineal and dorsal labial branches [4].

The innervation of the external genitalia of the cow consists of the pudendal nerve and its branches. The pudendal nerve carries motor, sensory, and parasympathetic nerve fibers [2]. The pudendal nerve passes through the pelvic cavity medial to the sacrosciatic ligament and divides as it approaches the lesser ischiatic notch of the pelvis into proximal and distal cutaneous branches that supply the skin of the caudal hip and thigh [2, 3]. The pudendal nerve continues through the ischiorectal fossa and terminates as the dorsal nerve of the clitoris and a mammary branch [3]. Parasympathetic components of the pudendal nerve come by way of the pelvic nerve, which originates as a coalescence of branches of the sacral spinal nerves at the sacral plexus [4]. Sympathetic components of the pudendal nerve arise from the paired hypogastric nerves, which contribute sympathetic fibers from the caudal mesenteric plexus to the genital system [4].

Placenta

The cotyledonary bovine placenta is composed of the fetal cotyledons and the maternal caruncles that fuse and form the placentomes [4]. The placentomes are the sites for the transfer of maternal nutrients to the fetal circulation. The fetal membranes consist of two fluid-filled sacs. The innermost sac is the amnion, which surrounds the developing embryo; the outermost sac is the chorioallantois, which encircles the amnion and is composed of two separate tissues that fuse as the embryo develops. The outer layer is the chorion that develops from the trophoblast layer, which is the outer layer of the blastocyst of the embryo. As the embryo develops, the allantois, a sac that arises from the embryo hindgut, expands and eventually fuses with the chorion to form the chorioallantois.

Initiation of Puberty in Heifers

Charles T. Estill

Department of Clinical Sciences, Carlson College of Veterinary Medicine, Oregon State University, Corvallis, OR, USA

Introduction

Puberty is a critical physiological milestone in a heifer's reproductive life. In general terms, puberty can be defined as the process whereby animals become capable of reproducing themselves [1]. At the onset of puberty, a rise in plasma progesterone concentrations indicates cyclic ovarian activity before the first observed estrus [2]. Thus, puberty can be defined as the first day that serum progesterone (determined in blood samples collected at weekly intervals) exceeds 1 ng/ml [3]. Other authors define puberty as when ovulation is accompanied by visual signs of estrus with subsequent normal luteal function as evidenced by serum progesterone concentration above baseline for over two consecutive weeks [4]. Puberty involves a complex series of interactions between genetic, nutritional, and environmental factors that direct endocrine events that culminate in the attainment of reproductive capacity. In heifers, puberty is triggered when the hypothalamic–pituitary–gonadal axis first loses its sensitivity to the negative feedback effects of estradiol-17β, allowing a surge of luteinizing hormone (LH) to occur [5]. It is now accepted that puberty and first ovulation are not necessarily coincident since in most heifers "silent" ovulations and short luteal phases may occur during the peripubertal phase [5].

Endocrine Events

Puberty encompasses the transition from the anovular state to one of regular recurring ovulations. The mechanism by which the hypothalamic–pituitary–gonadal axis loses its sensitivity to the negative feedback effects of estradiol-17β has been the subject of research efforts for many years. The classical "gonadostat" theory, originally developed in a rodent model, appears applicable to cattle [6]. Ramirez et al. proposed that first ovulation results when sensitivity to steroid negative feedback diminishes, allowing sufficient gonadotropin output to drive follicular maturation, ovulation, and formation of a corpus luteum [6]. The hypothalamic–pituitary–gonadal axis of female cattle goes through several changes during its development. In utero, the fetus secretes gonadotropins for the first seven months of gestation. After this period, circulating gonadotropins are substantially reduced due to stimulation of the fetal central nervous system (CNS) [7]. In sheep, it has been demonstrated that the CNS-stimulated reduction in gonadotropin release that occurs in late gestation is mediated through inhibition of *N*-methyl-D-aspartate (NMDA) receptors, which have been demonstrated to be stimulatory to the gonadotropin-releasing hormone (GnRH) pulse generator nucleus in the fetal hypothalamus [8]. It has become well established that kisspeptin-1 (kiss-1) neurons are the final common pathway regulating GnRH neurons [9]. However, NMDA may also act directly on GnRH cell bodies in a kisspeptin-independent fashion [10]. Postnatally, mean plasma LH concentrations reach a maximum around three months of age, then slowly decline, before rising again and culminating in ovulation – typically around 10–11 months of age [11]. This transient increase in the circulating concentration of LH is associated with early follicular development and is thought to play a role in the timing of puberty.

In an attempt to hasten the onset of sexual maturity, Madgwick et al. [12] noted that the early rise in LH concentration was advanced by injecting heifer calves with GnRH twice daily from four to eight weeks of age. Treatment with GnRH increased mean circulating concentrations of LH at eight weeks of age, increased LH pulse frequency at four and eight weeks of age, and reduced the mean age at puberty by six weeks. Body weight gain was greater in

GnRH-treated calves than in control calves and the rate of weight gain was shown to be a significant covariate with age at puberty. This early transient rise in circulating LH stimulates ovarian follicular development, resulting in estradiol-17β synthesis that has a negative feedback effect on gonadotropin secretion [13].

Although an increase in circulating estradiol-17β has not been consistently demonstrated during this time period [14, 15], it is assumed the decline in LH is due to increased sensitivity to negative feedback by estradiol-17β on the hypothalamus–pituitary [14, 15]. From this point until just prior to puberty, estradiol-17β continues to exert negative feedback, after which sensitivity to the negative feedback effect of estradiol-17β gradually declines. This period is known as the peripubertal period and begins about 50 days before puberty [13, 16]. The decline in sensitivity to negative feedback by estradiol-17β has been associated with a reduction in the number of cytosolic estradiol-17β receptors in the anterior and medial-basal hypothalamus [16]. The result is that estradiol-17β becomes ineffective at suppressing LH secretion and an ovulatory surge of LH is released [17]. Progesterone levels are very low (300 pg/ml) in the peripubertal period, but there are two distinct elevations of progesterone prior to the first preovulatory peak of LH [18]. The return to baseline levels subsequent to the first elevation in progesterone is always followed by the priming peak of LH, while the second elevation in progesterone precedes the pubertal peak of LH [18]. The profile of concentrations of LH between the two major LH peaks, coincident with the second progesterone elevation, appears as a transition between prepubertal and postpubertal LH baseline concentrations. This suggests that progesterone plays a key role in the changes leading to the establishment of the phasic LH release characteristic of the postpubertal heifer by priming the hypothalamus to respond to E2 positive feedback [18]. During the peripuberal period, growth-related cues are monitored and regulate the activity of the GnRH pulse generator. When sufficient body size/composition is attained, the frequency of LH pulses increases because sensitivity to estradiol-17β inhibitory feedback decreases [14]. The high-frequency LH pulses stimulate follicular maturation and estradiol-17β accelerates the GnRH pulse generator, resulting in the ovulatory surge of LH [19].

Pro-opiomelanocortin (POMC) neurons in the arcuate nucleus (ARC) comprise a critical metabolic-sensing pathway controlling the reproductive neuroendocrine axis. The POMC–kisspeptin pathway may be important in mediating the nutritional acceleration of puberty in heifers [20].

The first ovulation is not synonymous with puberty and the first luteal phase is typically of shorter than normal duration. Prostaglandin ($PGF_{2\alpha}$) released from the endometrium is responsible for the reduction in luteal lifespan (premature luteolysis) following first ovulation in heifers [21, 22]. Presumably, this occurs because of an abundance of endometrial oxytocin receptors that mediate release of $PGF_{2\alpha}$ [23]. Subsequently, endometrial oxytocin receptor concentration is downregulated by exposure to progesterone for 12–14 days [24]. Frequency of LH pulses increases during the 50 days preceding first ovulation and reach about one per hour around the time of first ovulation [17]. Amplitude of LH pulses also increases during this time, but increased pulse frequency appears to be critical for initial ovulation [17]. Follicle-stimulating hormone (FSH) concentrations in blood do not fluctuate as much as LH in the peripubertal period, suggesting that FSH may play more of a permissive role in the initiation of puberty [18]. Other hormones undoubtedly play a role in initiation of puberty, but LH appears to be of paramount significance. Prolactin may play a role in heifer puberty, but blood concentrations do not change at puberty as they do in bulls. There is abundant evidence to suggest that heifers are actually capable of ovulating from early on in life but fail to do so because of insufficient gonadotropic stimulation. In fact, McLeod et al. [25] were able to induce preovulatory gonadotropin surges in GnRH-treated five-month-old heifers. Even more impressive was the research of Seidel et al. [26] who induced ovulations in one-month-old heifers with gonadotropin administration. Although ovulations can be artificially induced with gonadotropins, it is notable that the hypothalamus–pituitary becomes increasingly sensitive to GnRH stimulation as the time of puberty approaches. It has been shown that the positive feedback effect of estradiol-17β on surge LH release becomes functional between three and five months of age [27]. Collectively, available data indicate heifers are capable of ovulating long before puberty but fail to do so spontaneously until the inhibitory effect of estradion-17β on GnRH release wanes.

Development of the Female Reproductive Tract

Overall, body growth and development of the reproductive tract occur in an asynchronous pattern. For example, the ovaries grow at a rate 2.7 times faster than the body until puberty, whereas the tubular reproductive tract grows at about the same rate as body growth until about six months of age, and then enters a period of accelerated development until puberty [28]. No ovarian follicles are macroscopically visible at birth, but their numbers increase to maximal at four months, decrease through eight months of age, and remain relatively constant thereafter [28]. Growing and antral follicles increase in number during the first three to four months of age, which corresponds to the transient

increase in circulating LH concentrations observed during that time period [29].

Height of the luminal epithelium of the tubular reproductive tract is stimulated at birth but regresses by one or two months of age. Thereafter, increases in height of epithelia are most rapid after six months. From this information it is concluded, at least for Holstein heifers, that rapid peripubertal growth of the reproductive tract commences during the seventh month and is largely terminated by 10 months of age [28].

Factors that Influence Age of Puberty

It is generally accepted that puberty in cattle occurs at around 9 or 10 months of age. However, there are reports of puberty occurring any time between 6 and 24 months [1], with anecdotal reports of heifers calving at 13 months indicating that puberty can occur as early as 4 months of age. Recently, the author assisted an induced delivery of a near-term calf in a 14-month-old Shorthorn heifer, indicating that puberty in this heifer must have been around 5 months of age. Age at puberty is influenced by body weight and composition, breed, nutrition, genetics, and season of the year. Any adverse factor that decreases prepubertal growth, such as protein-energy malnutrition, scours, pneumonia, parasitism, or harsh weather conditions, results in delay of the onset of puberty.

Weight and Body Composition

An early study by Sorensen [30] showed that attainment of puberty in heifers was more influenced by weight than age. He found that heifers on a higher plane of nutrition reached puberty at an earlier age than similar heifers with lower average daily gain [30]. However, heifers may have similar body weights but vary in frame size, indicating they have differing body composition. For any given frame size, heifers that are heavier reach puberty at an earlier age. Body weight at puberty has a heritability coefficient of 0.40 [31]. Overall, heifers reared on higher planes of nutrition are heavier but younger than nutritionally restricted animals at puberty [32]. However, puberty does not occur at similar body composition or metabolic status in all heifers [33] but is positively correlated with body fat percentage and negatively correlated with carcass moisture percentage [33]. The precise mechanisms involved in the relationship of body composition and puberty are not clearly defined. However, it is known that somatotropin and the insulin-like growth factor (IGF)-I system are involved [34]. This fact was demonstrated by Armstrong et al. [35] who immunized heifers at three or six months of age against growth hormone releasing factor. By 14 months of age 75% of control heifers but only 22% of immunized heifers had reached puberty and had significantly fewer follicles >7 mm by six months of age.

Breed

Age and weight at puberty are affected by several factors, including breed. Generally, breeds of a larger size at maturity are older and heavier upon reaching puberty [36]. A classic example of the effect of breed on puberty is illustrated in the study by Laster et al. [37]. Their group found that female progeny of a Charolais bull were 50 days older and 120 kg heavier at puberty than progeny of a Jersey bull when all dams were Angus cows. Although the Charolais × Angus heifers grew faster than the Jersey × Angus heifers, they did not reach puberty at as young an age as the Jersey × Angus heifers due to breed effect, which, in this case, overrode the influence of rate of gain. Generally, European breeds reach puberty younger but at slightly heavier weights than Hereford or Angus heifers [37]. In a study on the effects of heterosis on age at puberty, Wiltbank et al. [38] found half to three-fourths of the heterosis effect on age at puberty was independent of heterosis effects on average daily gain. Individual sire within a specific breed also has a significant effect on age of puberty of female offspring. The heritability coefficient for age at puberty is 0.41 [31].

Plane of Nutrition

Body energy reserves and metabolic state are relevant modifiers of puberty onset and fertility. Heifers in a peripubertal state may be induced to ovulate by abruptly increasing the plane of nutrition [39, 40]. A study by Chelikani et al. [41] involving Holstein heifers illustrates this point. Heifers were fed to gain 1.1, 0.8, or 0.5 kg/day from 100 kg liveweight. Age at puberty for the three groups was 9, 11, and 16 months, respectively. Precocious puberty (<300 days of age) can be induced in beef heifers by early weaning and feeding a high-concentrate diet [42]. The mechanism by which early weaning and feeding a high-concentrate diet results in precocious puberty in heifers is associated with advancement of the reduction of estradiol negative feedback on secretion of LH. The mechanisms linking nutrition and metabolism to puberty are not clearly understood, but it appears several neuropeptides operating in a reciprocal manner (orexigenic and anorexigenic) are involved.

Kisspeptin is a primary candidate for modulating the effects of nutrition on reproduction. Kisspeptin acts in the role as a final common pathway to integrate stimulatory and inhibitory inputs to influence GnRH synthesis and release. Much of the work with this hormone has

been in a rodent model, but one may speculate that the same mechanisms are operational in cattle. Kisspeptin signaling in the hypothalamus has been suggested as the primary positive regulator of the GnRH pulse generator [43]. In the mid-1990s, the adipose hormone leptin was shown to be an essential signal for transmitting metabolic information to the centers governing puberty and reproduction and kisspeptins have emerged as conduits for the metabolic regulation of reproduction and putative effectors of leptin actions on GnRH neurons [44]. Leptin is produced by adipocytes and regulated by long-term and recent nutritional status [45]. Circulating leptin concentrations increase as puberty approaches but do not change appreciably in response to dietary change when percentage of total carcass body fat is above a minimum threshold, indicating that a certain minimum body condition is required for puberty [46]. Ghrelin and other metabolic effector hormones known to modulate the hypothalamic–pituitary–gonadal axis, such as neuropeptide Y, melanocortins, and melanocyte-concentrating hormone, are additional putative regulators of the hypothalamic/kisspeptin system [44].

Genetic Markers for Age at Puberty

Two of the major factors that influence reproductive efficiency and hence profitability due to greater lifetime production in cattle are age at puberty and postpartum anestrous interval. Heifers that have an earlier age at puberty generally have greater lifetime productivity. Age at puberty is moderately heritable, so selection over multiple generations should reduce the number of days to puberty. We now have the technology to evaluate genetic markers for age at puberty in cattle. For example, quantitative trait loci have been identified that predict male reproductive traits including age at puberty in cattle [47]. Similarly, random amplified polymorphic DNA markers have been used for identifying Nelore bulls with early (precocious) or late (non-precocious) puberty [48]. In heifers, an association weight matrix (AWM) has been constructed based on 22 related traits with single nucleotide polymorphisms [49]. The AWM results recapitulated the known biology of puberty, captured experimentally using validated binding sites, and identified candidate genes and gene–gene interactions for further investigation. Takada et al. [50] evaluated Nelore heifers to detect known polymorphisms in candidate genes related to sexual precocity and identified five genes that influence sexual precocity. Advances in genomic technologies will likely provide a powerful tool for selecting heifers at birth that will have a greater probability of being reproductively successful if managed correctly [51].

Correlation Between Sire Scrotal Circumference and Age at Puberty of Daughters

Early studies reported a favorable correlation between yearling scrotal circumference (SC) in bulls and age at puberty in half-sib heifers in populations of purebred animals [52, 53]. Estimates of genetic correlation between SC in yearling bulls and age at puberty in half-sib heifers of −0.71 and −1.07 (favorable) have been reported by Brinks et al. [52] and King et al. [53] In a study designed to estimate genetic correlations between testicular measurements and female reproductive traits in Hereford cattle, the authors concluded that heritability of female reproductive traits tended to be low to moderate but "selection for increased testicular size would lead to improvement in female reproduction, particularly an increase in calving rate and a decrease in age at first breeding" [54]. A favorable relationship between SC in Brahman bulls and age at puberty in Brahman heifers reared under subtropical conditions has also been reported [55]. However, more recent work suggests that the correlation between genetic response in female reproductive traits (including age at puberty) and sire yearling SC may be expected to be less than previously reported in the literature. The study by Martinez-Velazquez et al. [56] calculated the correlation between yearling bull SC and age at puberty in daughters to be only −0.15. Morris et al. [57], in a 14-year study involving Angus cattle, reported a correlation of −0.25 between sire SC and age of puberty in heifer offspring. In an Australian study, no significant relationship was found between age at puberty in heifers and age and SC at puberty in related bulls [58]. Results of a subsequent experiment designed to investigate this correlation using Limousin bulls bred to crossbred cows indicated that selection of resulting replacement heifers based on sire SC phenotype did not significantly influence heifer age at puberty [59]. However, when sire SC estimated progeny difference was used instead, selection resulted in a significant reduction in heifer age at puberty. The authors concluded that when sires are selected for high SC estimated progeny difference within a crossbreeding system, a large percentage of heifers should reach puberty early enough to calve at two years of age or younger. Nonetheless, it has been reported that age of puberty in bulls, based on attainment of a critical SC, is correlated with age at puberty in female offspring [60]. One explanation of the conflicting data may be that heterosis has a significant effect on the percentage of heifers reaching puberty by 368, 410, and 452 days, with the greatest effect at the younger age [61].

Management Options to Influence Age at Puberty

Management of replacement beef heifers should focus on factors that enhance physiological processes that promote puberty [62]. Procedures that ultimately affect lifetime productivity and reproductive performance of heifers begin before birth and include decisions that involve growth-promoting implants, feeding, breed selection, calving and weaning date, social interaction, sire selection, and exogenous hormonal treatments to synchronize or induce estrus. This is especially relevant in systems where heifers are expected to calve by two years of age or where the breeding period is restricted [36]. Heifers that calve as two year olds produce more calves in their lifetime than heifers that calve as three year olds [63]. Breed and postweaning rate of gain have a large influence over onset of puberty [36]. For optimal fertility, heifers should not be bred at their pubertal estrus as calving rate has been reported to be 21% less than for heifers bred at third estrus [64]. This implies that heifers should reach puberty within one to three months before the age at which they will be bred in order to mitigate the reduced fertility associated with breeding at pubertal estrus.

Photoperiod

Consideration should be given to time of year when calving occurs. Although cattle are not considered to be strictly seasonal breeders, there is a seasonal effect on reproduction. For example, it has been reported that fertility, cycle length, and postpartum anestrous period length vary with season. More specifically, a winter environment (northern hemisphere) delays onset of puberty. Schillo et al. [65] reported that fall-born heifers were younger at puberty than those born in spring, and that heifers exposed to simulated changes in daylength from spring to fall after six months of age showed advanced onset of cyclic ovarian activity. The effect of season is likely mediated through photoperiod and is not a direct consequence of improved nutrient availability. As further evidence of this effect, puberty can be advanced in heifers by administration of melatonin-containing implants [66]. Treatment of three- to four-month-old winter-born heifers with exogenous melatonin for a period of five weeks at the beginning of summer significantly increased the incidence of animals attaining puberty by March of the following year (58 vs. 17%) [66]. Exposure of prepubertal heifers from 22 or 24 weeks of age until first ovulation to an artificially extended photoperiod will also advance first ovulation [67].

Growth-Promoting Implants

Growth-promoting implants are widely used in the beef industry. However, in heifers to be retained for breeding, implants containing estradiol, zernol, or trenbolone acetate inhibit the development of a mature reproductive endocrine system when administered to suckling beef heifers and consequently delay onset of puberty. For example, zeranol implants at birth delay the onset of puberty and decrease uterine horn diameter. Furthermore, zeranol-implanted heifers have lower pregnancy rates and higher rates of abortion than non-implanted herdmates [68]. In contrast, Rosasco et al. [69], in a study comparing performance of crossbred Angus heifers implanted with Synovex® C (Zoetis, Parsippany, NJ, USA) at three months of age, reported no deleterious effects on reproductive performance through four calving seasons (note: product label specifies for heifers 45 days and older up to 400 pounds). The implanted calves were heavier at weaning than control heifers such that producers who do not make selection of replacement heifers until weaning may expect some profit advantage from heifers not retained as replacements. Replacement heifers that are identified early in life should not be implanted as there is no benefit in terms of age at puberty or incidence of dystocia.

Use of Progestins to Advance Onset of Puberty

It is well established that progesterone sensitizes the hypothalamus to the positive feedback effect of estradiol-17β that results in the preovulatory LH surge. Progestin administration hastens puberty by accelerating the peripubertal decrease in estradiol-17β negative feedback effect, thereby facilitating the LH surge [72]. Furthermore, progesterone priming has been shown to enhance follicular estradiol-17β synthesis in ewes [70] and it has also been demonstrated that circulating estradiol-17β concentrations were higher at the first ovulatory estrus than in the preceding silent estrus [71]. As an example of the use of an exogenous progestin, melengestrol acetate (MGA) fed for eight days followed by withdrawal, in turn, enhanced onset of puberty by stimulating pulsatile LH secretion that accelerated follicle growth to the preovulatory stage [73]. In synchronization programs for heifers that may be peripubertal and prone to premature luteolysis, the incorporation of a progestin improves pregnancy rates. Treatment with some progestins, but not others, before first ovulation was able to eliminate the occurrence of short-lived corpora lutea [74–76]. Specifically, progesterone administered via intravaginal implant for five days was found to be more effective in

reducing incidence of premature luteolysis after GnRH-induced ovulation than oral MGA [75].

Nutritional Optimization of Puberty

Rapid growth from birth to weaning (6–10 months) and from weaning to puberty (11–16 months) is critical for beef heifer calves to attain puberty at an early age. It is now clear that the interval between four and nine months of age is a critical period for metabolically programming the neuroendocrine axis to achieve early reproductive maturation. The requirement for rapid growth in breeding heifers is to ensure that they will reach puberty in advance of the breeding season and be bred to calve by 24 months of age. Therefore heifers must exceed both the age and weight "threshold" to attain puberty. Nutritional programs for breeding heifers are designed to grow animals at a rate that allows them to exceed the weight threshold before or soon after the age threshold for puberty is surpassed [77]. Across several breeds, heifers were 55–60% of mature body weight at puberty [78]. The practice of developing heifers to reach a target body weight (typically ≥65% of mature weight) prior to breeding is commonplace in the industry. However, one must bear in mind that the target body weight will vary by breed. Methods to estimate effects of heifer nutrition protocols have been developed. For example, residual feed intake (RFI) is the residual from a regression model regressing feed intake on average daily gain (ADG) and body weight $(BW)^{-0.75}$ [79]. Body fat stores are greater in heifers with greater RFI than in their more efficient herdmates. A 1-unit increase in RFI resulted in a reduction of 7.54 days in age at puberty in *Bos taurus* beef heifers. However, *Bos indicus*-influenced heifers, which reach puberty at older ages, were not found to have sexual maturity influenced by selection for higher RFI [79]. From a management standpoint, selection for low RFI results in selection of leaner heifers that reach puberty at older ages [79]. Therefore, at some point, it becomes counterproductive to select replacement heifers on the basis of low RFI. This is because reproduction has been reported to be five times more important to commercial cattle producers than growth rate or milk production [80], and heifers that calve early in their first calving season tend to calve early throughout their lives and have greater lifetime calf production [81].

Precocious puberty (<300 days of age) in beef heifers can be induced by early weaning and continuous feeding of a high-concentrate diet. As in the case of progestin administration, puberty is preceded by increasing frequency of LH pulses [82]. Heifers experiencing induced precocious puberty weigh significantly less at puberty than their traditionally weaned and fed counterparts [82]. Furthermore, it has been determined that feeding a high-concentrate diet from 126 days (after weaning at 112 days) through 196 days was as effective at inducing precocious puberty as continuous high-concentrate feeding [83]. Taken together, data indicate that high preweaning growth rate and heavy weaning weights are associated with early puberty and heavier weight at puberty [84].

The concept of fetal programming was proposed by Barker [85] to explain a geographical association between poor maternal physique and health, poor fetal growth, and high death rates from cardiovascular disease in adult humans. Similarly, there are numerous studies in animals that demonstrate that transient adverse events in prenatal or early postnatal life have enduring and profound effects on physiology, although such effects may remain latent until the animal is mature. One example of this comes from experiments in which the nutrition of pregnant and lactating rats was manipulated. The adult body size of the offspring was more powerfully determined by their mothers' nutritional status during pregnancy and lactation than by their genetic constitution [86]. Prenatally undernourished female rats displayed delayed puberty which was associated with decreased hypothalamic kisspeptin action [87]. It is now established that maternal nutrient status can cause epigenetic alterations to the genome of the developing fetus, which can potentially impact future generations. Epigenetics is defined as heritable changes in gene expression resulting from alterations in chromatin structure but not in DNA sequence. Epigenetic programming can have lasting effects on future generations through intergenerational influences. These are described as factors, conditions, exposures, and environments in one generation that impact the health, growth, and development of subsequent generations. Three main mechanisms cause epigenetic changes to the genome: DNA methylation, histone modification, and non-coding microRNAs [88]. Non-coding RNAs are RNA transcripts that are not transcribed into proteins, but have been shown to regulate transcription, stability, or translation of protein-coding genes [89]. These processes regulate both the intensity and timing of gene expression during cell differentiation [90, 91]. In cattle, nutrient restriction of gestating cows resulted in heifer offspring with reduced wet ovarian weight and decreased luteal tissue mass compared with heifers born to control-fed cows [92]. Funston et al. [93] also reported that heifers born to cows protein-supplemented during the last one-third of pregnancy attained puberty 14 days earlier than heifers from non-supplemented dams. In sheep, fetal growth restriction altered pituitary LHβ expression and number of follicles in the fetal ovary [94]. Similarly in cattle, nutrient restriction for the first 110 days of gestation resulted in calves with fewer antral follicles compared with calves born to non-restricted cows [95]. This may impact the onset of puberty in heifers as there is evidence from ultrasonographic studies that development of ovarian

antral follicles and tubular genitalia occur in parallel [95] and this development is necessary for puberty.

In dairy heifers it appears that factors including colostrum intake, preweaning growth rate, and body composition influence age at puberty. As an example of the effect of preweaning (0–42 days) growth rate, heifers fed an intensive milk replacer diet were 15 days younger at first pregnancy and 14 days younger at calving than heifers fed a conventional milk replacer diet [96]. The conventional diet consisted of a standard milk replacer (21.5% crude protein [CP], 21.5% fat) fed at 1.2% of BW on a dry matter basis and starter grain (19.9% CP) to attain 0.45 kg of daily gain. The intensive diet consisted of a high-protein milk replacer (30.6% CP, 16.1% fat) fed at 2.1% of BW on a dry matter basis and starter grain (24.3% CP) to achieve 0.68 kg of daily gain [96].

Finally, one should bear in mind that consumption of certain feedstuffs may actually be deleterious to attainment of puberty. One such example is endophyte-infected tall fescue. Cattle consuming this forage are prone to decreased calving and growth rates, delayed onset of puberty, and impaired function of corpora lutea [97].

Effect of Heifer Temperament on Age at Puberty

A study by Cooke et al. [98] evaluated the influence of temperament on various performance measures including age at puberty in *Bos indicus* heifers. *Bos indicus* heifers classified as "excitable" (based on chute exit velocity) had reduced growth, increased plasma cortisol concentrations, and hindered puberty attainment compared to heifers classified as "adequate" or less excitable temperament.

Influence of Bull Exposure on Age at Puberty

Unlike other domestic species (sheep, goats, swine), exposure to a bull has no effect on the incidence of precocious puberty [99].

Influence of Age of Dam on Follicular Reserves

Walsh et al. [100] reported that maternal age affected the number of antral follicles detectable by ultrasonography in the ovaries of the daughters at a year of age. Holstein heifers that were born to heifers had fewer antral follicles detectable by ultrasonography at a year of age than Holstein heifers that were born to multiparous cows. Similarly, Angus heifers with diminished numbers of antral follicles detectable by ultrasonography (14.5 ± 0.8 follicles) had dams that were younger than the dams of Angus heifers with increased numbers of antral follicles (31.1 ± 0.8 follicles) [101]. These studies suggest that the lesser number of antral follicles detectable by ultrasonography in heifers born to primiparous dams is due to fewer ovarian follicle reserves. Selecting replacement heifers from mature dams may result in daughters with greater fertility and reproductive longevity; however, further research is necessary to determine if interactions between size of the ovarian follicle reserve and age at puberty influence fertility and reproductive longevity in replacement heifers.

Monitoring Heifers for Attainment of Puberty

The rearing of replacement heifers is a major financial investment for both beef and dairy cattle producers. The investment expenses do not begin to be recovered until after the first calf is weaned and sold, or in the case of dairy heifers, the onset of lactation, so having heifers calve at an optimal age is paramount to enterprise profitability. For this to occur it is essential that operators know when their heifers have attained puberty and become eligible for breeding. This is most critical for herds using a restricted breeding season.

Observation of signs of estrus can predict onset of puberty but is impractical for application to larger herds. Another observational tool, reproductive tract score (RTS), is a useful predictor of heifer fertility [102]. There is a positive correlation between high RTSs in heifers and percentage of heifers conceiving by artificial insemination [103]. RTS is a subjective estimate of sexual maturity based on ovarian follicular development and diameter of the uterine horns. An RTS of 1 is assigned to heifers with infantile tracts, as indicated by small, toneless uterine horns and small ovaries devoid of significant structures. Heifers with an RTS of 1 are likely the furthest from puberty at the time of examination. Heifers assigned an RTS of 2 are thought to be closer to puberty than those scoring 1, due primarily to larger uterine horns and ovaries. Those heifers assigned an RTS of 3 are thought to be on the verge of estrous cyclicity based on uterine tone and palpable follicles. Heifers assigned a score of 4 are considered to be cycling, as indicated by uterine tone and size, coiling of the uterine horns, and presence of a preovulatory-sized follicle. Heifers assigned an RTS of 4 do not have an easily distinguished corpus luteum. Heifers with an RTS of 5 are similar to those scoring 4 except for the presence of a palpable corpus luteum [104].

Introduction

The neuroendocrine control of the estrous cycle involves the integration of multiple regulatory signals. These signals form an intricate network that permits the fine control of gonadotropin release required for the complex sequence of ovarian follicular development, steroidogenesis, and ovulation. Secretion of gonadotropin-releasing hormone (GnRH) into the hypothalamic–adenohypophyseal portal circulation is considered the primary endocrinological mechanism regulating gonadotropin synthesis and release. Internal factors (e.g. gonadal and metabolic hormones, growth factors, and signaling molecules) and external factors (e.g. environmental chemicals, photoperiod, and stressors) are perceived at the level of the central nervous system and control GnRH secretion directly or through intermediate pathways. Under stimulation by GnRH, gonadotropes synthesize and release luteinizing hormone (LH) and follicle-stimulating hormone (FSH). These two gonadotropins reach the gonads through the blood circulation and act in the ovary to stimulate follicle growth and maturation, ovulation of the preovulatory follicle, and synthesis of gonadal steroid and peptide hormones. Gonadal hormones, in turn, exert feedback actions at the central and adenohypophyseal levels to control the release of GnRH and gonadotropins. This intricate regulatory mechanism leads to dynamic changes in circulating concentrations of reproductive hormones during the estrous cycle (Figure 24.1).

The length of the bovine estrous cycle ranges from 17 to 24 days, averaging 21 days. Day 0 of the estrous cycle is considered the day on which the female exhibits estrus (standing to be mounted) and other proceptive behavior such as mounting herdmates, restlessness, and vocalization. Estrus is induced by an elevation in circulating concentrations of estradiol-17β associated with enhanced follicular steroidogenesis during follicle development [1]. Increased concentrations of estradiol reach a threshold 12–18 hours before onset of estrus, triggering a preovulatory surge of GnRH release and, consequently, a surge in gonadotropin release [2]. Onset of the preovulatory surge of LH generally occurs coincident with the onset of estrus. Ovulation is induced approximately 30 hours after the onset of estrus and is followed by an abrupt decline in circulating concentrations of estradiol. Following ovulation, follicular cells undergo functional transformation into luteal cells, which synthesize and release progesterone [1]. During corpus luteum formation and maturation, concentrations of progesterone in the circulation increase gradually to reach their peak approximately eight days after ovulation. The period of progesterone dominance is defined as the luteal phase of the estrous cycle. During the luteal phase, mean circulating concentrations of LH are relatively low due to infrequent episodic release of LH. In contrast, concentrations of FSH and estradiol fluctuate in association with waves of follicular growth and atresia [3, 4]. At approximately day 16–17 of the estrous cycle in the cow, luteolytic pulses of prostaglandin (PG)$F_{2\alpha}$ released by the endometrium cause luteal regression and a consequent decrease in circulating concentrations of progesterone [1]. Therefore, the progesterone restraint of GnRH/LH release that characterizes the luteal phase declines and the frequency of episodic release of GnRH/LH increases. Increased gonadotropin support promotes follicle growth and maturation, enhanced follicular steroidogenesis, elevations in the circulating concentrations of estradiol and, ultimately, estrous behavior. The period characterized by low circulating concentrations of progesterone and enhanced follicular development leading to ovulation is termed the follicular phase. The cyclic changes in

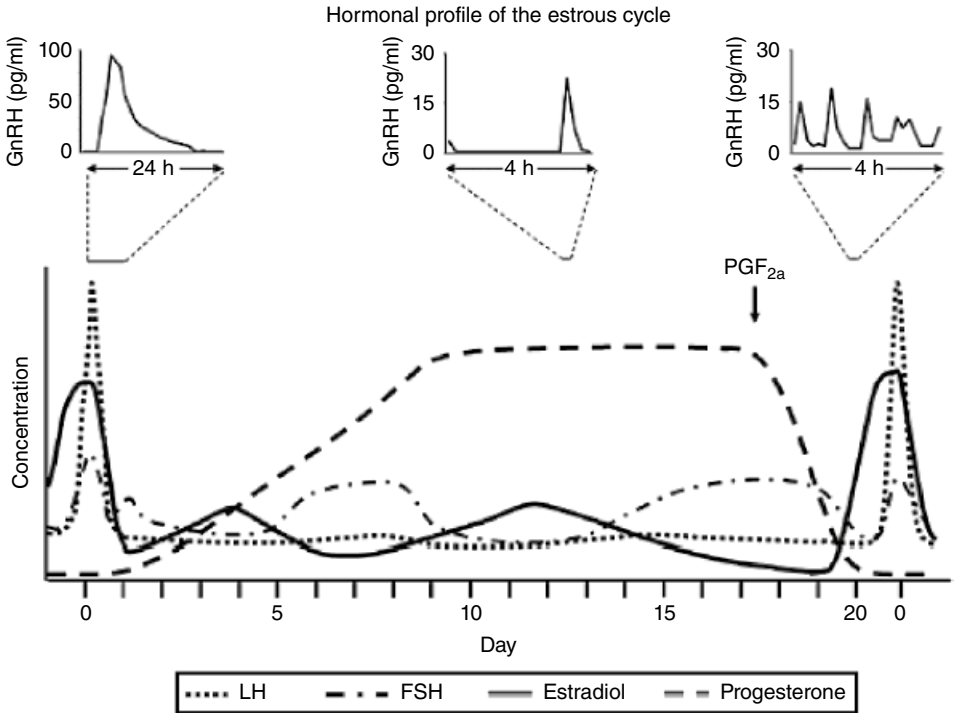

Figure 24.1 Relative changes in circulating concentrations of luteinizing hormone (LH), follicle-stimulating hormone (FSH), estradiol, and progesterone during the estrous cycle in cows. The day on which estrous behavior is observed is denoted as day 0 of the estrous cycle. Circulating concentrations of progesterone increase after ovulation with formation and maturation of the corpus luteum, and remain elevated for the duration of the luteal phase. Release of prostaglandin (PG)$F_{2\alpha}$ causes luteolysis, which is followed by a decrease in circulating concentrations of progesterone. The period of rapid follicular growth and maturation, and elevated concentrations of estradiol in circulation, that follows luteolysis characterizes the follicular phase. Elevated estradiol, in the absence of progesterone, leads to estrous behavior and the preovulatory surge of gonadotropin-releasing hormone (GnRH; top, graph on left). During the luteal phase, progesterone inhibits the frequency of pulsatile release of GnRH (top, graph in middle) and consequently the pulsatile release of LH. During the follicular phase, escape from progesterone inhibition leads to increased frequency of GnRH (top, graph on right) and LH pulses, which supports follicular maturation and enhanced ovarian steroidogenesis. Fluctuations in circulating concentrations of FSH and estradiol are observed in association with initiation and progression of follicular waves.

gonadotropin and ovarian hormone release, and resulting follicular activity, are usually recurrent, except when pregnancy is established or pathological conditions (e.g. undernutrition, disruption of normal luteolysis) are introduced.

The dynamic changes in concentrations of circulating LH and FSH during the estrous cycle are largely representative of distinct changes in the pattern of episodic secretion of GnRH. During the luteal phase, the frequency of episodic release of GnRH, and the correspondent pulses of LH [5], is approximately one pulse every four to six hours [2]. During the follicular phase, the episodic release of GnRH/LH is increased to approximately one pulse per hour [2, 5]. The follicular phase pattern of GnRH/LH release is essential for final follicle development and maturation, and enhanced steroidogenesis. The elevation in circulating concentrations of estradiol during late follicular phase leads to the preovulatory surge of GnRH. The GnRH surge is characterized by a sustained increase in concentrations of GnRH in the hypophyseal portal blood. At the onset of the surge, the pulsatile release of GnRH is of high frequency and high amplitude. With progression of the surge, the pulsatile pattern of GnRH release switches to a continuous elevation of GnRH in the portal blood [2]. This leads in turn to a massive discharge of LH from the adenohypophysis into the peripheral circulation, similar to that of GnRH in the portal circulation [2, 5]. Therefore two modes of endogenous GnRH/LH secretion are characteristic of the estrous cycle: the tonic episodic release and the preovulatory surge release [6]. These patterns of GnRH/LH release are regulated primarily by estradiol and progesterone, and their negative and positive feedback effects are mediated at the hypothalamic and adenohypophyseal levels.

Functional Anatomy of the Hypothalamic–Hypophyseal Unit

The cell bodies of neurons that synthesize GnRH in cattle are located in a continuum that extends from the preoptic area to the mediobasal hypothalamic region of the

diencephalon [7, 8]. GnRH neurons project to the median eminence, where GnRH is stored in secretory vesicles and released adjacent to capillaries of the hypothalamic–hypophyseal portal vasculature upon stimulation. Through this specialized vasculature that connects the hypothalamus and the adenohypophysis (Figure 24.2), GnRH reaches the adenohypophysis in functionally relevant concentrations, binds to the GnRH receptor on the surface of gonadotropes, and stimulates synthesis and release of gonadotropins. Disruption of the hypothalamic–hypophyseal vasculature by surgical lesion leads to decreased adenohypophyseal content and circulating concentrations of LH and FSH due to the lack of gonadotrope stimulation by GnRH [9, 10]. The transport of GnRH secreted from GnRH neurons in the median eminence is largely regulated by afferent neuronal signals and factors released by glial cells [11, 12]. Evidence for structural changes in glial cells that surround the capillaries of the median eminence also exists [13] and may contribute to the regulation of GnRH diffusion into the hypothalamic–hypophyseal circulation following a secretory episode.

Hierarchical Control of Gonadotropin Secretion: The GnRH Pulse Generator

In the early 2000s, the discovery and characterization of the hypothalamic neuropeptide kisspeptin, its functional roles in both pathological (hypogonadotropic hypogonadism) and physiological states (puberty), and ultimately its direct regulatory effects on secretion of GnRH revolutionized our understanding of how GnRH neurons are regulated [14–23]. Kisspeptin, a product of the *Kiss1* gene, is expressed in two discrete populations of neurons located in the preoptic/periventricular area and in the arcuate nucleus of the hypothalamus [24]. Kisspeptin is processed from a precursor peptide to produce several isoforms that vary in length. All biologically active forms of kisspeptin contain the C-terminus sequence common to all forms. The decapeptide form of kisspeptin appears to be the shortest isoform with full capacity for stimulation of GnRH secretion. The role of kisspeptin in the regulation of reproductive function was first characterized in studies investigating mutations in the kisspeptin receptor (*Kiss1r*) gene [14, 15]. Humans and mice with loss of function of kisspeptin receptors exhibit hypogonadotropic hypogonadism. Following these studies, the action of kisspeptin as a potent GnRH secretagogue was characterized in several species including cattle [19–23]. GnRH neurons contain the kisspeptin receptor, and kisspeptin acts directly on GnRH neurons at the level of the cell body and dendrites, as well as at the level of the terminals in the median eminence. Indirect effects of kisspeptin via modulation of other neuronal inputs to GnRH neurons [21] and direct action on adenohypophyseal cells *in vitro* [25] have also been reported. However, the physiological relevance for a direct action of kisspeptin in the adenohypophysis is unclear because kisspeptin fails to stimulate release of LH in hypothalamic–hypophyseal disconnected sheep [22].

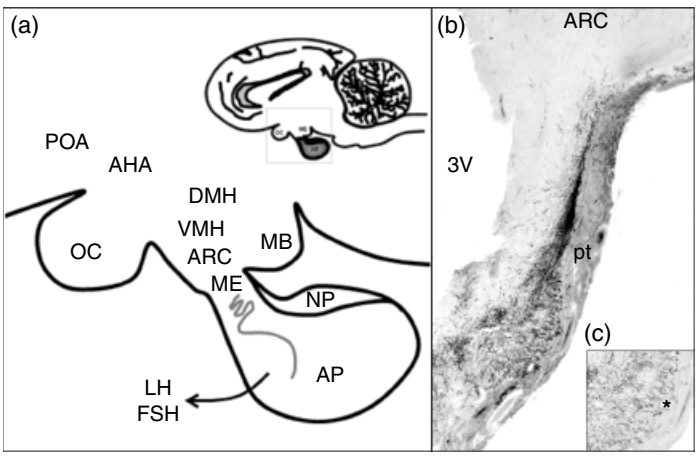

Figure 24.2 Sagittal view of the lower portion of the bovine brain and the hypothalamic areas involved in the neuroendocrine control of reproduction. In cattle, GnRH neuronal cell bodies are distributed in a continuum that extends from the septum/preoptic area (POA) to the basal portions of the hypothalamus (a). GnRH neurons project to the median eminence (ME) where neuronal terminals are adjacent to capillaries of the hypothalamic–hypophyseal portal system. GnRH released in the ME reaches gonadotropes in the adenohypophysis (AP) and stimulates synthesis and release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Low (b) and high (c) magnification images of GnRH-immunoreactive neuronal fibers that project basolaterally toward the ME and terminate adjacent to capillaries (*) of the zona externa of the ME. AHA, Anterior hypothalamic area; ARC, arcuate nucleus; DMH, dorsomedial hypothalamus; MB, mammillary body; NP, neurohypophysis; OC, optic chiasm; pt, pars tuberalis of the adenohypophysis; POA, preoptic area; VMH, ventromedial hypothalamus; 3V, third ventricle.

GnRH is the sole hypothalamic neuropeptide responsible for the secretion of pituitary gonadotropins [26]. It is released in a pulsatile pattern into hypophyseal portal vessels of the median eminence as a consequence of synchronous secretory activity of GnRH neurons located within the medial basal hypothalamus. This activity is characterized by volleys of multiunit electrical activity that can be detected by placing electrodes in the vicinity of these neurons [27–29]. A pulse of GnRH in hypophyseal portal blood precedes a corresponding pulse of LH released from the anterior pituitary into the peripheral circulation [30]. Occasionally, pulses of GnRH with very small amplitude do not result in a detectable LH pulse. During the estrous cycle, the high-frequency, relatively low-amplitude pattern of pulsatile LH release observed during the follicular phase is converted to a much lower frequency, high amplitude pattern during the luteal phase due to high circulating concentrations of progesterone [2]. When measured using highly specific radioimmunoassays, the episodic pattern of FSH secretion observed in the peripheral bloodstream is less distinct than for LH [31]. Although FSH secretion is driven ultimately by hypothalamic GnRH release, other factors secreted from both the dominant follicle (inhibin, activin, estradiol-17β) and locally in the pituitary (activin) significantly modulate changes in its peripheral plasma concentration, as discussed in the section "Differential Control of Gonadotropins: FSH".

The phenomenon of synchronous release of GnRH from hypothalamic GnRH neurons has been referred to historically as the GnRH pulse generator [32, 33]. Until recently, the mechanistic basis of the pulse generator has remained elusive. Based on *in vitro* cultures of immortalized GnRH neurons (GT1 cells), the idea that GnRH neurons have the intrinsic ability to generate autonomous pulses of GnRH was once widely accepted [34]. However, none of these studies demonstrated the ability of GnRH neurons to communicate with surrounding cohorts to stimulate a pattern of synchronous release. More recently, the concept of extrinsic pulse generation has gained favor with the discovery of specialized neurons that release the neuropeptide kisspeptin. The latter is released from two subsets of kisspeptin-expressing neurons, one located in the preoptic area and the other in the arcuate nucleus of the medial basal hypothalamus [35, 36]. Those within the arcuate nucleus localize three peptides, kisspeptin, neurokinin B (NKB), and dynorphin, and are now called KNDy neurons. KNDy neurons co-express receptors for NKB and dynorphin and secrete kisspeptin in response to their own release of NKB. This results in GnRH release from both GnRH cell bodies and their terminals in the median eminence [37, 38]. The activation of KNDy neurons results in release of dynorphin which inhibits KNDy neuron activity (Figure 24.3, left panels). This repeating cascade of KNDy neuron activity has provided convincing evidence that

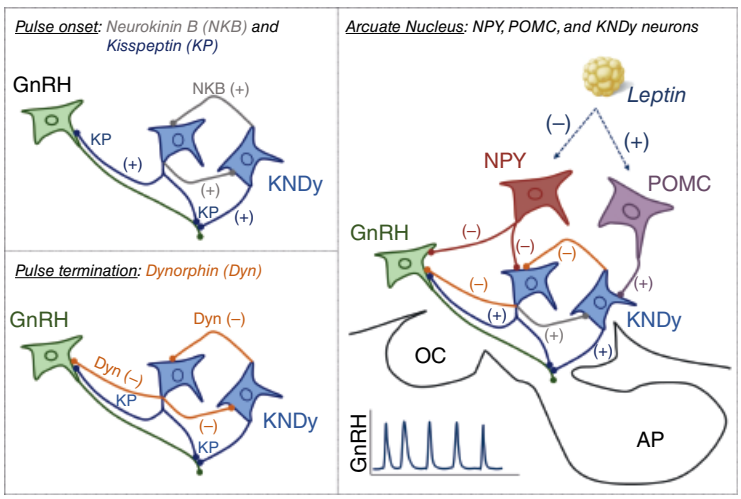

Figure 24.3 Proposed model for the neuroendocrine control of the pulsatile secretion of GnRH. *Top left panel*: Neurons co-expressing neurokinin B (NKB), kisspeptin (KP), and dynorphin (Dyn; termed KNDy neurons; blue) are a critical component of the GnRH pulse generator. Each GnRH pulse is initiated by NKB (gray) acting upon KNDy neurons (autocrine/paracrine) to stimulate kisspeptin (blue) release. Kisspeptin stimulates GnRH neurons (green) to depolarize and secrete GnRH in a pulsatile manner. *Bottom left panel*: GnRH release is terminated by the release of dynorphin (orange) from KNDy neurons acting directly on KNDy neurons (autocrine/ paracrine) and GnRH neurons. Dynorphin acts via the κ opioid receptor as an inhibitory neuropeptide, thus hyperpolarizing GnRH and KNDy neurons and terminating the GnRH pulses. *Right panel*: Leptin regulates episodic GnRH/LH secretion by acting upon an upstream hypothalamic neurocircuitry that includes neurons expressing neuropeptide Y (NPY; red) and pro-opiomelanocortin (POMC; purple). NPY inhibits GnRH secretion by acting directly on GnRH neurons as well as via KNDy neurons. POMC neurons stimulate GnRH secretion by acting primarily on KNDy neurons in the arcuate nucleus.

KNDy neurons serve as an extrinsic GnRH pulse generator [39–41]. In the ewe and in rodents, both NKB and dynorphin are absent from kisspeptin neurons in the rostral part of the hypothalamus [41]. Nonetheless, this population of cells does contain estrogen receptor alpha (ES1) [24]. Several studies have demonstrated that estradiol suppresses *Kiss1* expression in the arcuate nucleus while positively modulating kisspeptin neurons in the rostral hypothalamus [42, 43]. If ES1 is knocked out in all kisspeptin-expressing neurons, the onset of puberty can be advanced [42]. In ruminants, there is clear evidence supporting the concept that estradiol inherently restrains GnRH/LH secretion, ovarian function, and pubertal onset through ES1 [44–48]. Disturbance within the kisspeptin signaling network impedes secretion of GnRH, resulting in the failure to attain puberty [14, 15]. However, in conditions associated with inadequate kisspeptin synthesis, this deficit can be overcome by both peripheral and central administration of kisspeptin [18, 23].

Role of Gonadal Steroids

Positive and negative feedback actions of estradiol and progesterone at the level of the hypothalamus and adenohypophysis explain most of the alterations in the patterns of GnRH and LH release during the estrous cycle (Figure 24.4). Estradiol has a profound effect on the expression of the *Kiss1* gene, but estradiol actions differ between the two populations of kisspeptin neurons. In the preoptic/periventricular area, estradiol stimulates *Kiss1* gene expression. In contrast, estradiol inhibits *Kiss1* gene expression in the arcuate nucleus [49, 50]. This effect of estradiol on regulation of *Kiss1* expression may be involved in the feedback actions of estradiol on gonadotropin release. In ewes, estradiol induces activation of kisspeptin neurons in the preoptic/periventricular areas, indicating that this population of neurons may be important for mediating estradiol positive feedback and onset of the preovulatory surge of LH [51, 52]. Although controversial, the population of kisspeptin neurons in the

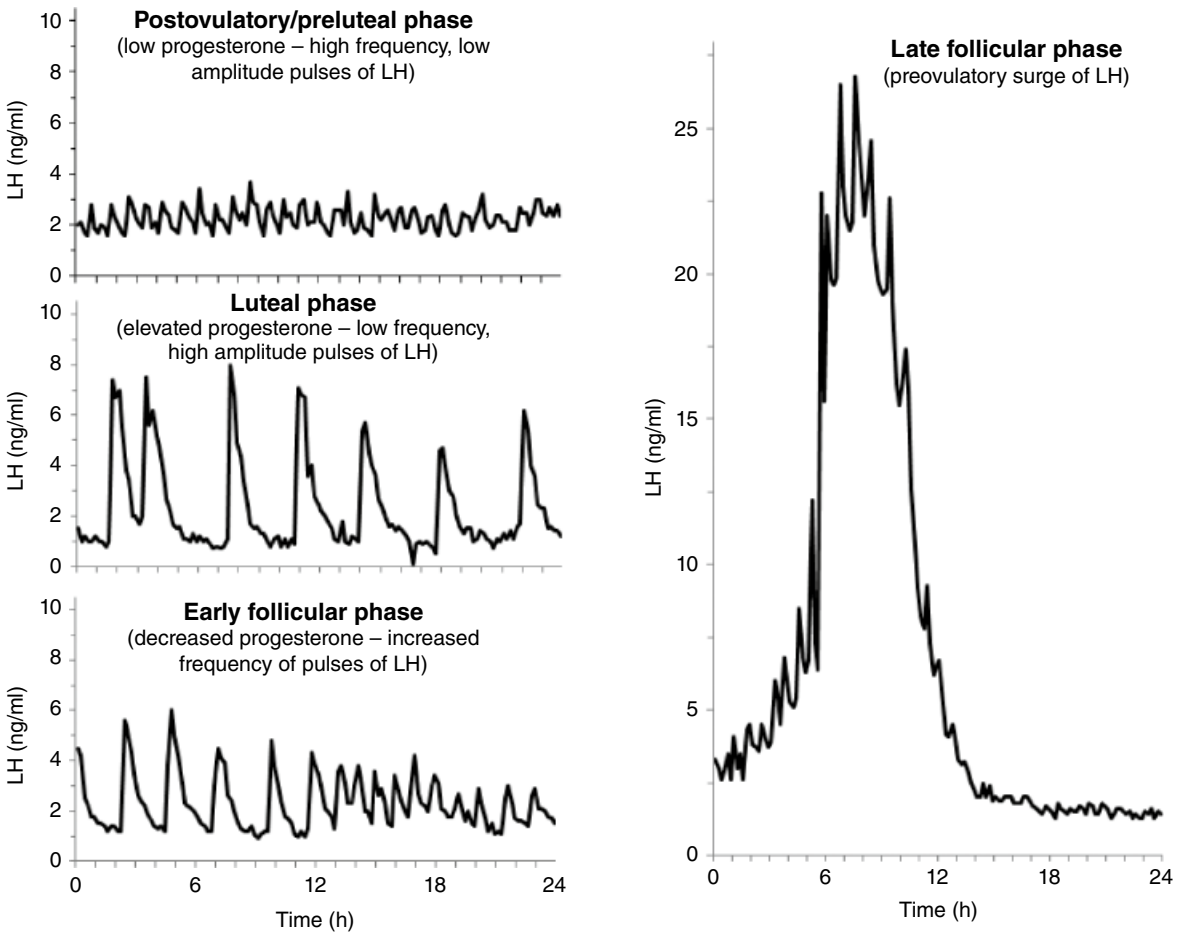

Figure 24.4 Patterns of release of luteinizing hormone (LH) during the estrous cycle in cows. Blood samples from the jugular vein were collected at 10-minute intervals for 24 hours in four distinct phases of the estrous cycle in a cow. *Source:* From [2], © 1980, Oxford University Press.

arcuate nucleus may also be activated during the preovulatory surge of GnRH/LH release. Nevertheless, the observation that constant exogenous treatment with kisspeptin induces sustained release of LH in anestrous ewes and synchronizes the LH surge [53, 54] has promoted investigations seeking to utilize kisspeptin, or its analogs, for pharmacological control of the estrous cycle in domestic livestock, including cattle.

The effect of progesterone in controlling the episodic release of GnRH/LH is well characterized: progesterone inhibits the frequency of LH release [55] by its action at the level of the hypothalamus [56, 57]. However, the negative feedback effect of estradiol is more complex and appears largely additive to the action of progesterone [58]. Estradiol positive feedback is the primary physiological mechanism driving the development of the preovulatory surge of GnRH and LH release during the late follicular phase [2, 5, 6]. Interestingly, although progesterone can block the estradiol-induced LH surge in heifers and ewes [59, 60], prior exposure to endogenous (luteal phase) or exogenous (pharmacological treatment) progesterone enhances the estradiol-induced LH surge [61].

The mechanisms by which progesterone inhibits the frequency of episodic release of LH appear to be mediated by endogenous opioid peptides, particularly dynorphin [62, 63]. Studies in sheep have indicated that progesterone, by acting on progesterone receptor-containing dynorphin neurons located in the arcuate nucleus of the hypothalamus, inhibits the frequency of GnRH pulses via activation of endogenous opioid peptide neurotransmission. This effect appears to be mediated by the κ opioid receptor within KNDy neurons. Support for this mechanism of action is demonstrated by the observations that (i) intracerebroventricular injection of progesterone inhibits the pulsatile release of LH [57]; (ii) antagonists of endogenous opioid peptide [64] and of the κ opioid receptor [63], injected in the mediobasal hypothalamus, increase the frequency of LH pulses; and (iii) progesterone receptor-containing dynorphin neurons, located in the arcuate nucleus of the hypothalamus and in KNDy neurons in particular, project extensively to GnRH neurons in the mediobasal hypothalamus, but to a lesser extent to GnRH neurons in the preoptic area [63]. Importantly, the population of GnRH neurons located in the mediobasal hypothalamus appears to be the major group of GnRH neurons activated during an LH pulse in sheep [65]. This provides compelling evidence that the neuronal circuitry located in this area represents a pathway by which progesterone inhibits the frequency of GnRH/LH episodic release during the luteal phase. Although the mechanisms of progesterone negative feedback on regulation of LH release have not been extensively investigated in cattle, evidence indicates that endogenous opioid peptides have a role similar to that characterized in sheep [66].

The estradiol negative feedback actions on LH release are more complex. During periods of elevated progesterone (e.g. luteal phase), estradiol enhances progesterone inhibition of LH pulsatility [57]. This effect may involve direct actions of estradiol on endogenous opioid peptide neurons, including arcuate nucleus dynorphin neurons that are known to express ESR1 and progesterone receptor in sheep [67, 68]. Because estradiol increases the expression of progesterone receptor in the arcuate nucleus of ovariectomized ewes [69], estradiol's enhancement of progesterone negative feedback may involve increased responsiveness of hypothalamic neurons to progesterone actions. Estradiol negative feedback is also demonstrated by the ability of estradiol to decrease the amplitude of LH pulses during the follicular phase in ewes [70]. However, this effect may be a consequence of the increased frequency of LH release observed during the late follicular phase [2] or by inhibition of gene expression of the α-subunit of glycoprotein hormones (common to LH, FSH, and thyrotropin) and the β-subunit of LH [71, 72].

Estradiol appears to have a biphasic effect on secretion of LH during progression of the follicular phase. Administration of estradiol at physiological doses capable of inducing the preovulatory surge of LH leads initially to an acute reduction in the frequency of LH release [70, 73]. Evidence for this effect also exists during the late follicular phase of the estrous cycle [5]. The brief period (approximately six hours) of estradiol-induced inhibitory tone is followed by a considerable increase in the frequency and amplitude of GnRH/LH pulses and, subsequently, progression toward a large sustained elevation in concentrations of LH characteristic of the preovulatory surge (estradiol positive feedback; Figure 24.5) [5, 6]. Although the mechanisms by which estradiol exerts the positive feedback are unclear, it appears to involve activation of estradiol-receptive neurons in the hypothalamus and transmission of the estradiol signal to GnRH neurons for stimulation of the surge release at the median eminence [74]. The ventromedial hypothalamus and the arcuate nucleus have been identified as critical sites for the positive effect of estradiol in ewes [75, 76]. Changes in norepinephrine, β-endorphin, glutamate and γ-aminobutyric acid (GABA), neurokinin B, and kisspeptin transmission may be implicated in the transmission of estradiol positive feedback. At the level of the adenohypophysis, estradiol enhances expression of the GnRH receptor [77]. This effect is physiologically relevant because an increased response of the gonadotrope to GnRH during the late follicular phase might be critical for maintaining elevated secretion of LH during the preovulatory GnRH surge.

Prior exposure to progesterone enhances the estradiol-induced surge of LH release. This effect of progesterone appears to occur at both hypothalamic and adenohypophyseal

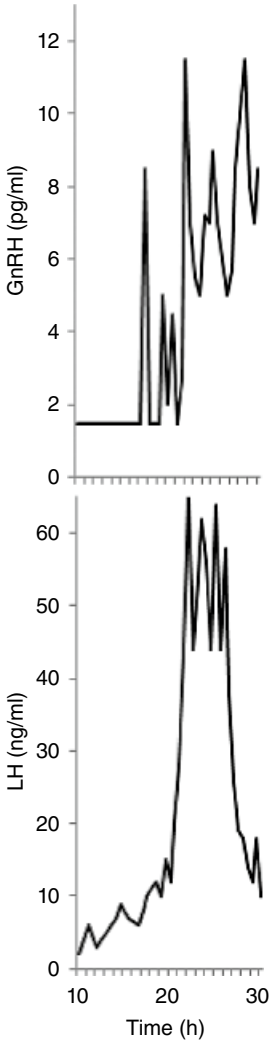

Figure 24.5 Estradiol-induced GnRH and LH surges in cows. Estradiol (1 mg) was injected intramuscularly at hour 0. Cerebrospinal fluid (CSF) from the third ventricle and blood from the jugular vein were obtained at 10-minute intervals. Concentrations of GnRH in the CSF (*top*) increased considerably and remained elevated for longer than 12 hours. Concentrations of LH (*bottom*) increased consistently with elevations in GnRH and returned to pre-surge concentrations in approximately 10 hours. *Source:* Modified from [5].

levels. In ovariectomized ewes, the magnitude of the GnRH surge was greater in ewes pretreated with progesterone during an artificial estrous cycle than in ewes not pre-exposed to progesterone [61]. Although evidence indicates that this effect occurs by alterations in GnRH secretion, direct effects in the adenohypophysis also occur. In ovariectomized ewes with the hypothalamic–adenohypophyseal connection surgically blocked, responsiveness to estradiol-induced surge of LH was enhanced in ewes pretreated with progesterone [78]. Progesterone priming appears to influence responsiveness to estradiol feedback in cows as well [79, 80].

Differential Control of Gonadotropins: FSH

The control of FSH synthesis and release from gonadotropes is exquisitely regulated by GnRH and gonadal hormones, including steroid and protein hormones. Intra-adenohypophyseal factors may also have a role in regulating FSH secretion by paracrine and autocrine actions [31]. In addition, the existence of a hypothalamic factor with FSH-releasing activity distinct from GnRH has been proposed [81], although such a factor is yet to be identified.

Similar to the release of LH, release of FSH has been shown to be pulsatile [82, 83]. However, using antisera produced against the β-subunit of FSH [84], which eliminates possible cross-reactivity with LH, yielded results in which distinct pulses of FSH release were difficult to detect in the peripheral circulation. This has been attributed in part to the long half-life of FSH in circulation [31]. In addition, fluctuations in concentrations of ovarian peptides (inhibin, follistatin) and estradiol that occur during the estrous cycle play major roles in regulating the pattern of secretion of FSH in cattle [3, 4, 85]. Nevertheless, studies in which concentrations of FSH were determined in blood samples collected from the hypophyseal portal vasculature in sheep have demonstrated that secretion of FSH is clearly pulsatile [31]. Interestingly, although a considerable proportion of the FSH pulses coincide with episodes of GnRH release, many non-GnRH-associated episodes are also observed.

The GnRH-associated pulses of FSH observed in sheep occur coincidently with pulses of LH. In sheep, LH and FSH are co-synthesized in a subpopulation of gonadotropes [86], although the two gonadotropins are stored in distinct vesicles. Therefore the coincident release of LH and FSH could reflect the concurrent exocytosis of readily releasable pools of vesicles containing gonadotropins. In cattle, however, there is a clearer distinction in FSH- and LH-synthesizing cells in the adenohypophysis [87]. Nevertheless, FSH is clearly secreted following GnRH administration in cattle [82, 88]. In addition, the preovulatory surge of LH is accompanied by a surge in FSH [89, 90]. These observations indicate that although FSH and LH might be synthesized in distinct populations of gonadotropes, both types of gonadotropes are responsive to GnRH. However, the control of secretion of each gonadotropin appears independent, and the interaction of GnRH-dependent and GnRH-independent mechanisms is important for the fine control of FSH secretion.

The mechanisms by which the non-GnRH-associated pulses of FSH are generated remain unclear. Direct actions of gonadal hormones at the level of the adenohypophysis are believed to be a major regulatory mechanism. Peptide (e.g. inhibin) and steroid (e.g. estradiol) hormones are

likely to control FSH synthesis and release at the level of the gonadotrope. Inhibin, a dimer of α and βA (inhibin A) or βB (inhibin B) subunits, is produced in follicular cells and acts as an endocrine factor regulating FSH release in gonadotropes. Inhibin suppresses FSH release in bovine pituitary cell cultures [91]. The role of inhibin has also been shown in immunization studies. Basal circulating concentration of FSH and GnRH-stimulated FSH release is increased in ewes immunized against bovine inhibin [92]. Similarly, mean concentrations of FSH increase in heifers immunized against inhibin, an effect associated with an increased number of small follicles present in the ovary [93]. The effect of inhibin on the regulation of gonadotropin release appears specific to the control of FSH release because there is no clear effect of inhibin on the release of LH [94]. In addition, it is unlikely that inhibin acts at the hypothalamic level for the control of GnRH secretion [95, 96].

Estradiol has been demonstrated to inhibit FSH synthesis and secretion in the adenohypophysis. The direct action of estradiol appears to occur through inhibition of *FSH-β* gene expression [72]. However, studies investigating the replacement of estradiol and inhibin in ovariectomized ewes indicate that a combination of estradiol and inhibin negative feedback is required for full inhibition of the post-ovariectomy rise in concentrations of FSH [97]. Additional ovarian hormones may contribute to the regulation of FSH release during the estrous cycle. Activin, a dimer of the inhibin β subunits (βAβA, βAβB, and βBβB), and follistatin, a β-subunit-binding protein, are produced in follicular cells and can regulate FSH secretion. Although the endocrine actions of ovarian-derived activin and follistatin are unclear, these proteins, as well as inhibin, are synthesized in the adenohypophysis and may control FSH synthesis and release by autocrine and paracrine mechanisms [98, 99]. Activin stimulates FSH synthesis and release, while follistatin inhibits activin actions by averting activin binding to the receptor. Inhibin, on the other hand, disrupts activin actions by binding to the activin receptor and inducing intracellular signaling via a β-glycan-mediated pathway. Therefore the postovulatory elevation in circulating concentrations of FSH observed shortly after the preovulatory LH and FSH surges (Figure 24.1) is largely explained by changes in feedback actions of gonadal hormones at the level of the adenohypophysis following disappearance of the dominant follicle after ovulation and decreased circulating concentrations of estradiol and inhibin. Increases in FSH in circulation at this time contribute to recruitment of the first follicular wave observed during the early luteal phase and at subsequent waves during the remainder of the cycle.

The existence of a distinct molecule of hypothalamic origin with the ability to regulate FSH release has been proposed. Evidence in support of this hypothesis includes the observations that ablation of anterior hypothalamic neurons and their projections impair release of FSH, without clear effects on release of LH [100, 101]. In addition, inhibition of LH release without notable effects on FSH release has been observed after immunization against GnRH and inhibition of GnRH actions by administration of GnRH antagonists in sheep [31, 102]. Nevertheless, isolation and identification of a molecule that can be characterized as an FSH-releasing factor distinct from GnRH would be required for confirmation of this hypothesis. Interestingly, lamprey GnRH III (lGnRH III) has been reported to selectively release FSH in cattle and was proposed as the mammalian ortholog for the mammalian FSH releasing hormone [103]. However, an in-depth evaluation of this hypothesis revealed that in fact lGnRH III acts as a weak competitor for the mammalian GnRH receptor and does not selectively release FSH in the bovine [88].

Nutritional Influences on the Hypothalamic–Hypophyseal Axis

The nutritional control of gonadotropin release occurs primarily through the regulation of GnRH release in the median eminence. Severe nutrient restriction suppresses secretion of LH in reproductively mature and prepubertal cattle [104, 105]. However, short-term restriction of feed intake has a differential impact on gonadotropin release in mature and immature female cattle. In cows, the frequency of episodes of LH release is not affected by two to three days of fasting [106, 107]. In contrast, fasting for 48–72 hours reduces LH pulsatility in prepubertal heifers [108, 109]. Gonadal steroids have a marked effect on the nutritional regulation of gonadotropin release. Pulsatile release of LH is suppressed in ovariectomized estradiol-treated rats fasted for 48 hours [110]. However, acute feed restriction does not suppress LH release in ovariectomized rats without estradiol replacement [110]. Thus, gonadal steroid hormones interact with nutritional and metabolic signals to regulate gonadotropin release.

Studies determining the concentrations of GnRH in blood samples collected from the hypothalamic–hypophyseal portal vasculature of normal-fed and feed-restricted ewes have demonstrated a considerable reduction in the frequency of GnRH pulses in response to feed restriction [111]. The reduction in the frequency of LH pulses was greater than the reduction in the episodic release of GnRH because some low-amplitude pulses of GnRH were not accompanied by a pulse of LH. Therefore, diminished amplitude of GnRH pulses may also play a role in the overall reduction in mean concentrations of LH observed during undernutrition. A major consequence of low frequency of GnRH stimulation

of gonadotropes in response to feed restriction is the decrease in synthesis of LH and GnRH receptors in the adenohypophysis [112]. Pulsatile administration of GnRH in feed-restricted ewes restores circulating concentrations of LH to normal and increases pituitary expression of *LH-β* and *CGA* (α-subunit) genes [113]. These observations are in concordance with the hypothesis that a high frequency of GnRH stimulation is necessary for optimal expression of the common α-subunit of adenohypophyseal glycoprotein hormones and the β-subunit of LH [114]. Therefore, in conditions of low synthesis and storage of gonadotropins in the adenohypophysis and diminished numbers of GnRH receptors in gonadotropes, small-amplitude pulses of GnRH may not be sufficient to stimulate a clear episode of LH release. This may explain the observation that some small-amplitude pulses of GnRH are not followed by an episode of LH release [111]. In addition, it is possible that small-amplitude pulses of GnRH prime the adenohypophysis for enhanced responsiveness to large-amplitude pulses that induce clear episodes of gonadotropin release [115].

Nutritional and metabolic status are perceived largely at the level of the hypothalamus, although integration with signals controlling other areas of the brain, as well as peripheral organs, are important for the precise control of gonadotropin secretion and action in target tissues. The signals that mediate the nutritional control of gonadotropin release include nutrients (e.g. glucose, fatty acids, amino acids) and metabolic hormones (e.g. leptin, insulin, ghrelin). Glucose serves as a major energy source for the central nervous system and, along with fatty acids and amino acids, serve as signaling molecules to control cellular metabolic pathways [116–118]. In sheep, insulin-induced hypoglycemia [119] and treatment with 2-deoxyglucose [120], a competitive antagonist of glucose metabolism, inhibit secretion of LH. In cattle, hypoglycemia induced by phlorizin, an inhibitor of glucose transporter that increases renal excretion of glucose, was observed to lead to similar decrease in concentrations of LH [121]. Although it is generally accepted that glucose is essential for normal hypothalamic function, the mechanisms by which glucose deficiency impairs the release of LH are unclear. Restoration of LH pulsatility in fasted monkeys occurs not only after feeding carbohydrate-based meals, which increase circulating glucose, but also after feeding protein-/fat-based meals, which do not elevate blood glucose [122]. Amino acids and fatty acids, in addition to serving as important precursor molecules for cellular biosynthesis, appear to also serve as signaling molecules for the control of reproductive neuroendocrine function [116]. Glutamate and the glutamate-derived GABA are neurotransmitters that act directly on GnRH neurons to regulate firing activity and GnRH release [123, 124].

Hormones such as insulin, insulin-like growth factor (IGF)-1, ghrelin, and leptin are reliable markers of nutritional status and play important roles in mediating the metabolic control of gonadotropin secretion [125]. Leptin, a protein hormone synthesized and secreted primarily by adipocytes, has been investigated extensively as a metabolic signal for the control of reproductive neuroendocrine function in various animal species, including in cattle [126]. Circulating concentrations of leptin correlate positively with adiposity [127] and increase with elevations in body weight [128]. In young prepubertal heifers, there is a linear increase in plasma concentrations of leptin as puberty approaches, with increasing body weight and adiposity (body condition score). However, marked changes in leptin synthesis and secretion in blood in cattle are related most strongly to type of diet fed and directional changes in energy balance. High concentrate diets (e.g. high in soluble carbohydrate or fat), which are ruminally propionergic and gluconeogenic in ruminants, create rapid and sustained increases in circulating concentrations of leptin in heifers and mature cows relative to isocaloric high forage diets [129]. Cessation of the high concentrate diet results in an abrupt decline in circulating leptin to levels similar to those observed in cattle on a high forage diet. Moreover, fasting causes an acute decline in circulating leptin [107–109]. However, chronic undernutrition in ruminants results in adaptation and plasma leptin tends to return to values similar to those of full-fed, non-obese cattle on maintenance diets [130]. Thus, the direction of body weight change has a greater influence than body weight or adiposity per se. When full-fed cattle are treated with exogenous leptin, no changes in gonadotropin secretion or metabolic hormones are observed [107]. However, if cattle are fasted for at least 48 hours, they become hypersensitive to leptin. Treatment with recombinant leptin prevents the fasting-induced decrease in LH pulsatility in peripubertal heifers [109], and enhances secretion of LH in mature cows [107] by acting at both the hypothalamus to increase the amplitude of GnRH pulses [131] and the adenohypophysis to increase sensitivity to GnRH [132].

Mediators of leptin actions include neuropeptide Y (NPY) and pro-opiomelanocortin (POMC) neurons in the arcuate nucleus. These neurons contain leptin receptors [133]. NPY is a potent stimulator of feed intake and feed restriction increases expression of the *NPY* gene [134]. The anorexigenic actions of leptin are likely associated with the ability of leptin to decrease *NPY* expression [135]. NPY inhibits GnRH release in cows [5] (Figure 24.6). In contrast to its inhibitory effects on *NPY* gene expression, leptin enhances *POMC* expression [136]. One of the peptide products of the *POMC* gene, α-melanocyte-stimulating hormone (α-MSH), has been shown to also exert direct stimulatory effects on

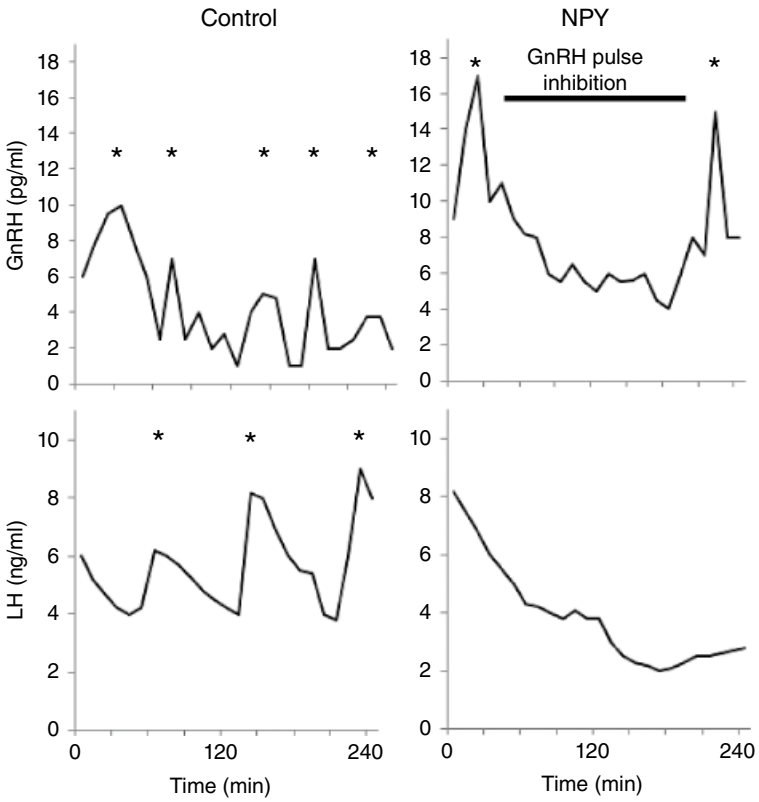

Figure 24.6 Neuropeptide Y (NPY) inhibition of release of GnRH in cows. The pulsatile release of GnRH (top panel) and LH (lower panel) is inhibited following intracerebroventricular administration of NPY (panels on right). Asterisk denotes detected pulses of GnRH and LH. *Source:* From [5], © 1998, Oxford University Press.

GnRH neurons [137]. Therefore the actions of leptin on stimulating GnRH secretion appear to involve suppression of the inhibitory actions of NPY and stimulation of excitatory effects of α-MSH (Figure 24.6, right panel).

Pubertal Development

Puberty is the process through which individuals acquire reproductive maturity. It involves physiological and behavioral changes that are largely driven by activation of gonadal function. In mammalian females, activation of the hypothalamic–adenohypophyseal axis, and the downstream effects of gonadotropins on gonadal function, support enhanced folliculogenesis and steroidogenesis (primarily estradiol synthesis) and lead to first ovulation [138]. The onset of puberty is characterized by an increase in the episodic release of LH, resulting from a heightened frequency of GnRH release and stimulation of gonadotropes [139]. Interestingly, exogenous estradiol induces a surge-like release of LH in prepubertal females [140, 141], indicating that estradiol positive feedback is functional before reproductive maturation is complete. Therefore a major limiting factor for the onset of puberty is the lack of high-frequency episodic release of LH necessary for enhanced estradiol synthesis that will lead to the preovulatory surge of GnRH and LH release.

During the prepubertal period, estradiol negative feedback inhibition of episodic release of LH is enhanced. Ovariectomy in prepubertal heifers, and consequent removal of the major source of estradiol, is associated with a rapid increase in circulating concentrations of LH [45]. Replacement with physiological levels of estradiol in ovariectomized heifers prevents this increase and maintains the pulsatile release of LH at a low frequency. Around the expected time of pubertal transition, the frequency of secretory LH episodes increases to that similar to an ovariectomized heifer receiving no estradiol replacement. Thus, it is hypothesized that decreased sensitivity to estradiol negative feedback during pubertal transition leads to increased episodic release of LH characteristic of the mature state. Although the mechanisms involved in diminished sensitivity to estradiol negative feedback remain unclear, they have been postulated to include changes in estradiol signaling in the hypothalamus [142]. However, a more recent investigation in the ewe lamb using more sophisticated techniques indicated that changes in the

expression of ESR1, particularly in kisspeptin neurons in the arcuate nucleus, failed to explain the pubertal escape from estradiol negative feedback [48]. Also, a population of neurons that synthesize the neuropeptide kisspeptin has been implicated in mediating estradiol's effect on GnRH secretion [143–145]. Kisspeptin is a potent GnRH/LH secretagogue [146, 147]. In addition, estradiol regulates the expression of the gene encoding kisspeptin, likely through direct actions on kisspeptin neurons [143].

Puberty in heifers occurs normally at approximately 10–15 months of age in *Bos taurus* breeds. In *Bos indicus* and *B. indicus*-influenced breeds, puberty usually occurs later and over a wider time range (15–27 months of age) [148, 149]. However, age at puberty is influenced to a considerable degree by nutrition [150]. Undernutrition delays puberty in heifers [104]. In contrast, elevated body weight gain during the prepubertal period advances the onset of puberty [151, 152]. The acceleration of puberty in response to increased weight gain in heifers has been associated with an earlier reduction in the sensitivity to estradiol negative feedback and hastening of the peripubertal activation of the reproductive neuroendocrine axis [153, 154]. Nutritional signals that mediate the nutritional control of pubertal development include nutrients and metabolic hormones. Leptin appears to be a major permissive signal for pubertal progression. In heifers, expression of the leptin gene in the adipose tissue and circulating concentrations of leptin increase as puberty approaches [128]. Among leptin's various functions are its ability to modulate axonal growth, neurogenesis, and synaptogenesis. Changes in leptin signaling during early life initiate changes in the morphology and function of adult hypothalamic circuitries involving nutrition and metabolism [155–157]. The effects of leptin must be placed in context. While fasting-induced suppression of LH pulse frequency in heifers is prevented by treatment with leptin [109], its chronic administration in prepubertal heifers fed a normal diet does not advance puberty [158], supporting observations made in rodents [159] that leptin is necessary but not sufficient to induce puberty in heifers.

Other metabolic hormones, such as insulin and IGF1, can influence neuronal remodeling, including the morphology of GnRH neurons. Therefore nutrition can influence reproductive function by promoting morphological alterations that result in reorganization of neurocircuitries capable of balancing inhibitory and stimulatory inputs to GnRH neurons. These have been shown to include enhanced or decreased numbers of NPY and POMC neurons projecting to GnRH neurons in response to heightened or restricted dietary energy, respectively [156, 157]. Such modifications appear to be long-lasting and may impact lifetime functional phenotype.

Neuroendocrinology of the Postpartum Period

The interval from parturition to resumption of ovarian cycles in the bovine female represents a physiologically distinct and economically critical period of the bovine reproductive lifecycle. Therefore it is not surprising that research to understand the biological basis of postpartum anovulation and to develop strategies for its managerial control has been the subject of intense investigation since the early 1970s [160–165].

In the cow, three main factors contribute to the evolution and maintenance of a state of ovarian quiescence after parturition: (i) a marked depletion of anterior pituitary stores of LH during late gestation, (ii) peripartum nutritional status, and (iii) suppression of high-frequency pulses of GnRH by suckling in the presence of a maternal–offspring bond. Figure 24.7 summarizes the influence of various factors that contribute to the maintenance of anovulation in the postpartum cow and the physiological events during postpartum anovulation.

Depletion of releasable pools of LH within the adenohypophysis occurs in both ewes and cows during the last third of pregnancy and is quite evident at the time of parturition [114–116]. Its basis is the ability of chronically elevated, placental-derived estradiol to suppress anterior pituitary gonadotrope synthesis of the α- and β-subunits of LH and, to a certain extent, FSH [71, 166, 167]. However, this does not appear to be mediated through changes in mRNA expression for the gonadotropin subunits. In experiments with ovariectomized ewes, in which the estrogenic environment of late pregnancy was simulated, pituitary content of both LH and FSH was markedly reduced but abundance of mRNA for the α-subunit or β-subunit of LH and FSH was unchanged or increased. Moreover, treatment with exogenous GnRH in these ewes did not restore pituitary synthesis of gonadotropins. Therefore it was concluded that the negative effects of chronically elevated estradiol are downstream of mRNA expression and represent post-translational regulation of gonadotropin synthesis [71, 166]. In considering this model, it should be noted that in cows neither adenohypophyseal content [167] nor releasable pools [168] of FSH change appreciably during the postpartum period. This may be the result of a more rapid restoration of the β-subunit for FSH by gonadotropes after parturition [169]. Thus, the negative impact of high circulating concentrations of estradiol during gestation in the cow, and its carry-over into the postpartum period, is primarily mediated through effects on LH.

Although progesterone is also elevated during pregnancy, it does not have major direct effects on the pituitary [165]. The main effects of high concentrations of progesterone are

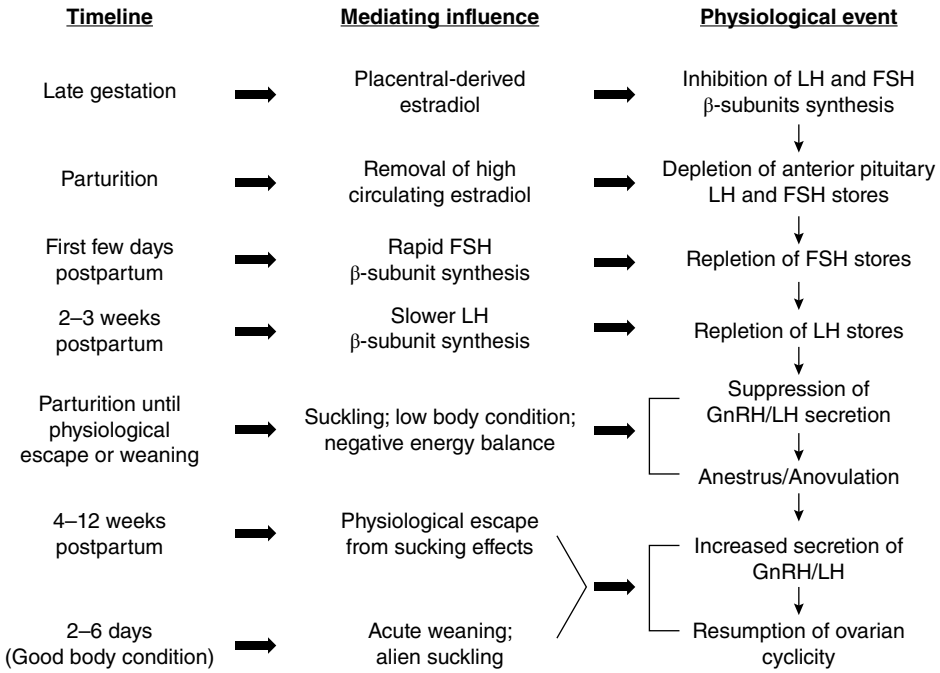

Figure 24.7 Timeline and mediating influences underlying the postpartum anovulatory period of the cow, with emphasis on the suckled beef cow. In the high-producing dairy cow, negative energy balance, as opposed to suckling, is the predominant influence inhibiting reinitiation of estrous cyclicity after calving.

on hypothalamic secretion of GnRH and this inhibition is lifted at parturition. Moreover, hypothalamic content of GnRH does not change from days 1 to 35 postpartum in cows or ewes [165, 170]. Perhaps more important to postpartum recovery is the stimulatory low-level increases in progesterone observed during the resumption of ovarian cycles [171, 172]. Short-lived luteal phases created by premature regression of corpora lutea during the first 30 days postpartum precede the establishment of normal length cycles [173]. In this role, progesterone serves as a positive modulator of postpartum reproduction by priming the entire hypothalamic–pituitary–ovarian–uterine axis for normal gonadotropin secretion [82], normal timing of uterine prostaglandin release [174], and normal luteal function [175–177].

Within two to three days following parturition, the high gestational levels of placental steroids are cleared from the circulation in both cows and ewes [172, 178]. This is accompanied by large increases in the concentration of mRNA for the α- and β-subunits of LH [165]. Within two to three weeks postpartum, total anterior pituitary content and releasable pools of LH are replete in both dairy and beef cows [167, 168, 179]. This process proceeds in the presence of suckling, although the amplitude and/or frequency of GnRH pulses remains low [5]. Thus, in the absence of elevated circulating concentrations of estradiol, the ruminant gonadotrope appears to require very little GnRH stimulus to synthesize and store LH [165]. By 30 days postpartum, release of LH in response to pharmacological challenge with GnRH is notably greater in suckled than in weaned cows [168]. This occurs because the pulsatile release of LH from the pituitary increases dramatically in weaned cows within the first two weeks after calving due to the absence of suckling [163, 180, 181]. Correspondingly, suckled cows accumulate more GnRH within the median eminence [182] and more LH within the anterior pituitary [168] during this period than non-suckled cows. Thus, more LH is available for release in response to GnRH challenge in suckled compared with weaned cows during the first few weeks post calving. Since the repletion of adenohypophyseal LH is essentially complete within three weeks after calving, it would seem reasonable to assume that a normal pattern of LH secretion and onset of ovarian cycles would also occur within this period. However, while first ovulation often does occur within two to three weeks postpartum in milked dairy cows and weaned beef cows, it is delayed for extended and variable periods in the presence of suckling [162, 163]. Suckling frequency must be reduced to no more than once daily in order for duration of postpartum anovulation to be decreased [183, 184]. Moreover, up to six days are required in order for the effects of complete weaning on secretion of LH to result in resumption of ovulatory cycles in a majority of cows [185, 186]. Time of suckling during the solar day had no effect on length of the postpartum anovulatory

interval [187]. However, low body condition at calving and postpartum undernutrition interacts with suckling to exacerbate its negative effects on postpartum reproduction. In some cases, the period of suckling-induced anovulation can extend for 100 days or more due to this interaction, although the average is usually 60–70 days in mature cows calving in good body condition [183, 188]. Of additional interest has been the biostimulatory effect of the bull on resumption of postpartum ovarian function [189, 190]. Data indicate that a pheromonal component of bull urine can hasten the recovery of a pulsatile pattern of gonadotropin secretion in postpartum cows and thus first estrus, although the neuroendocrine mechanism has not been elucidated.

How does the suckling calf influence the neuroendocrine regulation of GnRH and LH secretion? In the 1980s and 1990s, several laboratories around the world focused on this question. Based on historical perspectives in the literature, it was assumed that the suckling calf inhibited the secretion of GnRH and/or the gonadotropins through neural signals mediated by tactile stimulation of the teat [191, 192]. Early endocrine-related work focused on the potential roles of neurohumoral mediators in this process, including prolactin [172, 193, 194] and cortisol [194, 195]. It is now clear that neither of these hormones accounts for the suppressive effects of suckling on the hypothalamic–pituitary axis of cows during the postpartum period. Additional studies addressed the role of ovarian estradiol. Results indicated that enhanced sensitivity to estradiol negative feedback plays a role in mediating the suckling effect [196, 197]. However, estradiol negative feedback is not required for the inhibitory effects of suckling to be manifested [198]. Concomitant with this effect is an apparent increase in endogenous opioid tone that decreases as the postpartum interval increases and in response to weaning [199, 200].

In order to define more clearly whether physical manipulation of the teat alone could account for the inhibitory effects of suckling on gonadotropin secretion, a series of experiments were conducted to examine the effects of various exteroceptive stimuli. These included chronic milking by hand as well as mechanical, electrical, and thermal stimulation of the teats of ovariectomized cows. None of these stimuli was able to recreate or simulate the suckling effect [194, 201–203]. Contrasting studies attempted to simulate the "weaning effect" through mechanical masking of the udder during suckling [203] or by using either complete mastectomy or mammary denervation [204, 205]. Neither approach altered gonadotropin secretion in cows suckling their own calves. Mammary denervation did impair oxytocin secretion and milk let-down following suckling, but this physiological deficit was only temporary. However, denervation had no effect on secretion of prolactin or milk production in beef cows. Collectively, the foregoing studies resulted in the conclusion that chronic tactile stimulation of mammary somatosensory pathways is not required in order for the suckling effect to be manifested [205], and spawned a new avenue of research to assess the role of maternal behavior as a regulator of postpartum anovulation.

Initial experiments involving the role of maternal behavior demonstrated unequivocally that if a cow is forced to suckle an "alien" calf under controlled conditions, the neuroendocrine system responds as if the cow has been weaned: pulsatile secretion of LH increases and first postpartum ovulation occurs within two to six days [186]. This led to experimental observations that cows must be able to identify the calf as "own," using either vision or olfaction, in order for suckling to inhibit the GnRH pulse generator and to sustain the anestrous state [206]. Elimination of both senses prevented calf identification and the negative effects of suckling by the cow's own calf on the reproductive neuroendocrine system. At the neuroendocrine level, suckling appears to suppress secretion of LH by dampening the amplitude of individual GnRH pulses (based on measurements of GnRH secretion in third ventricle cerebrospinal fluid), rather than reducing the number of detectable pulses. This has been interpreted to mean that the number of biologically effective GnRH pulses reaching the adenohypophyseal portal vessels is reduced, thus lessening the frequency of LH pulses secreted by the anterior pituitary [5].

In addition to fundamental studies, a plethora of applied studies have been reported using temporary weaning, alien suckling, and limited suckling to hasten the timing of first postpartum estrus and ovulation, and to enhance synchronization of estrus and ovulation. A detailed consideration of this topic is beyond the scope of this chapter. The reader is referred to published reviews [162–164, 207] and other reports that consider the topic in greater detail.

Novel Neuroendocrine Regulators of GnRH Neuronal Function

An increasing number of neuropeptides have been investigated for their potential roles in controlling reproductive function. In addition to those discussed earlier (in sections "Hierarchical Control of Gonadotropin Secretion: The GnRH Pulse Generator" and "Differential Control of Gonadotropins: FSH"), arginine-phenylalanine-amide-related peptide 3 (RFRP-3), now referred to as gonadotropin-inhibitory hormone, has received great attention [208, 209]. This peptide is synthesized in the hypothalamus and projects to GnRH neuronal cell bodies and/or terminals in the median eminence,

where it has been shown to exert direct control on GnRH neuronal activity and GnRH secretion in rodents, cattle, and sheep. However, reports demonstrating regulatory effects of RFRP on GnRH/LH secretion have been countered by a number of others indicating failure of its ability to exert such effects in the ewe and the mare [210–212].

Although studies investigating the physiological actions of RFRP in cattle are limited, evidence from studies in cattle [213] and other species [214–217] indicate that RFRP-3 acts as an inhibitor of LH release by potential actions in the hypothalamus and at the level of the pituitary. The avian homolog of the mammalian RFRP-3 was the first peptide of the family to be isolated in vertebrates [214]. Because the avian peptide inhibited LH synthesis and secretion [214–216], it was named GnIH. In mammals, the gene that encodes RFRP-3 can produce more than one bioactive peptide of the RFRP family [217]. Expression of the RFRP gene has been localized in the paraventricular and dorsomedial nucleus of the hypothalamus of ewes [50]. Neuronal fibers containing RFRP immunoreactivity are observed to extend to the median eminence, where they are in close proximity to GnRH-containing fibers [215, 216]. Neuronal projections containing RFRP are also observed in close proximity to GnRH cell bodies and proximal dendrites [50]. Thus, RFRP-3 may control gonadotropin release by acting on GnRH neurons and/or at the level of the gonadotrope following its release into the hypothalamic–hypophyseal vasculature. The presence of GPR147, the receptor for RFRP-3, in the hypothalamus and adenohypophysis supports RFRP-3 actions at both levels. Studies in sheep [218] and pigs [219] indicate that RFRP-3 inhibits the release of LH *in vivo;*. However, controversy on the effects of RFRP-3 exists because studies in sheep [210], pigs [220], rats [221], and horses [182] failed to support a clear effect of RFRP. Nevertheless, the observation that RF9, a putative RFRP antagonist, increased gonadotropin release in laboratory rodents [183, 184], sheep [179], and mares [212] suggested that RFRP-3 might function within a complex biological system to effect regulation of gonadotropin release. However, more recent reports have refuted this experimental approach because RF9, the putative ligand for the RFRP receptor (NPFFR1), has been shown to function primarily as a KISS1R agonist, the receptor for kisspeptin on GnRH neurons [222].

Ovarian Follicular and Luteal Dynamics in Cattle

Gregg P. Adams and Jaswant Singh

Veterinary Biomedical Sciences, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Saskatchewan, Canada

Introduction

The intent of this chapter is to provide an overview of our present understanding of ovarian function in cattle, with emphasis on the dynamics and control of follicular and luteal gland development. The following sections are arranged, more-or-less, in a chronological order, beginning with fetal ovarian development and follicle assembly, early folliculogenesis and oogenesis, antral follicle dynamics during the estrous cycle, ovulation, and development of the corpus luteum (CL). A following section includes a description of ovarian dynamics during different reproductive states (i.e. pre- and peripubertal periods, during pregnancy and the postpartum period, and during old age). Lastly, reference is made to implications of our new-found knowledge of ovarian function on clinical and breeding management practices in cattle, particularly on the design of modern protocols for ovarian synchronization and superstimulation.

Ovarian Development and Follicle Assembly

The gross, ultrasonographic, and histologic morphology of the mature bovine ovary is illustrated in Figures 25.1 and 25.2. Similar to most mammalian species (except the horse), the bovine ovary is arranged with an outer cortex containing the transient CL and thousands of follicles at differing stages of development, and an inner medulla composed primarily of connective tissue, vessels, nerves, and the rete ovarii.

The ovarian primordium develops from an elongated gonadal ridge on the ventral aspect of the embryonic kidney (mesonephros). Recent immunohistochemical studies of bovine ovaries suggest that the ovarian primordium does not initially have a distinct surface epithelium with a basement membrane separating it from the underlying stroma, but instead is composed of a cluster of "gonadal ridge epithelial-like" cells (GREL) (Figure 25.3) [1]. The GREL cells likely develop from the surface epithelium of the mesonephros and are precursors of ovigerous cords, granulosa cells of future follicles and the surface epithelium of the future ovary [2]. Primordial germ cells (PGC) migrate from the yolk sac/developing hind-gut to the dorsal celomic wall of the embryo via the dorsal mesentery to colonize the gonadal ridge. The PGC undergo massive mitotic proliferation and intermingle with the resident GREL cells. Invading fingers of stroma ("cell streams") from the underlying mesonephros penetrate the gonadal ridge/ovarian primordium and separate the clumps of PGC and associated GREL cells into ovigerous cords that radiate from the surface epithelium toward what will become the ovarian medulla at the base of the ovary [3, 4]. The developing medulla contains stroma, blood vessels, and mesonephric tubules that will persist in the adult ovary as the rete ovarii. The penetrating stroma has a basal lamina at its leading edge, hence the ovigerous cords become surrounded by a basal lamina. As the ovary develops, the ovigerous cords break down into smaller groups of PGC/GREL cells, resulting in the formation of primordial follicles containing an oocyte surrounded by flattened granulosa cells separated from surrounding tissue by a basal lamina. After forming a primordial follicle, mitotic division of the oogonium ceases, it enlarges, and it becomes arrested in the early stages of meiosis I. The first follicles form close to the medulla, while the outer cortex still contains shorter ovigerous cords. The gradual progression of follicle formation extending from the medulla to the surface has been observed in fetal ovaries of human, cattle, and sheep, and in postnatal rat ovaries (reviewed in [1]). At later stages of ovarian development, when preantral and antral follicles appear, the cells on the ovarian surface become single-layered and the stroma

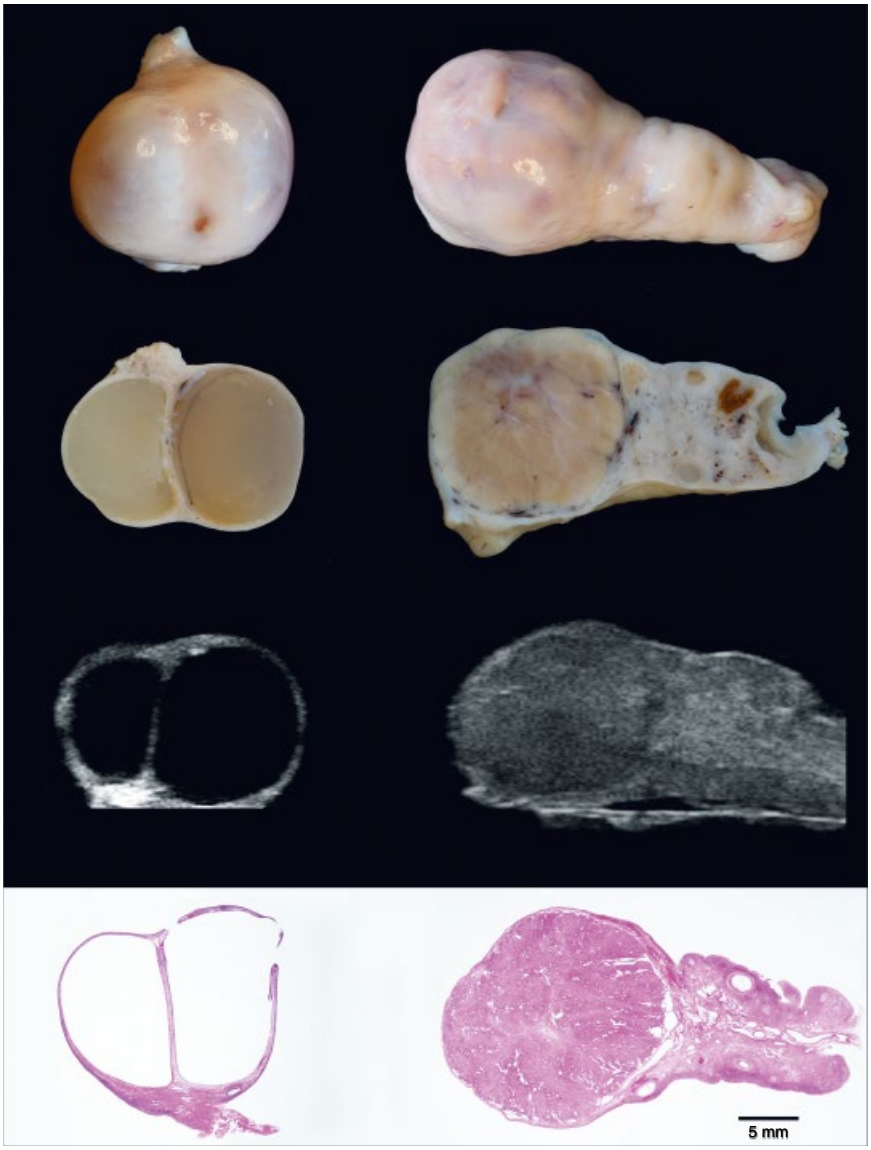

Figure 25.1 Left and right ovaries from a cow in proestrus (top to bottom: surface view, cut surface, ultrasound image, and histological section stained with H&E). In the left ovary, two large antral follicles are apparent side-by-side, a regressing former dominant follicle (on the left) and the preovulatory dominant follicle (on the right). In the right ovary, a regressing CL is the predominant structure. The scale bar is 5 mm for all images.

underlying the surface thickens to become the tunica albuginea. Ovigerous cord formation begins around day 79 of gestation in the fetal bovine ovaries, the cords start to break down by 127 days, follicles are formed by 173 days, while ovarian surface epithelium is detected by 234 days of gestation [5].

Folliculogenesis and Oogenesis

Folliculogenesis is the developmental process in which an activated primordial follicle develops to a preovulatory size through the growth and differentiation of the oocyte and its surrounding granulosa cells [6–8]. Ovarian follicles have been classified in various ways based on morphologic characteristics such as the number of granulosa cell layers surrounding the oocyte, the morphologic features of the granulosa cells, the diameter of the oocyte and the follicle, and the absence or presence of a fluid-filled antrum, but in general may be categorized as primordial, primary, secondary, or tertiary (antral or vesicular; Table 25.1) [9, 10, 12].

Initiation of follicular growth, referred to as activation, begins with the transformation of the flattened pre-granulosa cells of the primordial follicle into a single layer of cuboidal granulosa (follicular) cells, at which point the follicle is referred to as a primary follicle [9, 11, 13]. Factors such as increased mTOR1 in the granulosa cell of activating

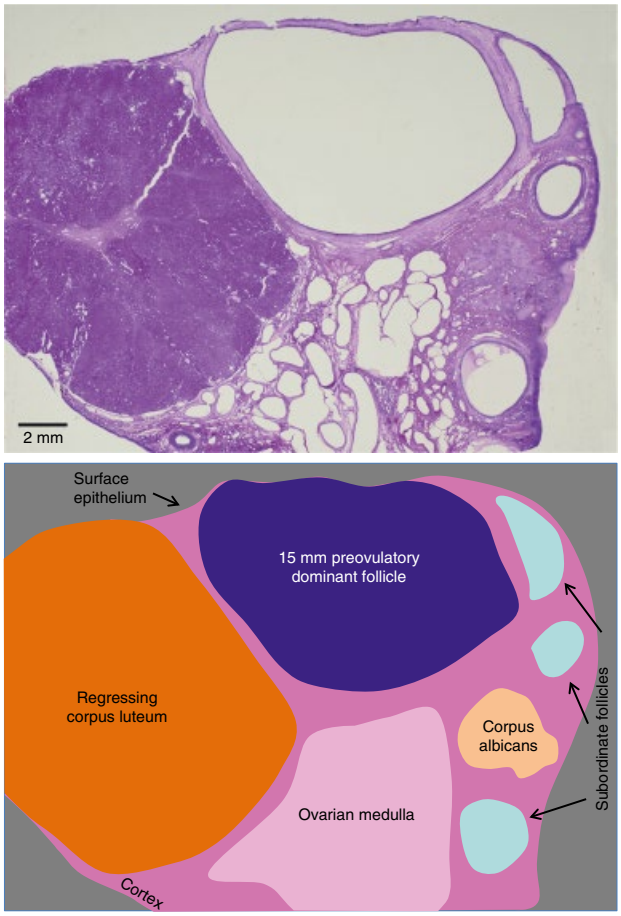

Figure 25.2 Histological section (stained with H&E) and diagram of the ovary of a cow at day 18 of the estrous cycle (day 0 = ovulation) showing structures of the outer cortex (regressing CL, preovulatory and subordinate follicles, corpus albicans) and the inner medulla (rete ovarii, blood vessels, connective tissue).

primordial follicles have been proposed to activate KIT signaling in the oocyte, resulting in activation of the PI3K pathway which is normally kept inhibited by PTEN [14, 15]. It is clear that both granulosa cells and the oocyte participate in the activation process, but the exact mechanism is far from clear at the present time. Proliferation of granulosa cells results in an increase in the number of layers around the oocyte. A follicle with two to six layers of granulosa cells is referred to as a secondary follicle, and a follicle with more than six layers of granulosa cells and a fluid-filled antrum is referred to as a tertiary (or antral) follicle [9, 10]. The diameter of a primordial follicle is about 0.04 mm and the diameter of the smallest antral follicle is 0.25 mm [10]. The largest antral or Graafian follicle becomes the ovulatory follicle following the preovulatory gonadotropin surge [9]. In cattle, primordial, primary, secondary, and tertiary follicles first appear at days 90, 140, 210, and 250 of gestation, respectively [16, 17]. The time required for a follicle to grow from the large preantral stage (secondary follicle) to a mature ovulatory size has been estimated to be about 42 days (Table 25.2; Figure 25.4) [10]. It appears that the growth rate of a follicle changes from slow to rapid after formation of antrum [18].

Antral Follicle Dynamics

While early histologic studies provide insight regarding the morphologic changes that occur during folliculogenesis and an overall impression of the time required, they do not provide an understanding of day-to-day dynamics and control of antral follicle development during the estrous cycle. By inference from Rajakoski's 1960 review [19] of the early literature it appears that two schools of thought prevailed at the time (Figure 25.5): (i) follicular growth and regression is a continuous process and is independent of the phase of the reproductive cycle; or (ii) a reservoir of antral follicles remains in a resting stage, and at a particular time in each species, one or several of these follicles begin to grow and reach maturity during the ensuing estrus. Based on gross and histologic evaluation of ovaries obtained from cows slaughtered on known days of the estrous cycle (n = 1–3 cows/day); however, Rajakoski concluded that for antral follicles (>5 mm) two growth waves occurred during the estrous cycle. The first wave of growth was initiated on the 3rd and 4th days of the estrous cycle (estrus = 1st day) and the second between the 12th and 14th days. His interpretation was that the follicles in each wave that did not ovulate regressed and became atretic.

Contrary to the conclusions of Rajakoski, interpretation of later histological studies supported the notion that follicular growth is continuous and independent of the phases of the cycle [21–23]. Controversy regarding the wave theory of follicular dynamics was evident in later reviews in which the two-wave theory was refuted [24–26]. Evidence was presented to support the concept that follicles are recruited continuously throughout the cycle and the follicle destined to ovulate was a result of coincidence of its stage of maturity (readiness) and the occurrence of the preovulatory gonadotropin surge; i.e. the "propitious moment" theory (Figure 25.5). However, with the introduction of ultrasonography in the late 1980s, the barrier to our understanding of the dynamic process of follicle development was suddenly removed.

The technique of detecting and monitoring ovarian structures by transrectal ultrasonography was described initially in 1984 [27]. By comparing the results of ultrasonography with the results of slicing excised ovaries, the ultrasound technique was validated as a tool for detecting follicles >2 mm in diameter and for monitoring the CL [28, 29]. Subsequent studies using ultrasonic imaging to monitor follicle populations in different size categories [30] or to

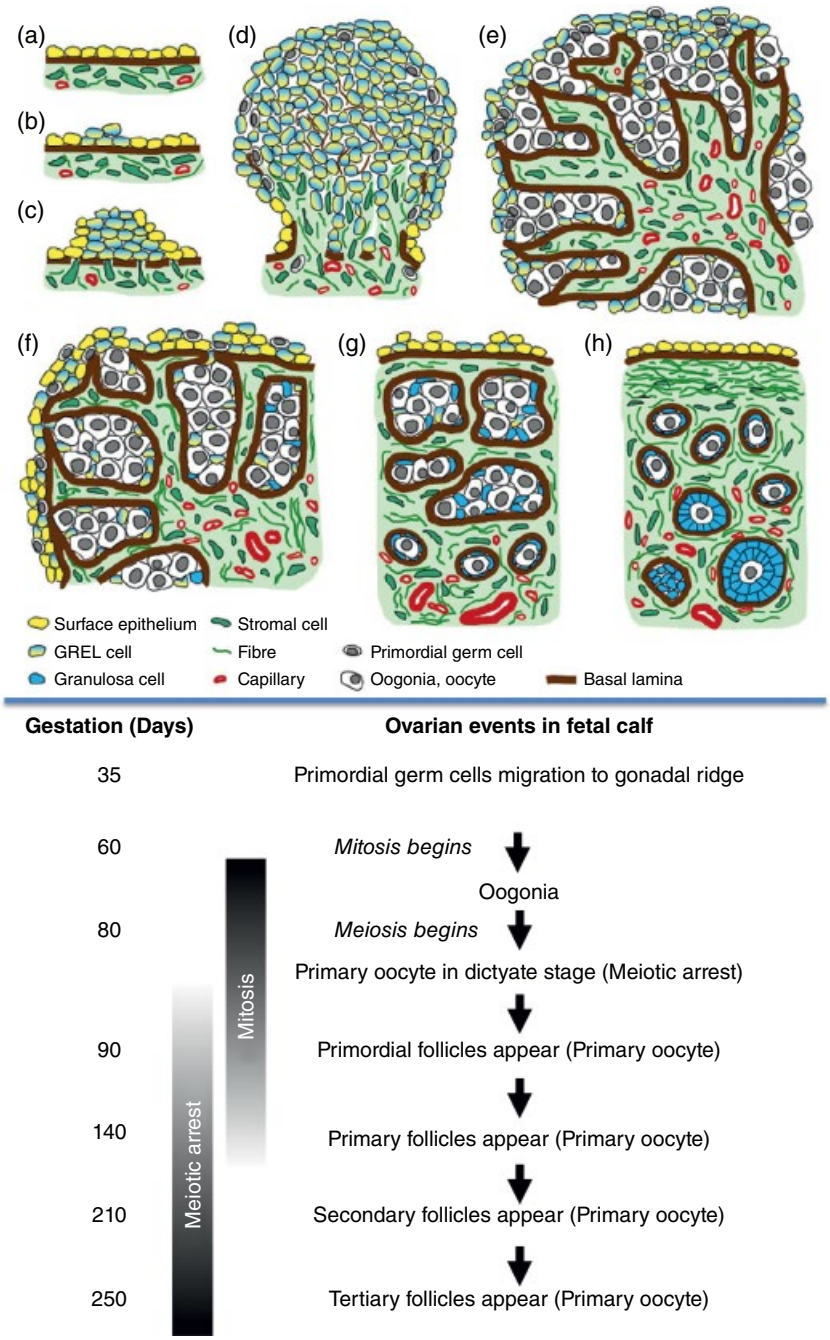

Figure 25.3 (*Above*) Model of bovine fetal ovarian development and follicle assembly and (*below*) chronology of early folliculogenesis and oogenesis. (a) Ovary development commences at the mesonephric surface epithelium (yellow) in the location of the future gonadal ridge. (b) Some surface epithelial cells change phenotype into GREL cells (yellow-blue). (c) GREL cells proliferate and the basal lamina underlying the surface epithelium breaks down, allowing stromal cells (green) to penetrate into the gonadal ridge. (d) GREL cells continue to proliferate and primordial germ cells (gray) migrate into the gonadal ridge between the GREL cells. The mesonephric stroma, including vasculature (red), continues to penetrate and expand in the ovary. (e) Oogonia proliferate and the stroma penetrates further toward the ovarian surface, thus enclosing oogonia and GREL cells in ovigerous cords. The cords are surrounded by a basal lamina at their interface with the stroma, but are open to the ovarian surface. (f) Compartmentalization into cortex and medulla becomes obvious. The cortex is characterized by alternating areas of ovigerous cords and stroma, whereas the medulla is composed of stromal cells, vasculature, and tubules originating from the mesonephros (rete ovarii). As the stroma penetrates toward the periphery, GREL cells at the surface of the gonadal ridge are aligned by a basal lamina at their interface with the stroma and begin to differentiate into typical ovarian surface epithelium (yellow cells). (g) Ovigerous cords are partitioned into smaller cords and eventually into individual primordial follicles as GREL cells mature to granulosa cells (blue cells) and surround an oogonium. (h) Finally, the surface epithelium becomes mostly single-layered and a tunica albuginea, densely packed connective tissue, develops from the stroma below the basal lamina of the surface epithelium. Some primordial follicles become activated and commence development into primary and preantral follicles. *Source:* [1]. Licensed Under CCBY 4.0.

Table 25.1 Characteristics of bovine ovarian follicles during development.

Follicle stage	Follicle type	FSH/LH receptors	Granulosa cell layers[a]	Granulosa cells per section[a]	Follicle diameter (mm)	Oocyte diameter (μm)	Zona pellucida	Theca interna
Primordial	1		1	<10 flattened	<0.04	30	Absent	Absent
Transitory	1a		Entered growing pool and surrounded by a mixture of flattened and cuboidal cells					
Primary	2	FSHr form (granulosa)	1–1.5	10–40[b] cuboidal	0.04–0.08	31	Absent	Absent
Secondary	3 Small preantral		2–3	41–100	0.08–0.13	50	Begins to form	Begins to form
	4 Large preantral	LHr form (theca)	4–6	101–250[c]	0.13–0.25	69	Partially formed	Partially formed
Tertiary (antral)	5 Small antral		>6	>250	0.25–0.5	93	Fully formed

monitor individually identified follicles [31–34] convincingly documented that follicular growth in cattle occurs in a wave-like fashion and that the majority of estrous cycles in cattle are comprised of two or three such waves. The method by which individual follicles may be monitored throughout one interovulatory interval by ultrasonography is illustrated in Figure 25.6. During daily examinations, a sketch of each ovary is made to record the number, diameter, and relative positions of follicles and the CL. Despite that the ovaries are quite moveable at the end of the mesovarium, their position remains remarkably consistent from one examination to the next, allowing accurate "mapping" of ovarian structures over time. The results of ultrasound studies are consistent with those in which three waves of follicular growth were hypothesized [35] based on the presence of one "estrogen-active" follicle during three different periods of the estrous cycle [36, 37] and increases in estradiol in blood from the utero-ovarian veins during approximately the same time periods [38].

Follicular Waves During the Estrous Cycle

Follicular wave emergence in cattle is characterized by the sudden (within two to three days) growth of 8–41 small follicles that are initially detected by ultrasonography at a diameter of 3–4 mm (Figures 25.6 and 25.7) [30, 33, 34, 39–42]. The growth rate is similar among follicles of the wave for about two days, after which one follicle is then *selected* to continue growth (dominant follicle) while the remainder become atretic and regress (subordinate follicles). In both two- and three-wave estrous cycles, emergence of the first follicular wave occurs consistently on the day of ovulation (day 0). Emergence of the second wave occurs on day 9 or 10 for two-wave cycles, and on day 8 or 9 for three-wave cycles. In three-wave cycles, a third wave emerges on day 15 or 16. Under the influence of progesterone (e.g. diestrus, pregnancy), dominant follicles of successive waves are anovulatory and undergo atresia [43]. The dominant follicle present at the onset of luteolysis becomes the ovulatory follicle, and emergence of the next wave is delayed until the day of the ensuing ovulation. The CL begins to regress earlier in two-wave cycles (day 16) than in three-wave cycles (day 19), resulting in a correspondingly shorter estrous cycle (20 versus 23 days, respectively). Hence, the so-called 21-day estrous cycle of cattle exists only as an average between two- and three-wave cycles.

Two-Wave vs Three-Wave Patterns

The majority of bovine estrous cycles (i.e. >95%) are composed of either two or three follicular waves [44, 45] (Figure 25.7). Some have reported a preponderance (>80%) of either the two-wave or the three-wave pattern during an interovulatory interval, while others have reported a more even distribution. There appears to be no breed- or age-specific predilection for a given wave pattern in *Bos taurus*. An increase in the proportion of three-wave patterns has, however, been associated with a low plane of nutrition [46, 47] and heat stress [48, 49]. In *Bos indicus*, no seasonal effect on wave pattern was detected [50], but the pattern was influenced by parity. The majority of Nelore heifers (65%) exhibited a three-wave pattern, whereas the majority of cows (83%) exhibited a two-wave pattern [51]. Others have reported that up to 27% of estrous cycles in *B. indicus* cows consist of four waves of follicular development, compared to only 7% in *B. indicus* heifers (reviewed in [52]).

Predictive factors associated with a two- versus three-wave pattern may provide insight into mechanisms controlling the pattern, and have important implications for breeding management and the development of effective protocols for ovarian synchronization, superstimulation, and fixed-time artificial insemination. Pregnancy rates in

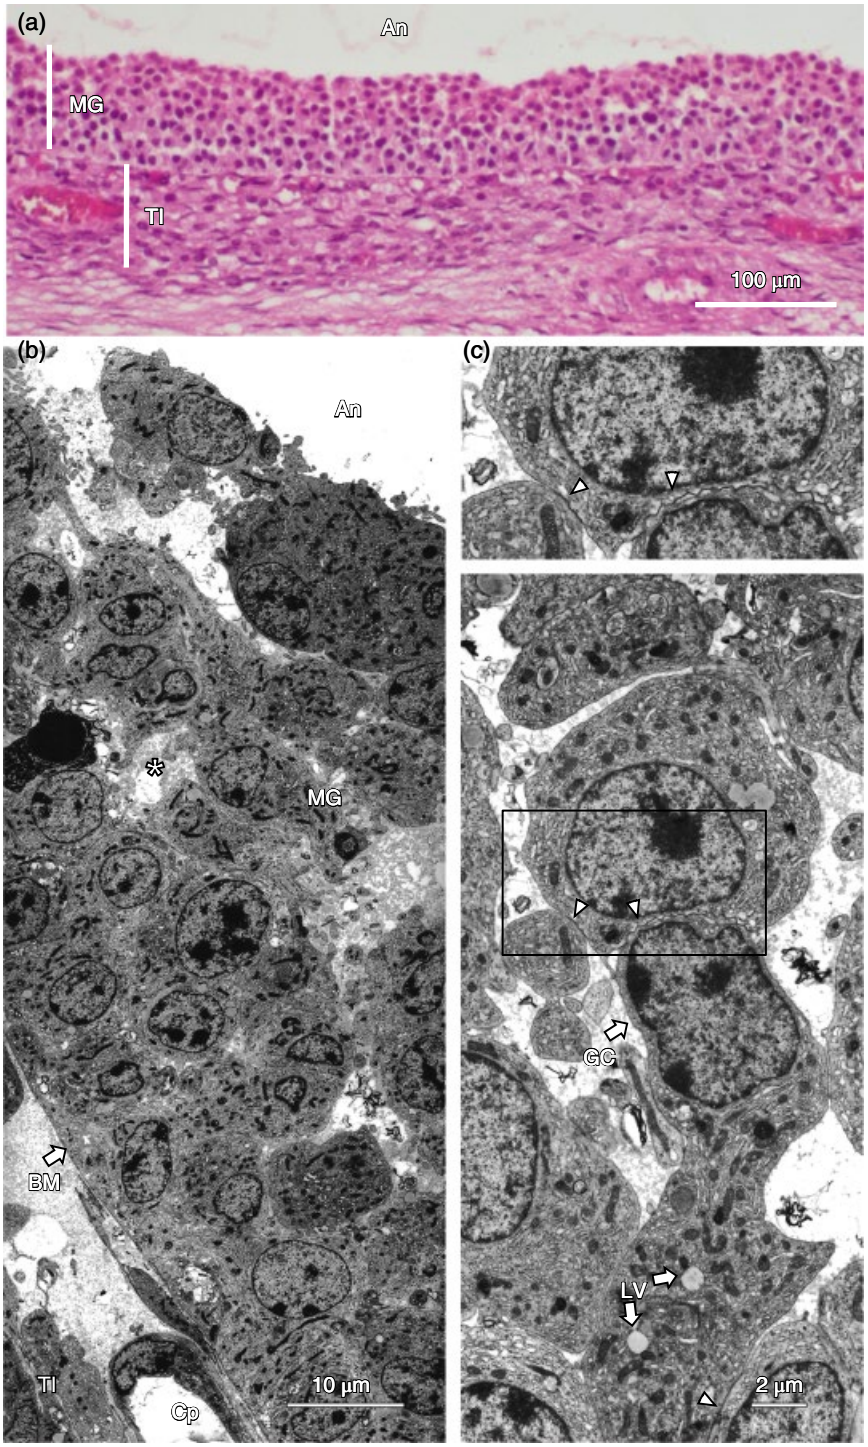

Figure 25.4 Histological section (stained with H&E) and transmission electron micrograph of the wall of the dominant follicle during (a, b) the growing phase (three days after ovulation) and (c) the early static phase (six days after ovulation, right) in cattle. Antrum (An), basement (BM), intercellular spaces (*), membrana granulosa (MG), granulosa cells (GC), theca interna (TI), capillary (Cp). The granulosa cells of the growing dominant follicle have many cytoplasmic processes projecting into intercellular spaces. In the early-static dominant follicle, most of the granulosa cells are polyhedral (others are elongated) and the intercellular spaces are wide. The granulosa cells contain abundant mitochondria, smooth- and rough-endoplasmic reticulum, and occasional lipid vacuoles (LV). The area enclosed in the box is magnified in the upper right corner to show that gap junctions (arrowheads) between the cells are frequent.

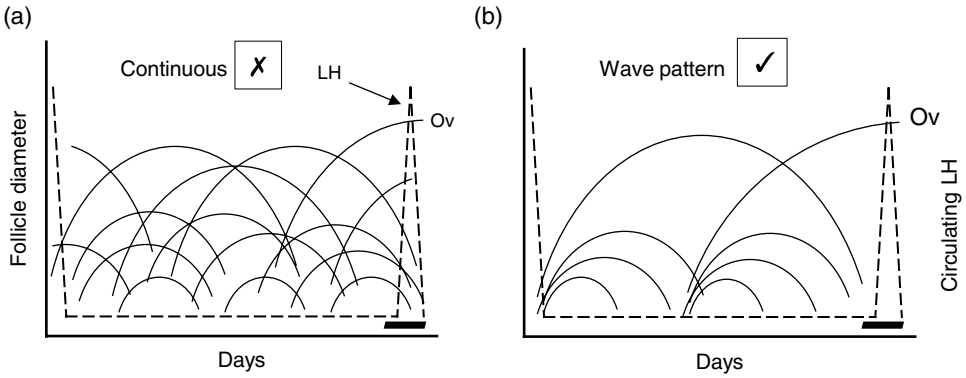

Figure 25.5 Theories of ovarian follicular dynamics during the estrous cycle in cattle, illustrated from one ovulation to the next (i.e. one interovulatory interval). Estrus is indicated by the solid bar along the x-axis and plasma LH concentrations by the dashed line. (a) The theory of continuous recruitment or "propitious moment theory" is that antral follicles grow and regress continuously throughout the interovulatory interval and the ovulatory follicle is the one that by happenstance is at the appropriate stage of development to respond to the preovulatory surge of LH. (b) The wave theory of follicle recruitment is that two or more cohorts (i.e. waves) of antral follicles are recruited (i.e. emerge) during the ovarian cycle, regardless of the presence of a CL (follicular phase or luteal phase). The dominant follicle that develops in the final wave of the interovulatory interval ovulates while preceding waves are anovulatory. *Source:* Modified from [20].

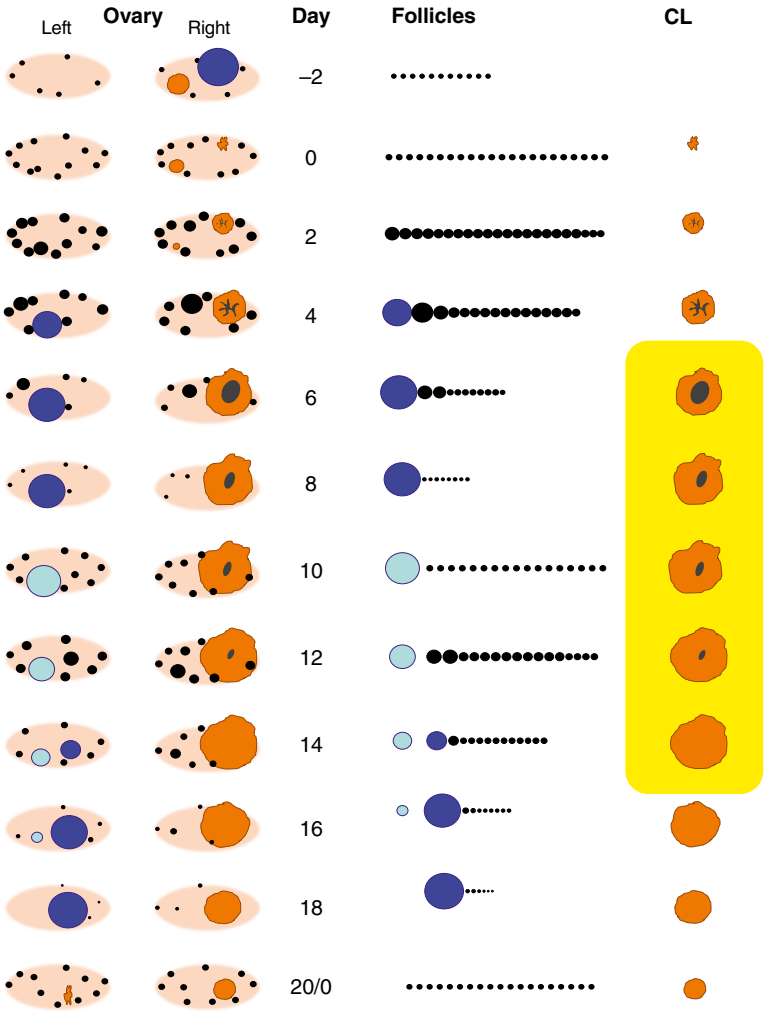

Figure 25.6 Mapping ovarian follicular and luteal dynamics in cattle by serial ultrasonography. During daily examinations (day 0 = ovulation), a sketch of each ovary is made to record the number, diameter, and relative positions of follicles and the CL. The data are used to identify the number of follicular waves during the interovulatory interval (two waves in this example), follicular wave emergence (days 0 and 10), the dominant follicle of each wave (growing: dark blue; regressing: pale blue), the preselection and subordinate follicles of each wave (black), the occurrence of ovulation (days 0 and 20), and the growth and regression of the CL (dark yellow). Note that both ovaries contribute to a given follicular wave and successive dominant follicles may be in either ovary (random). The size and number of ovarian structures in each sketch are tabulated under the respective follicle and CL columns. The high progesterone (luteal) phase is outlined in the yellow box.

cattle with two- versus three-wave patterns were compared [53–55] based on the notion that the preovulatory follicle in the two-wave pattern grows for a longer period [41] and may, therefore, contain a relatively aged oocyte. However, results have been contradictory; pregnancy rates did not differ between two- versus three-wave cycles in some studies [53, 54], whereas a lower pregnancy rate following ovulation at the end of the two-wave pattern was reported in another study [55].

In a more recent study involving ultrasonographic data from 91 interovulatory intervals [44], two- and three-wave patterns of follicular development were compared to determine the repeatability and predictive characteristics of a given wave pattern. Two-wave cycles were three days shorter than three-wave cycles (19.8 ± 0.2 vs 22.5 ± 0.3; $P < 0.01$). The majority of cycles ≤21 days were of the two-wave pattern (88%; $P < 0.05$), while the majority of cycles ≥22 days were of the three-wave pattern (78%; $P < 0.05$). The proportion of successive cycles in which the pattern remained the same (i.e. repeatability) was more than two-fold greater than the proportion of cycles that changed patterns (70% vs 30%; $P < 0.01$). The repeatability of wave pattern and the proportion of two- versus three-wave patterns within the herd were not affected by the season of the year; i.e. they were not affected by pasture-based (spring and summer) versus non-pasture-based (fall and winter) seasons. Interestingly, the strongest correlate to the number of waves in the interovulatory interval was the duration of follicular dominance of wave 1. The duration of dominance of the wave 1 dominant follicle was three days longer and the onset of regression was later in two-wave patterns than in three-wave patterns ($P < 0.01$). Dominance of wave 1 was associated with a subsequent delay in the attainment of maximum diameter by the dominant follicle of wave 2, as well as early onset of luteolysis (Figure 25.7). Results supported the hypothesis that factors that influence the development of the dominant follicle of wave 1 are responsible for regulating the wave pattern.

Two Ovaries – One Wave

The two ovaries act as a single unit; that is, one ovary does not have follicular waves independent of the other. The ovaries respond in unison to factors regulating follicular wave dynamics; hence a follicular wave is the result of multiple follicle growth in both ovaries (Figures 25.6 and 25.7). In a critical study of the intra-ovarian relationships among follicles and the CL [40], the authors concluded that the dominant follicle suppresses subordinates and new wave emergence via systemic rather than local channels. The presence of a dominant follicle in one ovary had no effect that could not be seen equally in the other ovary. Hence, no intraovarian relationships were found in the location of successive dominant follicles during the estrous cycle; i.e. the side of anovulatory and ovulatory dominant follicles was random. These observations are consistent with the findings of early studies on the effects of unilateral ovariectomy. Removal of the ovary with the largest follicle resulted in an increase in follicle development in the remaining ovary, but removal of the ovary without the largest follicle resulted in no such compensatory effect (cited in [40]). While intrafollicular (autocrine and paracrine) factors are important for growth, health, and demise of an individual follicle, there is no convincing *in vivo;* documentation of one follicle affecting the health/regression status of its neighbors directly.

Asymmetry in follicle dynamics in the left and right ovaries has been used to elucidate local versus systemic mechanisms of control of ovarian function, and some have reported greater follicular activity and proportion of ovulations in the right ovary in cattle (c. 60%) [19, 42], whereas others report no such differences [34, 40]. Ovarian follicular asymmetry has also been attributed to the presence of a CL. A positive intra-ovarian effect of the CL on the development of small antral follicles (≤3 mm) has been documented in sheep [56] and cattle [42], but the positive effect did not extend to large dominant follicles [40, 42]. To the contrary, the CL of pregnancy has been associated with a negative intraovarian effect on the dominant follicle [40, 57]. Dominant follicles of successive waves were more frequently (75–80%) found in the ovary contralateral to the CL during pregnancy. The cause of the negative local association between the CL and the follicles is unknown, but it may be directly related to the conceptus rather than to the CL. Support for this notion is found in the observation that there were no ovarian asymmetries during the first two follicular waves in pregnant cattle or in ten successive follicular waves in unmated progesterone-treated heifers [43]. The latter observation, however, is confounded by the fact that exogenous progesterone did not forestall luteolysis in treated heifers; luteal regression occurred at the expected time for a non-pregnant animal regardless of progesterone treatment. However, an experimental design involving hysterectomy during mid-diestrus permitted direct comparison of the effects of a persistent CL due to hysterectomy or due to pregnancy [58]. Results demonstrated that unilateral attenuation of follicle development was due to the conceptus or the ipsilateral gravid uterine horn, and not the CL.

Hormonal Interplay Controlling Follicular Wave Dynamics

Results of early studies of follicle dynamics gave rise to the hypothesis that the dominant follicle suppresses the growth of the subordinates in the existing wave and suppresses the emergence of the next follicular wave [39, 41]. Support for this hypothesis was provided in a series of studies involving

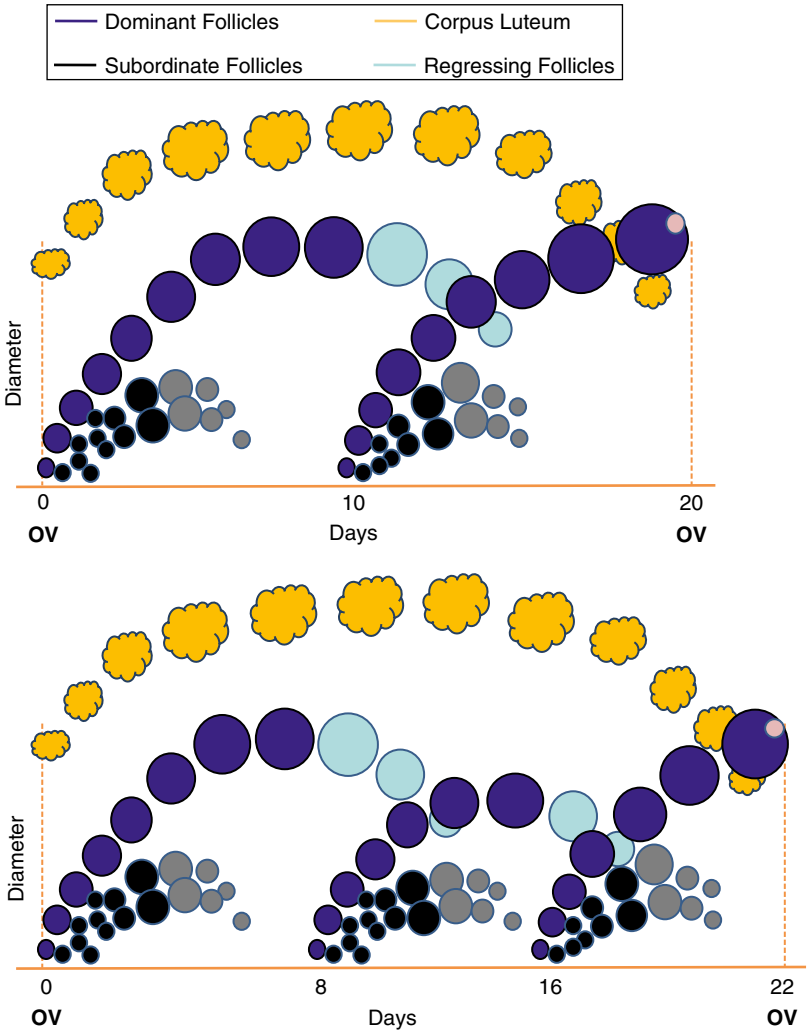

Figure 25.7 Follicular dynamics during two-wave (upper) and three-wave (lower) estrous cycles in cattle. Data from both ovaries are used to identify the dominant follicle of each wave (growing: dark blue; regressing: pale blue), the subordinate follicles of each wave (growing: black; regressing: gray), the occurrence of ovulation, and the growth and regression of the CL (dark yellow). A follicular wave in cattle is characterized by the sudden emergence (within two to three days) of a group of small follicles (n = 8–41) that grow at a similar rate for about two to three days, at which time one follicle is selected to continue growth (dominant follicle) while the rest become atretic and regress (subordinate follicles). The often referred to "21-day" estrous cycle of cattle exists only as an average between two-wave (20 days) and three-wave (22 days) cycles.

systemic treatment with the proteinaceous fraction of follicular fluid and by electrocautery of the dominant follicle [59–62]. The applied implications of these findings were immediate and far-reaching, and marked a new era for ovarian synchronization and superstimulation in cattle (reviewed in [63–65]).

Emergence of a follicular wave and selection of the dominant follicle are temporally and causally associated with a rise and fall in circulating concentrations of FSH [61] (Figure 25.8). Emergence of a follicular wave is preceded by a surge in plasma FSH concentrations in both spontaneous waves and induced waves [61, 67]. Surges in FSH preceding each wave are of similar magnitude; i.e. mid-cycle surges are similar in amplitude and breadth to that of the preovulatory gonadotrophin surge [61, 67]. Follicular products, especially those from the dominant follicle, are responsible for suppressing FSH release and, therefore, the emergence of the next follicular wave [68] (Figure 25.9). A direct relationship between the number of follicles emerging in response to the FSH surge and the subsequent degree of FSH suppression [70–72] documents that all follicles of the new wave contribute to FSH suppression.

Estradiol and inhibin-A and -B are the principal follicular products responsible for suppressing FSH [68, 73–77]. Inhibin-A produced by all the small growing follicles of the wave appears to be the most important suppressor of FSH

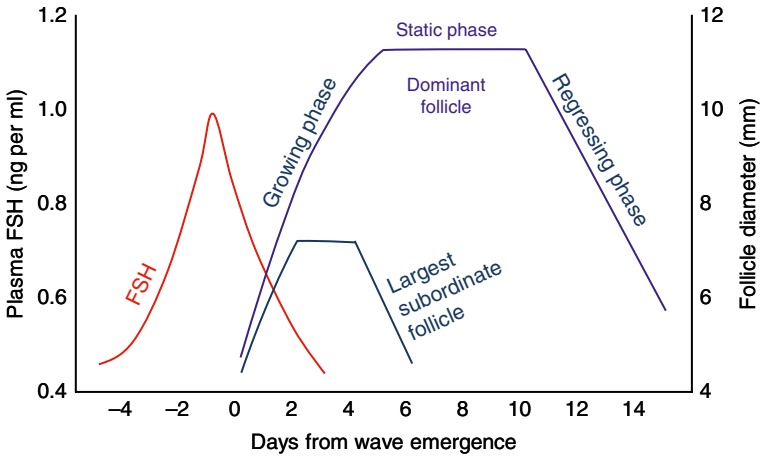

Figure 25.8 Temporal and causal relationship between surges in circulating concentrations of FSH and follicular wave emergence in cattle. Peak concentrations of FSH occur on the day before follicular wave emergence (at 4 mm) and decline to nadir by three days after wave emergence at the time the dominant follicle can be distinguished from the subordinates. Development of a dominant or subordinate follicle may be divided into a growing phase (best characterized by a quadratic equation), a static phase, and a regressing phase (best characterized by simple linear equations). *Source:* Data from [61, 66].

during the first two days of wave emergence, and oestradiol secreted from the dominant follicle is the most important FSH suppressor thereafter [78–81]. The nadir in FSH is reached four days after wave emergence and levels remain low for the next two to three days. At the end of the period of dominance (i.e. at ovulation or the mid-static phase of an anovulatory dominant follicle), circulating concentrations of FSH begin to rise over the next two days and peak about 12–24 hours before emergence of the next follicular wave, when the future dominant follicle is 4–5 mm in diameter. If an existing dominant follicle is removed (i.e. follicular ablation), a surge in FSH begins within the next 12 hours and results in emergence of a new follicular wave within the next 24 hours [59, 82]. Interestingly, FSH rose again only when inhibin-A concentrations reached nadir, despite estradiol declining two days earlier [74].

An inverse relationship between circulating progesterone concentrations and dominant follicle growth was suggested by the observations that (i) in three-wave estrous cycles, the maximum diameter of the dominant anovulatory follicle was greater for wave 1 (under minimal luteal dominance during its growing phase) than for wave 2 (under maximum luteal dominance); (ii) the maximum diameter attained by the dominant anovulatory follicle was greater for wave 1 than for all subsequent waves in pregnant and non-mated progesterone-treated heifers; and (iii) high concentrations of progesterone (endogenous plus exogenous) resulted in a smaller maximum diameter of the dominant follicle of wave 2 compared with subsequent waves (exogenous progesterone only) in non-mated progesterone-treated heifers (reviewed in [83]). A cause-and-effect relationship was established in studies in which progesterone was shown to suppress the dominant follicle during its growing phase in a dose-dependent manner [83] through the negative feedback effect of progesterone on LH pulsatility [84–86]. The suppressive effects on the dominant follicle were not mediated by decreased circulating FSH since progesterone treatment did not suppress FSH [83]. High plasma progesterone during follicular growth resulted in a smaller, shorter-lived dominant follicle and an earlier surge in FSH preceding the next follicular-wave, and hastened emergence of the next follicular wave (Figure 25.10). Conversely, low concentrations of progesterone resulted in an oversized persistent dominant follicle, a delayed surge in FSH, and delayed emergence of the next wave [83]. The oversized dominant follicle in the low-dose group would have been considered a pathological follicular cyst because of its size and persistence for more than 10 days in the absence of a CL [87, 88]. Low-level progesterone exposure (and therefore less inhibition of LH) at the time the dominant follicle normally stops growing appears to be a fundamental component in the etiology of ovarian follicular cysts [83].

Selection of the Dominant Follicle

In monovular species, the term "selection" refers to a process by which a single follicle becomes functionally and morphologically dominant over other follicles of a wave. In cattle, the mechanism of selection of the dominant follicle is based on relative reliance of follicles within a wave on FSH and their relative responsiveness to LH. The transient rise in FSH permits sufficient follicular growth so that some (not all) follicles acquire LH responsiveness. The ability to respond to LH imbues the follicle with the ability to survive without FSH.

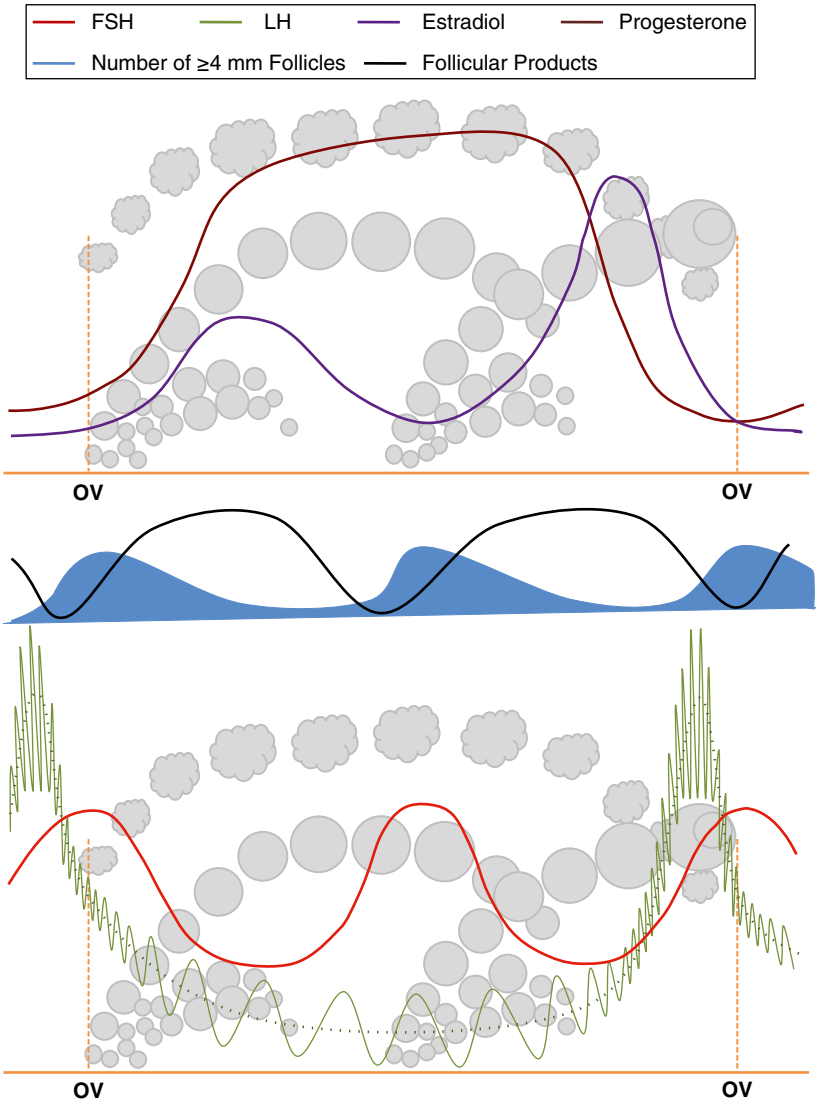

Figure 25.9 Hormonal interplay controlling follicular wave dynamics during a two-wave interovulatory interval in cattle. Dominant and subordinate follicles of each wave are indicated as gray-shaded circles, and the CL is the gray-shaded irregular shape drawn above the follicles. A surge in circulating concentration of FSH precedes emergence of each wave. A surge in circulating concentration of LH precedes ovulation. The LH surge is preceded and succeeded by a period of high LH pulse frequency as a result of low circulating concentrations of progesterone (i.e. period of luteolysis and luteogenesis, respectively). The number of follicles ⩾4 mm fluctuates in a wave-like fashion in response to surges of FSH. Products of the follicles of each wave (primarily inhibin and estradiol) feedback on the hypothalamus and pituitary to suppress FSH. Concentrations of FSH decline at the time that selection of divergence in growth rate of the dominant vs subordinate follicles and follicle numbers decline. The dominant follicle of each wave is the primary source of estradiol and production is twice as high in the ovulatory vs anovulatory dominant follicle. Upon the demise or ovulation of the dominant follicle, the follicular products responsible for suppressing FSH drop and circulating concentrations of FSH are again allowed to surge, resulting in new wave emergence. *Source:* Adapted from [69].

It remains unclear precisely when the process begins, but selection of the dominant follicle is associated with declining levels of FSH in circulation during the first three days of the wave [60, 61]. By using the ablation-replacement approach, a recent study documented that dominant follicle selection in cattle and growth thereafter is due to LH actions [89]. Small follicles of the emerging wave (i.e. <6 mm) are dependent on elevated circulating concentrations of FSH for continued development. In the face of the post-surge decline in FSH, the growth of most of the follicles of a wave stops and they begin to regress within two to five days of emergence. Conversely, the follicle destined to become dominant can maintain cell proliferation and estradiol production despite declining FSH concentrations – an ability that appears to be brought about by maintaining high FSH receptor mRNA expression and

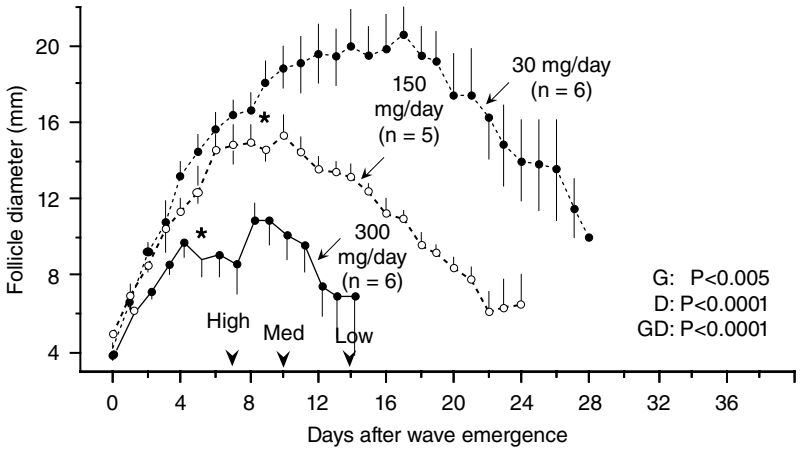

Figure 25.10 Suppressive effect of progesterone on the growth of the dominant follicle in cows. Exogenous progesterone administered in low (30 mg/day), medium (150 mg/day), and high (300 mg) doses for 14 days resulted in progressively greater suppression of the growth of the dominant follicle and progressively shorter interwave intervals (arrowheads on x-axis). Maximum plasma progesterone concentrations were 2, 9, and 17 ng/ml in the low-, medium-, and high-dose groups, respectively. The suppressive effect on the growing phase of the dominant follicle is attributed to progressively more suppression on LH pulse-frequency. P-values from the analysis are include. G, Group effect; D, day effect; GD, group by day interaction. *Source:* Adapted from [83].

FSH-binding affinity [36, 37, 90, 91]. It is becoming clear that the initial exposure to FSH and the ability of the dominant follicle to transition from FSH to LH are critical for the selection of a single dominant follicle in cattle [92].

Divergence in the growth profiles (defined as a significant difference in diameter) of the largest and second largest follicle is a manifestation of the selection process and is apparent by 2½ days after wave emergence (Figures 25.8 and 25.9) [60]. Similarly, follicle "deviation" (defined as a difference in growth rate between the dominant and subordinate follicles) is manifest at 2½ days after wave emergence, when the future dominant follicle reaches a mean diameter of 8.5 mm in Holstein heifers (reviewed in [93]). Continued development of the dominant follicle beyond the 8-mm threshold (point at which divergence in the growth rate of the largest two follicles becomes evident) is associated with a transition from FSH- to LH-dependence [78, 80, 94]. Granulosa cells from the dominant follicle acquire an enhanced ability to bind LH compared to that of the subordinates and have greater LH receptor mRNA expression [37, 90, 91, 95, 96]. Although a slight increase in LH receptor mRNA expression was detected in granulosa cells from the largest follicle a few hours before the onset of deviation [97], it is not yet clear whether the observed increase in LH receptor expression in the dominant follicle is the cause of dominance or a consequence of the selection process. Perhaps the increased LH receptor expression is merely a reflection of a follicle with a developmental advantage before such an advantage becomes ultrasonographically apparent. In this regard, results of a critical study of the development of small follicles support the hypothesis that the follicle destined to become dominant has a size advantage over the others in the wave from its earliest detection at 1 mm (Figure 25.11; see next section on small antral follicles).

Differential production of follicular-fluid factors of the dominant vs subordinate follicles has been associated with the development of greater sensitivity to LH and FSH in the developing dominant follicle, and close temporal coupling between changes in FSH and follicle diameter likely accounts for the increase in growth rate of the dominant follicle before the subordinate follicles can reach a similar stage of development [80]. In this regard, intrafollicular concentrations of IGF-1 remain elevated and estradiol begins to increase in the incipient dominant follicle, while both begin to decrease in the incipient subordinate follicles [98]. Higher concentrations of free IGF-1 in the largest follicle near the beginning of deviation are temporally associated with greater proteolytic degradation of IGF binding protein (IGFBP) -4 and -5 in the largest follicle [99]. Concomitantly, the concentrations of IGFBP-4, -5 [99], and -2 [97] are greater in the second-largest follicle. Not surprisingly, more recent transcriptomic studies have confirmed that major functional pathways in the growth and selection of dominant follicles in cattle involve genes regulating cell differentiation/proliferation and apoptosis/cell death [95, 100–102]. Even when follicle selection is prevented by superstimulatory treatment, multigene bioinformatic analysis confirmed that markers of fertility and follicle maturity are upregulated after longer seven-day FSH treatment than the conventional four-day treatment [103], thereby indicating that duration of follicle differentiation is also a vital factor.

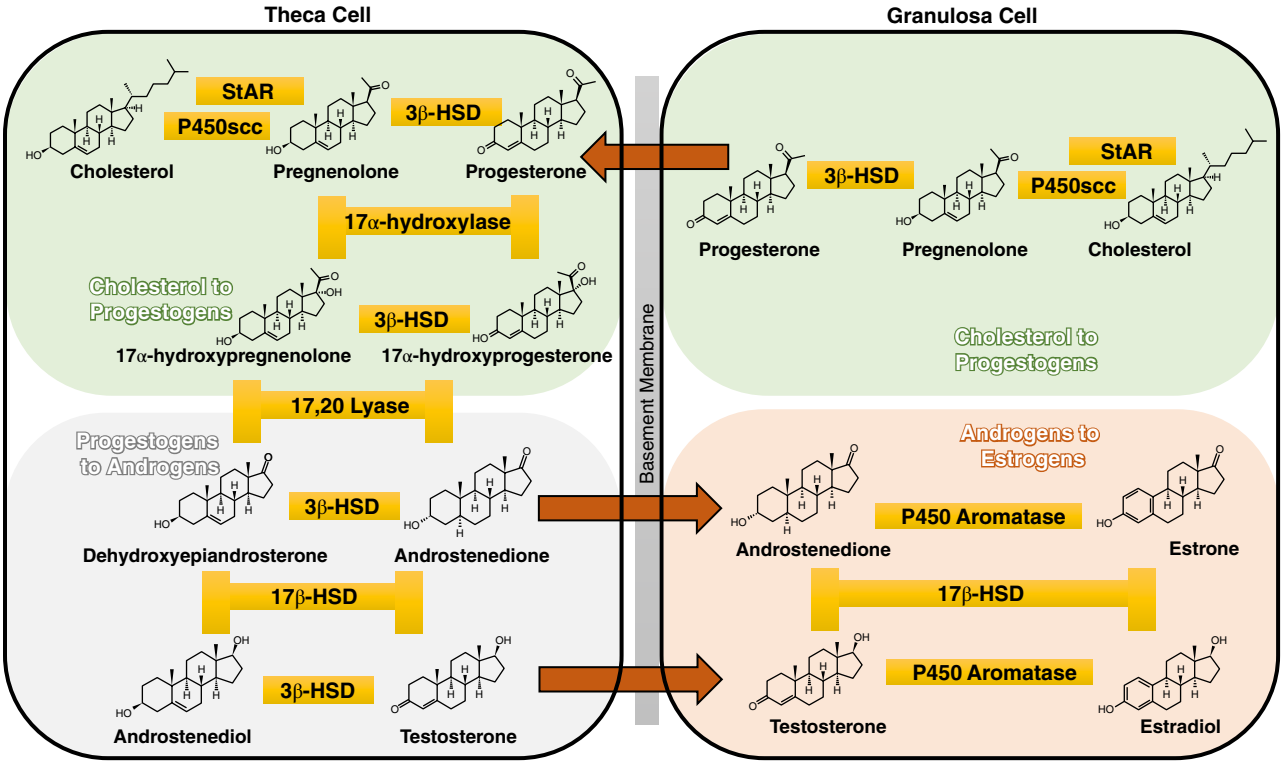

Figure 25.11 Steriodogenesis in ovarian follicles entails the cooperation between granulosa (right) and theca (left) cells and requires P450 side cleavage chain (P450scc), 3β-hydroxysteroid dehydrogenase (3β-HSD), 17α-hydroxylase, 17,20-lyase, 17β-hydroxysteroid dehydrogenase (17β-HSD), and P450 aromatase enzymes. Both cell types are capable of producing progestogens from cholesterol. Conversion from progestogens to androgens occurs only in theca cells, while conversion from androgens to estrogens is confined exclusively to granulosa cells.

Co-dominance

Subordinate follicles can achieve dominance if the original dominant follicle is removed [60, 71] or if exogenous FSH is supplied [59]. Similarly, co-dominance (more than one dominant follicle in a wave) is associated with a smaller-diameter profile [59, 104], suggesting competition over limited availability of LH. Double ovulations result from co-dominance during the ovulatory wave. The incidence of co-dominance and double ovulation was low or nil in studies of non-lactating heifers [34, 39, 105–107], but co-dominance ranged from 21 to 36% of follicular waves in lactating dairy cows [107]. A high incidence (10–39%) of multiple ovulations in high-producing dairy cows has been described in several studies [104, 108, 109]. In cows that ovulated multiple follicles, all ovulatory follicles emerged from the same follicular wave [107]. In cows that developed multiple dominant follicles, the process of deviation was associated with lower circulating concentrations of inhibin and progesterone than in cows that developed a single dominant follicle [104]. These effects are consistent with higher circulating concentrations of FSH and LH at the expected time of deviation, continued growth of the second and third largest follicles of the wave, and development of multiple dominant follicles.

Follicular Steroidogenesis – Estradiol Production

Early antral follicles primarily produce proteins and growth factors. Follicular fluid obtained from 1-mm antral follicles contains a very small amount of estrogens, whereas three days later the newly selected dominant follicle (8–9 mm) has >15 times more estradiol than progesterone in its follicular fluid [68]. Steroid production requires a coordinated effort by theca and granulosa cells and is independent of oocyte status. Circulating low-density lipoproteins in blood provide the precursor molecule cholesterol for the biosynthesis of steroids (Figure 25.11). In the granulosa and theca cells, the steroidal acute regulatory protein (StAR) is required to transport cholesterol from the outer into the inner mitochondrial membrane and is one of the key regulatory enzymes in the ovarian steroid pathway. StAR mRNA levels increase with follicular development; levels are highest at the time of maximum size of the dominant follicle and become low or undetectable in atretic follicles [90]. Inside the mitochondria, the conversion of cholesterol to pregnenolone is regulated by the P450 side-chain cleavage enzyme (P450scc; encoded by CYP11A1 gene) in the granulosa and theca cells [110]. Pregnenolone can be converted to either 17α-hydroxypregnenolone by 17α-hydroxylase (encoded by

CYP17A1 gene) or progesterone by the 3-beta-hydroxysteroid dehydrogenase enzyme (3β-HSD). Further, progesterone to 17α-hydroxyprogesterone conversion can be catalyzed by 17α-hydroxylase, while 3β-HSD converts 17α-hydroxypregnenolone to 17α-hydroxypregnenolone. Conversion of progestogens to androgens occurs only in theca cells. Progesterone produced by the granulosa cells must get exported to the theca cells for this conversion to happen. The enzyme 17,20-lyase in the theca cells then coverts 17α-hydroxypregnenolone to dehydroepiandrosterone (DHEA) or 17α-hydroxyprogesterone to androstenedione. DHEA can yield either androstenediol by 17β-HSD or androstenedione via 3β-HSD. Both androstenediol and androstenedione can produce testosterone by 3β-HSD and 17β-HSD, respectively. Coversion of androgens to estrogens requires aromatase enzyme ($P450_{arom}$; encoded by CYP19A1 gene) and occurs exclusively in the granulosa cells. $P450_{arom}$ catalyzes conversion of androstenedione and testosterone into estrone and estradiol, respectively. Finally, estrone can be converted to estradiol by 17β-HSD [110, 111]. Successful production of estradiol by a dominant follicle requires the optimal health and balanced effort of both the theca and granulosa layer of the follicle wall.

Small Antral Follicles – When Do Follicles Join a Wave?

Previous ultrasonographic studies have detailed the developmental dynamics of follicles ≥4 mm (described above), but with the availability of newer ultrasound scanners capable of resolving structures as small as 1 mm, the developmental pattern of 1- to 3-mm follicles in cattle has been examined in detail [112]. Results revealed a change in the number of 1- to 3-mm follicles over days, with a maximum one or two days before conventionally defined wave emergence (i.e. when the dominant follicle is first detected at 4 mm), followed three to four days later by a maximum in the number of ≥4 mm follicles. The future dominant follicle was first identified at a diameter of 1 mm and emerged 6–12 hours earlier than the first subordinate follicle ($P < 0.01$; Figure 25.12). After detection of the dominant follicle at 1 mm (0 hours), its diameter was greater than that of the first and second subordinate follicles at 24 and 12 hours, respectively, when the dominant follicle was 2.4 ± 0.17 mm and 1.7 ± 0.14 mm (Figure 25.12). The growth rate of the dominant follicle was greater than that of the first and second subordinate follicles at 120 and 108 hours, respectively, when the dominant follicle was 9.5 ± 0.30 mm and 8.8 ± 0.49 mm. The authors concluded that: (i) 1- to 3-mm follicles develop in a wave-like manner in association with surges in plasma concentrations of FSH; (ii) such follicles are exquisitely responsive to transient elevations in FSH (i.e. within six hours); (iii) selection of the dominant follicle is manifest much earlier than previously documented; (iv) follicular dominance is characterized by a hierarchical progression over a period encompassing the entire FSH surge (five days; Figure 25.12); and (v) divergence in growth rates [93] (referred to as "deviation") of the dominant and largest subordinate follicles is apparent when the largest follicle reaches a diameter of 8–9 mm.

While the developmental dynamics of follicles ≥1 mm have now been well characterized, the dynamics of smaller follicles remain a mystery. An early study demonstrated the binding of FSH to the granulosa of follicles with only a single layer of granulosa cells [113], but it has been argued that they may not be coupled to the adenylate cyclase-second messenger system during early stages of folliculogenesis and may be non-functional [114]. However, the growth-promoting effect of FSH on preantral and small antral follicles in cattle produced *in vitro;* [115] and *in vivo;* [116, 117] suggests a role for FSH in the development of early-stage preantral and antral follicles. These observations challenge the old dogma that early follicle growth is gonadotropin-independent. In this regard, the activation of primordial follicles is thought to be gonadotropin independent.

If small follicles are responsive to FSH, it is logical to postulate that their developmental dynamics follow a wave-like pattern in response to periodic endogenous surges of FSH. Until recently, reference to a follicular wave was limited to follicles ≥4 mm, based simply on the limit of resolution of existing ultrasound equipment. At the microscopic level, there is no morphologic distinction between mid- to late-stage antral follicles <4 mm and those ≥4 mm [9, 10]. At the cellular level, both size categories of follicles not only express FSH receptors but also have a similar level of expression on a per granulosa cell basis (reviewed in [90]). The periodic emergence of waves of follicles ≥4 mm in response to periodic surges in the circulating concentrations of FSH [61] and the consistency in the number of follicles ≥2 mm [118] or ≥3 mm [70] recruited into successive waves indicate that the follicles may become progressively entrained to waves from the earliest stages of development.

Ovulation and Oocyte Maturation

Ovulation involves a series of events that culminate in the evacuation of the antral contents of a follicle, including its mature cumulus-oocyte complex (Figure 25.13), and the initiation of development of a CL. Several events happen in succession and are tightly coordinated at systemic, cellular, and molecular levels. The process begins with endocrine changes triggered by luteolysis. A decrease in circulating concentrations of progesterone at the time of luteolysis

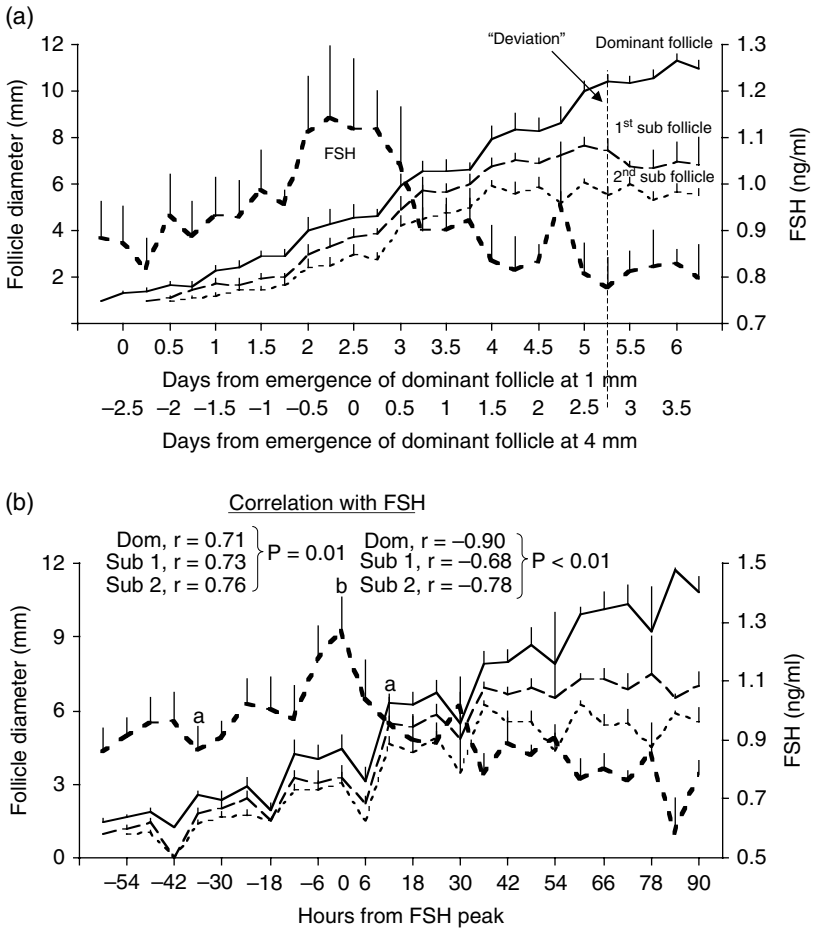

Figure 25.12 Growth (mean ± SEM) of dominant and subordinate follicles in cattle (n = 9) relative to: (a) wave emergence (defined as the day on which the dominant follicle was detected at 1 or 4 mm in diameter; double x-axis), and (b) the peak in plasma FSH concentrations (mean ± SEM). (a) The future dominant follicle had a size advantage over all other follicles of the wave from its earliest detection at 1 mm (much earlier than previously documented). Successive slowing of the growth rate of the third, second, and first largest follicles of a wave during the decline in the FSH surge suggests that the selection mechanism involves sequential suppression of progressively larger follicles over a period of 72 hours (i.e. selection hierarchy). "Deviation" is defined as the first day on which the growth rate of the largest and second largest follicles differed ($P \leq 0.05$). (b) Plasma FSH concentrations were positively correlated ($P = 0.01$) with follicle diameter from the time of follicle detection at 1 mm to the time at which FSH concentrations peaked. Transient elevations in plasma FSH concentration were followed within six hours by an increase in the growth rate of 1- to 3-mm follicles. *Source:* Adapted from [112]. [ab] For FSH, values with no common superscript are different ($P \leq 0.05$).

removes the negative feedback effects on the pituitary and hypothalamus, resulting in an increase in LH pulse frequency and amplitude. Availability of LH results in final maturation of the dominant follicle with an increase in production of estradiol and upregulation of LH receptors on granulosa cells. The preovulatory increase in LH results in extensive ovarian matrix remodeling (vascular changes, disintegration of the basement membrane, and rupture of the follicle wall), granulosa and theca cell responses (cumulus cell expansion, luteinization), and resumption of meiosis by the oocyte. At estrus, the high circulating concentration of estradiol in the absence of progesterone is responsible for a surge release of LH and estrous behavior (increased locomotion, phonation, mounting, and standing to be mounted).

Although LH receptors are present on both granulosa and theca cells [11], receptor distribution within the granulosa cells is confined to the mural granulosa cells. In addition, LH receptors are highly expressed in those layers closer to the basement membrane than those closer to the antrum [119]. Consequently, LH needs second messengers to be able to affect the entire follicle and the oocyte. The effect of second messengers is facilitated by the intimate relationship among granulosa cells and cumulus cells and the oocyte through gap junctions (Figure 25.4) [120]. The two main second messengers for LH are cAMP and intracellular calcium [121]. Binding of LH to the G protein receptors on the granulosa cell surface results in activation of adenyl cyclase, an increase in cyclic AMP, and stimulation

of the protein kinase A and C pathways. Stimulation of PKA and PKC cause phosphorylation and activation of transcription factors (Egr-1, C/EBPβ, CREB, Fos, Jun, Fra2, JunD) within four hours of the LH surge. Expression of some of these genes is transient, while others are sustained until ovulation (review in [122]). C/EBPβ controls expression of COX-2, which is a key gene in the prostaglandin pathway. Granulosa cell products of epidermal-like growth factor (EGF) expression (epiregulin, amphiregulin, and betarcellulin) are elevated one to three hours after the LH surge and are involved in transmitting the ovulatory signal to cumulus cells [123]. The LH surge also indirectly induces activation of the progesterone and prostaglandin pathways [124] that modify fibroblast function and produce chemokines that recruit inflammatory cells and growth factors that initiate angiogenesis (e.g. VEGF). The LH-induced

extracellular protease ADAMTS1 is synthesized in granulosa cells, but the protein is translocated to the extracellular matrix to induce the production of versican (chondroitin sulfate proteoglycan 2) (reviewed in [125]) and is implicated in the activation of tissue proteases such as the metalloproteinases required for follicle rupture.

The extracellular matrix that surrounds and supports cells is a major component of connective tissue (Figure 25.4). It is composed mainly of structural proteins (elastin and collagens), specialized proteins (fibrillin, fibronectin, laminin), and proteoglycans. It plays a prominent role in ovarian function by participating in processes such as cell migration, proliferation, growth, and demise during follicle development, ovulation, and CL formation. Two families of enzymes govern degradation of the ovarian epithelium during ovulation: metalloproteinases and plasminogen activators. Expression of both of these enzyme families is induced by the LH surge. Changes in gene expression of metalloproteinases and metalloproteinase inhibitors throughout the bovine estrous cycle have not been reported, but one factor that can induce expression is TNFα, which is secreted by preovulatory bovine follicles [126]. Heparanase (encoded by HPSE) cleaves heparan sulfate glycosaminoglycans during matrix remodeling and may also play a major role in follicle rupture during ovulation in cattle [127]. LH-induced ovulation is also associated with the increase in the expression of yet another group of proteases called kallikreins [128]. It appears that many paracrine factors, pro-inflammatory cytokines, and families of protease enzymes act in concert with each other, leading to degradation of extracellular connective tissue and ultimately follicle rupture, on average 30 hours after the LH surge [129].

Meiotic progression of the oocyte is arrested at prophase I (first meiotic arrest) during the fetal development of primordial follicles. The process of resumption of meiosis, release of half the set of chromosomes as a polar body, and progression to metaphase II is referred to as nuclear maturation (Figure 25.14). Shortly after the LH surge, the gap junctions between cumulus cells and the oocyte deteriorate [131, 132]. The loss in communication between cells removes inhibitory signaling and the oocyte can then resume meiosis. However, meiosis is stopped again at metaphase II (second meiosis arrest) until fertilization, when meiosis is finally completed. Mammalian oocytes have the propensity to resume meiosis if they are removed from the antral follicle in which they are housed [133–135], or if they are within preovulatory follicles under the influence of the LH surge [131, 136]. In cattle, a major proportion of oocytes reached MII at 20 hours of *in vitro* maturation [131] or 20 hours after a spontaneous or induced LH surge [136–138]. Cyclic AMP and GMP are considered the primary inhibitors of meiotic resumption in the oocyte [132]. Cyclic GMP produced by granulosa cells is thought to enter the oocyte via gap junctions between the oocyte and cumulus cells to maintain low levels of cAMP phosphodiesterase 3A (PDE3A) in the oocyte [139]. Low PDE3A is thought to maintain high levels of cAMP produced within the oocyte [140] and thus maintain meiotic arrest. Exposure to LH decreases cGMP production by granulosa cells through as yet unknown mechanisms, and uncouples the gap junctions (by phosphorylation of connexin-43) via mitogen activated protein kinase (MAPK) [139, 141, 142]. Reduced production and entrance of cGMP into the oocyte in turn increases PDE3A which ultimately hydrolyses cAMP and enables resumption of meiosis.

Luteal Dynamics

Based on the status of the CL, the estrous cycle may be divided into four successive phases: (i) proestrus, when the CL is regressing and an ovulatory follicle develops; (ii) estrus, the absence of a functional CL and the period of sexual receptivity when final follicular maturation and ovulation occur; (iii) metestrus, the period of CL formation; and (iv) diestrus, when the CL is mature and actively produces progesterone [143]. Proestrus and estrus have been referred to as the follicular phase, while metestrus and diestrus are the luteal phase, though "luteal phase" should not be taken to imply the lack of follicle development. To the contrary, follicular waves continue to develop throughout follicular and luteal phases of the estrous cycle, as described above.

Origin of the CL

The growth and demise of the CL during the estrous cycle represents one of the most rapid dynamic processes in the body. At the time of ovulation, antral contents are evacuated and the wall of the ovulatory follicle collapses into undulations within the vacated antrum (Figure 25.15). The granulosa and theca cells of the former follicle then expand beyond the volume of the former follicular antrum through a dramatic process of vascularization and luteinization to form a functional CL. This temporary steroid-producing gland undergoes marked structural and functional changes in a short time-span and has been the subject of extensive morphological studies (Figure 25.15) (reviewed in [144]). Plasma progesterone concentration is highly correlated with CL weight, volume [145], histomorphology [146], and ultrasound morphology [144].

During metestrus, blood vascular components occupy the greatest percentage volume of the CL. The luteal cells undergo hypertrophy at mid-diestrus, during peak progesterone production, in association with their greatest volume density. An increase in luteal cell size during the formation phase and decrease during the regression phase

parallel progesterone secretion. During proestrus, the regressing CL decreases in weight, in volume densities of luteal cells and blood vascular components, and in progesterone production. There is a concurrent increase in connective tissue and hyalinization of blood vessels. Individual luteal cells undergo degenerative changes reflected by decreased cell size and accumulation of coarse lipid droplets in the cytoplasm. These morphological changes are associated with progressive changes in plasma progesterone concentration from <2 ng/ml at three days after ovulation to about 4 ng/ml by six days and peak concentrations >6 ng/ml between 10 and 14 days postovulation, followed by decreasing levels after 16 days due to luteolysis [83].

Ultrasonographic Detection and Morphology of the CL

The reliability and accuracy of ultrasonography for detecting the CL and the relationship between ultrasound image attributes and CL function have important implications in clinical settings for assessing normalcy and stage of the cycle. In a comparison between ultrasonographic detection versus gross anatomic dissection, there was 83% agreement in inexperienced operators and 97% agreement in experienced operators [147]. The growing CL was detected by day 2 (day 0 = ovulation) in >95% of 80 estrous cycles, and the regressing CL was detected, on average, 1.4 days into the next estrous cycle [147].

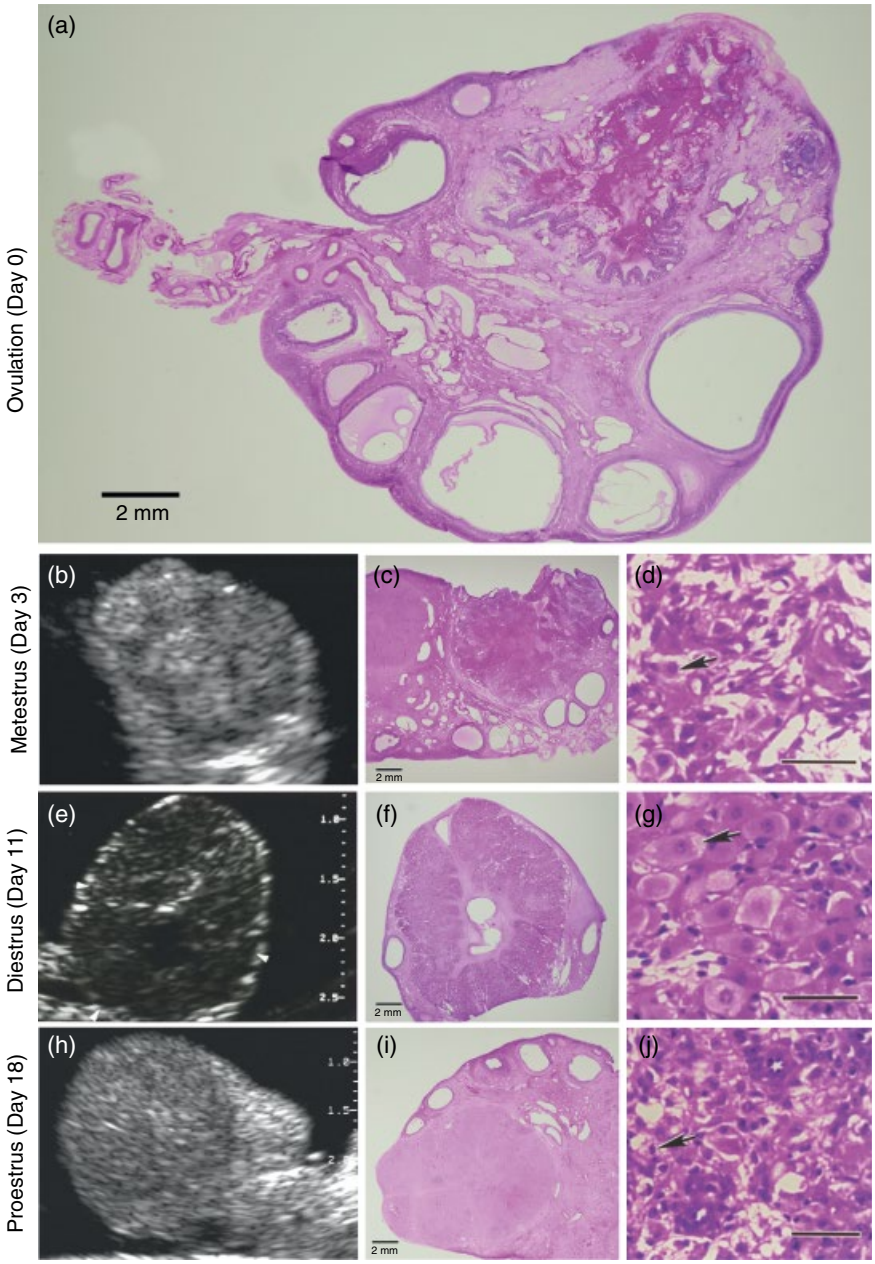

Figure 25.15 Development of the corpus luteum in cattle. (a) Histological section of an ovary taken within one hour of ovulation. Note the collapsed follicle with extensive crenulation of the follicle wall (arrowhead) and blood clot in the antrum. Note also numerous small antral follicles in the ovary, typical of new wave emergence at the time of ovulation. Ultrasound morphology (b, e, h), low magnification histology (c, f, i), and tissue details (d, g, j) of bovine corpora lutea during metestrus (b, c, d; day 3 after ovulation), mid-diestrus (e, f, g; day 11 after ovulation), and proestrus (h, i, j; day 18 after ovulation). Arrows indicate luteal cells. Greater angiogenesis during metestrus and hyalinization of blood vessels during proestrus (luteal regression) resulted in brighter echotexture of ultrasound images at these stages compared to diestrus. Histological images were taken from 5-μm-thick paraffin sections stained with hematoxylin and eosin. Scale on the ultrasound images (b, d, f, h) is in centimeters. Scale bar is 2 mm for a, c, f, i and 10 μm for d, g, j.

A large proportion (40–70%) of normal corpora lutea have a central fluid-filled cavity during their development; the remainder are solid structures (reviewed in [144, 148]). The cavity of the CL is filled with a serous transudate and remains anechoic during its entire existence, as opposed to the organized clot and appearance of a network of echogenic lines within the central cavity of the equine CL. The central cavity becomes smaller and often disappears as the CL matures. Plasma progesterone concentrations are not different between CL with or without a central cavity. The profile of luteal tissue area (minus area of a cavity if present) detected by ultrasound paralleled the profile of plasma progesterone concentration, with the exception that during luteolysis progesterone

began to decrease one to two days before ultrasonographic regression was apparent [62].

Changes in ultrasound image attributes (echotexture) of the CL are also reflective of CL function in cattle (Figure 25.15) [144]. Higher pixel values, obtained by computer-assisted quantitative echotexture analysis during luteal gland formation (metestrus) and regression (proestrus group) were similar to the pattern observed in horse and pony mares by subjective scoring of echotexture [149] and pixel analysis [150, 151] of corpora lutea recorded *in vivo;* by transrectal ultrasonography. In a test of the hypothesis that ultrasound images may be digitally "stained," computer algorithms were developed to produce a "virtual histology" through subtle differences in echotexture resulting from different ovarian structures [152]. Quantitative analysis showed that the "sticks" algorithms increased the statistical differences in the echotexture of ovarian stroma versus the CL, representing a first step toward virtual histology of ultrasound images and understanding dynamic changes in the ovary at the microscopic level in a safe, repeatable, and non-invasive way [153].

Vascular Flow Dynamics in the CL

Major changes in the microvasculature of the ovary occur during growth and regression of large follicles and the CL [144, 154, 155]. Three variations of the Doppler technique have been used to study vascular flow: (i) spectral Doppler is used to display vascular flow over time in a waveform; (ii) color-flow Doppler permits superimposition of information about vascular flow direction on the B-mode gray-scale image; and (iii) power-flow Doppler is used to superimpose low velocity vascular flow information (without directional information) on the B-mode gray-scale image. Doppler studies have provided visual evidence for time-related changes in blood flow within the preovulatory follicle wall of cows in relation to LH surge [154, 156]. Initial results indicate that a biphasic blood flow response to LH may occur in the bovine preovulatory follicle. An initial increase in blood flow was accompanied by serration of the follicular granulosa layer within 3 hours of LH treatment and a second increase in blood flow was detected around 20 hours after LH [156]. Distinct changes in vascular flow patterns during luteogenesis, luteolysis, and early pregnancy and in response to GnRH, prostaglandin F2α (PGF), PGE, PGI, oxytocin, and NOS have been reported in cattle [154, 157–161].

Luteolysis

In the early 1970s, PGF was found to be the natural luteolysin in cattle [162, 163], and since that time PGF has become the most commonly used treatment for elective induction and synchronization of estrus in cattle [164–166]. Pulsatile release of PGF from the uterus initiates luteolysis beginning four to six days before ovulation [167, 168]. Early studies showed that the maturity of the CL at the time of PGF treatment influenced the luteolytic response [169]; PGF did not effectively induce luteolysis during the first five or six days following estrus. Lack of responsiveness was thought to be a result of a lack of PGF receptors in immature CL, but more recent work has refuted this theory by demonstrating the presence of PGF receptors in CL as early as two days after ovulation [170]. The reason for the resilience of the immature CL to PGF remains unclear, but some suggest that the mature CL may possess a positive feedback loop involving luteal oxytocin and tumor necrosis factor which elicits endometrial release of PGF and sustains the process of luteolysis [171, 172]. If this notion is correct and immature CL do not possess the positive feedback loop, then multiple injections of PGF may be expected to complete the luteolytic process in early stage CL. In this regard, luteolysis and ovulation was induced in 56/60 heifers (93%) given PGF in the morning and evening of either the fourth or fifth day after estrus in two studies involving ovarian superstimulation [173, 175]. Recent studies show a distinct cause-and-effect balance between the luteotrophic effect of endogenous LH pulses and the luteolytic effect of pulses of PGF; repeated PGF pulses from the uterus ultimately overcome the resuscitating effects of LH to complete luteolysis (reviewed in [174]).

Ovarian Dynamics During Different Reproductive States

Pre- and Peripubertal Periods

In the only study on ovarian follicle dynamics during the pre- and peripubertal periods, transrectal ultrasonography was used to monitor daily changes in follicle development in calves as young as two weeks of age; calves were monitored at regular intervals during the first year of life [175–177]. Puberty was defined as the time of the first ovulation and was determined to be 52–56 weeks (12–13 months) in the Hereford-cross heifers used in the study. Remarkably, follicular development occurred in a wave-like fashion, similar to that in adults, at all ages examined. Individual follicle development was characterized by growing, static, and regressing phases, and periodic surges in serum concentrations of FSH were associated with each follicular wave emergence (Figure 25.8). FSH surges spanned a mean of three days and were maximal one day before wave emergence. It was concluded that the mechanisms controlling the well-ordered phenomena of wave emergence, follicle selection, and follicle regression in mature cattle were also extant in prepubertal heifers.

The diameter profile of the dominant as well as the largest subordinate follicle in prepubertal calves increased

with age (Figure 25.16). The rate of increase was greatest from 2 to 8 weeks of age and again between 24 and 40 weeks of age, in temporal association with increases in mean concentrations of LH [176]. The number of follicles detected (≥3 mm in diameter) also increased dramatically between 8 and 14 weeks of age, and then appeared to decrease as puberty approached, in temporal association with the early rise and subsequent tapering of mean FSH concentrations. The developmental reason for the early rise in circulating concentrations of LH and FSH between 4 and 14 weeks of age is not clear, but it may reflect initial maturation of the hypothalamo-pituitary axis and subsequent sensitivity to negative feedback by ovarian steroids. This notion is supported by data illustrated in Figure 25.16 and in observed changes in the interval between the emergence of dominant follicles of successive waves (interwave interval). The interwave interval was relatively long (8–9 days) at 2 and 8 weeks of age, but was significantly shorter (6.8 days) at 14 weeks. The interwave interval gradually increased thereafter until puberty (7–9 days).

Examination of data from the period immediately preceding first ovulation and encompassing the subsequent two interovulatory intervals revealed unique characteristics at the onset of ovulatory cyclicity in cattle [177]. The first ovulatory cycle was short (7.7 ± 0.2 days) and the first ovulation occurred after the dominant follicle had entered the static phase; that is, the dominant follicle was older at the time of ovulation than its counterpart of later cycles. The first CL (from the aged ovulatory follicle) was smaller and shorter-lived than corpora lutea of subsequent cycles, thus resulting in an abbreviated interovulatory interval. The second interovulatory interval was of normal duration (20.3 ± 0.5 days) and was composed of two or three follicular waves. Mean serum estradiol and LH concentrations, and LH pulse-frequency increased as first ovulation approached, but FSH concentrations did not. Surges in FSH were associated with follicular wave emergence, as seen previously. These results demonstrate a striking similarity between the onset of puberty in young heifers and recrudescence of ovulatory cyclicity in postpartum cows (see below).

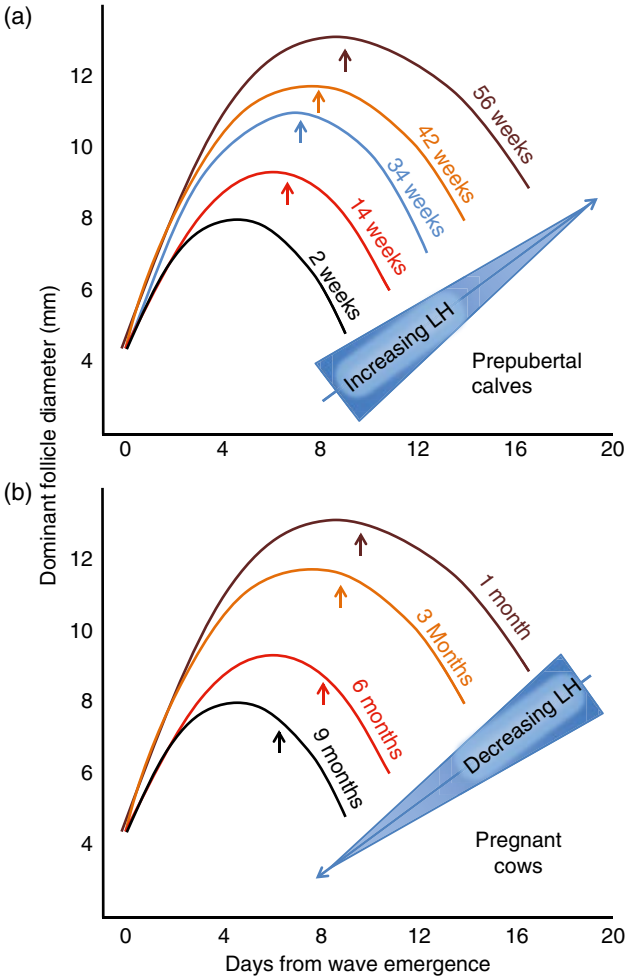

Figure 25.16 Diameter profiles of the dominant follicle of follicular waves during prepubertal development in calves (a) and during gestation in pregnant cows (b) as detected by daily transrectal ultrasonography. (a) The profile represented at 56 weeks of age is of the wave immediately preceding puberty (first ovulation). From 14 to 56 weeks of age, the interwave interval (indicated by arrows) increased from 6.8 to 9.2 days. (b) In pregnant cows from 1 to 9 months of gestation, the interwave interval (indicated by arrows) decreased from 9.6 to 6.4 days. *Source:* Data from [43, 57, 178]. Changes in dominant follicle profiles are associated with changes in circulating concentrations of LH.

Follicular Development During Pregnancy

Results of three separate studies are consistent in that the wave phenomenon occurs throughout pregnancy, except for the last 21 days when no follicles ≥6 mm were detected [43, 57, 178]. In the presence of progesterone [43] (endogenous or exogenous), anovulatory follicular waves emerge at regular intervals. However, the maximum diameter of the dominant follicle of successive waves decreased and was associated with a successive decrease in the interwave interval (i.e. the period of dominance became shorter; Figure 25.16). An initial decrease occurred immediately after the first follicular wave of pregnancy, and a subsequent sharp decrease occurred after the fourth month of pregnancy. Progesterone suppresses growth of the dominant follicle in a dose-dependent manner [83], and the progressive decrease in follicular dominance seen in pregnant cattle was attributed to the suppressive effects on LH of rising progesterone levels during mid-pregnancy and rising estrogen levels near term [178].

As in non-pregnant cows, periodic surges of FSH were associated with periodic emergence of follicular waves in

pregnant cows. In addition, the magnitude and frequency of FSH surges were influenced by the size of the dominant follicle. Waves in which the dominant follicle reached a diameter of ≥10 mm were associated with longer intervals between successive FSH surges and lower concentrations of FSH. Conversely, waves with smaller dominant follicles (i.e. 6–9 mm) were associated with shorter intervals and higher concentrations of FSH. A similar interrelationship between FSH and follicular wave dynamics was observed in prepubertal calves.

Follicular Development During the Postpartum Period

In all species in which it has been studied, lactation and suckling have been shown to have a suppressive effect on ovarian follicular development. The degree of suppression in cattle has been associated primarily with energy balance (nutritional status, body condition, milk production, parity) and periparturient disorders (metritis, endometritis, mastitis, lameness) (reviewed in [179–181]). The interval from calving to first ovulation in dairy cows was a mean of 21 days [182] (range 10–55 days), but was significantly longer in primiparous cows than multiparous cows [183] (31.8 ± 8.3 days vs 17.3 ± 6.3 days). Emergence of the first follicular wave postpartum ranged from 2 to 7 days (mean 4.0 days) after calving in primiparous Holsteins [178], and the dominant follicle of the first postpartum wave was ovulated in 14/19 multiparous Friesian cows (74%) [184] on mean day 27 (range 12–58) [185]. Recrudescence of follicular waves was observed within 10 days of calving in beef cattle [186], but the first ovulation occurred somewhat later than in dairy cattle (mean 30.6 days) and only rarely from the dominant follicle of the first postpartum wave (11%) [186].

The first postpartum ovulation is frequently associated with an absence of estrous behavior and is often followed by a luteal phase of short duration (reviewed in [187]). The first ovulation was not accompanied by estrus in 17/18 (94%) postpartum dairy cows [184], and the length of the first postpartum interovulatory interval varied depending on when the first follicle destined to ovulate emerged. The first postpartum interovulatory interval was short (mean 11.2 days) in approximately 25% of dairy cows, was of normal duration (mean 20.6 days) in another 25%, and was long (mean 30.0 days) in the remaining 50% of cows [184]. Short cycles were associated with later detection of the first follicle destined to ovulate (i.e. ≥10 days postpartum), whereas normal and long cycles were associated with earlier detection of the first follicle destined to ovulate (i.e. usually ≤10 days). These findings are remarkably consistent with those of another study [182] in which short postpartum anovulatory periods (around 14 days) were followed by a normal-length cycle (18–21 days), and longer postpartum anovulatory periods (21–25 days) were followed by a short cycle (<14 days). In the majority of beef cows (78%), ovulation occurred from the second, third, or fourth postpartum follicular wave, and as in dairy cattle, the first ovulations occurring after 20 days (16/18 cows) were followed by a short cycle (14/16 cows) [186]. Short cycles were associated with a short luteal phase, a smaller CL, and lower circulating progesterone concentrations. The short luteal phase following the first postpartum ovulation has been attributed to premature release of PGF2α by the uterus as a result of lower numbers of progesterone receptors and greater numbers of oxytocin receptors in endometrial cells (reviewed in [187]); however, luteal inadequacy as a result of altered preovulatory granulosa/theca cell differentiation in a low LH environment remains to be tested.

Follicular Development During Old Age

Decreased fertility with maternal aging has been well documented in cattle and humans [188–190]. Endocrine and ovarian characteristics of reproductive aging were characterized in a series of studies in which old cows (≥15 years) were compared with their young daughters (≤5 year) [191–193]. Mean circulating FSH concentrations were consistently higher in old cows than in their daughters, but the expected pattern of FSH secretion and wave emergence was maintained in old cows, i.e. each ovarian follicular wave was preceded by a surge in circulating FSH. Despite elevated FSH, fewer 4- to 5-mm follicles were recruited into each follicular wave in old cows than in their daughters. This interesting inverse relationship between the number of follicles recruited into a wave and the peak concentrations of FSH has also been reported in studies documenting the repeatability of follicle numbers within individuals [70, 118]. The duration of the interovulatory and interwave intervals did not change with age, but the ovulatory follicle of old cows with a two-wave pattern was smaller at the time of ovulation than that of young cows. Similarly, the diameter of the CL was smaller and the plasma concentration of progesterone tended to be lower in old versus young cows. There was no age effect on circulating LH concentrations or LH pulse frequency.

The responsiveness of the hypothalamo-pituitary axis in young and old cows was examined in a study involving estradiol/progesterone-based ovarian synchronization [192]. Steroid treatment suppressed circulating FSH in both age groups, and the intervals from treatment to subsequent FSH peak and wave emergence were not different between old and young cows. In a study of the ovarian response to superstimulatory treatment [194], fewer small (<5 mm) follicles were recruited into the follicular wave

and fewer follicles in all size categories developed after ovarian superstimulation in old cows than in their young daughters. On average, the young daughters had eight more ovulations per cow than their mothers. Lastly, data from a study in which embryos from old cows and their daughters were transferred to age-matched recipient cows [191] revealed that the oocytes from old cows were markedly less competent and produced only half as many embryos as their daughters.

Conclusions and Implications

Knowledge of normal follicular and luteal dynamics and the mechanisms controlling these dynamics have had a direct impact on clinical and breeding management practices in cattle. The concepts represented in Figure 25.9 have been used as a basis for developing protocols for ovarian synchronization for fixed-time insemination and for ovarian superstimulation for the purposes of *in vivo;* and *in vitro;* embryo production and embryo transfer, and for controlled breeding management programs in dairy and beef herds. The concepts of the wave pattern of follicle development and selection imply predictable variations in the number and maturity of specific classes of follicles (e.g. growing, static or regressing, dominant, and subordinate follicles) that may or may not be capable of responding to certain treatments. Importantly, the dynamics of follicular development are overlain by distinct influences of the CL. Some examples of the impact of endogenous ovarian rhythms on practice are offered below.

Synchronization

In cows in which luteolysis is effectively induced by PGF treatment, the ensuing estrus is distributed over a six-day period [195]. The most consistent response (i.e. the least variability in interval to estrus) resulted from PGF treatment during early diestrus (7 and 8 days after estrus) and later diestrus (15 days after estrus) than from treatment during mid-diestrus (10–13 days after estrus) [195]. Subsequent studies have documented that much of this variation is due to follicular status at the time of treatment. Treatment when the dominant follicle of a wave is in its late growing (≥9 mm) or early static phase will result in ovulation of that follicle within two to three days, whereas treatment after the mid- to late-static phase (i.e. when it is no longer viable) will result in ovulation of the dominant follicle of the next wave four to five days after treatment. That is, if PGF is given at the end of the period of functional dominance of one follicle, several days are required for a new dominant follicle to grow sufficiently to ovulate [167, 196, 197].

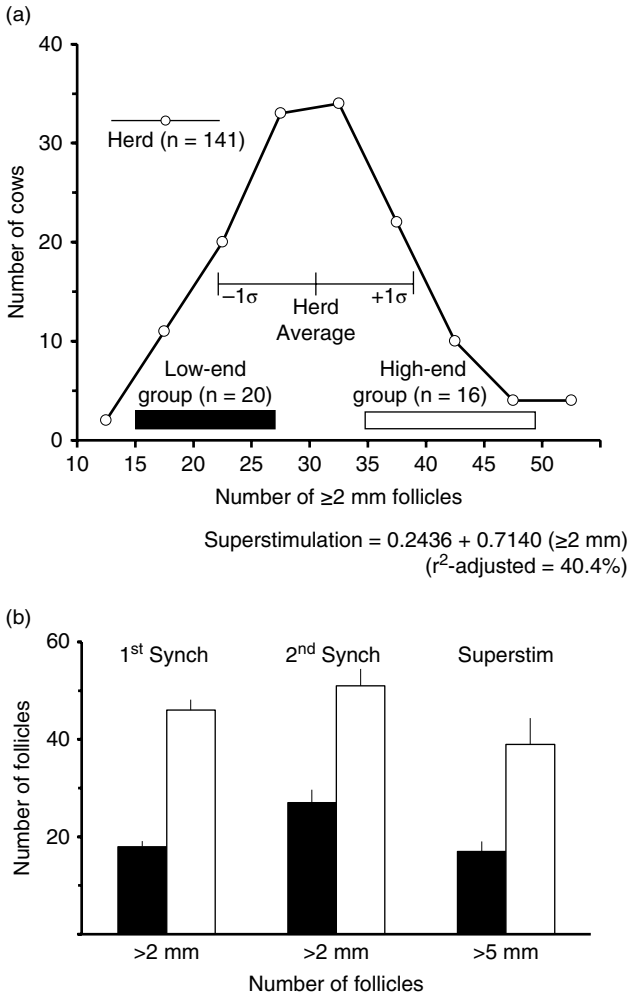

Figure 25.17 Frequency distribution of Hereford-cross beef cows in a herd (n = 141, line) based on the number of follicles detected in both ovaries by ultrasonography at the time of follicular wave emergence. (a) Based on antral follicle count, a sample of cows from the low end (n = 20, black bar) and high end (n = 16, white bar) were selected for successive synchronization and superstimulation to determine the repeatability and impact of antral follicle count. (b) The number of follicles detected at emergence of the first and second synchronized waves, and after ovarian superstimulatory treatment in the low-end group (black bars) and high-end group (white bars). The number of follicles detected was significantly greater in the high-end group after both synchronizations and after superstimulation. The superstimulatory response was related in a simple linear fashion to the number of follicles detected at wave emergence [superstimulatory response = 0.2436 + 0.7140 (# of follicles ⩾2 mm); r^2-adjusted = 40.4%]. *Source:* Adapted from [118].

Antral Follicle Count

The number of follicles detectable by ultrasonography varies widely among cows and according to follicular wave status [44, 70, 112, 118]. However, differences in follicle numbers are not associated with wave sequence (i.e. similar between wave 1, wave 2, and wave 3) or the number of

waves per estrous cycle (i.e. two- and three-wave patterns; reviewed in [44]). Although individuals vary greatly, the intrinsic number of follicles at wave emergence is highly repeatable within individuals [70, 118]. In a direct comparison of high-follicle count vs low-follicle count cows [118], the number of follicles recruited into a wave was highly correlated with the number of follicles recruited into successive waves, and the superstimulatory response was highly correlated with the number of follicles recruited into a follicular wave for a given individual (Figure 25.17). This characteristic now forms the basis of a simple ultrasound test to predict the superstimulatory response in cattle.

In a recent study of the effect of restricting maternal nutrition to 60% of maintenance requirements during the first third of gestation, calves born to nutritionally restricted mothers had 60% lower antral follicle counts compared to calves born to mothers fed control diets [198]. Furthermore, results suggest that fertility may be compromised in animals with low antral follicle counts due to effects on oocytes, progesterone, and the endometrium compared to animals with high antral follicle counts; postpartum dairy cows with high antral follicle counts had higher pregnancy rates and shorter calving to conception intervals, and received fewer services during the breeding season compared to cows with low counts [198].

Ovarian Superstimulation

The greatest sources of variability in response to ovarian stimulation are the status of the follicular wave at the time stimulatory treatment is initiated and the intrinsic number of follicles present at the time of wave emergence in a given individual. Results of studies in cattle have documented that the superstimulatory response is (i) inferior when treatment is initiated after selection of the dominant follicle; (ii) greater when treatment is initiated at the time of wave emergence rather than one or two days later; and (iii) similar between wave 1 (rising progesterone) and wave 2 (high-endogenous progesterone (reviewed in [118]). Only approximately 20% (four or five days) of the estrous cycle is available for initiating treatment at the time of follicular wave emergence. Therefore the majority (80%) of the estrous cycle is not conducive to an optimal superovulatory response. The superstimulatory response may be predicted to be approximately 70% of the number of follicles ≥3 mm at the time of wave emergence [118]. As a result of these findings, superstimulatory protocols in cattle now incorporate synchronization of follicular wave emergence.

Introduction

Maternal recognition of pregnancy encompasses the process whereby a biochemical signal is generated to prevent luteal regression, allowing the corpus luteum to persist and continue to secrete adequate progesterone. The requirement of progesterone for the successful maintenance of pregnancy exceeds the length of the bovine estrous cycle and therefore the pregnant female must quickly recognize that a conceptus is present. In cattle, this signal involves conceptus secretion of interferon (IFN)-tau which further stimulates luteotropic and antiluteolytic signals. Although some studies use these words interchangeably, we will further define a luteotropin as a signal that stimulates luteal secretion of progesterone, while antiluteolytic substances act as a signal to block luteolysis by inhibiting or masking endogenous luteolytic signals. This maternal recognition of pregnancy signal is also occurring well in advance of conceptus implantation, which begins during the third week of pregnancy and is classified as a superficial attachment in cattle.

Several biological assays have focused on elucidating substances involved in prolonging the lifespan of the bovine corpus luteum. The majority of these earlier assays focused on examining estrous cycle length in non-pregnant cattle injected with pituitary extracts. In 1965, researchers at Cornell University reported that luteinizing hormone (LH) was the luteotropin for cattle and, indeed, injections of pituitary extracts or purified bovine LH extended the bovine estrous cycle by 11 or 16 days, respectively [1]. This study confirmed the luteotropic actions of LH, which could serve as the endogenous biochemical signal from the conceptus; however, apart from primates and mares, no other mammals appear to possess both genetic subunits for a chorionic gonadotropin. Therefore a chorionic gonadotropin possessing LH properties is not the signal for maternal recognition of pregnancy in cattle. However, these early studies did contribute to the foundational groundwork examining mammalian species differences in prolonging the lifespan of the corpus luteum, which is an important component of the conceptus–maternal cross-talk during maternal recognition of pregnancy.

These early results led researchers to examine other potential substances originating from the conceptus that may act in a luteotropic and/or antiluteolytic nature to prevent luteolysis during pulsatile release of prostaglandin (PG)$F_{2\alpha}$. Intrauterine infusions of estradiol-17β and prostaglandin E_2 (PGE_2) prolong the lifespan of the bovine corpus luteum as well as progesterone secretion by five to six days compared with non-pregnant controls [2]. The luteotropic actions of estradiol-17β are more than likely indirect because estrogens have been shown to inhibit LH-induced secretion of progesterone by cultured bovine luteal cells [3]. The indirect actions of intrauterine estradiol-17β on prolonging luteal lifespan may involve an increase in uterine and/or ovarian blood flow. A local increase in blood flow to the gravid uterine horn occurs coincidental with maternal recognition of pregnancy in the sow, ewe, and cow [4]. In addition, this local increase in uterine blood flow may help to redirect prostaglandin transport from the uterine horn to the adjacent ovary via the utero-ovarian plexus. PGE_2 directly stimulates progesterone secretion and cyclic adenosine monophosphate (AMP) production of bovine luteal cells *in vitro* and in a similar manner to that of LH [5]. Moreover, both the bovine endometrium and corpus luteum express the complete prostaglandin biosynthesis pathway and the differential expression of these components during the critical period of maternal recognition of pregnancy (days 15–17 of the estrous cycle) and can exert luteotropic or antiluteolytic actions [6].

Interferon (IFN)-tau, first identified as bovine trophoblast protein 1 [7], is recognized as the maternal recognition of pregnancy signal in cattle [8]. IFN-tau secretion by embryonic trophoblast cells is highest between days 15 and 17 and is observed up to day 28 of pregnancy; an inadequate response of the endometrium to IFN-tau is likely to be one of the major reasons for improper production and action of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$) and PGE_2 leading to pregnancy failure. *in vitro* cultures of bovine endometrial cells with increasing concentrations of IFN-tau show preferential production of PGE_2 compared with $PGF_{2\alpha}$ [9]. Moreover, the spatial and temporal relationship of prostaglandin metabolism, transport, and receptor density changes substantially in the uterine endometrium and myometrium following IFN-tau exposure [6]. Elevated physiological concentrations of IFN-tau from the conceptus will selectively increase the ratio of PGE_2 to $PGF_{2\alpha}$. This relationship sets up an antiluteolytic effect of IFN-tau combined with a luteotropic effect of PGE_2 which eventually leads to prolonged corpus luteum lifespan and proper establishment of pregnancy. In addition, embryonic secretion of PGE_2 may produce a synergistic effect with the increased endometrial production of PGE_2 that was stimulated by conceptus secretion of IFN-tau. This PGE_2 can be competitively transported through the utero-ovarian plexus to the ovary, where it increases production of luteal PGE_2, thereby favoring luteal maintenance as a luteotropin [6]. In contrast, an elevated ratio of $PGF_{2\alpha}$ to PGE_2 will stimulate uterine contractility and competitive transport of $PGF_{2\alpha}$ through the utero-ovarian plexus toward the corpus luteum, thereby initiating luteal regression. Together, uterine contractility and luteal regression can lead to pregnancy failure and/or a return to a new estrous cycle following a normal lifespan of the corpus luteum.

Prevention of corpus luteum regression and continual secretion of adequate progesterone is vital for successful maintenance of pregnancy to term. The primary targets for progesterone are the reproductive tract. The amplitude of progesterone secretion can influence the early uterine environment, including the inhibition of mitotic division of the endometrium, the induction of stromal differentiation, and the stimulation of additional glandular secretions of the uterine epithelium or histotroph [10]. This increase in glandular uterine secretions of nutrients and growth factors is essential for early conceptus development [11]. In 1956, researchers proposed the progesterone block hypothesis, which states that progesterone maintains pregnancy by directly blocking labor, and removal of the progesterone source will initiate parturition [12]. Later studies revealed that progesterone supplementation prevented the insertion of gap junction proteins between uterine smooth muscle cells by decreasing the expression of connexin-43 [13]. Progesterone has also been shown to downregulate uterine contractility-associated genes [14]. In general, cows with less than 0.5 ng/ml of progesterone have elevated contractility in circular smooth muscle cells of the myometrium compared with that in diestrus cows (>4.0 ng/ml progesterone) [15]. These differences in myometrial excitation–contraction are brought about by the genomic actions of progesterone, which lead to a relaxed and quiescent uterus able to maintain a successful pregnancy until progesterone withdrawal [14]. In addition, progesterone synthesis depends on luteal production for the first 200 days of gestation; however, the extragonadal source of progesterone, primarily the bovine placenta, does not secret adequate amounts of progesterone until the third trimester of pregnancy. This placental progesterone secretion is dependent on luteal ovarian input. The luteal placental shift in progesterone secretion, which may contribute to the maintenance of pregnancy, only occurs after $PGF_{2\alpha}$-induced luteolysis or in ovariectomized animals [16]. Moreover, in the cow, the corpus luteum may exert control over placental steroidogenesis, which does not take over progesterone secretion until ovarian luteal deficiencies become apparent during late gestation.

Conceptus Elongation and Extraembryonic Membranes

The early elongation of the bovine conceptus involves exponential increases in length and width of the trophectoderm and requires differentiation of extraembryonic membranes as well as maternal endometrial influences. This elongation begins on day 14, following the hatching of the ovoid blastocyst at approximately day 9–10, and forms a filamentous conceptus by day 19–20 after insemination [17]. On day 14, the majority of ovoid or tubular embryos of approximately 5 mm in length will start to form an epiblast, defining the embryonic disk, which is discernible from the epithelium of the trophoblast. Both of these compartments are internally lined by the continuous hypoblast, of which the majority stains positive for α-fetoprotein [18]; however, the histological appearance of the hypoblast varies in relation to its spatial orientation to the epiblast versus the trophoblast cell layers. The spatial orientation results in two types of hypoblast cells: squamous cell types if located next to the trophoblast layer, or cuboidal to columnar cell types underneath the epiblast or embryonic disk [18]. At this point a distinctive basal lamina is formed between the trophoblast or epiblast and the hypoblast cell layers. In addition, adjacent epiblast cells are connected via tight junctions, as well as peripheral epiblast cells next to the trophoblast cells. Presumptive signs of early embryonic mortality in the tubular conceptus consist of apoptotic epiblast cells or a loosening of the hypoblast

from the trophoblast. During this elongation phase the initial folds of the amnion will form as an outgrowth of the trophoblast cells adjacent to the epiblast, while the hypoblast is not included in the formation of this extra-embryonic membrane. The most discernible difference during this time-frame is the hypertrophic and hyperplastic trophectoderm growth of the differentiating chorionic sac, which may grow from a few centimeters up to 30 cm or more [19].

The early attachment period of days 20–33 post insemination proceeds with sequential stages of precontact, apposition, and adhesion between the uterus and the chorion, and ends in a microvillous interdigitation of the uterine epithelium and trophoblast. This time period coincides with several reports of limited success in flushing intact conceptuses for experimental use [20]. During the early attachment phase the development of the allantois begins, and on day 21 after insemination a strong positive association between embryo length and width of the allantois can be observed [18]. Some researchers have observed abnormalities or underdevelopment of the extra-embryonic membranes following *in vitro* fertilization or somatic cell nuclear transfer; however, the underlying mechanisms for development failure are not clearly understood. Therefore embryonic mortality during these time points may be caused by a difficulty in nutrient mobilization brought about by the allantois showing deficient vascularization, growth retardation, or its absence [21]. In relation to the dramatic elongation of the trophectoderm of the chorionic sac, the allantois undergoes gradual growth from days 21 to 25 post insemination, when it will start to occupy both uterine horns and begin fixation to the chorion to form the chorioallantois placenta; however, this fusion remains incomplete until days 60–70 of pregnancy [21].

In addition to the morphological change from a spherical conceptus into a filament-like tube during conceptus elongation, several molecular markers have been characterized in relation to growth and cellular differentiation. The trophoblast mononucleate cells of the trophectoderm will begin to proliferate and differentiate, which may be induced by specific transcription factors such as POU-domain class 5 transcription factor, ERG, and CDX2 [22]. These transcription factors have been shown to regulate genes such as IFN-tau and trophoblast domain proteins, which are upregulated during maternal recognition of pregnancy. In addition, the differentiation of trophoblast mononucleate cells into trophoblast giant cells coincides with an increase in pregnancy-associated glycoproteins, prolactin-related proteins, and placental lactogen. These proteins are associated with cellular differentiation of the trophectoderm; however, they may not be associated with the proliferation of the trophectoderm during conceptus elongation into the filament-like tube [22]. Transcriptome profiling using a bovine-specific microarray has revealed the upregulation of approximately 500 genes and the downregulation of only 26 genes during transition from a blastocyst (day 7) to an ovoid tubular conceptus (day 14). Of these genes, IFN-tau was positively correlated with conceptus size; therefore it may be a key factor in trophectoderm proliferation during the elongation phase. After further elongation of the bovine conceptus (gestational days 17–19), specific genes involved in trophoblast cell differentiation, migration, and adhesion are upregulated, all of which play a role in fusion of the trophoblast cells to the endometrium of the uterus. Of the 80 genes upregulated during this phase, the *CD9* gene, which encodes for cell-surface glycoprotein belonging to the tetraspanin family, of the differentiated trophoblast giant cells more than likely plays a role in cellular migration and adhesion of the conceptus to the maternal endometrium during early attachment (gestational day 20).

Uterine Histotroph

The growth, development, and welfare of the bovine conceptus depend on uterine histotrophic nutrition derived from the secretions of uterine endometrial glands. The uterine endometrium is a complex tissue composed of a luminal epithelial cell layer, superficial glandular epithelium, and deep glandular epithelium, as well as stromal cells with a fibroblast-like morphology. In addition to autonomous regulation of trophectoderm proliferation and differentiation during conceptus elongation, uterine input via endometrial secretions will drive early conceptus development. As previously mentioned, the bovine conceptus must secrete sufficient quantities of IFN-tau by day 16 of pregnancy in order to inhibit the production of luteolytic pulses of $PGF_{2\alpha}$ by the endometrium to allow for maternal recognition of pregnancy. In addition to conceptus secretions that alter endometrial pathways in a paracrine manner, ovarian hormones have been shown to stimulate or inhibit endometrial secretions and glandular output. A number of studies have demonstrated that peripheral concentrations of progesterone during the early postconception period are associated with advanced conceptus elongation and higher pregnancy rates in cattle and sheep. In contrast, lower concentrations of progesterone in dairy cows are associated with decreased conceptus development. Ovarian progesterone can influence the early uterine environment, including endometrial sections of nutrients and growth factors that are essential for early conceptus development. Moreover, supplementing exogenous progesterone from day 5 to 9 after insemination resulted in a fourfold increase in trophoblast length and a sixfold increase in

uterine concentrations of IFN-tau [23]. In addition to the concentrations of progesterone in peripheral circulation, progesterone receptor expression in the endometrium (both luminal epithelium and superficial glandular epithelium) is altered in cows with decreased versus elevated concentrations of progesterone during early postconception. In cows with low postconception concentrations of progesterone, not only are specific nutrient transporters decreased in the endometrium but also progesterone receptor expression is maintained for a longer period of time in the luminal and superficial glandular epithelium. In contrast, elevated concentrations of progesterone, brought about by exogenous treatment, increase nutrient transporter expression and decrease progesterone receptor expression in the luminal and superficial glandular epithelium [24]. Moreover, this downregulation in endometrial progesterone receptors is required to establish uterine and endometrial receptivity to conceptus attachment.

Placental Vascularization

The placenta plays a major role in the regulation of fetal growth. The ruminant placenta is morphologically classified as cotyledonary and histologically as syndesmochorial. On the uterine wall there are specialized areas of endometrium called caruncles, with a button-like appearance [25]. In non-pregnant ruminants, the caruncles are organized in two dorsal and two ventral rows that run lengthwise along the uterine horns. There are approximately 100 caruncles and they can be seen even in uteri from fetal calves [26]. The chorioallantois, which has a flat surface, becomes irregular when it starts to cover the caruncles; this is caused by the growth and expansion of the conceptus on the lumen of the uterus. This process is followed by the recognition of the cotyledons [26]. The caruncular-cotyledonary unit is called a placentome and is formed from the growth and interdigitation of fetal villi and caruncular crypts adopting a convex shape [25]. Contact surface area is enhanced because the cotyledon fingerlike projections enter the crypts formed in the caruncles. Placentomes vary in size, but they are bigger in the horn and decrease in size close to the tip of the horns [26]. The placentome is the primary functional area of physiological exchanges between mother and fetus.

The efficiency of placental nutrient transport is directly related to uteroplacental blood flow [27]. All nutrients and wastes that are exchanged between the maternal and fetal systems are transported via the uteroplacental unit [27, 28]. Establishment of functional fetal and uteroplacental circulations is one of the earliest events during embryonic/placental development [29, 30]. In order to support the exponential increase in fetal growth during the last half of gestation [31], proper growth and development of the uteroplacental vascular bed must occur during the first half of pregnancy [27, 32]. Understanding the factors that impact uteroplacental blood flow will directly impact placental efficiency and thus fetal growth. However, despite intensive research in the area of placental–fetal interactions, the regulators of placental growth and vascularization as well as uteroplacental blood flow are still largely unknown, particularly in cattle.

Limited data on development of the bovine placentomal capillary bed are available. In the cow, cotyledonary growth progressively increases throughout gestation [33, 34]. Histological analysis of capillary bed development in the cow has been performed at mid and late gestation [34]. From mid to late gestation, capillary area density, a measure related to blood flow, decreases by about 30% in caruncular tissue, while it increases about 186% in cotyledonary tissue (Figure 26.1). The numbers of capillaries increase by about 150 and 80% in caruncular and cotyledonary tissue, respectively, during this time. Capillary surface density, a measurement related to nutrient exchange, is also increased in both caruncular and cotyledonary tissues (32 and 172%, respectively), while capillary size decreases 67% in caruncular tissue but increases 71% in cotyledonary tissue from mid to late gestation (Figure 26.1). The pattern of capillary development is very different between the maternal and fetal portions of the placentome possibly due to the energetic demands of these independent tissues that share a similar function – delivery of nutrients to the developing calf.

It is clear that the placenta plays a fundamental role in providing for the metabolic demands of the fetus. Although placental growth slows during the last half of gestation, placental function increases dramatically to support the exponential rate of fetal growth [35, 36]. For example, in sheep and cattle, uterine blood flow increases approximately threefold to fourfold from mid to late gestation [27, 37, 38]. The relationship between uteroplacental blood flow and conceptus size throughout gestation is further defined in the next section.

Maternal Cardiovascular Function

During pregnancy the physiologic state of the dam is associated with significant but reversible alterations to metabolic demand as well as alterations to the endocrine and cardiovascular systems. As previously mentioned, during early gestation (e.g. maternal recognition of pregnancy and conceptus elongation) endocrine secretions of the ovary and conceptus help establish a healthy pregnancy. Moreover, these secretions serve as biochemical cross-talk between

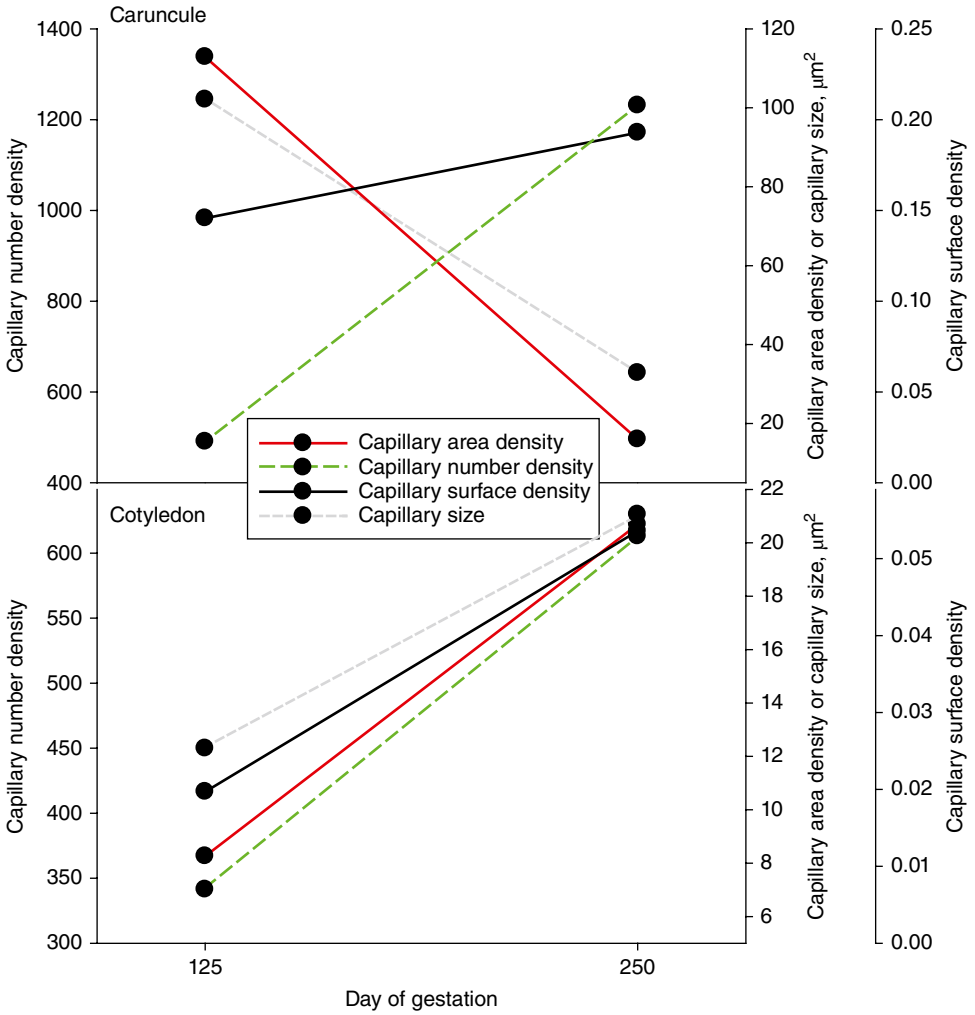

Figure 26.1 Capillary number density, area density, surface density, and size in the maternal (caruncular) and fetal (cotyledonary) portion of the bovine placentome from mid (day 125) to late (day 250) of gestation.

the maternal endometrium and fetal membranes of the placenta during mid to late gestation and help assure proper nutrient and waste exchange during exponential growth of the fetus. Maternal cardiovascular functional capacity changes dramatically during pregnancy, whereby systemic arterial blood pressure and vascular resistance decrease and cardiac output, heart rate, stroke volume, and blood volume increase [39]. Although not all these variables have been determined during bovine pregnancy, several mammalian species including the ewe have shown a decrease in mean arterial pressure in early pregnancy that persists throughout gestation. Moreover, the decrease in arterial pressure (estimated as 5–10%) is minor compared with the approximate 20–30% decrease in total peripheral vascular resistance. Maternal cardiac output has been shown to increase as much as 30–40% in pregnant versus non-pregnant ruminants. Therefore the increase in cardiac output is associated with a dramatic fall in systemic vascular resistance, allowing researchers to characterize pregnancy as a state of systemic vasodilation resulting in profound increases in total systemic flows to all vascular beds. The majority of these studies characterize this relationship by the following equation:

$$\text{Systemic vascular resistance} = \frac{\text{Mean arterial pressure}}{\text{Cardiac output}}$$

Using this equation we can see that the decrease in systemic vascular resistance during pregnancy and the increase in cardiac output (total systemic blood flow) help to maintain arterial pressure. In addition, apart from this relationship, increases in blood volume and activation of the renin–angiotensin system may contribute to maintaining blood pressure during this physiological state of substantial vasodilation; however, limited data exist in cattle. To determine specific contributions to the increase in cardiac output occurring during pregnancy we must first

examine the cardiac output equation, which states that cardiac output = heart rate × stroke volume, where stroke volume equals the volume of blood pumped from one ventricle of the heart with each beat. In the majority of mammalian species, heart rate increases by approximately 15% during pregnancy, which does not fully explain the 30–40% increase in cardiac output. Therefore stroke volume may increase as much as 30–35% during pregnancy and is one of the major contributors to this increase in cardiac output. In sheep treated chronically with estrogen, researchers have shown a similar pregnancy-induced increase in left ventricular heart dimensions and enlargement; therefore the changes to the endocrine system during pregnancy may help mediate the temporal changes to maternal cardiovascular function [39].

The rise in maternal cardiac output during pregnancy is also associated with an increase in plasma and blood volume in cows [40]. This increase in blood volume varies between species and will depend on the nutritional status of the dam as well as singleton versus twin pregnancies. In cattle, blood volume expands by only 10–20% during pregnancy, while in litter-bearing species blood volume may expand by 30–50% during pregnancy. With the increase in plasma volume, the dam must maintain a proper balance of water and electrolyte retention; therefore, similar to the alterations in maternal arterial pressure, this increase in plasma volume will be integrated with the renin–angiotensin system which can serve an additional purpose as an extrinsic modulator of kidney function and urinary secretion. In addition to the dramatic changes in the maternal cardiovascular system during pregnancy, it is even more noteworthy to point out that the majority of mammals will return to non-pregnant levels of cardiovascular function within two to five weeks after parturition. Although lactating, high-producing, non-pregnant dairy cattle will show a substantial increase in cardiac output compared with their non-pregnant, non-lactating counterparts, this redistribution of blood flow during the transition period from the uteroplacental vasculature toward the mammary gland is still a phenomenal physiological feat to allow for peak lactation shortly after parturition.

Maternal Nutrient Partitioning and Endocrinology

Interactions between the maternal endocrine system and the conceptus, and vice versa, are vital to assure continual development of the bovine fetus and healthy offspring fit for life outside the uterus. One example of this interaction is the ability of the bovine conceptus to stimulate mammary growth and development during gestation. This controlled programmed development of the mammary gland allows for synchronization of milk production and secretion with the delivery of a mature calf [41]. Hormonal production by the conceptus may act in a paracrine manner to stimulate its own growth; however, this hormonal production may also interact with the maternal endocrine system to regulate mammary growth, development, and lactogenesis. Secretion of bovine placental lactogen peaks at around 160–200 days of gestation and then remains high until term. Dairy cows have elevated concentrations of bovine placental lactogen compared with beef cows; furthermore, within a subpopulation of dairy cows, a significant positive association has been observed between placental lactogen concentrations during gestation and subsequent milk yield. In addition, production of estrone, conjugated estrone sulfate, and estradiol is observed to increase between days 70 and 110 of gestation. This increase in estrogens should allow for an increased exposure of maternal tissues to estrogenic activity; however, considerable conjugation of estrogen by the uterus and conceptus before transfer into peripheral circulation will decrease maternal tissue exposure. This increase in production should correspond to an increase in aromatase activity as well as estrogen sulfotransferases, generating an estrone sulfate metabolite with low biological activity but a longer peripheral half-life. However, irrespective of the lowered biological activity of conjugated estrogens, the concentration of total estrogen (conjugated and unconjugated) is highly correlated with birthweights and subsequent preweaning growth rates in beef calves, which may be associated with subsequent milk production of the dam. Apart from these associations between conceptus hormone production and subsequent milk production of the dam, it is still important to note that several hormones of pregnancy (progesterone, estrogens, and placental lactogens) regulate cell numbers and vascularity of the mammary gland.

Regulation of nutrient partitioning during pregnancy is an orchestrated event helping to maintain the metabolism of body tissues necessary to support the physiological state [42]. In dairy cows, pregnancy imposes a substantial cost to the animal, so that nutritional plane at the end of gestation is about 75% greater than in a non-pregnant cow of the same weight [42]. After seven months of gestation the fetus will have acquired approximately 40% of its birthweight, while during the last two months of gestation fetal demands for glucose and amino acids are equal to mammary use of nutrients, equivalent to about 5 kg of milk daily [42]. Therefore, in the dairy cow, drying off cows at approximately 60 days before expected calving helps ease the competition between nutrient use for lactation and the major phase of fetal growth.

There is limited information on the specific nutrient requirements of the bovine fetus compared with the extensive amount of research accomplished in the sheep fetus. Gross carbon uptake of the sheep fetus is approximately 8 g/day per kilogram of fetal weight, of which 40% is retained and the remainder is shuttled back to the dam as either carbon dioxide or urea carbon. Apart from glucose, amino acids provide a large portion of the metabolic fuel, estimated at a gross nitrogen accretion rate of 0.65 g nitrogen per kilogram of fetus per day, which is in excess of the average fetal uptake of 1.5 g of nitrogen per kilogram of fetus per day. As mentioned with the carbon excretion via urea, nearly 0.3 g of nitrogen per kilogram of fetus per day is excreted as urea, indicating amino acid catabolism, presumably via gluconeogenic pathways of the fetus and placenta. It is important to note that the influxes of nutrient substrates to meet the needs of fetal oxidative metabolism are also used for fetal anabolism and it has been proposed that specific nutrient substrate fate (catabolism vs anabolism) is controlled autonomously by the fetus. This has led some researchers to propose that the fetus should not be regarded as a "passenger" but rather that it has some self-control or autonomy in its own fate. This is more apparent when we examine some of the changes in the fetus and placenta that allow the fetus to adapt to specific environmental insults bestowed upon the dam.

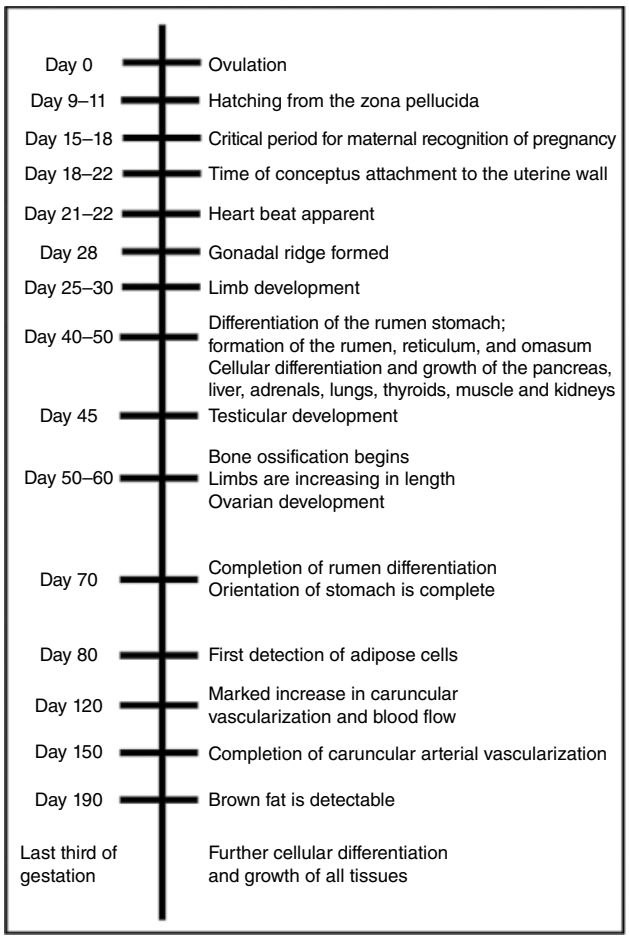

Figure 26.2 Time-line of bovine fetal development. See text for references.

Embryogenesis, Fetal Growth, and Organ Development

The embryonic period in cattle is defined as the time from conception (i.e. single-cell embryo, referred to as a zygote) to the completion of organogenesis. This period typically runs from day 1 to day 42 of gestation and the largest percentage of pregnancy wastage occurs during the embryonic period. The fetal period is defined as the remainder of gestation from day 42 until day 280 when the completion of organ differentiation occurs (Figure 26.2).

Embryogenesis

During early embryogenesis and prior to conceptus attachment, differentiation of the germ cell layers is becoming apparent. The three germ cell layers are referred to as the endoderm, mesoderm, and ectoderm. The endoderm, the innermost layer, will differentiate into the entire alimentary tract, except for part of the mouth and terminal part of the rectum, which are lined by protective involutions of the ectoderm. In addition, the endoderm will develop into the respiratory tract (trachea, bronchi, and lung alveoli), the majority of the endocrine glands, and the urinary systems. The ectoderm is the most exterior germ cell layer and will give rise to the nervous system and the integumentary system. The middle germ cell layer, the mesoderm, will give rise to cardiac, skeletal, and smooth muscle, the circulatory system, as well as the majority of the reproductive tract, excluding the external portions of the genitalia which develop from the ectoderm.

During embryogenesis, an invagination of the oral ectoderm toward the neural epithelium results in a diverticulum referred to as Rathke's pouch. During the formation of this diverticulum, it will lose contact with the oral ectoderm, forming the anterior portion of the pituitary. This anterior lobe is sometimes referred to as the adenohypophysis, because of the glandular derivation of the tissue. Few studies have characterized the formation of Rathke's pouch during early bovine embryogenesis; however, a common disorder known as a residual cleft cyst of the pituitary gland has been recently examined using postmortem magnetic resonance imaging of cattle [43]. Residual cleft cyst of the pituitary was observed in 26–35% of slaughtered

cattle, which showed several morphological similarities to the human disorder known as Rathke's cleft cysts. These structural abnormalities of the pituitary may allow gradual accumulation of endocrine secretions over time and Holstein cattle may be more at risk for developing fluid-filled lesions compared with other breeds. More than likely, these residual pituitary cysts are formed early during embryogenesis and early formation of Rathke's pouch; however, pathological conditions and/or productivity have not been associated with the appearance or relative size of the pituitary cysts in cattle [43].

Sexual Differentiation and the Freemartin

In the realm of bovine fetal organogenesis, no other organ system has garnered as much attention as the development of the reproductive tract. From a sexual differentiation standpoint, the genetic sex of the offspring is established at the time of fertilization when the sperm delivers either an X (female) or Y (male) chromosome to the homogametic oocyte. In cattle, following a few weeks of embryogenesis the process of gonadal sexual differentiation will begin. One of the first steps in sexual differentiation of the gonad involves migration, proliferation, and invasion of primordial germ cells. It is now accepted that the first primordial germ cells also represent hematopoietic stem cells originating from the wall of the allantois as well as the yolk sac of the mesoderm [44]. Hematopoietic stem cells also originate in other parts of the mesoderm and more recent findings suggest that the final proliferative primordial germ cells of the gonad originate exclusively in the aorta–gonad–mesoderm region, while short-lived hematopoietic stem cells of the yolk sac have a restricted differentiation capacity. It is important to note the early common lineage of hematopoietic stem cells (undifferentiated blood cells) and primordial germ cells (undifferentiated gametes). The apparent differences between these cell types in the adult may be due to the presence of surrounding interstitial and stromal cells of the gonad, which help to further differentiate these early hematopoietic stem cells into germ cells. By 23–25 days of embryonic age in cattle, the primordial germ cells are located in the midgut and hindgut in close proximity to the undifferentiated gonad. By 27–31 days of embryonic age these primordial germ cells start to populate the undifferentiated gonad, which rests on the dorsal body wall known as the gonadal ridge. This accumulation of primordial germ cells at the gonadal ridge will continue until day 40 of embryonic age.

Two potential pathways for the transportation of primordial germ cells to the gonadal ridge have been proposed. First, most mammalian species are thought to have active migration of primordial germ cells via a chemoattractant produced by the gonadal ridge. The second pathway involves passive transportation via the bloodstream toward the gonadal ridge, which occurs in avian species and some reptiles. Recent advances in localizing the temporal-spatial distribution of bovine primordial germ cells during early embryogenesis have argued against both of these pathways [45]. The active migration of primordial germ cells may not be necessary because early bovine primordial germ cells (day 18 of embryonic age) have been localized to the proximal yolk sac at a distance of less than 100 μm from the indifferent germinal disk. Therefore focus on the transportation system may be redundant due to the close proximity of the primordial germ cells to the developing gonadal ridge during early development. However, keep in mind that from day 18 to day 25 the growth and elongation of the embryo will continue to move the primordial germ cells further from their point of invasion; therefore some form of transportation and proper signaling from the gonadal ridge of the indifferent gonad would be necessary as embryo length increases.

The embryo develops three separate renal systems: the pronephros, mesonephros, and metanephros. These systems develop in pairs. The pronephros is the most basic of the three excretory organs of the bovine embryo and it will degenerate via apoptosis shortly after formation of the mesonephros (the embryonic kidney). In lower animals, the mesonephros will remain as the adult kidney; however, in the cow the final differentiation of the metanephros will form the functional adult kidney. The mesonephros is also referred to as the Wolffian ducts. At the same time as mesonephric development another pair of ducts will develop next to the mesonephros, referred to as the paramesonephric ducts or Müllerian ducts. At this stage of development the embryo is still uncommitted to sexual differentiation of the reproductive tract [46]. If the genetic sex is male (XY), the paramesonephric ducts will regress and the mesonephric ducts will differentiate to form the epididymis, vas deferens, and seminal vesicles of the male reproductive tract. If the genetic sex is female (XX), the mesonephric ducts will regress and the paramesonephric ducts will differentiate to form the oviducts, uterus, and anterior portion of the vagina.

This process of differentiation starts at the level of the indifferent gonad, where mesothelial cells start a chain reaction of events based on the expression of a transcription factor known as SRY (Sex-determining Region of the short arm of the Y chromosome) [47]. These mesothelial cells or surface epithelial cells of the indifferent gonad infiltrate the gonad during invasion and proliferation of the primordial germ cells and become the gonadal ridge. Furthermore, in the male these mesothelial cells will differentiate into Sertoli cells, and following activation of the SRY gene these Sertoli cells begin to secrete anti-Müllerian hormone. This anti-Müllerian hormone causes the regression of the paramesonephric ducts. The interstitial cells of

the differentiating testis, also known as Leydig cells, begin to secrete testosterone that helps to further differentiate the mesonephric ducts as well as the accessory sex glands of the male. In the absence of the Y chromosome (female genetic sex, XX), the ovaries will begin to differentiate and the lack of anti-Müllerian hormone leads to differentiation of the paramesonephric ducts, while the lack of testosterone leads to the regression of the mesonephric ducts. Several pioneering experiments have further elucidated the mechanisms behind sex differentiation and sex reversal [46]. For example, bilateral castration of the indifferent gonad of either a genetically sexed male (XY) or female (XX) leads to regression of the mesonephric ducts and development of the paramesonephric ducts (phenotypically female irrespective of genetic sex).

The focus on sex determination and sex reversal in the bovine is partly due to the phenomenon known as the freemartin. A freemartin is a sterile heifer born as a co-twin to a bull, and it is explained by the anastomosis that occurs between the placenta of the female and male fetuses. Because of the shared blood supply the sexually differentiating female tract (mesonephric and paramesonephric ducts) is exposed to anti-Müllerian hormone and testosterone from the male co-twin. One of the problems with studying the freemartin is reproducing the syndrome efficiently during an experimental study. For example, the presence of testosterone during critical periods of development will produce a masculinized female fetus (by helping to differentiate a portion of the mesonephric ducts); however, this experimental model is not truly a freemartin because the female fetus produced is not a chimera (containing both XX and XY cell types). This chimerism, presumably from the invasion of male (XY) hematopoietic stem cells or white blood cells from the anastomosis of the placenta, leads to an intersexed gonad, which sometimes contains a mixture of seminiferous tubules of the medulla and follicular pools in the cortex of the gonad. Interestingly, the hematopoietic stem cells may function similar to the primordial germ cells of the developing gonad because of the similarities in the lineage of these cell types. Although the regression and/or rescue of the duct system is primarily under the control of hormonal input, further research is needed to elucidate the formation of the intersexed gonad, which is presumably a function of invasion of XY blood cells of the male twin.

Fetal Growth and Organ Development

The characterization of bovine fetal growth throughout gestation has allowed researchers to determine specific environmental insults that may perturb normal development in utero. In addition to the extrinsic environmental effects altering fetal growth, several inherent intrinsic mechanisms are associated with fetal growth and development. During days 70–100 of gestation, fetal weight across several breeds of cattle has been shown to increase at approximately 10 g/day [48]. Further along in gestation, from days 200 to 250 of pregnancy, the rate of fetal growth increases to approximately 200–300 g/day; however, the absolute growth of the late-term fetus declined to 100 g/day, which may be due to an inherent function of the fetus exceeding the capabilities of uteroplacental exchange near term. Alternatively, the fetus may be secreting or altering its own hormone profiles near term, favoring proper maturation and differentiation of organs over growth.

During these characterization studies, several researchers noted that bovine fetal growth typically lags behind allantoic fluid volume and expansion of the chorioallantoic membrane [48, 49]. As mentioned above, nutrient partitioning by the uteroplacental unit and a continuous supply of nutrients is a prerequisite for fetal growth. The chorioallantoic expansion over the endometrium allows maximal surface area for nutrient exchange during development, which should support the acceleration in fetal growth. A significant positive correlation was observed for total amniotic fluid volume and fetal weight; however, no correlation was observed for total allantoic fluid volume and fetal weight [48]. The cloning of cattle by somatic cell nuclear transfer has allowed researchers to further define this association between fetal fluid homeostasis and fetal and placental development [50]. Cloned bovine fetuses that show abnormal placentation are usually associated with excessive fluid accumulation in the fetal sacs, known as hydrops syndrome. In this experimental model, cloned embryos with hydrops syndrome surviving until mid-gestation show overgrowth of the placentomes, fetal liver, and fetal kidney compared with normal pregnancies [50]. In addition, in several studies utilizing different mammalian species, organomegaly of the offspring's liver, kidney, and heart is typically accompanied by polyhydramnios. Moreover, the underlying mechanisms of fluid sac homeostasis are not fully understood in the pregnant cow and further research is needed to elucidate the proper cause and effect relationship.

Failure of proper organ development occurs in cloned calves that die shortly after birth. Using this experimental model, researchers have examined eight developmentally important genes in six different organs (heart, liver, spleen, lung, kidney, and brain). Of these developmental genes, the kidney was the least affected organ associated with calf mortality, while the heart was the organ most affected by gene dysregulation compared with normal offspring [51]. Of these developmental genes, vascular endothelial growth factor (VEGF) was upregulated in cloned offspring associated with early neonatal mortality. VEGF has been implicated in

stimulating vasculogenesis and angiogenesis to restore oxygen supply to tissues when blood circulation is inadequate. The proper concentrations of VEGF during organogenesis and early organ development are vital for proper establishment of the fetal cardiovascular system. Downregulation of VEGF could lead to a decrease in fetal organ angiogenesis, with fatal consequences for the fetus (pregnancy wastage) or neonate (calf mortality); however, upregulation may result in organomegaly or fetal cardiac dysfunction, with similar fatal consequences to the newborn.

Uterine Blood Flow

Several techniques (electromagnetic probes, heavy water, Doppler) have been used to characterize uterine blood flow in pregnant cows. During early pregnancy and around the time of maternal recognition of pregnancy, uterine blood flow relative to the side of pregnancy (ipsilateral or contralateral) responds differently, which may be due to conceptus secretions during early establishment of pregnancy [52]. Comparing electromagnetic blood flow probes with recent observations using Doppler ultrasonography, we can see a similar increase in uterine artery blood flow during the first trimester of pregnancy (Table 26.1). Moreover, the diameter of uterine arteries remains relatively constant during this period, while the arterial resistance index decreases [53]. During the second trimester of pregnancy, uterine artery blood flow increases from approximately 1–2 l/min to approximately 4–5 l/min (Table 26.2). Moreover, the first signs of increased maternal cardiac output may become apparent during this stage of pregnancy. In addition, uterine blood flow relative to the side of pregnancy (ipsilateral or contralateral) begins to diverge, allowing an increase in oxygen and nutrient delivery as well as waste exchange across the gravid pregnant uterine horn (Table 26.2). In examining Holstein cows over 147 days of gestation, Herzog et al. [54] reported similar total uterine artery blood flow in cows carrying heavy versus light calves; however, at day 175 of gestation, cows carrying heavy calves had an increase in uterine artery blood flow compared with cows carrying light calves. Similarly, Lemley et al. [60] found that maternal nutrient restriction during mid-pregnancy, resulting in growth-restricted fetuses, decreased total uterine artery blood flow compared with adequate-fed pregnant heifers (Table 26.2). This characterization of uterine blood flow versus relative size of the offspring may allow researchers to determine specific time points in gestation where supplements or insults may be used to alter offspring growth and outcome. These pathways will be further discussed in Chapter 27.

The greatest increase in uterine blood flow has been shown in late gestation during the third trimester of pregnancy (Table 26.3). Moreover, this exponential increase in uterine blood flow during the third trimester of pregnancy corresponds to the greatest increase in fetal weight deposition. The variation in reported blood flow during late gestation is a result of laboratory technique as well as individual animal variation. Using electromagnetic blood flow probes, Ferrell and Ford [55] reported uterine blood flow between days 202 and 224 as 4.0 ± 0.5 l/min and between days 230 and 258 as 3.1 ± 0.2 l/min. In a later study using a different technique the same laboratory reported late-gestation ipsilateral uterine artery blood flow at day 226 as 2.9 l/ min and at day 250 as 13.1 l/min. In addition, there was a 4.5-fold increase in ipsilateral blood flow from days 137 to 250 and maternal heart rate was also increased [56, 57]. The next experiment used Charolais cows carrying either Charolais or Brahman fetuses and Brahman cows carrying either Charolais or Brahman fetuses. At day 220 of gestation ipsilateral uterine artery blood flow of Brahman cows carrying Charolais or Brahman fetuses was similar but lower than

Table 26.1 Bovine uterine blood flow (UBF) during the first trimester of pregnancy.

Breed	Stage of pregnancy	Method	Response	Additional response	Reference
Hereford	First 30 days	Electromagnetic blood flow probes	↔ UBF until day 13 Two- to threefold ↑ ipsilateral UBF days 14–18 ↔ contralateral UBF	Days 19–25 ↓ UBF ipsilateral UBF ↑ until day 30 Contralateral UBF ↓	Ford et al. [52]

↑, Increased; ↓, decreased; HR, heart rate.

in Charolais cows carrying Charolais or Brahman fetuses. However, with regard to the Charolais cows, those carrying Charolais fetuses had increased blood flow compared with those carrying Brahman fetuses. This study shows that late-gestation uterine blood flow and function of the uteroplacental unit may be the limiting factors for fetal growth [38]. The third study used two different breeds (Charolais and Hereford) but also looked at single versus twin fetuses. At day 190 of gestation, there was a decrease in ipsilateral uterine artery blood flow for Hereford versus Charolais cows. Another observation from this experiment was that the cows carrying twins had decreased blood flow compared with cows carrying singletons regardless of cow breed. Therefore twin pregnancies with reduced birthweight compared with singletons may be due to the reduced blood flow per fetus that was observed [58].

More recent studies have been conducted utilizing Doppler ultrasonography to examine uterine blood flow during late gestation. Bollwein et al. [53] reported ipsilateral and contralateral uterine artery blood flow on days 210, 240, 270, and 284 of gestation. They observed an increase in blood flow and arterial diameter during gestation and decreased resistance of the uterine artery during the first eight months of gestation while the last

[62]

↔, Steady change; ↑, increased; ↓, decreased; RI, resistance index; D_2O, deuterium oxide.

month arterial resistance was similar. The second experiment by Herzog et al. [54] measured blood flow on days 203, 231, 259, and 273 of gestation. Throughout this experiment they observed a linear increase in total uterine artery blood flow. Also, heavy cows had a greater increase in blood flow compared with light cows; however, similar-weight cows carrying heavy fetuses had greater blood flow than those carrying light fetuses. In addition to characterization studies, Brockus et al. [61] and McCarty et al. [62] observed increased uterine artery blood flow in Holstein heifers and beef cattle supplemented with melatonin during the last third of pregnancy (Table 26.3). These changes in uterine blood flow responses during pregnancy have direct consequences on the growth and development of offspring, as will be discussed in Chapter 27.

Fetal Programming

Caleb O. Lemley, Brittni P. Littlejohn, and Derris D. Burnett

Department of Animal and Dairy Sciences, Mississippi State University, Starkville, MS, USA

Introduction

Irrespective of an animal's genotype, an environmental stimulus or insult during a critical period of development can program the observed phenotype of an animal. Importantly, this exposure may establish a permanent phenotype throughout the remainder of an animal's life, which can have adverse consequences for milk production, carcass yield, feed efficiency, and/or reproductive function. This process of permanently altering an animal's phenotype through environmental stimuli has been referred to as the developmental programming hypothesis. For example, two animals possessing the same genotype but raised in different environments are expected to have differing lifelong phenotypic characteristics, which is further explained by developmental plasticity. Importantly, the magnitude of phenotypic change is vastly different between these two animals possessing the same genotype if their exposure to different environments occurred while they were embryos, fetuses, calves, weaned heifers, or mature cows. Furthermore, the changes to these animals' developmental trajectory and any lasting consequences are thought to be greatest in embryos and fetuses, with decreasing developmental plasticity with increasing animal age. The study of developmental programming during the fetal period, an age of high developmental plasticity (Figure 27.1), is known as fetal programming.

Studies from different laboratories have shown overwhelming support for the concept of fetal programming by reporting a strong association between birth weight and lifelong developmental consequences. For example, low birth weight offspring are at an increased risk of morbidity and mortality, slowed postnatal growth, poor body composition (increased fat and reduced muscle growth), metabolic disorders, cardiovascular pathologies, and dysfunction of several organs, such as the ovaries, testes, mammary gland, and gastrointestinal tract [1, 2]. Livestock are specifically at risk due to poor nutritional environments during pregnancy, such as breeding of young, growing, peripubertal dams that are competing for nutrients with the fetus. In addition, poor pasture conditions or environmental heat stress in relation to seasonal breeding can specifically decrease nutrient availability for both dam and fetus during critical periods of development. Although these initial fetal programming studies focused exclusively on offspring (fetal or birth) weight, we now understand that multiple measurements of offspring size at birth can predict their developmental trajectory. Therefore phenotypic changes in cattle production as a result of fetal programming may be independent of calf weight at birth. This is evident when environmental insults occur during early pregnancy alone, such that birth weights are unaltered but evident phenotypic changes still impact calf production.

Insufficiencies during pregnancy, resulting in reduced fetal growth and development, are detrimental to all livestock species, where the newborns represent the next generation of meat and milk-producing animals. Several animal models of fetal and placental growth restriction (e.g. maternal nutritional plane, maternal age, heat stress, hypoxic stress, and fetal number) have been developed to better unravel the relationship between uterine blood flow and offspring development [3–6]. Establishment of functional fetal and placental circulation is one of the earliest events during conceptus development [7, 8] and the exponential increase in placental exchange is vital for maintaining the exponential growth and development of the fetus during the last half of gestation [9]. Therefore understanding the impacts of maternal environment on placental function is especially relevant, as the majority of mammalian livestock raised for red meat production spend 30–40% of their life being nourished by the placenta. The percentage of total time in each phase of beef

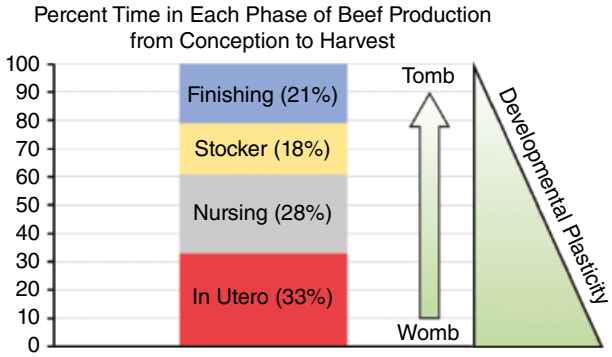

Figure 27.1 Percentage of total lifetime in each phase of beef production from conception to harvest (womb to tomb). Nearly a third of life is spent developing in utero, when the fetus is most vulnerable to the environment because of increased developmental plasticity.

production from conception to harvest is depicted in Figure 27.1. In addition, the amount of developmental plasticity of offspring varies during their lifespan, with maximal influences of developmental programming occurring during the embryonic and fetal stages of life (Figure 27.1).

Adaptations During Pregnancy: Fetal and Placental Development

The embryonic period in cattle is defined as the time from conception to the completion of organogenesis. This embryonic period typically runs from day 1 to 42 of gestation, with the largest percentage of pregnancy wastage occurring during this period of development. The fetal period is defined as the remainder of gestation from day 42 until day 280 when the completion of organ differentiation occurs (see Figure 26.2). The characterization of bovine fetal growth throughout gestation has allowed researchers to hypothesize phenotypic changes to offspring that experience specific periods of environmental insults that may perturb normal development in utero. For example, nutrient deprivation or heat stress during days 60–120 of pregnancy will undoubtedly have different impacts on fetal development compared to the same environmental insults from day 180 to 240 of pregnancy. This is where timing becomes a critical component of fetal programming outcomes. Offspring growth in utero is sensitive to direct and indirect effects of the maternal environment, particularly during the early stages of embryonic life [10]. During early pregnancy hormone secretions from the ovary and conceptus help establish a healthy pregnancy. During mid to late pregnancy the dam undergoes significant but reversible changes in physiology to help maintain the increase in metabolic demand. Of these maternal changes, adequate blood flow to the reproductive tract is critical for normal development of the offspring. In addition, the magnitude decrease in blood flow is reflective of the magnitude decrease in fetal weight. In all domestic livestock species, offspring born at average weight have an increased chance of survival compared with those born below average weight. While the literature is booming with increasing evidence of how nutrient restriction or overfeeding impairs several physiological parameters, fewer concentrate on enhancing postnatal growth in livestock species.

Several animal models of fetal programming have been extensively studied in the ewe [6], and extrapolation to cattle should be minimal because of the drastic differences in placental development between sheep and cattle. In the ewe, the placenta reaches its maximum size during the first two-thirds of gestation, while approximately 90% of fetal growth occurs during the last third of gestation [9]. In contrast, the bovine placenta continues to increase in size exponentially as gestation proceeds; however, the exponential rate in growth of the bovine fetus is much greater compared to the growth of the placenta [11]. The placenta is involved in transporting nutrients and wastes between maternal and fetal circulation and altered placental function has been associated with abnormalities in fetal development. Fowden et al. [12] reviewed key factors affecting placental nutrient transfer capacity, which were size, nutrient transporter abundance, nutrient synthesis and metabolism, and hormone synthesis and metabolism. Large increases in blood flow to the reproductive tract are necessary to support both nutrient and waste exchange between the mother and offspring. This relationship is best depicted by placental efficiency calculations (Figure 27.2).

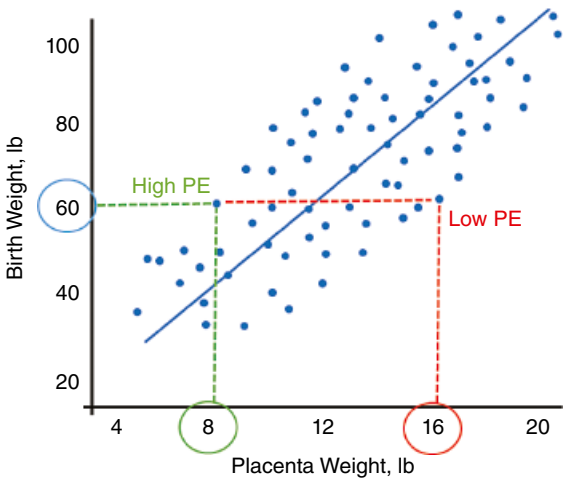

Figure 27.2 Positive association between calf birth weight (y-axis) versus placenta weight (x-axis). Placental efficiency is calculated as birth weight divided by placental weight (pounds of calf that can be grown per pound of placenta). The green lines depict a high placental efficiency, while the red lines depict a low placental efficiency, even though both calves weighed 60 lbs at birth.

Placental efficiency is calf birth weight divided by placental weight and explains the pounds of calf that can be grown per pound of placenta. Undoubtedly, a strong positive relationship exists between calf birth weight and placenta weight; however, focusing on the calves born above or below this trend line (Figure 27.2) shows that some calves are born from an efficient placenta and other from an inefficient placenta. One of the most important indicators of placental efficiency is uterine and umbilical blood flow. Using Doppler ultrasonography researchers have investigated alterations in blood flow to the reproductive tract during specific windows of development. Several environmental factors have been shown to negatively impact placenta development and blood flow during pregnancy, all of which can hinder offspring health and vigor.

Maternal Nutrient Restriction

Poor forage quality in grazing systems can negatively impact the nutritional intake of beef cattle. Pregnant beef cows grazing poor forage can alter fetal growth during increased periods of developmental plasticity. Thus, provisions from the environment can program these offspring to experience changes in mortality and morbidity rates, slowed postnatal growth, altered carcass weights, and meat quality characteristics [13]. The relationship between maternal nutritional plane during late gestation and calf mortality was examined as early as 1975, where maternal nutrient restriction for 100 days prepartum decreased calf birth weight by 7% and increased calf mortality rate by 10%, while an additional 20% of calves died between birth and weaning due to scours [14]. The direct effects of nutritional plane on offspring production characteristics are dependent on the timing of insult and magnitude of nutrition deprivation in relation to fetal and placental development [15]. In dealing with timing, it is also important to consider the separation of prenatal versus postnatal maternal factors that may influence these developmental programming responses. For example, changes in meat quality of offspring born to dams experiencing a late pregnancy maternal nutrient restriction may carry over into the early lactation period of this dam, preventing researchers from identifying the important time of maternal nutritional insult that led to the negative outcomes of the offspring. This is vital when considering the most economically feasible therapeutic interventions to mitigate negative developmental programming outcomes.

The adaptations of the placenta during maternal nutrient restriction are incomplete and less is known about specific differences among breeds of cattle. Normal physiology such as gestation length, fetal growth, placentome weight, and even uterine blood flow can differ substantially between breeds of cattle [16, 17]. Therefore the magnitude of fetal programming is expected to be breed dependent and further research is needed to identify when and with what breeds interventions should be sought. Researchers have examined the effect of early to mid-gestational nutrient restriction on uterine blood flow and fetal development in Brahman and Angus heifers [18]. In this study, heifers were restricted to 60% of net energy requirements for gestating cattle from days 50 to 180 of pregnancy. This early to mid-pregnancy nutrient restriction decreased uterine artery blood flow and fetal weight at day 180 of pregnancy irrespective of heifer breed. Moreover, the efficiency of uterine artery blood flow relative to fetal weight was improved in nutrient-restricted dams versus adequate-fed dams. A similar response was observed in Brahman heifers irrespective of nutrient restriction, signifying a lesser amount of uterine blood flow needed to grow the same weight fetus from a Brahman dam as compared to an Angus. A portion of these responses has been associated with increased placental efficiency in nutrient-restricted dams and Brahman dams [18].

Apart from nutritional management during pregnancy, researchers have examined heifer development practices and season on uterine artery blood flow during mid to late gestation. For example, beef producers opting for low-input forage-based replacement heifer management programs see lighter weights at breeding, with some heifers reaching only 50–55% of expected mature body weight at breeding versus a traditionally recommended target weight of 60–65% of expected mature body weight. Heifers developed on low-input management schemes until confirmation of pregnancy (days 30–45 of gestation) showed no compromise in uterine blood flow or calf birth weights compared to conventionally developed heifers. Moreover, the volume of late gestation uterine artery blood flow relative to maternal body weight was significantly increased in low-input heifers versus conventionally developed, which may be a compensatory mechanism to safeguard fetal growth and development [19]. In addition to low-input heifer development programs, calving season is expected to alter uterine artery blood flow, as differences in postpartum anestrus interval, conception rates, and weaning weights have been reported between fall and spring calving herds [20, 21]. A portion of these responses could be programmed in utero via changes in nutrient and waste exchange between dam and fetus.

Offspring Performance

Quantitatively, meat production is dependent on the efficient development of skeletal muscle. The amount of meat produced is dependent on the amount of muscle tissue an

animal deposits prior to slaughter. Genetic selection has resulted in livestock that are leaner and more efficient at muscle deposition than ever before. Still, the biology of tissue prioritization leaves skeletal muscle development susceptible to environmental and developmental cues in order to ensure that the needs of more vital systems and organs are satisfied before muscle receives its share of substrates to support growth. As meat production becomes more refined and global markets become more competitive, US producers will rely on innovative technologies and novel management strategies to maximize the efficiency, quantity, and compositional quality of muscle growth in the pre- and postnatal phases of production. The amount and distribution of muscle and adipose tissue (fat) on a beef carcass are the primary determinants of the United States Department of Agriculture (USDA) yield and quality grades. These metrics provide economic incentives for beef cattle producers and effectively estimate the amount and quality of boneless closely trimmed retail cuts that the carcass will ultimately produce. This gridded valuation process occurs at the end of the meat production cycle; however, the tissues that contribute to the final carcass have embryonic and fetal origins that are extremely impressionable during the period of prenatal growth and development.

The events and environmental milieu encountered by the developing offspring during these critical prenatal developmental windows establish the metabolic disposition of muscle and adipose tissue for the postnatal stages of production. While there are obvious overt signs of nutrient restriction during gestation such as low birth weight or failure to thrive, there are also underlying tissue-level molecular paradigms that persist despite the best postnatal management and nutritional practices. This is due to the establishment of metabolic predispositions that are less responsive to postnatal nutritional regimens. Therefore the potential to manipulate the representative cells that comprise the muscle, adipose, and connective tissues that make up the muscles and ultimately the meat products that arise from them is highest during the prenatal phase and diminishes over time.

Muscle growth and development begins in utero and this period represents, in earnest, the beginning of the beef production cycle. The relative preponderance, distribution, and composition of skeletal muscle are established prior to birth and then interact with the postnatal environment to determine final meat composition, yield, and quality. While skeletal muscle, as the precursor for meat, is of the utmost economic importance for producers and packers, it has a lower physiological priority compared to other more vital organs and tissues in the developing animal. This makes it particularly vulnerable to perturbations in the metabolic environment in utero. Total muscle fiber number is established by day 90, 105, and 180 of gestation in pigs [22], sheep [23], and cattle [24], respectively. This means that beef cattle, like all mammals, are born with the total number of muscle fibers that they will have at their disposal for postnatal growth and development, and all subsequent growth will be due to longitudinal and radial hypertrophy of these existing muscle fibers. Because muscle growth potential is positively correlated to muscle fiber number [25], and because hyperplasia does not occur postnatally [26, 27], the prenatal window must be deliberately managed to optimize the potential for high yield and high-quality carcasses. Moreover, precision management approaches to maximize postnatal muscle growth must consider the in utero developmental window.

Adipose tissue is intricately involved in whole-body energy balance and the prenatal period establishes a preparatory metabolic program so that the offspring can effectively manage the nutrients that it anticipates will be available in postnatal life. This includes several layers of transcriptional regulation that set up a metabolic program that loses plasticity in anticipation of a restricted postnatal environment similar to the prevailing in utero environment [28]. This can lead to a metabolic mismatch and undesirable carcass development in postnatal life when nutrients are not provided in congruence with the established restricted metabolic program. These offspring become particularly frugal with nutrient utilization and may experience a period of transient compensatory growth that places them on par with their non-restricted contemporaries in terms of weight. However, in many cases the composition of the catch-up growth is adipose tissue, and as a result their metabolic predisposition is toward nutrient storage as lipids in adipose tissue instead of using the energy and metabolic substrates for lean muscle growth and development. It is important for beef producers and packers to understand the impacts of amount of growth versus composition of growth on the final yield and quality of their retail product.

In the Brahman vs Angus nutrient restriction study described above, a subset of the Angus and Brahman heifers were allowed to calve, and postnatal growth was followed through to weaning (unpublished observations). Most postnatal measurements of growth were unaffected by maternal nutrient restriction from days 50 to 180 of pregnancy. However, heart girth was increased in calves born to nutrient-restricted versus adequate-fed dams, which may show in utero overcompensation of fetal growth when nutrient-restricted dams are realimented to adequate nutrition during late pregnancy. These cattle were not carried out to harvest, however, and that would be the defining determination of how fetal nutrient restriction impacted the quantity and quality of muscle and adipose tissue growth in the postnatal phase.

Maternal Melatonin Supplementation

The amplitude of melatonin secretion has been associated with improved oxidative status and altered hormone metabolism in rats and sheep, as well as altered cardiovascular function in several mammalian species [29–31]. Some studies have shown that melatonin partially regulates blood pressure and blood flow [32]. Melatonin has both direct and indirect effects on the cardiovascular system and may cause either arterial vasodilation or vasoconstriction depending on the origin of the blood vessel under investigation. Taking into account the above physiological responses, which can be partially altered by peripheral concentrations of melatonin, researchers have examined the effects of melatonin supplementation on uteroplacental development and functional capacity. Specifically, uterine artery blood flow was increased in Holstein heifers supplemented with 20 mg of dietary melatonin from days 190 to 262 of gestation [33]. Surprisingly, calf birth weights were not different between treatments; however, calf body weight at nine weeks of age was increased in calves born to melatonin-supplemented dams vs control dams [34]. Therefore, similar to other pregnancy models, an increase in uteroplacental blood flow during mid to late pregnancy is associated with alterations in postnatal offspring growth and development. This is apparent in the dairy heifer study as calves were removed from dams, managed identically, and fed a similar milk replacer and starter diet prior to weaning at eight weeks of age. Therefore postnatal maternal factors were removed from this dairy project, allowing researchers to propose direct fetal programming responses.

Because of the observed differences in dairy calf body weights, a similar melatonin supplementation experiment was replicated in beef cows. In this follow-up study, heifers and cows were assigned to one of two treatments: melatonin implants (n = 29) or no melatonin implant control (n = 28) starting on day 180 of gestation and ending on day 270 [35]. As expected, uterine artery blood flow was increased in commercial beef heifers and cows supplemented with melatonin during the last third of pregnancy. Similar to the dairy heifer study, beef calf birth weights were not different; however, a 57-lb increase in weaning weights was observed in calves born to melatonin-supplemented dams versus control [35]. Although similar results to the dairy study, it is important to note that postnatal maternal factors (e.g. postpartum cow health, colostrum composition, and lactational performance) could be contributing to the increased weaning weight of calves born to melatonin-supplemented dams. Taken together, these results in both cattle studies following melatonin supplementation have allowed researchers to speculate on potential circadian alterations of the reproductive tract during pregnancy. For example, the rhythms generated from circulating concentrations of melatonin could mediate circadian rhythms in the placenta and developing fetus during pregnancy.

The modulation of reproductive functionality and physiology by melatonin has a considerable impact on the postnatal growth of muscle and adipose tissue. Prenatal influences may include direct and indirect mechanisms. In skeletal muscle, binding of melatonin to the melatonin receptor stimulates glucose transport into muscle cells [36], increases the number of satellite cells, reduces inflammation, and inhibits apoptosis by modulating associated signaling pathways, allowing for cell regeneration [37]. To determine the underlying etiology of the differences in weaning weights reported above, loin muscle tissues were dissected from a subset of fetal calves collected via cesarean section. Fetal loin muscle weight and length tended to be increased in calves from melatonin-treated dams compared to their control counterparts. In addition, fetuses from melatonin-treated dams had increased expression of adenosine monophosphate-activated protein kinase-α (AMPK), which is involved in energy and protein metabolism. At the histological level, the ratio of Pax7-activated myonuclei to total myonuclei (PAX7:Nuclei) tended to increase in fetuses collected from melatonin-treated compared to control dams, which is indicative of satellite cell activation, a necessity for pre- and postnatal muscle growth. Moreover, these fetuses exhibited decreased expression of adiponectin (ADIPOQ), CCAAT enhancer binding protein alpha (CEBPA), proliferator activated receptor gamma (PPARg), and stearoyl-CoA desaturase (SCD) in perirenal adipose tissue, which is indicative of reduced adipogenesis and lipid metabolism in these offspring. We hypothesized that the improved metabolic status of loin muscle coupled with the decrease in adipogenic gene expression resulted in calves from melatonin-treated dams having improved potential for lean muscle accretion and reduced overall adiposity during postnatal development.

To test this hypothesis, the remaining subset of treated dams were allowed to carry their offspring to term and, while there were no differences in birth weight, loin muscle biopsies were collected from the offspring at birth and throughout the nursing phase to garner a longitudinal perspective of molecular muscle growth over time. Calves from melatonin-treated dams have a tendency for increased AMPK relative expression at birth and exhibited increased myogenic determination factor 1 (MyoD), insulin-like growth factor-1 (IGF1), and IGF2 expression in biopsies collected at day 195 of age. This molecular signature indicates an enhanced myogenic paradigm in the offspring from melatonin-treated dams that persisted at least up until weaning and may explain

the increased weaning weight observed in this treatment group compared to the control group.

Epigenetics and Fetal Programming

The term epigenetics has classically been defined as heritable changes in gene function without a change in the DNA sequence itself. The prefix "epi-" is derived from a Greek word, meaning "on," "above," or "over." Therefore epigenetic modifications can literally be interpreted as modifications occurring on top of genes. Among the most studied types of epigenetic modifications are DNA methylation and histone modifications. DNA methylation is defined as the addition of a methyl group to the five position of a cytosine. Histone modifications are post-translational modifications of histone proteins, some examples of which include acetylation, methylation, and phosphorylation. Epigenetic modifications fundamentally exist to program cell-specific functions. Though every cell in the body possesses the same underling genetic sequence, cells throughout the body have vastly differing functions. Therefore the cell must package genetic material in a way that transcription factors can access necessary portions of the genome and condense or "pack away" unnecessary portions. Open and active portions of the genome are referred to as euchromatin, while condensed and inactive portions are referred to as heterochromatin. Not only do epigenetic modifications function to "package" and "unpackage" portions of the genome for cell-specific function, but also they act to alter gene activity to adapt cells and collectively the body to a changing environment. Specifically, epigenetic modifications can result in increased or decreased transcription of genes, thereby increasing or decreasing the products of those genes. For example, increased DNA methylation within the promoter region of a gene typically results in a conformational change that prevents transcription factors from interacting with the gene, resulting in gene silencing. The epigenome is most sensitive to change during prenatal and early life development. This likely plays a role in decreasing developmental plasticity as an animal ages, as noted in Figure 27.1. Due to the sensitivity of the epigenome during prenatal development, alterations in fetal environment can result in programming of the epigenome and in turn the transcriptome. This relationship is the foundation of proposed epigenetic mechanisms controlling prenatal programming. Furthermore, prenatal programming and corresponding epigenetic modifications are believed to influence subsequent generations. Specifically, prenatal programming influences not only the developing fetus, but also the developing gametes belonging to that fetus (Figure 27.3). Therefore the experience of one individual in utero has the potential to impact the phenotypes of subsequent generations, though it is largely unclear how epigenetic patterns are maintained through the process of epigenetic reprogramming following fertilization.

Epigenetic modifications have been primarily studied in humans and rodents. However, recent literature has emerged evaluating the role of epigenetic modifications in controlling bovine phenotypes. Epigenetic modifications in cattle have been associated with differences in pathology [38], muscle biology [39], temperament [40], milk yield [41], fertility [42], and tropically adapted breed types [43]. However, limited research has been conducted specifically evaluating the role of epigenetic modifications in prenatal programming of postnatal phenotype of cattle. Genome-wide differential methylation of genes related to immune function, behavior, stress response metabolism, and cell signaling was identified in leukocytes of calves that

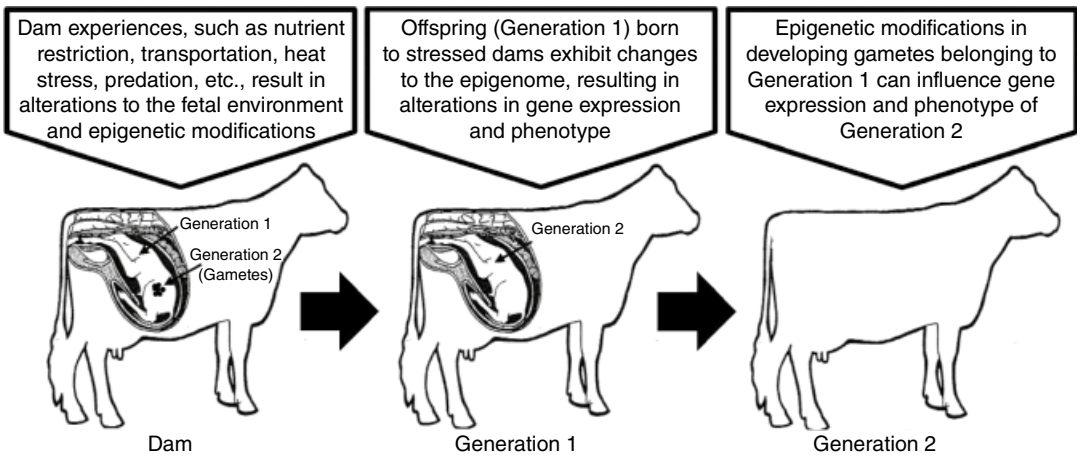

Figure 27.3 Model of prenatal programming in cattle.

experienced prenatal transportation stress [44]. Additionally, the *MIMT1* gene was found to be differentially methylated in placental tissue of intrauterine growth-restricted bovine fetuses [45]. Our current understanding of epigenomic and transcriptomic regulation of phenotype indicates a mechanistic role of epigenetics in prenatal programming. Though great attention has been previously placed on identifying gene markers associated with phenotypic characteristics and conditions in cattle, current literature indicates that more attention should be placed on epigenetic modifications which regulate the expression of such genes. By better understanding mechanisms controlling prenatal programming, we can better understand how to improve bovine production and management systems.

Biosecurity for Beef and Dairy Herds

Carla L. Huston

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

The goal of dairy and beef breeding operations is to produce offspring for future production in the forms of meat, milk, or genetics. Subsequently, reproductive diseases can have detrimental effects on the reproductive efficiency of dairy and beef breeding herds. There are many infectious diseases that affect reproductive performance in the bovine, including viral, bacterial, and parasitic. Specific pathogens may cause a range of clinical manifestations, from metritis and infertility to abortion and perinatal loss.

Biosecurity measures for a livestock operation are those taken to prevent the introduction or reintroduction of infectious disease agents into susceptible populations. While many biosecurity recommendations are good general management practices that can be applied across most operations, other recommendations should be more specifically tailored to an individual premises or group of animals.

Biosecurity measures are undertaken at national, state, and local levels. At the national level, biosecurity plans are often mandated by regulatory agencies such as the United States Department of Agriculture (USDA) and the United States Department of Homeland Security (USDHS) to protect livestock resources and consumer interests. Such plans are aimed at preventing the introduction of foreign animal diseases and other diseases of high economic consequence. The entry of animals, animal byproducts, germplasm (semen, embryos), and feed and feed products is carefully controlled at the national border. Producers and veterinarians participate at this level by adhering to recommendations with regard to international travel and by reporting unusual or suspicious conditions to their state or federal animal health official.

Biosecurity plans at the state level may focus on diseases targeted for eradication and control across state lines, such as brucellosis. State plans can also target diseases of regional significance, such as trichomoniasis, and are regulated through the state animal health official, most commonly the state veterinarian. Individual states may have different regulations for interstate animal imports, and both producers and veterinarians are responsible for knowing and adhering to a state's specific animal health regulations. The issuance of certificates of veterinary inspection (CVIs) is one example of an important tool used to prevent the spread of livestock diseases across state lines. Within states, an increasing number of states are also requiring intrastate or transfer of ownership testing of cattle for diseases such as trichomoniasis, and mandatory reporting of infectious disease diagnoses such as bovine viral diarrhea and Johne's disease.

While disease control measures at the national and state levels are critical to the protection of the overall US livestock population, individual producers and veterinarians have the greatest influence over the implementation of local biosecurity measures. It is ultimately individual livestock producers who are responsible for protecting their own herd against infectious reproductive diseases. Local biosecurity plans focus on preventing or controlling the spread of disease between operations and take into account endemic diseases and conditions unique to that population of animals. Local plans should consist of biosecurity measures as well as biocontainment measures – those taken to prevent or decrease the spread of a disease among groups of animals within an operation. Biological risk management (BRM) is the term used to describe the overall awareness and management of the risk of a pathogen or disease entering and spreading throughout a population. BRM often involves the evaluation, management, and reduction of pathogens that are already present in an operation.

Some challenges to recognizing reproductive inefficiencies in a breeding herd include the lack of individual animal identification and good reproductive records, the imperfection of

Companion website: www.wiley.com/go/hopper/bovine

diagnostic tests, and failure to identify the etiologies of abortions and perinatal losses. Furthermore, the intensive management of cattle in the USA, whether it is beef on pasture or dairy in confinement, creates challenges to ideal disease control conditions. Such challenges reinforce the importance for cattle producers to have a herd-specific biosecurity plan in place to protect their herd from reproductive diseases.

Developing a Biosecurity and Biocontainment Plan

A properly performed biosecurity risk analysis will help determine which biosecurity and biocontainment measures are appropriate for a specific operation. While general biosecurity measures are directed at non-specific pathogen threats, a biosecurity risk analysis can be agent specific, industry specific, or event specific [1]. Examples would be a Johne's disease herd risk assessment and management plan, a feedlot biosecurity analysis, and a biosecurity risk assessment for livestock exhibitions, respectively. Risk analyses can also be qualitative or quantitative, depending on the herd information available and desired outcome of the assessment. Many epidemiological tools are available to estimate the risk of specific disease transmission in a population, including statistical simulations and mathematical modeling [2, 3]. Such risk assessments should be made using multiple sources of information, such as targeted producer surveys and diagnostic testing, to predict probabilities of disease transmission, prioritize resources, or monitor progress following changes in management [4].

A biosecurity risk analysis approach involves risk assessment, risk management, and risk communication, considerations that are all key to comprehensive and effective biosecurity planning. The risk analysis approach should center on specific epidemiological characteristics of the agent, host, and environmental factors affecting reproductive health in the herd (Figure 28.1). A risk analysis for disease control is similar in concept to a hazard analysis and critical control point (HAACCP) system, which helps identify critical control points throughout a production chain where disease incursions may happen and incorporates control measures at each point. Whether a risk analysis or HAACCP system approach is used for protection against reproductive diseases, considerations should involve seeking input from not only producers and veterinarians but possibly also farm employees, family members, economists, and others involved in the daily farm operations.

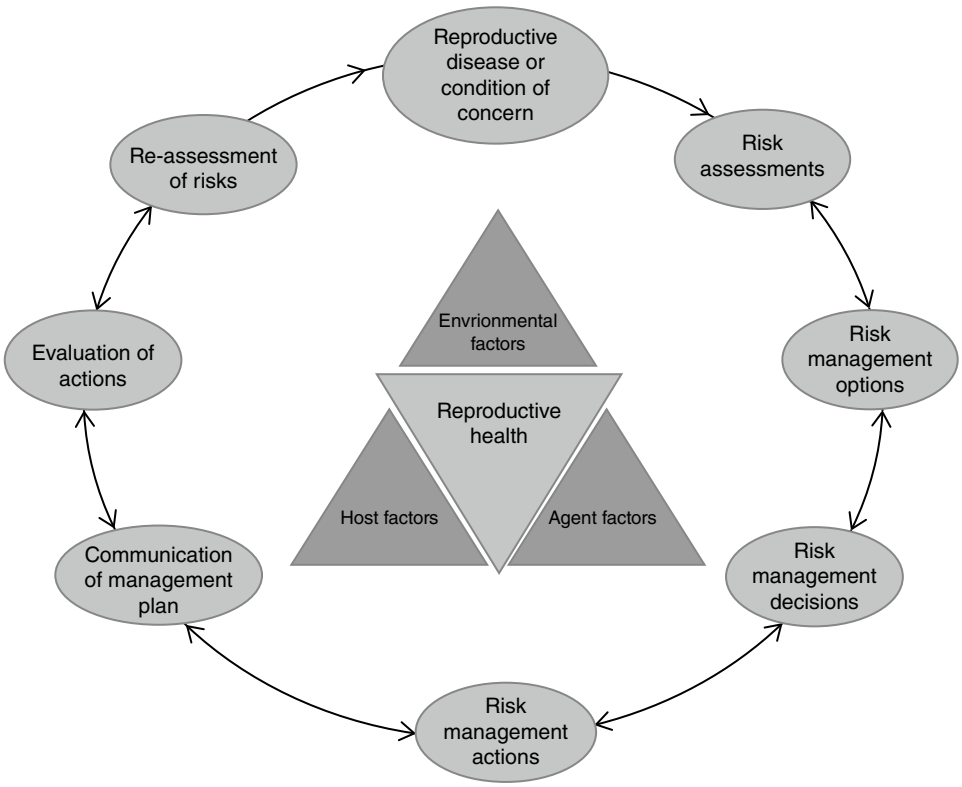

Figure 28.1 The risk analysis approach should center on specific epidemiological characteristics of the agent, host, and environmental factors affecting reproductive health in the herd.

Risk Assessment

It should be recognized in livestock production that every animal in a herd cannot be completely protected against every pathogen affecting reproduction. The purpose of a risk assessment in biosecurity planning for reproductive diseases is to evaluate the true likelihood, impacts, and consequences of pathogen introduction or an outbreak occurring in the herd. This involves hazard identification, exposure assessment, dose–response assessment, and risk characterization. The identification of hazards involves an examination of potential agents involved in reproductive diseases, along with the population at risk or susceptible hosts for disease. A risk assessment should contain estimates of reproductive disease threats, using past and current herd records for production (conception rate, calving rate, calving interval, etc.), and medical history, including vaccination practices and diagnostic testing, where available.

Several infectious agents affecting reproduction should be considered in both beef and dairy herds in the USA, including viruses such as bovine herpesvirus type 1 (BHV-1) and bovine viral diarrhea virus (BVDV), bacteria such as *Brucella abortus* and *Leptospira* spp., and parasites such as *Tritrichomonas foetus* and *Neospora caninum*. Additional agents of concern are dependent on regional and environmental exposures. Host factors for susceptibility to reproductive diseases may be influenced by age, genetics, animal use, vaccination status, nutrition, body condition, and stress. Animals most at risk for reproductive diseases – the breeding females, breeding bulls, and replacement females – can be managed in ways to reduce reproductive disease risks. For example, the use of virgin animals will eliminate the risk of pathogens transmitted venereally such as *T. foetus* and *Campylobacter fetus*.

Other herd management factors, such as animal movements, and environmental conditions must also be considered. It is useful to create a visual map of the farm environment during the initial biosecurity risk assessment to visualize the flow of animal and people traffic throughout the operation. The farm layout should include any buildings, pastures, working areas, feed storage areas, and water sources. Documenting the slope of the ground as well as the location of natural structures such as trees, streams, and ponds can help identify natural barriers for disease control. Nose-to-nose contact points should be identified in indoor as well as outdoor areas, paying special attention to quarantine areas, sick pens, calving pens, and breeding areas. Visitor access points, as well as restricted areas, should be clearly identified. Visualization of these areas and knowledge of associated risks will allow the creation of a flowchart to aid in identifying potential critical control points within an operation as well as identify potential entry points for new pathogens and diseases [5].

Exposure and dose–response assessments determine if the animals at risk are actually exposed to the identified pathogens, how often such exposure occurs, and how much exposure would cause a reproductive health risk to the animals. Environmental factors such as soil type, the presence of natural water sources, pasture management, animal contacts, and housing will have a great impact on pathogen exposure. Risk characterization examines the magnitude of the health risks and how control of those risks should be prioritized. The end result of a properly performed biosecurity risk assessment is a risk determination where animal–pathogen–environment interactions are characterized as high, medium, or low priority for disease.

Risk Management

The risk management stage of a biosecurity risk analysis is often referred to as the "action stage." The purpose of risk management is to establish measurable goals from the risk assessment, determine disease risk reduction strategies using the biosecurity tools that are available, implement biosecurity practices, and evaluate the implemented strategies. Available resources (personnel, equipment, financial), current biosecurity practices, and short- and long-term herd goals must be considered when developing risk management strategies. Goal-setting should include the level of aggressiveness desired and relies on good communication between all parties involved. For example, a less aggressive reproductive goal may be desired by the producer such as cessation of abortions, while a more aggressive goal of a veterinarian might be to establish a herd free from persistent infection by BVD (BVD-PI).

Management techniques to control reproductive diseases include a combination of tools such as movement control, diagnostic test and removal programs, vaccinations, and other enhanced biosecurity measures discussed further in this chapter. Care must be taken to not implement too many changes in an operation at once such that an evaluation of impact cannot be accurately made. Furthermore, producers and employees may become overwhelmed with so many changes that none of them actually become implemented.

Risk Communication

The purpose of risk communication is to translate the results of the risk assessments and summarize risk reduction strategies to an easily understandable form. Documentation of current biosecurity practices and recommended changes will help guide benchmarks for future reproductive goals. Proper communication requires interaction between all parties involved in the initial herd assessment. Additional education of team members and employee training is often

indicated following risk assessment and management recommendations. Standard reproductive herd health protocols such as animal addition protocols, vaccination strategies, and visitor policies should be reviewed and provided in both oral dialogue and written form to have available for future reference.

Communication methods can be very simple, such as a sign hanging in the calving barn, or very complex, such as the development of a statistical process control chart of reproductive efficiency [6]. Regardless of the communication output chosen, it should be readily understandable to the end-user and updated when changes in management practices are made. Written biosecurity risk analyses or HAACCP plans, including treatment protocols and standard operating procedures, will also provide legal documentation if needed. Multilingual materials should be included as appropriate.

While a myriad of biosecurity educational publications are available, most are non-specific and contain wide variations in recommendations [7]. Therefore it is important that biosecurity plans are tailored to farm-specific concerns. Furthermore, it is important to note that a proper risk analysis should be a flexible system, allowing for continuous monitoring, reevaluation, and open communication with all parties involved.

Tools for Intervention: Reducing Effective Animal Contacts

The basic concept behind biosecurity and biocontainment recommendations is that diseases can be prevented or controlled by reducing effective animal contacts. This concept is even truer for reproductive diseases. Effective animal contacts are those contacts made by an uninfected animal that result in infection and disease. Effective animal contacts can be reduced by utilizing a combination of the following concepts:

- Controlling exposure to pathogens
- Reducing animal contacts
- Optimizing an animal or herd's immunity.

Controlling exposure to pathogens can be accomplished by implementing barrier protections such as traffic control and following proper cleaning and disinfection measures. The use of vaccinations and prophylactic medications can complement other pathogen reduction measures by reducing pathogen shedding and exposure. Reducing animal contacts may also involve traffic control and preventing fenceline contacts with outside herds. The use of artificial insemination (AI) and embryo transfer (ET) are two ways to reduce animal contacts in a breeding herd and also prevent exposure to many of the reproductive pathogens of concern. Optimizing animal immunity is accomplished by a variety of methods but should include management strategies such as providing good nutrition, reducing stress, and delivering an appropriate vaccination scheme.

An evaluation of herd production records (including reproductive history, disease incidence, and disease screening tests) will help set goals, identify needs, document actions, and benchmark progress in disease control. However, one of the challenges involved when evaluating the impact of risk reduction strategies in a breeding herd is that results are not often observed until the next calving season. This makes timely record-keeping and monitoring of all health aspects of the herd, such as body condition scores, crucial to the overall health of the herd.

The use of biosecurity practices in beef and dairy herds has been studied and described for various regions and populations across the USA [8, 9]. Management factors such as confinement and pasture utilization are not easily changed, but an awareness of factors predisposing cattle to reproductive diseases under these situations can help make decisions regarding reproductive health more practical. Most biosecurity and biocontainment practices aimed at reducing effective animal contacts will focus on the utilization of movement control, barriers, cleaning and disinfection, and vaccination strategies.

Movement Control

Animal Additions

The biggest risk to reproductive health on a beef or dairy operation is the addition of animals from outside the farm. Animal additions include newly purchased animals as well as animals returning from outside premises such as heifer-rearing facilities and exhibitions. Maintaining a closed herd is an ideal situation where no new animals enter the herd. Unfortunately, this is not always a realistic expectation given the advances in genetics and herd expansions that often need to be made. In general, producers accept that sources of new animal additions, from perceived lowest to highest risk of disease introduction, include private sales, cattle dealers, cattle auctions, and sale barns. Animal additions should only come from herds with a known health status. For example, breeding animal additions should come from farms with effective herd health plans, as demonstrated through herd records, vaccination history, and disease surveillance programs, to minimize the potential for disease introduction. Avoid bringing in non-virgin breeding animals if possible to prevent introduction of venereal diseases. Performing breeding

soundness examinations on all bulls prior to arrival, including trichomoniasis testing on all non-virgin bulls over 12 months of age, will help to identify potentially infectious processes prior to the breeding season.

Quarantine and Isolation

Quarantine refers to the separation of animals exposed to pathogens or at high risk of contracting or carrying pathogens, whereas isolation refers to the separation of animals that are actually sick or known to be infected. Quarantine procedures should be followed whenever animal additions occur. The length of quarantine should cover the incubation period of the most important infectious diseases, generally a minimum of three weeks. Quarantine can be effective in preventing new cases of diseases transmitted by direct contact, such as BVDV, BHV-1, and leptospirosis. However, many diseases, such as neosporosis and BVD-PI, can be present in the subclinical or persistent form and not easily identifiable by visual inspection during this time. In these cases, diagnostic disease testing and vaccinations specific to the operation's herd health program should be performed before the animals are allowed to commingle with the resident herd. This time will also allow the animal to acclimate to the new environment and feed sources.

Dairy herd expansion efforts may pose unique challenges, given space and equipment limitations [10]. The use of a modified receiving pen, with solid-sided walls or double walls, can be used as an alternative quarantine area when separate facilities are not available [5], but strict traffic control and cleaning and disinfection procedures must be followed. If not performed prior to arrival, bull breeding soundness examinations including trichomoniasis and BVD-PI testing should be performed under quarantine in order to detect carriers and to allow ample time to find replacements if needed.

Sick animals should be placed under isolation for effective biocontainment. It is important that the producer understands that the medical treatment of an animal does not equate to cessation of pathogen shedding and that convalescent carriers of disease are possible. Animals that have experienced an abortion or pregnancy loss should be separated from the herd to allow investigation into the cause of the loss, which may include diagnostic testing of the dam or the aborted fetus. Prompt disposal of aborted fetuses, dead calves, and placenta should occur to prevent any transmission by contact or scavenging. Within an operation, animal and personnel movements should occur from the least susceptible animal populations to the most susceptible animals. Sick or high-risk animals, such as those under quarantine, should be handled last whenever possible. In larger facilities, separate personnel may be designated to care for high-risk populations.

Ideal quarantine and isolation facilities should be located as far away from the resident herd as possible – separate and downwind/downstream from the rest of the operation. Water and manure runoff should not be able to flow into common areas or near the resident herd. Separate equipment and protective wear (boots, clothing) should be utilized in quarantine and isolation areas and clearly identified to avoid their use in other animal areas.

Visitor Access

Both farm personnel and visitors can serve as mechanical vectors for reproductive pathogen transmission. This includes neighbors, salespersons, hoof trimmers, AI and ET technicians, and veterinarians. Such persons should be categorized into low-risk, medium-risk, or high-risk individuals based on the number and extent of animal contacts and farm visits made per day. Disease management recommendations can thus be made depending on the individual risk of disease transmission. For example, persons who have contact with animals on multiple farm visits in one day, such as veterinarians and AI technicians, are considered high risk and would be expected to follow more stringent biosecurity protocols. Employees who have their own cattle or have contact with outside animals on a regular basis should also be considered high risk. At a minimum these persons should be expected to have clean clothing and footwear when on the premises and perform stringent cleaning and disinfection before arrival. Lower-risk individuals would be those such as salespersons or equipment mechanics, who should have no contact with animals or animal areas. Visitors should have limited access to the farm, with designated entry points. Signage should be posted restricting visitor access to other areas. A visitor log should be kept and all visitors should be made aware of the farm's biosecurity protocols for visitors, including the required reporting of recent international travel.

Barriers

In addition to movement control, barrier precautions can be used to prevent airborne and contact pathogen transmission between animals. Effective barriers will help decrease unwanted animal contacts by providing an extra layer of protection between infected and susceptible cattle.

Personal Protective Equipment

Personal protective equipment is essential when working with the breeding herd. Obstetric sleeves, gloves, and protective clothing should be used when working with breeding animals, especially when working with potentially infected

uterine fluids, placental tissues, and aborted fetuses. A change of clothing is recommended between farms for persons who make multiple farm visits daily, such as veterinarians and AI technicians. However, this may not always be possible or practical, and guidelines are often made following an appropriate assessment of the true risk of pathogen transmission [11]. For operations with multiple farm locations, separate clothing can be kept at each premises to prevent carrying pathogens from site to site. Protective gear such as disposable coveralls and boots should be provided to visitors who are given access to animal areas if they do not have their own. Whenever possible, used or soiled protective gear should be left on the farm for disposal or cleaning.

Wildlife

Wildlife commonly share ranges and forages with breeding herds and have been shown to be efficient carriers of reproductive pathogens. However, effective physical barriers do not exist to prevent all livestock contact with wildlife. Alternative barriers should be considered to reduce the risks of disease transmission from these populations, which usually occur through the contamination of water and feed.

Wildlife can serve as direct and indirect sources of infectious reproductive pathogens and should be discouraged from feeding and cohabitating with cattle herds. BVDV has been detected in wild ungulates, and deer have experimentally transmitted the virus to naive calves [12]. While the natural transmission of BVDV between deer and cattle has not been demonstrated, the potential should not be overlooked in areas where common feeding occurs. *Brucella abortus*, a pathogen that has eluded national eradication efforts for many years due in part to its persistence in wildlife, has been shown to be transmissible from infected bison to cattle [13, 14]. Wild or feral swine have also become increasingly prevalent in pasture environments. While specific cattle pathogens have yet to be isolated from these swine herds, cases of *Brucella suis* have been reported and remain a concern to the US pork industry [15, 16]. In addition to the potential risks to the reproductive herd, contact with wild ungulates can pose a significant risk to the US livestock population in the event of a foreign animal disease outbreak, such as foot-and-mouth disease. Population control of deer and swine herds may be complicated and should involve collaboration between wildlife management professionals and livestock operators.

Feed and Water Sources

Clean feed and water sources are important for maintaining the health of the breeding herd. *Leptospira* spp. are shed through the urine of infected domestic and wild animals such as deer and other small mammals and are known contaminants of natural water supplies. In operations where multiple water sources are available, pregnant heifers and cows should have access to the cleanest water, avoiding natural streams and ponds. When possible, areas of heavy standing water should not be used for grazing as contaminants such as toxic algae blooms can persist in such conditions. Vaccination schedules may be adjusted to more fully protect the breeding herd against leptospirosis when they are exposed to outside conditions and aversion of natural water supplies is not possible [17].

Storing commodities and feed in an enclosed or protected area helps to prevent fecal contamination with potentially harmful pathogens. Wild canids are the definitive host for *N. caninum*, a parasite causing mid- to late-term abortions in cows (see Chapter 65). Cattle become infected with the parasite when they ingest feed contaminated with feces of infected canids. The parasite has been detected more frequently in dairy cattle populations, where stored feeds are more likely to be ingested. Canines are attracted to feed due to the presence of small rodents such as mice and rates, so rodent control should be routinely practiced. Birds and rodents have also been shown to contaminate feeds by shedding *Salmonella* spp. in their droppings. Birds should be kept from roosting in feeding areas or feed storage areas. Population control of birds and rodents by roost and nesting removal or hazing should be considered. Pesticides should only be used with care. Domestic pets should also be prevented from contaminating livestock feed and water sources.

Farm Environment

Operations may be more at risk to certain pathogens due to their geographical location. Geographical barriers such as streams, wooded areas, tree lines, and ridges, while not easily modified, can be strategically utilized to create barriers between operations or groups of animals. Perimeter control by maintaining good fences is important not only to keep unwanted animals from having contact with the resident herd, but also to keep the resident herd from moving outside the protected area. In addition to maintaining good fences, preventing fenceline contact of the resident herd with other herds is important to prevent nose-to-nose contact and potential transmission of pathogens. Within an operation, high-risk animals should not be allowed to have nose-to-nose contact with the resident herd. If a fenceline must be shared, a temporary fenceline or strand of hotwire can be used to keep animals at least 4 m apart.

The environment in which cattle are housed has a tremendous impact on the risk of reproductive disease development. Beef cattle spend much of their lives on pasture, making it difficult to create effective barriers to other animals and wildlife. An example of proper pasture utilization would be to ensure that weaned or stocker cattle have no fenceline contact with pregnant heifers to reduce the potential for

BVDV transmission. Cattle raised mainly in confinement, as many dairy cattle are, may be more susceptible to pathogens that contaminate feed and water supplies, such as *Neospora caninum* transmitted by canines or *Salmonella* spp. carried by bird and rodent droppings. Most reproductive pathogens such as IBR, *Campylobacter* spp., and *Tritrichomonas* do not survive outside of the animal host for long periods of time. Inclement weather, such as extreme moisture, heat, or drought, can create added stress on a breeding herd, potentially affecting nutrition, decreasing immunity, and increasing susceptibility to disease.

Cleaning and Disinfection

The farm environment is conducive to the survival of many potential bovine pathogens. While the elimination of all debris and manure is impossible, measures can be taken to reduce the pathogen load in the farm environment. Fortunately, many reproductive pathogens are susceptible to common cleaning and disinfection practices. Many excellent resources are available on cleaning and disinfection, and veterinarians and producers should be familiar with the characteristics and limitations of commonly used disinfectants in a farm environment [18].

Equipment and tools used on individual animals should be cleaned and disinfected after each use. Special attention should be given to equipment exposed to animal body fluids such as AI guns, obstetric equipment, and nose leads. Tools such as rakes, shovels, buckets, and halters are ideally not shared between high-risk animals and the resident herd.

Separate machinery or equipment should be used under the following situations: feeding high-risk groups of animals, handling feed and manure, and handling carcasses. However, this is not always possible or practical, and common equipment should be cleaned and disinfected after use in any of these situations. Equipment used off-farm or shared with other operations should also be thoroughly cleaned and disinfected upon return.

The physical removal of debris such as manure and mud from equipment is important to inhibiting pathogen survival. Many viruses and bacteria are susceptible to desiccation and ultraviolet lighting, so the use of chemical disinfectants on large flooring areas or large equipment such as trailers or breeding boxes may not always be indicated in low-risk situations such as daily farm use in a single area. Vehicles of all visitors should be clean of visible mud and manure on arrival. A designated vehicle washing area, which could consist simply of running water, detergents, and disinfectants, should be placed in an area that can be used prior to entry to the farm or animal area. Runoff from the washout area should not have contact with any animal areas.

Quarantine and isolation areas should be thoroughly cleaned and disinfected between groups to avoid cross-contamination in all-in, all-out situations. Where all-in, all-out management of groups is not possible, quarantine, isolation, calving, and other commonly used areas should be scraped and cleaned frequently to avoid manure build-up and the potential for increased pathogen exposure. Placentas should be removed promptly in confinement situations to avoid ingestion by other livestock. Any animal carcasses, including aborted fetuses and tissues, should be removed promptly under any conditions to avoid contact and ingestion by other cattle, wildlife, or domestic pets. Carcass disposal should be performed in compliance with local regulations. In cases of suspected or confirmed reportable animal diseases, specific cleaning and disinfectant measures may be mandated [19].

Feed bunks and water troughs should be cleaned out frequently. Special attention should be paid to waterers that contain lids or floats that may trap debris. BVDV has been shown to survive outside the host for extended periods of time in aqueous materials and in synthetic mucus [20], potentially increasing the risk of transmission through feed and water sources.

Vaccination

Vaccination protocols should be evaluated and updated periodically for optimum timing, type, and antigen selection. Vaccination is one of the most commonly used biosecurity practices by producers and veterinarians. While vaccines rarely prevent infection, proper vaccination strategies may help reduce the incidence or clinical severity of reproductive diseases. Common pathogens targeted by vaccine manufacturers are covered elsewhere in this book and include BHV-1, BVDV, multiple *Leptospira* spp., and *C. fetus* [21]. Uncommonly used vaccines include those against *B. abortus* in females, *N. caninum*, and *T. foetus*. The use of these and other vaccines should be considered only after a thorough biosecurity risk assessment is performed by the producer and the veterinarian to avoid any unnecessary costs. The safety and efficacy of vaccines, including a comparison of the use of modified-live versus killed vaccines, should be determined specific to the animals on the operation. However, the use of vaccines should not be the sole source of protection for a breeding herd and should be used to complement other biosecurity practices.

Diagnostic Disease Testing

Knowledge of a herd's current disease status is important in assessing disease risks and prioritizing control measures. Diagnostic disease testing is a tool that can be used to identify infectious disease risks associated with a single animal or group of animals. Given herd production parameters, statistical probabilities can also be calculated on the

likelihood of disease introduction under specific herd conditions [3]. Diagnostic testing is commonly used to diagnose cases of illness, to augment test and removal programs, to monitor progress in disease control, and to document freedom from disease in prepurchase or postpurchase examinations. Prepurchase testing strategies can be performed prior to bringing new animals onto a premises, and diagnostic disease testing is valuable in detecting subclinically or persistently infected animals, as in the case of trichomoniasis, neosporosis, and BVD-PI. However, in a herd setting it is not always practical to test all incoming animals for all potential reproductive pathogens, and therefore the testing of subsets of animals or pooling of samples may be indicated. As discussed in the section "Vaccination," quarantine of all animal additions will help prevent the spread of any disease while diagnostic test results are pending. Testing for causes of abortion is also important to identify reproductive pathogens that may be present, even though only a small percentage of abortions submitted will actually have a causative agent identified. Diagnostic tests are not perfect and should always be interpreted with characteristics such as test sensitivity and specificity in mind. Sensitivity of a diagnostic test is its ability to correctly identify a positive or diseased animal, and specificity is the ability to correctly identify a negative or non-diseased animal.

While the sensitivity and specificity are characteristics of the diagnostic test itself, predictive values are based on the estimated prevalence of a pathogen or disease, along with sensitivity and specificity to provide a better prediction of the risk of disease in a given population. A positive predictive value estimates the probability of an animal having the pathogen or disease given that the test was positive, and the negative predictive value estimates the probability of the animal being disease-free given that the test was negative. The negative predictive value will have the most importance in prepurchase testing as new owners wish to ensure that imported animals are free from disease. Diagnostic testing schemes are an important part of a herd biosecurity plan but should not be the sole basis for decision-making. The overall health program of the source herd is often more important to consider than a diagnostic test from a single animal. A more complete description of diagnostic testing schemes for the breeding herd can be found in Chapter 43.

Breeding Management

In addition to utilizing the previously described disease intervention tools, a comprehensive reproductive management plan should include having a defined breeding season and performing pregnancy testing in a timely manner. Most beef cattle are managed according to a seasonally defined breeding season, and an outbreak of a reproductive disease may not be recognized until pregnancy checking, often several months after breeding. Reproductive diseases could potentially affect an entire calf crop, and a delay in pregnancy testing could be even more costly. Having all bred females at the same or similar stage of pregnancy can also increase the risk of diseases whose incidence is dependent on the time of infection, such as BVD-PI caused by exposure of the dam from approximately 45 to 125 days of gestation. On the other hand, dairy cattle tend to be bred year around, and changes in reproductive status are likely to be detected sooner.

The purchase, lease, or borrowing of non-virgin bulls for breeding purposes constitutes a significant risk to the reproductive performance of a herd [22]. Trichomoniasis and campylobacteriosis cause decreased reproductive performance in breeding females but do not cause clinical signs in infected males. Breeding soundness examinations of all breeding-aged bulls should be performed prior to purchase and should incorporate trichomoniasis testing. As previously mentioned, states have increasingly been implementing mandatory testing for trichomoniasis for interstate and intrastate movement of animals, and producers and veterinarians should familiarize themselves with their state's regulations. Breeding animals should also be current on vaccinations, including vaccination against BVDV, campylobacteriosis, and leptospirosis. In addition to vaccination, proper external parasite control will help reduce potential transmission of tick-borne diseases which may cause reproductive losses.

AI and ET are effective barriers to the transmission of venereal and other reproductive diseases, while allowing for advancement in genetics and herd expansion. While the production and distribution of semen and embryos pose some risks for pathogen transmission, these are considered to be safe procedures when internationally accepted standards such as those recommended by the Certified Semen Services (CSS) and International Embryo Transfer Society (IETS) are followed [23]. Pathogens such as BVDV and *N. caninum* can cross the placental barrier, so it is important that both donors and recipients are tested free of the disease and properly vaccinated if indicated prior to embryo implantation. Disposable equipment should be used when possible; any items used on multiple animals should be thoroughly cleaned and disinfected between use. Additional information on pathogen control through AI and ET technologies is given in Chapters 81 and 83, respectively.

Special Considerations

Zoonoses

Several reproductive pathogens encountered in beef and dairy operations can be zoonotic [24]. All persons involved in animal handling during the reproductive management of the

herd should take personal protective measures when handling reproductive tissues, fluids, or pharmaceutical products such as hormones. At a minimum, personal protective equipment such as gloves and sleeves should be used and proper cleaning and disinfection procedures followed. While safer strains of modified-live *B. abortus* vaccines are now used, personal protection against iatrogenic infection is still warranted. Reproductive hormones, while not containing pathogens, can be harmful to humans and should be handled with care.

Disaster Preparedness

Beef and dairy cattle producers should include emergency provisions in their biosecurity plan. Unexpected events such as tornadoes, fires, or flooding may require animals to be quickly moved to a different location. Prior to an event, producers are encouraged to identify other producers, sometimes called "sister farms," with similar health programs and biosecurity plans that their animals could be sent to with little risk of disease transmission. Quarantine procedures should be followed on arrival at the sister farm as well as on return to the home farm in order to protect both farms. Animals to be moved should be identified according to a risk assessment, with special consideration given to protecting highly susceptible animals such as pregnant heifers.

In addition to identifying alternative housing, producers should ensure that vaccinations are always current, animals are properly identified, and health records are kept in more than one location. Additional protection against waterborne pathogens such as *Leptospira* spp. may be indicated in flooding situations or events resulting in large amounts of standing water. In emergency situations, the sharing of trailers, loaders, and feed troughs may be unavoidable. If equipment must be shared, cleaning and disinfecting after use and between herds is warranted. Provisions for emergency transportation should be included in preparedness planning. A shelter-in-place system may be most appropriate following certain emergency situations when it may be more harmful to try to move cattle out of a disaster zone. Producers can contact the local county emergency management agency or the state's animal emergency preparedness office for additional disaster planning resources or assistance with emergency sheltering or confinement.

Heightened biosecurity measures may be necessary in the event of an outbreak of a foreign or emerging animal disease. Tools are available to assist beef and dairy producers in developing business continuity plans in the event that animal and product movement restrictions occur in affected areas [25].

Summary

There are many tools available to protect the beef and dairy breeding herd against reproductive pathogens. While taking herd goals into consideration, practical and effective biosecurity plans must be made so that they are acceptable and likely to be followed. Biosecurity and biocontainment plans should be flexible and include disease monitoring and surveillance programs to continually identify operation needs, document management plans, and benchmark progress. A combination of environmental management practices, movement control, barriers, and cleaning and disinfecting protocols can reduce the incidence of reproductive diseases by reducing effective animal contacts. Ultimately, a properly performed risk analysis will assist the veterinarian and livestock producer in developing a comprehensive approach to implementing effective biosecurity practices against reproductive diseases.

Beef Heifer Development

Megan S. Hindman and Terry J. Engelken

Department of Veterinary Diagnostics and Production Animal Medicine, Lloyd Veterinary Medicine Center, College of Veterinary Medicine, Ames, IA, USA

Introduction

The replacement heifer represents the next generation of genetic progress for the cow herd [1]. Because of the required capital outlay that beef producers invest in these females and the time period required to recoup this investment, it is critical that reproductive efficiency is optimized. In order to get a return on this investment, replacement heifers must become pregnant early in the first breeding season, calve with a minimum of dystocia at two years of age, breed back in a timely fashion, and then continue to be productive for a number of years. Therefore it is critical that replacement females be selected, grown, and managed with these goals in mind.

There has been much discussion within the industry as to the best approach for heifer development. In areas of the USA where grazing land does not compete with crop production, extensive development systems may be advantageous. In this scenario, pasture land is more readily available and less expensive to rent or own. This allows the producer to utilize limited prebreeding selection criteria and expose a much greater number of heifers during the breeding season. Heifers that conceived early in the breeding season are identified and selected at pregnancy examination to fit the replacement needs of the ranch. Heifers that conceived later in the breeding season or remained open are then marketed.

In areas of the Midwest where there is significant influence of crop production on the price and availability of land, more intensive heifer development systems are utilized. Due to limited pasture resources, an aggressive prebreeding selection criterion is needed. This criterion emphasizes early selection, nutritional development, and prebreeding management so that heifers reach puberty prior to the start of the breeding season. The goal of this approach is to limit the number of heifers exposed to only 10–15% more than the number needed to meet replacement needs. Regardless of the system used for development, practitioners need to be involved with these programs to ensure that these females are meeting a set of performance benchmarks for both growth and reproductive targets. This will help ensure optimum reproductive performance, increased female longevity, and increased cow herd profitability.

Replacement Heifer Economics

Table 29.1 summarizes the cost structure of producing a heifer that will join the mature cow herd when she is confirmed pregnant [2]. This budget assumes that the heifer is born in the spring and weaned the following November. She will be bred the following summer and then subsequently calve as a two year old. The single biggest expense associated with the heifer development program is the opportunity cost associated with the market value of the heifer at weaning. This USD $825.46 cost (period 1: conception to weaning) is incurred when the producer decides to keep her in the replacement pool as opposed to selling her at market value.

Costs associated from heifer weaning until the start of the breeding season are primarily associated with the winter feeding program and summer grazing (Table 29.1). Over 85% of this $321 cost is accounted for by feed, labor, yardage, and interest. Dry lot rations or supplementation programs for heifers on forage need to balance feed costs with adequate growth performance. This emphasizes the need for sound nutritional consultation during this time, especially when feed commodity prices are high. The animal health program (including death loss) and grazing costs (pasture rent equivalent) make up the remainder of the inputs during this time frame.

The costs associated with developing replacements through the end of the breeding season are also illustrated

Table 29.1 Cost summary (USD) for developing a replacement heifer.

Period 1: Conception to weaning	$852.46
Period 2: Weaning to breeding	$321.00
Period 3: Weaning to pregnancy examination	$129.00
Subtotal	$1275.46
Adjust for 85% heifer conception rate	$1500.00
Adjust for cull heifer credit[a]	$1354.00
Calculated heifer development costs (born 2011)	$529.00

Source: From [2], © 2012, *Beef Magazine*.
[a] Assumes 369-kg heifer at $2.644/kg = $975.60 × 0.15 = $146.34.

in Table 29.1. This $129 estimated cost is primarily associated with grazing and breeding costs. The grazing season is estimated to last four months at $13.60 per month. This budget assumes the purchase of a $4000 bull that will breed 20 heifers per year for a total of four breeding seasons. This breeding cost also considers the annual cost of feeding the bull, interest on the initial investment, and the bull's salvage value when culled. This gives a total investment of $1275 to carry a replacement heifer to approximately 18–20 months of age (pregnancy examination).

Finally, the cost of heifer development must take into account the level of reproductive performance (percent pregnant) and cash value of the open heifer. In this example an 85% pregnancy rate increases the cost of production to $1500 for each pregnant heifer. The income from the sale of open heifers is then credited to the heifer enterprise, bringing the final cost to $1354 per pregnant heifer. This total represents a $529 developmental cash cost being added to the $825.46 opportunity cost incurred at the time of initial selection. With this magnitude of capital outlay, it is critical that these heifers be adequately developed to ensure optimum reproductive performance and longevity.

Selection at Weaning

Recent surveys indicate that approximately 85% of beef replacement heifers were raised on the operation where they calved [3]. Although the majority of herds in the USA utilize some form of individual cow and calf identification, this information is underutilized when it comes to making management decisions. Therefore it is critical that the practitioner help the client understand the importance of accurate data collection as it relates to the heifer development enterprise. Calf birth date, dystocia score or birthweight, female temperament, and calf weaning weight can all be used to make inferences about individual cow productivity over time. This information can then be used to make postweaning selection decisions easier.

The process of heifer development normally begins at the time of weaning with the initial selection of potential replacements. Females should be selected based on age, weight, temperament, and the productivity of their dam. Musculoskeletal soundness must also be evaluated as poor feet and leg structure can have a negative impact on productive longevity [4]. Selecting replacements from calves born in the first half of the calving season will increase the chance of the female reaching puberty by the time the breeding season starts [5–7]. Since the age and breed of the potential replacement are already established by the producer, weaning weight becomes the primary selection parameter and the basis for the developmental program.

Regardless of their birth date, the entire calf crop is typically weaned on the same day, so uniformity of the group of replacements may be an issue. Sorting heifers by weight and frame score is normally the first step in narrowing the pool of replacements at weaning [5]. Economic considerations should be evaluated when there is a wide disparity in heifer weights. Heifers that are too large (frame score) or too light (weight) may be targeted for culling in order to improve the economic efficiency of the replacement program. Beef operations that have a sound replacement development program should only need to retain an additional 10–15% more weaned heifers than they need to become pregnant. This will enable them to maintain current herd size and avoid the opportunity cost of retaining more heifers than needed.

Prebreeding Nutritional Management

Developing replacement heifers to a genetic specific pubertal weight is crucial to the success of the first breeding season and subsequent productivity. Feeding the replacement heifer represents the second highest cost associated with the development program, second only to the opportunity cost of her retention at weaning [8]. Based on a heifer's genetics and expected mature size, a target weight can be selected and the feeding program tailored to meet the needed average daily gain [5–7]. Target weight is simply an estimation of the weight at which individual heifers will reach puberty. Provided we know the weaning weight, target weight, and number of calendar days before the start of the breeding season, rations can be constructed to ensure that heifers reach puberty in a timely fashion. Typically, the rate of gain needed will fall into the range 0.5–0.8 kg/day and represent a total gain of approximately 91 kg for heifers of British breeding.

Traditional intensive developmental programs have emphasized the need for heifers to reach approximately 60–65% of their expected mature weight prior to breeding [5–7]. This practice is utilized to ensure that heifers

reach puberty and are cycling prior to the start of the breeding season. This increases conception rates and the chance of early pregnancies in heifers. Research done at the University of Nebraska-Lincoln has looked at the reproductive performance of heifers that were targeted to reach only 50–55% of their expected mature weight [9–11]. These heifers are overwintered on relatively poor forage (winter range or corn stalks) with supplemental protein. In these studies, reproductive performance was not different between heifers developed to reach 56% (EXT) versus 65% (DL) of their expected mature weight (Table 29.2) [10]. While fewer heifers in the EXT group reached puberty prior to the start of breeding, there was no difference in overall pregnancy rate or percent calving in the first 21 days of the subsequent calving season. However, heifers developed to only 50% of their expected mature weight run the risk of conceiving later in the first breeding season and weaning lighter calves [11]. Reproductive performance in subsequent years was not different among these different heifer groups. Any potential decrease in reproductive performance in these heifers must be weighed against lower feed costs. These cost savings have been documented to range from $22 to $45 per heifer compared with a traditional dry lot development and target weight.

Feeding ionophores to replacement heifers increased feed efficiency and average daily gain, and hastened the onset of puberty [12–14]. An individual daily dose of 200 mg of monensin has been used effectively in these trials. Also, heifers breeding on their third estrus have a higher first-service conception rate (21–36%) compared to those bred at puberty [15, 16]. Therefore gains should be managed so that heifers reach their target weight at least three weeks prior to the beginning of breeding. Selection of the target weight may be based on the average weight of the heifer group or a percentage of the expected mature weight, or extrapolated from the average frame score.

Table 29.2 Effects of dry-lot development (DL) or grazing a combination of corn residue and winter range (EXT) on heifer reproduction.

Trait	DL	EXT	SEM	*P*-value
n, first season	3	3	—	—
Puberty by AI (%)	88	46	0.04	0.01
Conceived to AI, first season (%)	69	58	0.08	0.23
Pregnant to AI, first season (%)	64	54	0.06	0.08
Pregnant, first season (%)	94	92	0.04	0.38
n, second season	2	2	—	—
Pregnant to AI, second season (%)	62	66	0.08	0.61
Final pregnancy rate, second season (%)	93	84	0.14	0.56

DL, Heifers consuming a diet in a dry lot post weaning; EXT, heifers supplemented three times per week with the equivalent of 0.45 kg/day 31% crude protein (CP) cube (dry matter [DM] basis) post weaning while grazing corn residue and dormant winter range and subsequently moved to dry lot; AI, artificial insemination.

Prebreeding Selection and Management

Approximately 30–60 days prior to breeding, heifers should undergo a prebreeding evaluation [5, 6, 17]. This is the last step in determining whether or not a heifer will actually enter the breeding program. Heifers should be evaluated on their body weight, reproductive tract score, pelvic dimensions, body condition score, and structural correctness. There is a growing body of evidence that indicates female temperament is highly correlated with that of her calf. Also, feeding performance of the offspring from cows with poor temperament can be negatively affected [18, 19]. There is anecdotal evidence that temperamental heifers have lower conception rates to artificial insemination (AI). At any rate, overly aggressive or easily frightened females should be considered for culling.

When evaluating the reproductive status of the heifer, there is an additional tool that can be used to enhance reproductive tract scoring. The reproductive cycle of the bovine consists of two or three waves of growing and regressing follicles followed by the ovulation of a dominant follicle. These follicular waves consist of secondary follicles that are also known as antral follicles. Antral follicle counts (AFC) can be used to assess reproductive longevity for cows and heifers prior to breeding [20, 21]. This is based on the fact that AFC is correlated with the number of primordial follicles or ovarian reserve. Using an ultrasound unit, each ovary is scanned and the number of antral follicles found on both ovaries is totaled [20]. This method is reliable and reproducible despite variation in genetics, size, stage of estrus, and age of heifers [20]. Research indicates that heifers with low AFC (<15 total follicles) had lower birth weight calves, smaller ovaries, and a decreased pregnancy rate as heifers compared to herdmates with high AFC (>25) [21]. An additional study demonstrated that cows that were repeat breeders had fewer antral follicles in the ovarian cortex compared to normal herdmates [22]. Thus AFC can be utilized in the field to predict fertility and longevity when selecting for replacement heifers prior to breeding.

Other heifers that fail to meet specific selection targets should be culled at this time as well. This evaluation should take place far enough in advance of the breeding season to allow adequate time for needed ration changes if accelerated growth is required. This handling also represents a good opportunity to deliver vaccines and dewormers. This information should be summarized and reported in a format that will justify program decisions to the client.

The health program for the replacement heifer should be targeted against reproductive disease and help to optimize growth rate. This program should complement the suckling calf vaccination protocol that was administered so that protective immunity is maximized. The heifer's first breeding season, first pregnancy, and subsequent reproductive performance should all be considered when defining the timing, delivery, and antigens to include in the vaccination schedule [23]. The history of disease on the ranch, traffic patterns on and off the operation, and previous diagnostic information should also be evaluated when attempting to manage the disease risk.

Vaccines that provide fetal protection against common viral and bacterial diseases should be utilized in these schedules and Beef Quality Assurance (BQA) guidelines should be followed. Deworming schedules can vary greatly depending on rainfall, temperature variation, and forage availability. The class of anthelmintic, level of pasture contamination with infective larvae, and the relative cost of the products will also impact strategic deworming programs [24–26]. Veterinary involvement in these decisions is critical for the successful application of current vaccine and parasite control programs.

Breeding Season Management

Planning for the breeding season should begin early enough to allow time for bull selection (AI or natural service), as well as acquisition and implementation of the estrus synchronization protocol. Evaluation of sires should be based on their ability to pass a breeding soundness examination and their expected progeny difference (EPD) values. Bulls with large scrotal circumferences and prebreeding bull exposure should be utilized, since this will hasten the onset of puberty in their progeny [5, 6]. Progesterone-based synchronization programs do offer the advantage of inducing puberty in some heifers [27]. There are multiple protocols and software programs that can be utilized to manage estrus synchronization [28, 29]. The selected protocols must be individualized for the operation and consider cost, animal handling, and breeding options.

Early pregnancy detection may be a useful management tool to better define the timing of pregnancy, the sire of the calf, and the overall success of the breeding season. This may occur 30–45 days after the end of the AI period or following bull removal [1, 6, 7]. This practice is especially helpful in that it gives an early indication of reproductive failure so that the practitioner can begin the diagnostic work-up much earlier. Early examination of pregnancy may also be used to hasten the culling of non-pregnant or late-bred heifers in the event of forage shortages.

Pregnancy examination provides an opportunity to provide the next step of the health program. Heifers should be dewormed between pregnancy examination and calving, and the health program should center on antigens that cause losses in mid and late gestation [23]. Vaccines for calf scours should be delivered according to label directions as needed. Herd health procedures should follow BQA guidelines and be documented by recording the name, dose, and serial number of the vaccine and the date that it was administered.

Information concerning individual pregnancy status, body condition score, overall pregnancy rate of the group, pregnancy distribution, and culling information should be reported to the client in the form of a written summary [30, 31]. This allows the practitioner and producer to evaluate the strengths and weaknesses of the heifer development enterprise and make needed changes. This type of communication enhances opportunities for proactive planning and fine-tuning of the program. This report will also serve as the planning document to ensure that the pregnant heifers are well managed all the way through the subsequent calving season.

Postbreeding Through Calving

Once heifers are determined to be pregnant, they need to be managed to calve in moderate body condition (average condition score 5.5–6.5). Heifers calving in moderate condition usually have less dystocia, a shorter postpartum interval, and higher pregnancy rates after their second breeding season. Nutrition prior to parturition can also affect postnatal development of the calf by influencing colostrum quality and quantity. Calves produced from first-calf heifers have decreased serum immunoglobulins at 24 hours of age compared to multiparous dams [32]. This is likely due to a decrease in volume and not necessarily the overall quality of the colostrum. A previous study showed calves born to two-year-old heifers in poor body condition exhibited less vigor and lower serum immunoglobulin concentrations at 24 hours of age [33]. Postnatal development in relationship to colostrum intake needs to be considered as it can directly impact the morbidity and mortality of future replacement heifers.

Following pregnancy examination, weight gains need to focus on having the heifers reach approximately 85% of their expected mature weight by the time they calve. Moderate daily gains in the range of 0.5 kg/day will usually be adequate to ensure that heifers reach their first calving with adequate frame, pelvis, and body condition. It is useful to remember that approximately 70–75% of fetal growth occurs during the last trimester of pregnancy and rations should be adjusted accordingly [7, 12]. These adjustments need to include adequate protein, energy, and trace minerals. This is especially important for the first three months after calving, if heifers are expected to be able to lactate, grow, and rebreed in a timely fashion [34, 35].

It could be argued that future replacement heifer development begins while that individual heifer is in utero. The maternal environment can have a great impact on subsequent productivity even after the calf is born. Studies have reported instances of compromised maternal nutrition during gestation resulting in neonatal mortality, intestinal and respiratory dysfunction, metabolic disorders, decreased postnatal growth rates, and reduced meat quality [36–38]. This phenomenon has been referred to as developmental or fetal programming. Nutritional shortages may have a negative impact on the developing fetus at all stages of pregnancy, but this can be especially severe during the last trimester.

Calves born to protein-restricted cows will show reduced feeding and reproductive performance [38]. Heifer calves from these cows had lower body weights at weaning, prebreeding, and pregnancy examination. Contemporary heifers from protein-supplemented cows reached puberty at an earlier age and had higher pregnancy rates after their first breeding season. This resulted in a 28% increase in the proportion of heifers calving in the first 21 days of the calving season. The steer mates to these heifers also showed an improvement in weaning weight, feedyard dry matter intake, percent grading choice, and marbling score [38]. Table 29.3 illustrates two studies that evaluated the effect of maternal protein supplementation on heifer progeny reproductive performance [38]. Heifers from supplemented cows exhibited improved weaning weight, growth, and pregnancy rate. A similar effect was observed in another study that utilized distillers grains to increase the energy content of a gestating cow's diet [39]. In this trial, cow supplementation resulted in an increase in heifer progeny conception rate to AI, even though there was no change in AFC or age at puberty. Although the mechanisms by which placental and fetal programming occur are not clear, managing resources to ensure proper female nutrition during critical points of gestation can improve calf performance, calf health, and future reproductive potential. In those cases of poor reproductive performance in replacement heifers, the nutritional management of the *entire* cow herd must be included as part of the diagnostic work-up.

Table 29.3 Effect of maternal protein supplementation on heifer progeny performance.

Summary

Replacement heifers represent a relatively large capital investment on the part of the producer. Therefore they need to be managed appropriately to ensure that they breed, calve, and rebreed in a timely fashion. Events crucial to heifer development center on proper selection, nutritional management, breeding season management, and program evaluation. Careful monitoring of heifer growth and performance at these critical times is an important component of successful development. Record systems should be created and utilized so that the replacement heifer program can be evaluated and benchmarked objectively over time. Practitioners are in a unique position to help their clients assess this part of their operation and make needed changes.

Dairy Heifer Development from Weaning to Calving

Ricardo M. Stockler

College of Veterinary Medicine, Auburn University, Auburn, AL, USA

Introduction

After weaning the replacement dairy heifer, one must have fully knowledge of the impact caused by dietary and health management associated with the task to raise a heifer that is efficient and profitable. It is of common understanding that performance, production, and reproduction during first lactation is the best indicator that a successful rearing program has been used.

Veterinary practitioners must educate producers about three basic ground rules: (1) the producer should never underestimate the costs associated with heifer rearing programs – roughly 25% of a dairy farm's production costs are allocated to replacement heifers, and of this 25%, feed is responsible for about 50% of the total cost of raising dairy heifers [1]; (2) excessive or too steep a rise in weight gain prior to puberty is known to directly negatively affect reproduction and production at first lactation; and (3) age at first calving should be around 22–24 months, with an optimal body weight; this is critical to minimize feed costs and increase productive life.

The Weaned Heifer

There are many alternatives with regard to housing and delivery of feed to recently weaned heifers. From pasture to confinement, it is imperative to avoid overcrowding and to move heifers out of the hutches in small groups of 5–10 head at a time [2, 3]. This is when the heifers experience the most stressful time as a group. The main advantage of having a small group is that this allows the heifers the opportunity to adjust to diet change, pathogen challenges, and proper growth. Ultimately, the goal is to raise healthy heifers that reach the breeding group as homogeneous and balanced as possible; however, it is imperative to keep in mind that when calves are grouped, the risk of diseases such as respiratory conditions and diarrhea, specifically coccidiosis in this age group (>30 days old), increases.

Body weight is directly correlated to puberty as well as first-lactation milk yield. An easy rule of thumb to remember is that target body weight at initiation of breeding should be around 55% of mature body weight and 82% of mature body weight at calving. It is important to stress that growth rate is by far the major contributory factor to a successful breeding heifer program [4]. Monitoring body condition (weight gain) provides valuable field information with regard to weight changes. One body condition score equals 54 kg of body weight [5]. Table 30.1 summarizes the ideal body condition score at different production stages.

Heifers express their first estrus at 9–12 months of age and weight of approximately 280–300 kg [3]. The identification of heifers that are suitable to be bred is essential. Individuals not reproductively sound, underdeveloped, or freemartins should be removed as soon as possible. Therefore it is recommended to move heifers into the breeding pool two to three months prior to expected initiation of breeding, so estrus and potential problems can be identified. The diet offered should provide a stable rate of gain, since excessive growth at this point is not necessary and wasteful. Heifers that are within two months from calving, often referred as "springing heifers," should be fed ingredients similar to the lactating group, with good-quality forages and a limited amount of concentrate (1–2% of body weight), with the intention of a smooth transition, which in turn supports a high dry matter intake (DMI) immediately after calving and optimum peak milk. Close attention should be paid to the sodium and potassium concentration in the diet as it is known to be one of the causes of udder edema after calving [6].

Table 30.1 Target body condition score and production cycle.

	Body condition score (1–5 scoring system)
Cows	
Calving	3.5
Peak milk	2.75
Mid lactation	3.0
Drying off	3.5
Replacement heifers	
Six months old	2.75
Breeding age	3.0
Calving	3.5

The accurate identification and removal of extra teats (if more than four teats are present in the mammary gland) is a procedure practitioners and producers routinely perform on farm and is of great importance for the health of the dairy heifer and her future performance, as it is common knowledge that the presence of extra teats on lactating cows interferes with milking procedures, especially on dairy farms that use robotic milkers, and increases the odds of subclinical and clinical mastitis. The most recent National Animal Health Monitoring System (NAHMS) Dairy 2014 survey reported that roughly 47% of dairy operations routinely remove extra teats. The same survey also reported a variation among regions (west versus east) when it comes to the age of the heifer, but short of 45% of operations routinely remove extra teats when the heifer calves are less than 12 weeks [7]. The author recommends the identification of extra teats and their removal using a sharp, clean Metzenbaum or Mayo pair of scissors at around weaning time (10–12 weeks of age). It is imperative that the producer and/or the practitioner observes a strict biosecurity protocol by utilizing cold sterilization of the scissors between animals to avoid the transmission of blood-borne diseases such as anaplasmosis, bovine viral diarrhea virus, and bovine leukemia virus.

A summary of the optimum target body weight and height as well as average daily gain for different age groups of Holsteins and Jerseys is provided in Table 30.2. It is important to note that these are typical guidelines to help practitioners and producers; however, these values may vary according to region and type of system used to raise replacement heifers.

Health events are undoubtedly a major driving factor that increases the costs of raising replacement heifers due to poor performance and/or extra labor associated with medical treatments, premature culling, or death loss. Protozoal (*Eimeria* sp.) diarrhea followed by respiratory diseases are the main causes of postweaning sickness. Ionophore antibiotics do not currently require a Veterinary Feed Directive (VFD) prescription; however, it is the veterinarian's and/or nutritionist's responsibility to always advise the producer to follow label directions. In this case, ionophores not only aid in preventing protozoal diarrhea (coccidiosis), but also increase feed efficiency by reducing methane losses and increasing propionate production in the rumen. Propionate is essential for gluconeogenesis in the liver and therefore energy produced. This class of antibiotics is widely used in beef-feedlot cattle and in the early 2000s a label for lactating dairy cattle was established. Table 30.3 summarizes the most common coccidiostats used in bovine medicine. Duffield and Bagg [8] published a review that addresses the use of monensin in lactating dairy cattle. Diets containing monensin when offered before calving have positive effects on energy metabolism and conversion in early lactation, and its use is associated with a reduction in subclinical ketosis and postpartum diseases. Despite the fact that 1 kg/day of milk production may be gained when monensin is used in early lactation, depression of milk fat components may occur with the use of ionophores.

Milk fat depression may be seen when lasalocid, specifically, is used, due to its effect on volatile fatty acid production in the rumen; however, this adverse effect is known to be dose dependent [9]. As per the label, a dose of monensin in calves to aid in the prevention and control of coccidiosis, as well as improve feed efficiency and therefore increase the rate of weight gain, must not exceed 200 mg/day per head [7].

Sulfonamides are also used to treat episodes of diarrhea cause by coccidians. Sulfadimethoxine and sulfamethazine are the only sulfa products labeled for use in food animals; all others are prohibited under the Animal Medicinal Drug Use Clarification Act (AMDUCA) of 1994 [10]. Sulfamethazine is available in sustained-release bolus for oral administration in non-lactating dairy cattle, and when used according to label directions provides therapeutic levels for up to 72 hours. If the intent is to treat lactating dairy cows, sulfadimethoxine is the only sulfa drug available. Intravenous and oral routes exist for this antimicrobial and label recommendations should be followed with respect to indication, dosage, and frequency of administration. Most importantly, a withdrawal period of seven days for meat and withholding period of 60 hours for milk must be observed.

Another important health condition is with respect to the incidence of external and/or internal parasites. Internal parasitism directly affects heifer development due to the decrease in rate of weight gain by decreasing the ability of the gastrointestinal tract to metabolize and absorb nutrients. Similarly, external parasites such as ticks, mosquitos, stable flies, house flies, horn flies, horse flies, deer flies, and lice may feed from the host's blood, skin, and/or hair, causing

Table 30.2 Summary of target body weight, height, and average daily gain (ADG) for different age groups of Holstein and Jersey heifers.

Age (months)	Weight (kg)		Height (cm)		ADG (kg/day)
	Holstein	Jersey	Holstein	Jersey	
6	160	113	100	90	0.7–0.8
12	295	204	119	107	0.7–0.8
18	408	272	127	114	(Post puberty) 0.6–0.7
24	544	363	132	122	(Post puberty) 0.6–0.7

Table 30.3 Summary of coccidiostats used in bovine medicine.

Active drug	Brand name (commonly used)	Prevention	Treatment
Amprolium	Corid®	5 mg/kg for 28 days	10 mg/kg for 5 days
Sulfamethazine[a]	Sustain III bolus®	N/A	32.1 g/200 lb once
Sulfadimethoxine[b]	Albon®	N/A	25 mg/lb followed by 12.5 mg/lb for 3–4 days
Lasalocid	Deccox®	0.5 mg/kg for 28 days	N/A
Decoquinate	Bovatec®	1.0 mg/kg for 28 days	N/A
Monensin	Rumensin®	1.2 mg/kg for 28 days	N/A

Note: Always read and follow label instructions. Consult the veterinarian for recommendations and establishment of proper withdrawal times for the production animal in question to ensure AMDUCA is observed.
[a]Sustained release bolus providing therapy for up to 72 hours. For use only in beef and female dairy cattle less than 20 months of age. Do not give to calves used for veal.
[b]Approved for use in lactating dairy cows. Milk withdrawal is 60 hours and meat withdrawal is 7 days.

severe skin conditions and even open wounds, which leads to pain, discomfort, and overall aggravation. Outbreaks tend to be seasonal and occurrence depends on the region, so treatment and control methods must be implemented accordingly. Additionally, lice and mites are a significant problem due to their potential capability as vectors, through vertical and horizontal transmission [11]. Flies are potentially one of the contributors to the increase in bacterial counts in milk due to a non-hygienic environment and are a major vector in the transmission of infectious bovine keratoconjunctivitis and certain blood-borne diseases [12].

McGuirk [13] summarizes the important points to be analyzed when investigating a respiratory outbreak. Morbidity and mortality data, vaccination and treatment protocols, nutrition, age, housing condition, and case definition are some of the records needed. These criteria facilitate the development of protocols designed to improve early detection of disease and, if indicated, the initiation of an effective treatment.

According to the NAHMS Dairy 2014 survey, respiratory disease accounts for roughly 59% of weaned heifer deaths. Of those diagnosed with respiratory disease, over 90% of the weaned heifers were treated with antimicrobials. Florfenicols, macrolides, and tetracyclines in that order are the top three antimicrobials used by the majority of dairy operations, according to NAHMS [7].

Prebreeding vaccination is imperative. As described in the companion chapter to this on developing beef heifers (Chapter 29), a booster of common core vaccines 30–45 days prior to breeding is strongly recommended. Although there is variability among farms and populations at risk, the general consensus is that ideally replacement heifers must receive a modified-live respiratory five-way vaccine (IBR, PI3, BRSV, BVDV type 1 and 2) before weaning and additional co-mingling, as well as pentavalent *Leptospira* serovars (*Pomona*, *Grippotyphosa*, *Canicola*, *Icterohaemorrhagiae*, and *Hardjo*) at breeding time. This provides the opportunity to acquire optimum protection. Always follow the label directions, especially with respect to the usage of a modified live vaccine product in pregnant cattle. Remember that pregnant cattle may only be boostered with a modified live product if that individual had been exposed to that same product within the past 12 months; also, if there is a high incidence of respiratory

disease in preweaned calves, it is crucial to evaluate the colostrum management program and lactating/dry cow vaccination protocols.

Several antimicrobials labeled for treatment of respiratory disease are available in the USA (Table 30.4). Dosage, frequency, route of administration, spectrum of activity, and meat withdrawal periods vary. One must consider that most of them have specific label directions with respect to age group allowed to be treated; if extra-label drug use is practiced, some of these products may or may not fall under the prohibited drug category of AMDUCA (e.g. fluoroquinolones and certain sulfonamides) [10].

Subclinical and clinical mastitis has been associated with milk and reproductive losses of first-calf heifers [14]. Intramammary (IMM) antimicrobial products are often used in springing heifers with the objective of decreasing the prevalence of IMM infection after parturition, reducing somatic cell counts, and potentially increasing milk production. A review of mastitis treatment published by Royster and Wagoner in 2015 [15] summarized all the available IMM treatments and stated that the evidence has shown that IMM treatments of springing heifers reduce the prevalence of intramammary infections (IMI) at calving; however, little evidence is available that actually supports the advantage of instituting this treatment protocol as it is neither economical nor practical unless there is a high risk of infection or the farm lacks other specific management programs/protocols.

The use of IMM antimicrobials in springing heifers is considered extra-label drug use; the treatment of heifers before calving should only be recommended and prescribed by a licensed veterinarian and in herds that have demonstrated high incidence of heifer mastitis [16, 17]. In 2012, de Vliegher et al. published a comprehensive review about mastitis in dairy heifers. The group concluded that often non-lactating heifers are infected with major mastitis-causing pathogens and there is potentially horizontal transmission. Prevention is the key; overall hygiene, especially at calving, fly control, and the prevention of cross-suckling are some of the recommendations. These authors also reported that, in general, coagulase-negative staphylococci are known to be the principal etiologic agent, followed by coagulase-positive staphylococci and environmental pathogens [17]. Therefore, when working with herds with a high incidence of heifer mastitis the cause must be identified and the specific risk factors for such analyzed. The IMM use of antimicrobials in non-lactating heifers has not always proven efficacious when it comes to improvements in overall udder health and milk yield; however, the combination of IMM antimicrobials and the use of a teat sealant has been shown to decrease the incidence of clinical and subclinical mastitis during the first nine months of lactation and have a positive long-term effect on the linear somatic cell score [18]. Table 30.5 summarizes the top four IMM antimicrobials commonly used in springing heifers. As mentioned above, it is considered extra label drug use and must be prescribed by a licensed veterinarian with a valid client patient relationship (VCPR) on record according to AMDUCA in the USA.

For welfare and biosecurity reasons, prompt identification of a sick yearling heifer is crucial; however, the author strongly stresses the importance of addressing the potential problem in a herd health manner. Treating

Table 30.4 Summary of most commonly used labeled antimicrobials available in the USA for treatment of respiratory disease in dairy cattle.

Drug	Product	Dose	Route of administration	Duration	Dairy older than 20 months of age	Milk/meat withdrawal
Oxytetracycline	200 mg/ml LA200®	4.5 ml/45 kg	Subcutaneously	48–72 hours	Yes	96 hours/28 days
Ceftiofur (one treatment)	Exceed®	1.5 ml/45 kg	Subcutaneously in base of ear	7 days	Yes (prohibited ELDU)	Zero/13 days
Tulathromycin	Draxxin®	1.1 ml/45 kg	Subcutaneously	10–14 days	No (ELDU)	N/A/18 days
Tilmicosin	Micotil®	1.5 ml/45 kg	Subcutaneously	48 hours	No (ELDU)	N/A42 days
Florfenicol	NuFlor®	3 ml/45 kg 6 ml/45 kg (single) treatment	Intramuscularly Subcutaneously (one-time dose)	48 hours 4 days	No (ELDU)	N/A/28 days (i.m.) N/A/38 days (s.c.)
Gamithromycin	Zactran®	2 ml/50 kg	Subcutaneously	10 days	No (ELDU)	N/A/35 days
Enrofloxin	Baytril®	1.1–2.3 ml/45 kg or 3.4–5.7 ml/45 kg	Subcutaneously	24 hours Single dose	Prohibited by FDA	N/A/28 days
Tildipirosin	Zuprevo®	1 ml/45 kg	Subcutaneously	Single dose	No (ELDU)	N/A/4 days

ELDU, Extra-label drug use; FDA, Food and Drug Administration; N/A, non-applicable.

Table 30.5 Summary of the top four dry cow therapy intramammary antimicrobials most commonly used in springing heifers.

Name	Product	Indication per label	Milk/meat withdrawal	Minimum dry period length
Cephapirin benzathine 300 mg	Cefa-dri® or Tomorrow®	*S. agalactiae*, *S. aureus*, including penicillin-resistant strains	72 hours/42 days	30 days
Ceftiofur hydrochloride 500 mg	Spectramast DC®	*S. aureus*, *S. dysgalactiae*, *S. uberis*	No milk discard/16 days	30 days
Procaine penicillin G + dihydrostreptomycin (1 000 000 IU/1 g)	Quartermaster®	*S. aureus*	96 hours/60 days	42 days
Cloxacillin benzathine 500 mg	Dry-Clox®	Gram-positive bacteria including *S. agalactiae*, penicillin-resistant and non-penicillinase-producing *S. aureus*	No milk discard/30 days	30 days

individual animals is important but does not solve the problem. On-farm monitoring and preventative methods are vital. This information allows the analysis of how efficacious the management program is in preventing the occurrence and transmission of the disease or condition in question.

The National Research Council [19] suggests an average daily gain of 0.7–0.8 kg, assuming that a healthy calf is being raised in a thermoneutral environment. In addition, Drackley [4] clearly states that a growth rate of 0.9 kg/day is achievable and does not affect mammary development, but needs to be adjusted to improve animal health and farm productivity. Therefore DMI must be managed properly based on environmental conditions. DMI should be increased when temperatures are below 15 °C; failure to provide extra energy can result in decreases of up to 0.2 kg/day of average daily gain [3]. If forage availability is not an issue, heifers raised on pasture should not have problems reaching the goal suggested by the National Research Council [19], despite the extreme variability in quantity and quality of the feedstuff offered. Special attention should be paid to the trace and major minerals, as supplementation may be warranted depending on the region and season.

In addition to the heifer grower ration, early-cut forages are preferred for the recently weaned younger heifers, as they are higher in energy and protein and lower in fiber. High-fiber products should be avoided in young calves as the rumen–reticulum is still under development and unable to fully digest fiber-rich diets [2]. The major goal when it comes to feeding is to sustain uniform weight gain and growth, which will allow the heifer calf to attain puberty and thus breeding at the recommended age.

Summary

In summary, a successful heifer rearing program consists of a consecutive series of systems employed to ultimately raise a heifer with minimum expense to be reproductively efficient and to deliver an excellent productive first lactation. Nutrition is known to be one of the most important factors at this stage of life, as it is directly correlated to reproduction, growth, and overall health.

Introduction

Nutrient requirements of beef cows vary in a predictable manner relative to the timing of breeding, weaning, and calving. Protein, energy, vitamin, and mineral requirements reach a zenith four to eight weeks postpartum, coincident with peak milk production. This is followed by a normal attenuation in nutrient requirements as milk production wanes; shortly after weaning takes place, nutrient requirements reach their annual nadir. It is not until the final 60–80 days of gestation that they begin to rise again to support exponential fetal growth and accelerated uterine metabolism [1]. Managers of beef cows and heifers are largely in control of the timing of these events; they decide when breeding exposure begins and, therefore, when subsequent calving will take place (i.e. an average of 282.5 ± 18 days following conception) [2]. Managers also determine when weaning will take place, bringing a halt to lactation and setting bounds for the net nutrient demands associated with milk production.

In spite of the predictability of beef cow nutrient requirements, provision of a cost-effective diet that meets animal requirements during each day of a 12-month production cycle can be challenging. When elevated nutrient demand coincides with poor diet quality, body energy and protein reserves will be mobilized to support metabolic processes with a presumed hierarchy. Basal metabolism is prioritized first, followed in descending order by: (i) motion necessary to gather food, (ii) growth, (iii) minimum energy reserves, (iv) maintenance of an existing pregnancy, (v) maintenance of a live offspring via lactation, (vi) secondary energy reserves, (vii) reproductive function including conception, and (viii) tertiary energy reserves [3].

Ironically, the most important feature of this hierarchy to long-term profitability of the beef cow, timely conception, is prioritized next-to-last. Nutritional shortfalls that occur during late gestation and early lactation, which immediately precede breeding exposure, result in mobilization of body reserves. Should mobilization of body reserves be significant during these times, either delayed conception or failure to conceive will be the likely result [4]. The former represents a loss of gross income because the resulting offspring is likely to be younger and lighter than its contemporaries at any given marketing date. The latter represents a loss of gross income because the affected female is usually sold, bringing a premature end to her earning potential.

Under the best of circumstances, lifetime net income derived from a beef cow is modest. Therefore care must be taken to strategically build body energy and protein reserves at a time during the production cycle when high-priority metabolic functions (i.e. late gestation and lactation) are not taking place. This minimizes the need for concentrate feeding and allows the beef cow to meet the majority of her nutrient needs with grazed forages and roughages.

This chapter focuses on strategic management of the 12-month cow-calf production cycle to leverage economic and biological efficiencies to support body energy and protein reserves of breeding females. Related issues such as heifer development, bull nutrition, fetal programming, and certain specific nutritional challenges will also be addressed.

The 12-Month Cow-Calf Production Cycle – The Driver of Nutrient Requirements

To begin any discussion of the cyclic nature of nutrient requirements in the beef cow, it becomes necessary to define how nutrient requirements vary with the physiological state of the animal. For practical purposes, 12 months are required for a breeding female to become pregnant, to carry a fetus to term, to give birth, to begin lactation, and to become pregnant again. At some point during this 12-month period, a live offspring will be weaned and lactation will come to an abrupt halt. Each of these physiologically significant events influences energy, protein, vitamin, and mineral requirements, either suddenly (as with birth and weaning) or over a continuum (as with gestation and lactation).

A 12-month interval between conceptions is effectively a biological maximum for breeding beef females, multiple births notwithstanding. It is possible but rare for cows to have calving intervals that are significantly less than 12 months, whereas cows with calving intervals greater than 12 months are at risk of being culled from the herd because they fail to conceive in a timely manner.

Table 31.1 provides an overview of a 12-month production cycle for a Hereford × Angus cow with a live weight of 589.6 kg (i.e. 1300 lb). It highlights the elasticity in requirements for net energy, metabolizable protein, calcium, and phosphorus needed to support maintenance, pregnancy, and lactation [3, 5]. The calculations in Table 31.1 represent minimum nutrient needs for a cow of specified shrunk body weight (i.e. live weight × 0.96), milk-production potential (i.e. 9.75 kg/day peak), milk composition, lactation duration (i.e. 210 days), and calf birth weight (36.3 kg). They assume thermoneutral conditions, confinement feeding, a dry and mud-free hair coat, no feeding of ionophores or non-ionophore antibiotics, and no fluctuation in cow body weight per se. Any changes in these assumptions can be expected to influence nutrient requirements in significant ways.

The value of reviewing a comprehensive summary of beef-cow nutrient requirements such as that found in Table 31.1 lies in developing an appreciation for the magnitude of change in nutrient requirements needed to support milk production, fetal growth, and uterine development. For example, the net-energy-for-maintenance (NEm) requirement of the cow in the example (i.e. 8.94 Mcal/day) was predicted to increase by over 78% at peak lactation (i.e. 15.94 Mcal/day). In addition, the extremely rapid growth of the fetus during the final month of gestation was predicted to result in a weight gain of 1.54 kg/day (nearly 3.4 lb) to the combined cow, gravid uterus, and fetus. Nearly 40% of that increase in mass was attributable to the gravid uterus alone; the combined gravid uterus and fetus were predicted to weigh approximately 60 kg during the last month of pregnancy, whereas calf birth weight was assumed to be only 36.3 kg.

The fact that these changes in nutrient requirements occur predictably relative to the timing of breeding, calving, and weaning dictates that managers of beef cattle not only be aware of when they occur but also must be capable of suppling additional nutrients in targeted amounts when needed. Managers must also be aware that significant locomotion, thermal stress, and degradation of hair-coat condition can compound the difficulties associated with maintaining reproductively adequate body reserves of protein and energy.

Body Condition Scoring – the Starting Point for Nutritional Management

Humans perceive the protein and energy reserves of beef cattle as *body condition*. Body condition is a collective term describing the relative amount of muscle and subcutaneous fat covering skeletal features. In general, timely achievement of moderate body condition allows optimal reproductive function, including minimized dystocia, minimized length of postpartum anestrus, and early rebreeding. Thin body condition at calving has been associated with dystocia and subsequent reproductive failure, whereas fat body condition at calving has been associated with poor feed intake, dystocia, metabolic disease, and excessive maintenance costs [6–10].

Body condition is generally quantified as body condition score (BCS). The most commonly applied body condition scoring systems use a nine-point scale, where BCS 1 is extremely emaciated and BCS 9 is extremely obese [11–13]. Optimum body condition is generally thought to be equivalent to a BCS score of 5 or 6. Estimated empty-body fat and protein percentages associated with each condition score are depicted in Table 31.2 [3].

Quantitative management of weight change in growing and finishing beef cattle is uncomplicated. If a manager knows current animal body weight and sets a goal for final body weight, a diet can usually be formulated that will allow the target body weight to be reached at a specified point in time. Unfortunately, assets needed for quantitative management of nutrition (e.g. animal scales, feed scales, diet formulation software, and detailed knowledge of nutritional chemistry) are fairly rare on cow-calf operations in the USA.

In situations where access to technology and instrumentation is limited, BCS change can be used as a proxy for weight gain in order to make desired changes in animal body weight. A recent review identified eight published reports in which shrunk body weight change in beef cows was compared with observed BCS change, the latter adjusted to a nine-point scale (Table 31.3) [3, 5, 9, 14–18]. Averaged across the eight publications, change in shrunk body weight per unit of BCS change was 41 ± 5.8 kg (i.e. 90 ± 12.8 lb). In order to hedge risk in underestimating necessary body weight change and also for the sake of simplicity, it is here suggested that this figure be rounded up to 45 kg in shrunk body weight per unit of BCS change (i.e. about 100 lb).

Practical application of these data in conjunction with observed BCS is then straightforward. Consider the following scenario:

1) Moderate BCS (i.e. 5) is desired as a particular beef cow enters late gestation. Late gestation is expected to begin in approximately 90 days.
2) Observation of BCS 90 days prior to expected onset of the final trimester of pregnancy resulted in a BCS of 4 being assigned to the cow in question.
3) Assuming one BCS unit is approximately equal to 45 kg (≈ 100 lb), the cow needs to gain 45 kg (≈ 100 lb) of body weight to reach BCS 5 as she enters late gestation.
4) A daily rate of gain of approximately 0.5 kg (≈ 1.1 lb) is necessary to effect the desired change in BCS (i.e. 45 kg ÷ 90 days or 100 lb ÷ 90 days).
5) A diet is formulated that will allow the cow to gain 0.5 kg daily at a dry matter intake of 2.3–2.7% of body weight.

Most body condition scoring systems for beef cattle were conceived to be visual evaluations of body condition from a distance of up to 30 m from the subject. Published descriptions of each BCS assume that human evaluators have fairly extensive knowledge of bovine anatomy [3]. In addition, extensive training and experience may be required in order to accurately interpret published descriptions of BCS and to assign them correctly to cows and heifers under field conditions.

Even with adequate training, the subjective nature of visual evaluations can lead to significant errors in BCS assignment and in the interpretation of nutritional status of beef cattle [3]. These problems can be exacerbated when several observers are assigning BCS within a single herd. Differences in bone structure between animals, level of gut fill, hide color, hair coat thickness, degree of lighting, and distance between the observer and the animal can contribute to the assignment of an erroneous BCS. Use of a decision-making tree in conjunction with visual appraisal of BCS minimizes the chances that an inappropriate score will be assigned (Table 31.4) [3].

Alternatively, tactile assessment of BCS via palpation removes visual prejudices and, done using appropriate anatomical reference points, minimizes the effects of gut fill on perceived body condition. The authors have developed a simple, rapid palpation system and an associated decision-making tree that remove significant subjectivity from BCS assignment and allow for more consistent scoring between human observers:

1) Animal posture and degree of restraint can influence perceptions of BCS during palpation. Ideally, the animal should be individually restrained, its head should be erect, and handling equipment (e.g. alleys and squeeze chutes) should not be in direct contact with an animal's flanks.

2) Ideally, the same anatomical reference points on all animals should be palpated. Paying close attention to these anatomical landmarks will improve scoring consistency.
3) Locate the withers. With a flat hand, palpate the spinous processes just posterior to the withers.
   a) If spinous processes can be detected with no hand pressure, BCS is 5 or less.
   b) If pressure must be applied to detect the spinous processes, BCS is 5 or greater.
4) Locate the point of the shoulder. Place a hand 30–40 cm (12–16 inches) posterior to the point of the shoulder on the rib cage.
   a) With a flat hand, palpate the ribs at this location.
   b) If ribs are detected with no hand pressure, BCS is 4 or less. Please note that differentiating between thin BCSs (i.e. 1, 2, or 3) requires additional visual assessment of muscling and locomotion (Table 31.4).
   c) If slight pressure allows detection of ribs, BCS is 5 or greater.
   d) Keeping the hand in contact with the same location, tent the fingers and gently move the hide from side to side. If the flesh does not feel spongy or slide easily over the ribs, BCS is 5.
   e) If the flesh feels spongy and slides easily over the ribs, BCS is 6 or greater.
5) If suspected BCS is 6 or greater, locate the tail head. Palpate both sides with finger tips.
   a) If the tail head is flat and firm, BCS is 6.
   b) If there are rippled deposits of fat on both sides of the tail head, BCS is 7 or greater.
6) If suspected BCS is 7 or greater, locate the middle of the rear of the round muscle (i.e. biceps femoris). Run a flat hand down the length of the rear of one round muscle. If a knot-like fat deposit about the size of a small apple is detected approximately midway between the tail head and the hock joint, BCS is 8 or greater.
   a) Verify that both round muscles have these symmetrical fat deposits to differentiate them from scars or inflammation.
7) Watch the cow exit the restraining device. If the animal seems to have significant difficulty moving, BCS is 9.

Advantages of this system include speed, scoring consistency, and relative ease with which it can be taught to others. Conversely, it has two disadvantages compared with visual appraisal of BCS. First, animals must be restrained for body condition to be evaluated via palpation. If coupled with normal processing activities that are associated with weaning, calving, and breeding, this problem is easily overcome. Second, this system is not sensitive to differentiating between BCS 1, 2, and 3. Additional ocular observation is required to differentiate BCS in extremely thin cows (Table 31.4).

Practically, BCS can be noted any time that human handlers are in close proximity to beef cattle; however, the most valuable annual assessment of BCS for breeding females is at or shortly after the point of weaning. The time between weaning and the onset of late gestation presents an opportunity to correct deficiencies in body condition when the number of competing metabolic priorities is at a minimum. In theory, adding to animal body weight during this point of the production cycle should be least expensive and more easily accomplished than at other points of the production cycle that coincide with either late gestation or lactation.

Post-Weaning Nutritional Management – Protein and Energy

Given that maintaining a 12-month calving interval is of paramount importance, failure to rebreed in a timely manner is a significant problem on many North American cow-calf operations. Loss of gross income due to delayed rebreeding was estimated to be between $14 and $15 USD for each beef cow in the USA in 2002 [19]; that loss would be expected to be between $20 and $22 USD per beef cow at the time of this writing, assuming a cumulative inflation rate of 42.6% [20].

Timely rebreeding by beef cows is related to pre- and postpartum intake of energy and protein. Prepartum intake of energy and protein may be of greater relative importance than postpartum intake in promoting return to a functional estrous cycle before breeding exposure begins [21]. A likely reason for this observation is that major sources of nutrient demand (i.e. late gestation and lactation) are either minimal or absent during the period between weaning and the onset of late gestation.

Recent research examining performance and reproductive responses to supplementation of forage-based beef-cow and heifer diets with ruminally degradable protein [22–24], ruminally undegradable protein [22, 24–26], fiber-based carbohydrates [27–29], starch-based carbohydrates [27–29], and fats [30, 31] is available; therefore a literature review will not be attempted in this manuscript.

Managers of ruminant livestock should be aware that associative effects between forages and supplements are common, albeit difficult to characterize quantitatively. Associative effects can have strong positive or negative influences on voluntary forage intake, total-tract diet digestibility, and, ultimately, the energy yield of low- to medium-quality forage-based diets [29, 32]. Conceptually, such associative effects represent deviations from the expected additivity in energy yields of feed ingredients combined in a single diet (Figure 31.1). In general, associative effects are not expected to occur when forage quality is relatively high (i.e. CP≥10%) or when the principal energy source in a supplemental feedstuff is based on structural carbohydrate. In these circumstances, the energy contents of forages and supplements are expected to be additive and, thus, predictable.

Associative effects are generally observed when forage quality is relatively poor. When forage quality is poor (i.e. CP<7%), protein supplementation has been associated with larger-than-expected voluntary forage intakes (up to 150% of non-supplemented controls) [33], whereas total digestible dry matter intake may increase by as much as 180% that of non-supplemented controls (Figures 31.1 and 31.2) [29, 34]. Forage intake and digestibility generally increase with

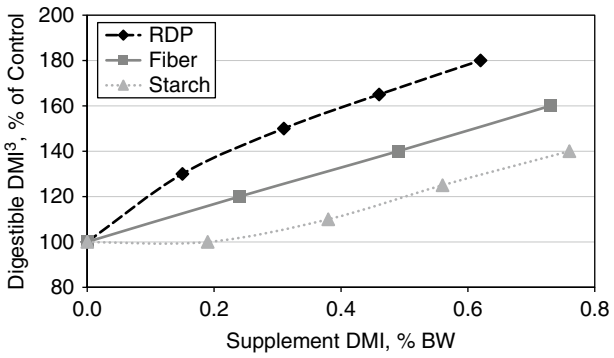

Figure 31.1 Effect of supplement type[1] and intake level on total digestible dry matter intake (DMI) of a medium-quality forage-based diet[2] fed to growing heifers. *Source:* Adapted from [29]. [1] Supplemental ruminally degradable protein (RDP) was delivered at 0, 0.05, 0.10, 0.15, or 0.20% of heifer BW/day using soybean meal (CP = 49.9%, RDP = 65% of CP; DM basis). Supplemental NDF (fiber) was delivered at 0.16, 0.33, 0.49, or 0.65% of heifer BW/day using soybean hulls (66.3% NDF; DM basis). Supplemental ruminally degradable starch (starch) was delivered at 0.10, 0.20, 0.30, or 0.40% of heifer BW/day using dry-rolled corn (total starch = 75%, ruminal starch degradability = 72% of total starch; DM basis). [2] Tall fescue hay (*Lolium arundinaceum*; 8.7% CP, 73.1% NDF, 46.5% ADF; DM basis). [3] Total digestible DMI = DM intake × (% total-tract DM digestibility/100); expressed as a percentage of non-supplemented controls.

protein concentration in supplemental feedstuffs [33–35]. By the same token, high-starch, low-protein supplements have been associated with significant depressions in low-quality forage intake and total digestible dry-matter intake and, therefore, dietary energy yield compared with non-supplemented animals (Figures 31.1 and 31.3) [29, 35, 36]. Development of cost-effective strategies for body condition management in the beef cow requires that managers be aware of these relationships. Beef cows are the most common marketing vehicle for low- to medium-quality forages in North America. Supplemental feedstuffs with modest concentrations of starch and relatively high concentrations of protein should be preferred when beef cows are maintained on low-quality forage diets.

Mineral and Vitamin Nutrition

Poor reproductive performance by beef cows is commonly attributed to subclinical deficiencies of a variety of trace minerals. Although this may be true in certain cases, Corah and co-workers indicated that trace mineral deficiencies were not a common cause of reproductive failure in beef cows [37]. Trace mineral deficiencies appear more likely to occur in high-producing herds and are more likely to affect calf health than dam weight or reproduction [37, 38].

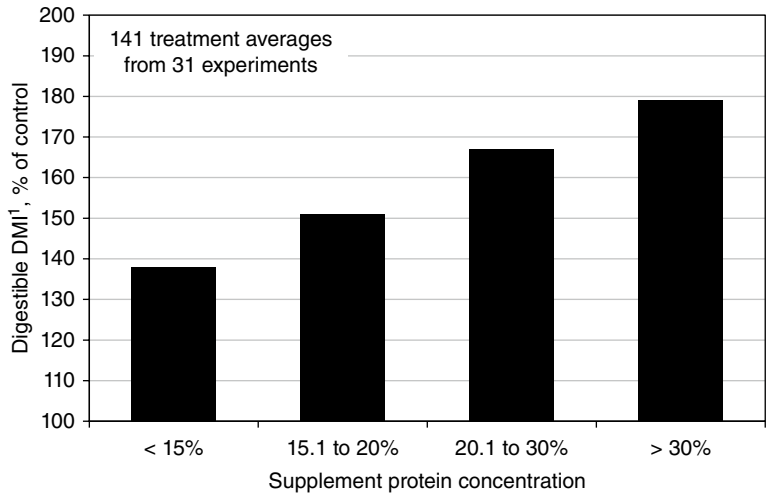

Figure 31.2 Effect of supplement protein concentration on total digestible dry matter intake[1] of low-quality forage (<7% CP)-based diets fed to beef cattle. *Source:* Adapted from [34]. [1] Total digestible DMI = DM intake × (% total-tract DM digestibility/100); expressed as a percentage of non-supplemented controls.

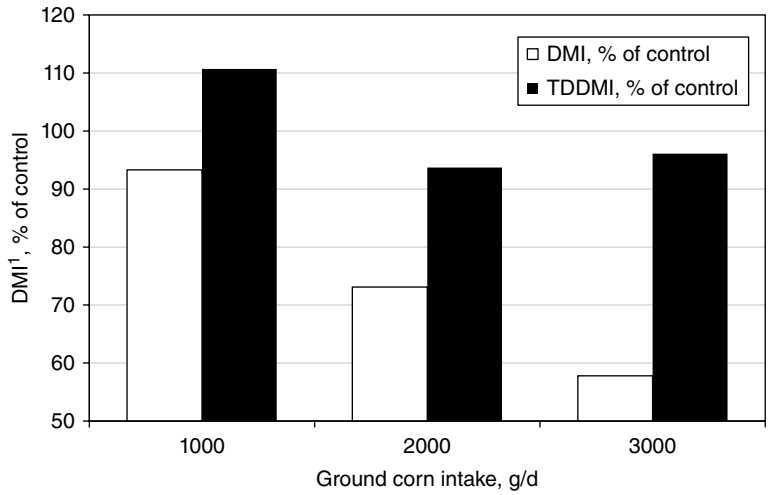

Figure 31.3 Effect of corn grain supplementation on intake[1] of low-quality (4.2% CP) grass hay and on total digestible dry matter intake by beef cows. *Source:* Adapted from [36]. [1] Intake expressed as a percentage of a non-supplemented control of dry matter intake (DMI) and total digestible dry matter intake (TDDMI). TDDMI = DM intake × (% total-tract DM digestibility/100); expressed as a percentage of non-supplemented controls.

There are 25 mineral elements recognized as having significance to beef cattle nutrition [3]. Daily requirements for calcium (Ca), phosphorus (P), sodium (Na), magnesium (Mg), potassium (K), cobalt (Co), copper (Cu), iron (Fe), zinc (Zn), manganese (Mn), iodine (I), and selenium (Se) for beef cattle have been defined. Significantly, only requirements for Ca, P, Mg, K, and Na are definitively changed by gestation or lactation (Table 31.5). Maximum tolerable concentrations have been established for many other mineral elements. Those with potentially toxic or antagonistic physiological effects include chromium, molybdenum, sulfur, aluminum, arsenic, bromide, cadmium, fluorine, lead, mercury, and strontium. Mineral elements most likely to be deficient in beef cow and heifer diets are Ca, P, Na, Mg, Mn, Zn, Co, Cu, I, and Se. In addition, S, Fe, and Mo in water and feedstuffs should be monitored because of their antagonistic interactions with Cu [3, 38].

Many managers of beef cattle supply mineral supplements to match animal appetite without regard for the animal's capability to conserve these elements in organs and tissues. There is clear evidence to support the contention that body mineral reserves can be mobilized in time of need; moreover, deficiencies can take long periods of time to manifest themselves [39]. It is also known that an

animal's appetite for minerals is not an indication of its mineral needs [40]. This evidence could be used to argue that mineral supplements should be delivered only to meet a targeted level of daily intake. If overconsumption of free-choice mineral supplement occurs (e.g. a two-week supply of mineral is consumed in one week), additional mineral can be withheld until an appropriate amount of time has elapsed to match the targeted intake level (e.g. two weeks). Similarly, underconsumed free-choice mineral supplements may need to be altered to improve palatability [38]. Overconsumption of mineral supplements can be managed with the provision of additional white salt fed ad libitum. Likewise, removal of white salt or the addition of small amounts of grain or oilseed meals to mineral supplements can stimulate consumption.

Ruminal microbes have the capability to synthesize most water-soluble vitamins (i.e. biotin, choline, B_{12}, folic acid, niacin, pantothenic acid, B_6, riboflavin, and thiamin), which are subsequently available for use in host animal metabolism. In addition, vitamin C (also water soluble) is synthesized *in vivo* by beef cattle in amounts adequate to meet animal requirements; therefore supplementation of ruminant diets with water-soluble vitamins is generally unnecessary [3]. The National Academies of Sciences, Engineering, and Medicine has defined beef-cow requirements for some fat-soluble vitamins (i.e. A, D, and K) but not others (i.e. E). Animals that are exposed to sunlight and fed sun-cured or actively growing forages generally do not require supplemental vitamins A or D. Similarly, vitamin K is synthesized *in vivo* in sufficient quantities to prevent deficiencies and associated problems with blot clotting. Requirements for vitamin E in non-stressed, mature cattle are small and likely met with normal dietary components.

Heifer Development

In modern beef production systems, heifers are expected to first calve at 23–24 months of age. Heifers that calve early in their first calving season tend to rebreed relatively early and wean more and heavier calves during their lives [41]. To accommodate this expectation, heifers should reach puberty by 12–13 months of age to allow one or two complete estrous cycles before breeding at 14 months of age. Age at puberty is influenced by breed, season, and plane of nutrition [41, 42]. Growth rates during the preweaning and postweaning periods are inversely related to age at puberty and postweaning growth rate is proportional to the plane of nutrition [41].

The onset of puberty appears to be associated with increased frequency of pulsatile luteinizing hormone (LH) secretion. Increased energy intake stimulates pulsatile LH secretion, whereas reduced energy intake suppresses LH secretion in heifers [43]. Delayed puberty is also coincident with low concentrations of insulin-like growth factor 1 (IGF-1). Steroidogenic capacities of thecal [44] or granulosa cells [45] are associated with increased concentrations of bovine somatotropin and IGF-1, respectively. Leptin may also act as a regulator of reproductive function and as a mediator for nutritional cues. Short-term fasting of peripubertal heifers decreased leptin gene expression; circulating leptin concentrations were coincident with reductions in circulating concentrations of insulin and IGF-1 and with LH pulse frequency, resulting in delayed puberty [46]. Conversely, serum leptin concentrations were positively correlated with increasing body weight in prepubertal heifers [47]. Addition of ionophores to the diet increases growth rate and tends also to decrease age at puberty, independent of body weight [48, 49].

Once puberty is reached, cessation of cycling requires moderate to severe nutrient restriction. Cassady and co-workers restricted intake of cycling heifers to 30% of NE_m requirements [50]. Heifers that started the restriction period at a BCS of 5 stopped cycling in 61 days, whereas heifers that started restriction at BCS 7 stopped cycling in 148 days. Both groups of heifers lost similar proportions of initial body weight (16–18%).

Historically, it has been recommended that heifers be fed to reach a target of 60–65% of their anticipated mature body weight at first breeding. Heifers fed to a prebreeding target weight of 318 kg (approximately 60% of mature body weight) were younger at puberty; they also had greater pregnancy rates after 20 days of breeding exposure (39 vs 9%) and had greater pregnancy rates at the end of the breeding season (82 vs 66%) compared with heifers fed to a prebreeding target weight of 272 kg (approximately 50% of mature body weight) [51]. Spring-born weaned beef heifers were fed to achieve 55 or 60% of mature weight at breeding. Heifers fed to reach 60% of mature weight were heavier at breeding, they had greater BCS (6.0 vs 5.6; nine-point scale), and more were cycling before the breeding season began (85 vs 74%). In contrast, final pregnancy rates at the end of a 45-day breeding exposure did not differ between groups (88 vs 92%). Heifer performance was then evaluated for three subsequent years; the only measure of productivity that differed between treatments was that 205-day adjusted calf body weights were greater for the heifers fed to achieve 55% of mature weight at first breeding compared with those fed to achieve 60% of mature weight at first breeding [52].

Although there appears to be some elasticity in prebreeding target weights, heifers should be managed to reach 80–85% of mature body weight by first calving [52]. In addition, breeding heifers beginning two to four weeks earlier than mature cows can mitigate reproductive failure at two years of age by allowing more time for uterine involution and resumption of estrus before the second breeding exposure begins.

Bull Nutrition

Rate of gain after weaning and level of nutrition influence the weight and age at which bulls reach puberty. Young bulls maintained on low planes of nutrition had reduced testicular growth, ejaculate volume, sperm production, and seminal vesicle development. Conversely, overfeeding energy to young bulls decreased reproductive performance due to increased fat deposition in the scrotum or the pampiniform plexus. Severe dietary protein restriction also reduced sperm-production capacity in young bulls. Re-alimenting nutritionally stressed growing bulls improved reproductive performance in some trials but not in others. Mature bulls appeared more resistant to dietary stressors than young bulls; however, overfeeding and severe protein restriction resulted in decreased libido [53].

Barth and co-workers conducted a series of experiments evaluating high and low levels of dietary energy prior to weaning or from weaning to puberty [54]. Restriction of nutrients prior to weaning resulted in delayed puberty and reduced testicular size at yearling age; these effects were not observed when plane of energy was altered post weaning. It appears that nutrient intake prior to weaning age has a more profound influence on age of puberty and testicular size than postweaning management.

Minerals influencing the breeding fitness of bulls include Cu, Mn, Se, and Zn. Subclinical deficiencies can negatively affect spermatogenesis [55], sperm motility [56–59], sperm morphology [56–59], testicular development [60], oxidative tissue damage [61], and testosterone biosynthesis [62, 63].

As Cu concentration in semen increased, progressive motility, total antioxidant status, sperm-cell viability following ejaculation, and general fertility of bulls increased [58, 64]. Manganese deficiency has been associated with inhibition of steroid hormone production; severe deficiencies resulted in poor libido, low sperm count, and degeneration of the epididymis and seminiferous tubules [62, 65]. The effects of Mn on reproduction may be related to antioxidant capabilities of Mn-superoxide dismustase [66], which only exists in mitochondria [67]. The activity of this enzyme is depressed when dietary Mn is restricted [68]. Resulting oxidative stress caused decreased mitochondrial membrane potential and poor sperm-cell motility [69].

Adequate Se status is important for normal spermatogenesis, sperm morphology, and sperm motility, independent of vitamin E status [70]. Early work demonstrated a positive association between sperm motility and supplemental Se [71]. More recent research identified a structural selenoprotein (phospholipid hydroperoxide glutathione peroxidase; PHGPx) in the mid-piece that is required for normal motor function of bull spermatozoa. Se deficiency resulted in poor expression of PHGPx, low sperm count, poor motility, and abnormal mid-piece morphology [59, 72].

The Se concentration in bull semen is 16 times greater than that in blood [73]; this may be related to the relatively large mid-piece mitochondrial volume of bovine sperm cells. Bull spermatozoa have greater mid-piece mitochondrial volume than humans, stallions, boars, or rams [74]. Bull spermatozoa also have greater PHGPx activity than other species.

Zinc has multiple roles in male fertility. Zn-deficient diets have been associated with poor sperm-cell plasma membrane integrity, abnormal tail morphology, and impaired motility [57]. Testicular growth of bulls was abnormally low during Zn deficiency but reverted to normal when Zn status was restored [60, 75]. Supplemental Zn also improved morphological and motility characteristics of bull spermatozoa; moreover, adequate Zn status is necessary for testosterone synthesis and normal libido [62, 63, 76].

Gossypol, a compound found in cottonseed-derived feedstuffs, immobilizes bull spermatozoa *in vitro* [49]. Short-term feeding of whole cottonseed or cottonseed meal (i.e. <60 days) is not likely to influence semen quality or spermatogenesis in postpubertal bulls [77]. Conversely, diets high in gossypol may delay puberty and decrease growth in peripubertal bulls [78].

Fetal Programming

Developmental programming is the concept that inadequate or excess maternal nutrition during gestation affects fetal development and has long-term impacts on the offspring [79]. Effects of nutrient restriction during gestation have been evaluated in beef cows more often than nutrient excesses because of the frequency with which pregnant females experience undernourishment in North American beef cattle production systems [3].

Fetal growth and subsequent development are regulated primarily by the placenta, which is developed in early gestation. Restricting beef cows to approximately 75% of metabolizable energy requirements during early pregnancy resulted in lighter fetuses at day 125 of gestation [80]. Additionally, undernutrition during early gestation increased adiposity and suppressed glucose intolerance in offspring [81, 82].

As gestation progresses, energy demand by the fetus increases. The supply of glucose and amino acids to the uterus is essential for proper offspring development [83]. Maternal dietary energy restriction during the third trimester resulted in calves with lighter birth weights and lighter weaning weights than calves from non-restricted cows [84]. Ewes that experienced energy restriction late in pregnancy also birthed lighter lambs [85, 86]. In contrast, growth restriction in lambs did not persist if ewes were adequately nourished during lactation [85].

Although much of the available research on fetal programming has been devoted to understanding how maternal nutrition affects fetal development, maternal nutrition also has an impact on neonatal offspring health and survival. According to the United States Department of Agriculture, 2.3% of calves are born dead and another 3.2% of calves that are born alive die before weaning [87]. There is no evidence directly linking these mortality estimates to developmental programming. Other factors such as weather, predation, and injury contribute to the estimates of calf mortality; however, there is evidence in the literature that prenatal nutrient restriction impacts calf survivability. Corah and co-workers observed increased morbidity and mortality of offspring when dams were restricted to 70% of maintenance energy requirements during the final 90 days of gestation [84]. This can likely be attributed to offspring born at below-average weight having decreased chance of survival in challenging environments [88]. Calves born to thin (BCS 3 and 4; 1–9 scale), two-year-old heifers were less vigorous and had reduced serum immunoglobulin concentrations at 24 hours of age [89]. Maternal undernutrition has been linked to poor colostrum quality and impaired immunoglobulin G (IgG) absorption by calves after birth [89, 90].

Research demonstrates a relationship between prepartum dam nutrition and offspring performance, but the effects are subtle and influenced by the offspring's postpartum plane of nutrition. Mild nutrient restriction is common across cow-calf operations in the USA, yet weaning percentage nationwide is estimated to be quite strong at 83% of females exposed for breeding [91]. Thus, data

describing the impact of developmental programming on current metrics of cow-herd productivity (i.e. pregnancy rates, weaning weights, and weaning percentages) remain equivocal at the time of this writing.

Specific Nutritional Challenges – Pine-Needle-Induced Abortion

In the 1920s, ranchers began speculating that ingestion of needles from the Ponderosa pine tree (*Pinus ponderosa*) were causing cows to abort late-term fetuses. In times of cold weather and increased snowfall, pine-needle consumption by beef cattle was subsequently documented [92]. Since many ranchers in the western USA schedule calving during the late winter and early spring, inclement weather is likely to coincide with the last trimester of gestation. MacDonald conducted the first experiment in which pine-needle consumption by beef cows during late gestation was associated with elevated risk of premature labor [93]. Stuart and co-workers later reported that feeding 0.71–0.85 kg (i.e. 1.5–1.9 lb; DM basis) of pine needles daily to beef cows during late gestation resulted in abortion coincident with retained placenta [94]. Histopathological examination revealed a severe constriction of the caruncular arteries that supply blood to the fetus.

Christenson and co-workers tested the effects of blood plasma collected from cows fed pine needles on placentomes collected from pregnant cows not fed pine needles using an *in vitro* model [95]. Plasma from pine-needle-fed cows increased perfusion pressure in placentomes harvested from cows not fed pine needles, which resulted in increased uterine tone. Increased uterine tone was associated with reduced blood flow to the fetus. Through extensive fractionation, Gardner and co-workers isolated and identified the abortifacient compound in pine needles as isocupressic acid [96]. Isocupressic acid was fed to beef cows during late gestation; a minimum dose of 100 mg/kg body weight twice daily was determined to cause abortion.

Short and co-workers evaluated several dietary factors to determine their effects on voluntary pine-needle intake [97]. Both high-protein and adequate-protein diets were fed to beef cows. The high-protein diet tended to be associated with greater pine needle consumption than the adequate-protein diet. Feeding pine needles that had been left at the site of collection for 12 months, a magnesium supplement, a silage-based diet, pine needles that were aged by grinding and air drying for several months, bentonite, or a complete mineral supplement mixed with pine needles did not change the abortifacient effects of pine needles. Cows evaluated in a 2 × 2 factorial arrangement of treatments (i.e. adequate-protein and high-protein diets, with and without access to salt-sulfur blocks) had an interval to parturition that was intermediate to pine-needle-fed positive controls and negative controls not fed pine needles. Dietary protein concentration or access to salt-sulfur block did not mitigate cow response to pine needles. Gestating cows fed corn silage with ad libitum access to pine needles did not abort, suggesting a possible link between energy intake and susceptibility to pine-needle-induced abortion.

In a later study, Pfister and co-workers evaluated the association between BCS and pine needle consumption [98]. Cows with poor BCS ate more pine needles than cows with adequate BCS. When fed a high-protein, low-energy diet, cows with poor BCS ate consistently more pine needles than cows with adequate BCS. In contrast, poor-BCS cows fed a low-protein, high-energy diet initially consumed more pine needles than cows with adequate BCS; however, differences in pine-needle intake between these treatments decreased over time. Authors speculated that cattle fed elevated levels of protein developed an increased appetite for pine needles because the condensed tannins therein relieved mild sensations of malaise associated with relatively high ruminal ammonia concentrations.

During late gestation, cows grazing in areas where Ponderosa pine trees are abundant are at risk for pine-needle consumption and subsequent abortion. Abortions are a result of decreased uterine blood flow caused by elevated plasma concentrations of isocupressic acid. Relatively high feeding levels of supplemental protein, poor BCS, and inadequate supplemental energy may exacerbate risk of pine-needle consumption and abortion. Therefore cows in the last trimester of gestation should be restricted from access to pine needles. Maintaining adequate energy balance and feeding relatively conservative levels of supplemental protein may also mitigate abortion risk.

Specific Nutritional Challenges – Fescue Toxicosis and Fertility

Widespread planting of tall fescue (*Lolium arundinaceum* [(Schreb.].) Darbysh) across the southeastern USA began in the 1940s [99]. Agronomists promoted establishment of tall fescue because of its persistence across a wide variety of environmental conditions, management, and soil types. Soon after, cattle grazing tall fescue pastures began exhibiting health problems and lesser-than-expected performance; these were later linked to a fungal endophyte (*Epichloë coenophiala*) [100].

The fungal endophyte conveys agronomic benefits to the plant, such as improved grazing tolerance, nitrogen-use efficiency, and water-use efficiency, but it also produces

toxic ergot alkaloids. When consumed by ruminants, ergot alkaloids cause a multifaceted malaise known as tall-fescue toxicosis. Symptoms of fescue toxicosis are generally exacerbated by extremes in ambient temperature [101]. The range of issues associated with fescue toxicosis is beyond the scope of this publication. Readers are directed to the recent review by Roberts and Andrae for a full discussion [102]. This section focuses on the effects of tall fescue toxicosis on beef cattle reproduction and potential strategies to mitigate negative consequences.

Reduced pregnancy and calving rates by beef cows grazing endophyte-infected tall fescue have been widely reported [103]. Reduced forage intake by beef cattle is also a hallmark of fescue toxicosis, which confounds reduced plane of nutrition with reproductive failure in many experiments [104]. Independent of reduced forage intake, ergot alkaloid intoxication increases vasoconstriction and decreases blood flow to limbs and extremities [105]. Poole and co-workers documented ergot alkaloid-induced vasoconstriction of bovine uterine and ovarian blood vessels [106]. Ergot alkaloids also induced a host of hormonal changes in females, which contributed to estrus-cycle irregularities, suppressed hormone secretion, reduced pregnancy rate, and agalactia [107].

One should not overlook the impact of fescue toxicosis on reproductive capabilities of bulls. Looper and co-workers reported that the number of normal sperm cells was reduced by approximately 20% when bulls grazed K31 tall fescue (i.e. endophyte-infected) compared with novel-endophyte tall fescue. Consequently, a greater number of bulls grazing K31 failed breeding soundness examinations [108]. More concerning is decreased scrotal circumference and increased scrotal temperature in bulls exposed to alkaloids. Recently, Page and co-workers reported that spermatozoa incubated with ergot alkaloids (i.e. ergotamine) had reduced cell viability [109]. This suggests a cause-and-effect relationship between grazing endophyte-infected tall fescue and decreased conception rates.

Managing beef cattle successfully in the "Fescue Belt" requires understanding of seasonal ergot alkaloid production so that steps can be taken to reduce alkaloid intake by grazing beef cattle. Bioaccumulation of alkaloids is common and has numerous impacts on cattle health and productivity [110]. Alkaloid production peaks in late spring and is concentrated in seedheads [111]. Plant scientists recommend clipping seedheads before grazing, increasing the biodiversity of pasture plants through interseeding, or conversion of endophyte-infected pastures to alternative varieties that produce few alkaloids or are infected with novel, non-harmful endophytes [112]. Animal nutritionists suggest ameliorating fescue toxicosis by diluting ergot alkaloids in beef-cattle diets through strategic supplementation using non-alkaloid-containing feeds or by timing calving and breeding so as to avoid peak alkaloid concentrations [113, 114].

Other strategies to manage fescue toxicosis have been evaluated. Johnson and co-workers reported that previous exposure to ergot alkaloids influenced stocker cattle performance when fed alkaloid-containing tall fescue [115]. Campbell and co-workers reported a link between a single nucleotide polymorphism for dopamine receptor D2 gene and serum prolactin concentrations in beef cows grazing tall fescue [116]. This suggested the potential to identify cattle with a genetic predisposition for alkaloid sensitivity, although this theory has yet to be validated in the scientific literature.

Many feed additives have been tested for reducing the effects of fescue toxicosis. Much of the data regarding efficacy of feed additives and novel feed ingredients for alleviating fescue toxicosis are proprietary and not reported in the scientific literature. Thus, it is difficult to objectively evaluate their potential role in mitigating fescue toxicosis. Overall, it is unlikely that a single alkaloid avoidance or dilution strategy will resolve symptoms of endophyte-produced alkaloids in beef cattle. A multifaceted approach is necessary to minimize economic losses associated with tall fescue toxicosis.

Summary

Postpartum resumption of estrus and subsequent conception are low priorities, metabolically speaking. They tend not to occur until other priorities such as those associated with maintenance, growth, lactation, and accumulation of basic energy reserves have been satisfied. Nutrient supply prior to parturition and resulting BCS at calving and breeding appear to be the most important factors in determining reproductive performance of beef cows and heifers. Postpartum energy intake above maintenance can improve reproductive performance; however, the least-costly time to build energy reserves in the form of body condition tends to be between weaning and the final 60–80 days of gestation. Early weaning can prevent significant losses in body condition that normally occur during lactation, and has been associated with greater conception to artificial insemination or greater overall pregnancy rates in the subsequent breeding season [117, 118]. Similarly, exposing yearling heifers for breeding two to four weeks before mature cows allows heifers more time to resume estrus before being re-exposed as two year olds.

Nutrient requirements of beef cows vary predictably with the timing of breeding, weaning, and calving. Managers of beef cows and heifers are largely in control of when these

events take place. Sustained reproductive success in the beef cow is predicated on managing the entire production cycle to strategically and economically produce the body reserves of energy and protein needed to support cows through late gestation and peak lactation and to allow resumption of estrus 20–40 days before breeding exposure begins.

Interaction of Nutrition and Reproduction in the Dairy Cow

Butch Cargile[1] *and Dan Tracy*[2]

[1] *Progressive Dairy Solutions, Twin Falls, ID, USA*
[2] *Multimin USA, Auburn, KY, USA*

Introduction

Successful reproductive management of the modern dairy cow results from the implementation of best management practices. In the absence of widespread infectious disease, the largest effector of reproductive performance is prior and current nutritional status. Nutritional status of the dairy cow involves a complex interaction between macronutrients and micronutrients and herd-level management. In this chapter we discuss several of these interactions and their effects on reproductive performance. From a veterinary perspective, the primary tenet of animal nutrition is preventative medicine. Cows are programmed to succeed or fail, reproductively, based on the degree of metabolic stress experienced during the transition period from the non-lactating late-gestation stage to the lactating postpartum stage.

Reproductive Goals

The goal of any commercial dairy's reproductive program is the establishment and maintenance of a subsequent pregnancy as soon as physiologically possible following parturition. This pregnancy leads to another parturition and new lactation cycle. Unfortunately, parturition is a biological event associated with considerable risk. The risks associated with several metabolic–immunological disorders are correlated with the transition period of a dairy cow, in addition to the possibility of dystocia which itself has a complex interaction with each of the metabolic disorders. Given the array of possible complications and negative outcomes associated with parturition, profitability is the only impetus strong enough to cause dairy farmers to expose their cattle to this degree of risk. Figure 32.1 displays the relative periods of the lactation cycle with regard to profitability. Over a cow's productive life, the more cumulative time she spends under the area of the curve associated with profitability, the more profitable she is for the operation. The only way to gain access to this phase of the lactation cycle is through additional parturitions.

Transition Period

The transition period is widely accepted as the three weeks immediately before parturition through three weeks immediately following parturition. Disorders associated with this period of the reproductive cycle of the dairy cow include, but are not limited to, periparturient paresis (milk fever), retained fetal membranes (retained placenta), metritis, hepatic lipidosis (fatty liver syndrome), ketosis, and displaced abomasum. These disorders exert both direct and indirect effects on reproductive performance via follicular memory, immune function, and endometrial status. Table 32.1 displays some incidence rates and there follows a discussion of some of these metabolic disorders.

Retained Placenta and Metritis

Placental detachment is an immunologically driven event. In a study by Kimura et al. [1], neutrophils isolated from the blood of cows with retained placenta had significantly lower function before and after parturition, extending up to two weeks after calving. Further evaluation in this experiment revealed lower plasma interleukin (IL)-8 concentrations in cows ultimately developing retained placenta. IL-8 functions as a chemoattractant for neutrophils and induces phagocytosis. Addition of anti-IL-8 antibodies to cotyledon preparations led to a 41% reduction in neutrophil chemotaxis *in vitro*.

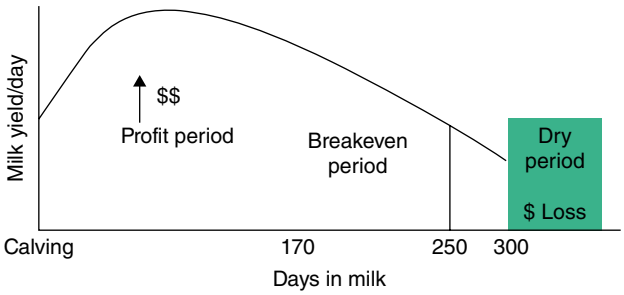

Figure 32.1 Periods of the lactation cycle with regard to profitability.

Table 32.1 Incidence of some metabolic disorders of dairy cows.

Disorder	Incidence (%)
Milk fever	5–10
Retained placenta	5–10
Clinical ketosis	5–10
Metritis	8 to >40
Clinical endometritis (four to six weeks after calving)	15–20

Metritis is the commonly accepted vernacular for an infection contained within the uterus of the postparturient cow. These are typically Gram-negative anerobic bacterial infections caused by invasion (growth) of microbes from the vagina or delivered to the uterus iatrogenically. Immunosuppression during the periparturient period has been shown to predispose the cow to metritis. This immune suppression has been described as starting one to two weeks prior to parturition [2–5]. Cows experiencing dystocia have been identified as being 2.58 and 4.32 times more likely to develop metritis than cows classified as having a normal parturition [6, 7].

One method being studied in an attempt to ameliorate this prepartum immunosuppression is alteration of the ratio of omega-6 ($n-6$) to omega-3 ($n-3$) fatty acids in the duodenum [8]. It appears that by increasing the n 6 : n 3 ratio in multiparous cows before calving, functional properties of mononuclear cells may be improved. It has been suggested that a dietary ratio of n 6: n 3 of 15 : 1 or more could be beneficial to reproductive performance during the lactation to follow.

Ketosis and Hepatic Lipidosis

Negative energy balance (NEB) is defined here as insufficient consumption of the calories necessary to meet metabolic requirements. This is the rule rather than the exception for late prepartum and early postpartum dairy cows. NEB begins in the prepartum period and progresses as dry matter intake (DMI) declines sharply several days before calving. This sharp decline in DMI is now thought to be the result, rather than the cause, of excessive lipolysis [9].

Ketosis is clinically classified as elevated plasma level of the ketone β-hydroxybutyrate (BHB). This occurs when the body's tissues, primarily muscular and neural, utilize less ketone than is being produced by hepatocytes. Increased production of BHB is a result of excessive mobilization of non-esterified fatty acids (NEFA). Ketosis, by itself, is a mammalian survival mechanism. However, animals of economic importance should not be approaching the survival threshold as this is well outside the zone of profitability and efficient production. Cows first testing positive for subclinical ketosis (BHB concentration 1.2–2.9 mmol/l) from three to seven days in milk were 0.7 times as likely to conceive to first service compared with cows first testing positive at eight days in milk or later [10], intimating effect(s) based on temporal occurrence as well as incidence.

Hepatocyte uptake of NEFA depends on the circulating NEFA plasma concentration. Once internalized, NEFA can be utilized, through esterification, and converted back into triglyceride (TG) for internal storage. TG can be repackaged into very low-density lipoproteins (VLDL) and exported from the liver for use by the mammary gland and other tissues. Internalized NEFA can also be oxidized partially, which results in ketone production, or oxidized completely for adenosine triphosphate (ATP) production. This process is termed β-oxidation. Intrahepatic repackaging of TG involves the inclusion of TG into VLDL. The bovine liver has a limited capacity to produce VLDL. Therefore, during periods of excessive lipolysis, the cellular machinery of the bovine hepatocyte becomes overwhelmed with TG and is physically impaired by the amount of TG being stored intracellularly. The upper end of the spectrum of this condition is termed hepatic lipidosis and typically occurs when TG constitutes greater than 5% of liver tissue on a wet basis.

The B vitamins niacin and choline are effectively used to alter the adipose–circulatory–hepatic axis. Niacin effectively limits lipolysis through binding and stimulation of the G-protein-coupled receptor GPR109A in humans [11]. Similar effects have been seen in dairy cattle fed 12 g/day per head of rumen-protected niacin [12]. While effective at reducing lipolysis, this method of control leads to a significant reduction in energy-corrected milk production and is unacceptable in commercial settings. Lipolysis and the subsequent metabolism of NEFA by the bovine liver is an evolutionary adaptation to conserve lactation through provision of VLDL as an alternative energy substrate and provide the substrate necessary for milk fat production in colostrum

and early lactation milk. When this process is limited, production is limited. Although potentially appealing from a reproductive standpoint, ultimately this control strategy is financially infeasible from a commercial perspective.

Supplementation with rumen-protected choline, on the other hand, addresses the rate-limiting step involving the inclusion of TG into VLDL, thus facilitating a net increase in hepatic energy production (translation) without increasing hepatic charge. Hepatic charge has been theorized to be a satiety initiator in the bovine [9]. Choline is integral in the production of phosphatidylcholine and critical for lipid transport and lipoprotein synthesis [13]. Feeding of rumen-protected choline in a study by Lima et al. [14] led to a reduction in mastitis approaching statistical significance. The link between postpartum mastitis and early reproductive performance is discussed later in this chapter in the section "NEFA Concentration and Oocyte Formation." Both choline and the amino acid methionine are methyl donors and can spare each other in this process (Figure 32.2).

Another effective nutritional strategy addressing clinical and subclinical ketosis is the use of the only ionophore currently approved for use in lactating dairy cattle, monensin sodium. In Canada and other countries, controlled-release indwelling capsules that reside in the rumen and provide continuous release of monensin are approved for use. This delivery system is not currently approved in the USA, but feeding of monensin is approved. Monensin has been shown in a meta-analysis to reduce the incidence of clinical ketosis and severity of subclinical ketosis [15]. Monensin exerts its effects by increasing ruminal propionic acid production as a result of bacterial selection. This effect seems counter to the hepatic oxidation theory proposed by Allen [16] as the production of propionate is involved in satiety signaling in ruminants. However, this can be reconciled because the additional production of propionate is spread over a longer timeframe than the spikes from the rapid fermentation of starch following meals [17].

β-Glucans

In its embryonic state in dairy cattle immunology, and infancy in human immunology, immune modulation by β-glucans is addressed crudely from a nutritional standpoint presently. The source and, more importantly, form of the specific β-glucan appears to have significant impact on its functionality regarding gene expression within target immune system cells. Extensive studies are needed to elucidate the exact proinflammatory and proresolving effects of β-glucans and their subsequent effect(s) on reproduction.

Milk Urea Nitrogen

Milk urea nitrogen (MUN) is closely associated with blood urea nitrogen (BUN). BUN is an indirect measure of "excess" dietary protein or, more specifically, ammonia. Within the normal range of commercial ration formulation, BUN concentration increases as the ratio of soluble protein to non-fiber carbohydrates increases. Absolute amounts of the different protein fractions must be matched with their corresponding carbohydrate fractions when considering their respective ruminal degradation rates. When matched, efficient use of dietary protein and carbohydrate results in efficient production of microbial protein with minimal ammonia needing to be detoxified by inclusion into urea by the liver. The biochemical process of converting ammonia to urea exerts an energy cost on the

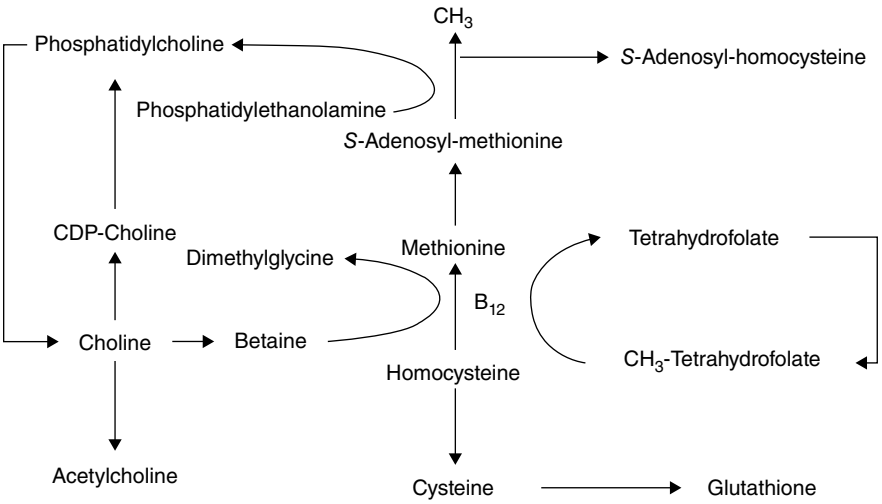

Figure 32.2 Methylation pathways (DNA, proteins, lipids).

cow. A study by Rajala-Schultz et al. [18] showed that cows with MUN levels between 10.0 and 12.7 mg/dl were 1.4 times more likely to be confirmed pregnant than cows with MUN levels above 15.4 mg/dl. In this same study, cows with MUN levels below 10.0 mg/dl were 2.4 times more likely to be confirmed pregnant than cows with MUN levels above 15.4 mg/dl. Studies suggest multifactorial negative fertility effects as a result of elevated BUN, including altered oocyte development [19, 20], embryonic maturation, and intrauterine environment [21, 22].

The use of metabolizable protein and amino acid balancing nutritional models has allowed crude protein and average MUN levels to be reduced. Rumen-protected forms of lysine and methionine are commercially available and appear to be economically viable. Use of these ingredients allows balancing of rations at considerably lower crude protein levels while still maintaining predicted production levels on a metabolizable protein basis since lysine and methionine are the first and second limiting amino acids in normal dairy rations.

NEFA Concentration and Oocyte Formation

The functional micro-unit of reproduction from the female perspective is the ovum. Follicular memory is a carry-over effect that delays the influence of metabolic status on reproductive performance by as much as 60 days [23–25]. As the investigation and understanding of the influence that individual fatty acids exert on reproductive performance increases, NEB becomes a more complex proposition as it relates to fertility in the dairy cow. The negative effects of oleic acid, and a combination of oleic, palmitic, and stearic fatty acids, have been studied with regard to their direct effect(s) on granulosa cells and cumulus–oocyte complexes [26] and theca cells [27]. *in vivo*, these negatively correlated effects are secondary to elevated circulating plasma levels of these individual and/or combinations of NEFA. Fatty acid composition of adipose tissue is influenced greatly by diet and degree of ruminal biohydrogenation of unsaturated fatty acids. Since NEFA result from the liberation of TG from adipose tissue, nutritional composition of absorbed fatty acids has a direct influence on the relative and absolute concentrations of NEFA.

Setting aside the direct influence that individual circulating fatty acids may exert on the ultimate fertility of the ovum, elevated circulating NEFA may be linked to runaway inflammatory response and insulin resistance, the latter being part of a vicious positive feedback loop that results in an ever-increasing NEFA concentration. Feeding of the omega-3 fatty acids α-linolenic acid and docosahexaenoic acid may directly dampen this hyperinflammatory state as a result of binding proliferator-activated receptors [28]. Studies completed recently have shown a decrease in embryonic loss and concomitant increase in milk production in cows supplemented with the essential fatty acids eicosapentaenoic acid and docosahexaenoic acid. Current reasoning for these results is a significant decrease in the caloric requirements of the cellular immune system, due to modulation, in these postpartum cows so that glucose is non-selectively spared, as glucose is the primary energy source for macrophages and neutrophils. As the bovine liver has a finite capacity for glucose production, primarily via gluconeogenesis, this sparing effect should return the postpartum cow to a positive energy balance at lower days in milk. In the bovine, resolution of NEB leads to reestablishment of normal ovarian cyclicity. On a molecular level, an intracellular shift from the production of proinflammatory eicosanoids to more pro-resolving eicosanoids likely explains the responses seen in these studies. This shift would break the positive feedback loop of proinflammatory eicosanoids leading to radical oxygen species production, tissue destruction, and further proinflammatory eicosanoids.

As alluded to above, tumor necrosis factor (TNF)-α production by adipocytes, and macrophages residing within adipose tissue, could enhance insulin resistance. Studies using exogenous TNF-α in cattle have led researchers to this conclusion [29–31]. This is especially significant in a transition cow that already has lower circulating insulin levels and decreased insulin sensitivity compared to that of a normal mid-lactation animal. One can see the possibility for a positive feedback loop here as well. It is possible this model explains obesity-induced diabetes in humans and the progression from normal periparturient lipolysis to a hyperketotic/hepatic lipidosis state in dairy cattle.

An indirect association between ketosis and reproductive efficiency, via clinical mastitis, can be created by a systemic inflammatory state. Cows experiencing ketosis have been shown to have twice the risk of developing clinical mastitis [32] and cows that experienced a case of clinical mastitis within 30 days after insemination were 16% less likely to conceive on first-service insemination. Cows experiencing subclinical or clinical mastitis prior to first-service insemination show increased days to first service, days open, and reduced first-service conception rate [33]. It is not difficult to visualize an impaired corpus luteum, hampered by proinflammatory prostaglandins, unable to produce progesterone at a level sufficient to maintain an early pregnancy.

Nutritional Heat Stress Abatement

Heat stress, a result of the cow's physiological response to elevated temperature humidity index (THI), has been shown to lower conception rates [34] and pregnancy rates [35]. Lactating dairy cattle typically begin to experience heat stress around a THI of 70. This stress is exacerbated by dietary fiber digestion. Per unit of dry matter, the ruminal degradation of neutral detergent fiber (NDF) carries the highest heat increment of any of the macronutrients found in dairy rations. Ether extract (EE) carries the lowest heat increment of digestion. Therefore it is common practice to adjust lactating rations to reduce NDF levels and increase EE levels in response to times of intense heat stress. This serves two purposes: it increases the caloric density of the ration at a time when the cow is expending additional calories in an attempt to maintain core body temperature, and it decreases the heat increment that would have been created by digestion of the marginal fiber. Care must always be taken to avoid ration extremes that would result in fiber levels that are too low and/or EE levels that are too high; these extremes would put cows at risk of ruminal acidosis and decreased fiber digestibility/depressed DMI, respectively.

An additional method of nutritionally cooling cows has been studied [36] in beef cattle and could have application in a dairy setting. It involves feeding an osmotically active ingredient during times of heat stress and has been shown in at least one controlled study to minimize the degree of body temperature elevation. More work is needed on this concept to determine its efficacy and feasibility.

Body Condition Score

Probably the most complex phenotypic expression, body condition score (BCS) of the dairy cow is a combination of genetic predisposition for both reproduction and production, and numerous variables associated with management decisions. Elevated BCS is usually associated with either prolonged days to conception or abortion, extending length of lactation in both cases. This allows these cows to remain on diets that are higher in energy density than needed for maintenance due to decreasing milk production, as the lactation curve progresses at approximately a negative 9% monthly slope. Cows that are obese (BCS > 3.75 on the five-point scale) at calving tend to have higher risk of metabolic disorder [37], extending the period of NEB and delaying conception. Current recommendations are to have cows at a BCS of 3.0–3.25 at the time of parturition. From a univariate standpoint, this management strategy does decrease the incidence of certain energy-related metabolic disorders. However, reducing the available energy reserves for the ensuing lactation could have negative effects on the lactation curve. Other strategies, such as choline supplementation in the postpartum period, could prove to be a more profitable pathway in the management of NEB. This axis between nutrition, reproduction, and body condition can be either coupled and provide a basis for continuous improvement in efficiency or decoupled, leading to challenges and economic loss.

Methionine

As an essential amino acid, and initiating amino acid in virtually all mammalian proteins, methionine supplementation is common in commercial dairy cattle. Sufficient data have accumulated since the previous publishing of this text to justify a discussion of methionine and its effects on the reproductive performance of the female bovine. Numerous pathways elucidated by researchers have shown increased embryonic retention in response to methionine supplementation. Toledo et al. in 2015 [38] compared multiparous cattle that were supplemented (treatment) or not supplemented (control) with 21.2 g/day of Smartamine® M from ~30 to ~126 days in milk (DIM). Cows supplemented with methionine during that period experienced a 6.1% pregnancy loss between pregnancy days 28 and 61 compared to 19.6% pregnancy loss compared to their non-supplemented counterparts at a p-value of 0.03. Embryonic abdominal diameter (5.9 mm vs 5.3 mm) and embryonic volume (209.3 mm^3 vs 160.5 mm^3) were both positively affected, with p-values at 0.008 and 0.005, respectively, on day 33 of pregnancy. In this study there were no significant differences measured in the reproductive performance of primiparous cows. Acosta et al. in 2016 [39] showed a higher cytoplasmic lipid concentration (7.02 ± 1.03 arbitrary units (AU) vs 3.61 ± AU) in embryos flushed 6.5 days after artificial insemination in Holstein cows supplemented with Smartamine M at 0.08% of the ration dry matter from 21 days prepartum to 30 days postpartum. The researchers proposed that this higher embryonic lipid content in the preimplantation period would be an explanation for the increased embryonic survival in methionine-supplemented animals.

Baez et al. have shown larger uterine size and decreased fertility in multiparous cows when compare to primiparous cows [40]. Baez et al. also have shown a decreased tendency in reproductive performance in recipient heifers with a larger uterine size [41]. It is rare that a single phenotypic expression can explain the response to an individual nutrient. But it appears in the case of methionine, and perhaps other essential amino acids, that the variable uterine

volume of the dam hosting the conceptus could determine the absolute dietary requirement for this amino acid. Increased uterine fluid concentration of essential and nonessential amino acids in the preimplantation phase of pregnancy was shown by Groebner et al. [42]. Genomic identification of this trait could influence the efficiency with which methionine is utilized for manipulation of the bovine pregnancy.

Minerals and Vitamins

Proper nutrition and management during the transition period are crucial for the prevention of postpartum reproductive disorders. The role of proper energy and protein supplementation in the prevention of uterine disorders is well defined, but mineral and vitamin balance and supplementation should not be ignored [1].

Cows suffering from clinical or subclinical periparturient hypocalcemia are more at risk of experiencing secondary disorders such as dystocia, uterine prolapse, retained placenta, and metritis [43–46]. The pathogenesis and prevention of parturient hypocalcemia or milk fever continues to be a topic of debate and research. However, current management practices to prevent parturient hypocalcemia attempt to reduce the physiological lag time between the potentially hypocalcemic demands of lactation and recovery back to a functional normocalcemic state.

Factors contributing to hypocalcemia include excessive prepartum dietary levels of calcium (1.35% DM), excessive levels of dietary phosphorus, low dietary levels of magnesium, increasing age, and breed – with Jersey cattle being at increased risk [43, 47]. The most commonly recognized presentation of milk fever (clinical hypocalcemia, parturient hypocalcemia) is during stage 2 and is diagnosed in the bovine by the clinical signs of recumbency, cold extremities, and a weak rapid pulse. Total serum calcium less than 8.0 mg/dl is considered diagnostic of hypocalcemia in the bovine [48]. The traditional nutritional method of limiting the incidence of clinical and subclinical hypocalcemia involved limiting calcium intake before calving so that the total absorbed calcium per head was less than 20 g/day. This stimulated bovine parathyroid hormone (PTH) secretion and increased bone resorption of calcium. This method has largely been replaced with the advent of dietary cation–anion difference (DCAD) diets. The equation for DCAD is (Na + K) – (S + Cl). Since sodium intake is held at a minimum during the immediate prepartum period as a means to limit udder edema and feeding excessive sulfur has negative implications, this equation can, practically, be simplified to (K – Cl). Anionic salts such as ammonium chloride, calcium chloride, and magnesium sulfate (used primarily as a magnesium source but also as an acidifier) are used to create a state of compensated metabolic acidosis. Newer commercial ingredients, usually a protein carrier treated with either hydrochloric acid or an organic acid, or a combination of organic acids serve the same function as the anionic salts. This method of hypocalcemia prevention has been described by Zeisel and Holmes-McNary [13]. Excessive acidification is undesirable as it increases the cow's caloric requirements in an effort to compensate for the greater degree of metabolic acidosis. This usually comes in the form of increased respiratory rate in an effort to reduce acid load. Decreased DMI is also associated with compensated metabolic acidosis and worsens with the degree of acidosis. Cows are typically fed these acidifying diets during the three weeks immediately before calving, when they are already mobilizing adipose tissue and declining in DMI. Diligent monitoring of urine pH as a measure of the degree of compensated metabolic acidosis is necessary in order for this program to be successful.

Since last publication, a novel product has been introduced to the market for the control of hypocalcemia. A synthetic zeolite, X-Zelit®, has been added to the list of feed ingredients available. Naturally occurring zeolite has been used for years as a mycotoxin binder and in the amelioration of ruminal ammonia effluence. Its porous 3-D structure lends itself to the binding of a plethora of molecules varying greatly in molecular mass. Fed to the prepartum bovine, this product binds calcium, phosphorus, and magnesium. In the author Cargile's experience this multifaceted approach is more effective in preventing peripartum hypocalcemia and hypophosphatemia than induced preparturient compensated metabolic acidosis. Care must be taken when using this product to provide additional magnesium supplementation and to provide micronutrients in a protected form to prevent iatrogenic hypomagnesemia and/or temporary micromineral deficiencies. The author feeds between 0.45 and 0.50% magnesium on a dry matter basis when utilizing this product.

Magnesium plays an essential role in calcium homeostasis and as a result may contribute to hypocalcemia when dietary levels are insufficient [47, 49]. Hypomagnesemia can blunt PTH secretion in response to low calcium and interfere with the interaction of PTH and its target tissues [49]. High dietary potassium will reduce the absorption of magnesium in the rumen as well as reduce the effectiveness of an anionic salt program. It is recommended that the magnesium content of the close-up ration should be between 0.35 and 0.4% of dry matter to ensure adequate absorption [49].

Trace minerals are present in the tissues at very low concentrations and their requirements are expressed in milligram or microgram amounts. Trace minerals considered to be of importance in dairy cattle include cobalt, copper, iodine, iron, manganese, molybdenum, selenium, zinc,

and possibly chromium and fluorine [43]. Trace minerals are components of metalloenzymes, hormones, and cofactors of functional proteins, or enzymes that are involved in many aspects of energy and protein metabolism, hormone synthesis, and immune function [43, 50]. Infertility in cattle, including decreased ovarian activity, reduced conception rates, increase in dystocia, abortions, and delayed onset of puberty, is linked to specific enzymatic dysfunction resulting from one or more trace mineral deficiencies [51]. In the bull, trace mineral deficiency is associated with a decrease in spermatogenesis, decrease in libido, increase in abnormal sperm, and a reduction in testicular size [44, 50]. Trace minerals affect reproduction directly or indirectly through multiple functional proteins and enzyme systems. For example, selenium (Se) is well known for its role as a cofactor in the enzyme glutathione peroxidase, an important antioxidant that is present throughout bodily fluids and organs, and within cells including sperm and cells of the ovary [50]. Such antioxidant activity helps maintain cellular function in the face of oxidative stress, improves cellular immunity, and, when supplemented with other antioxidants such as vitamin E, can improve fertilization, reduce retained fetal membranes, and reduce the incidence of cystic ovarian disease [52, 53].

Vitamins like trace minerals are cofactors. Vitamins required by dairy cattle are classified as being fat-soluble (A, D, E, and K) or water-soluble (B vitamins and vitamin C) [43]. Water-soluble vitamins are produced by rumen microbes and true deficiencies in cattle with functioning rumens are rare [43]. Vitamins A and E are the only ones with a true dietary requirement because vitamin D is produced through ultraviolet (UV) radiation of the skin and vitamin K by bacteria of the rumen and intestines [43]. However, a reasonable practice includes supplementation of dry cows with 20 000–30 000 IU vitamin D daily to ensure proper calcium absorption [49] and compensate for animals not receiving sufficient UV radiation for de novo vitamin D synthesis. These conditions are common in dairy cattle residing in extreme northern and southern latitudes. Vitamins and trace minerals also share a synergistic relationship. Vitamin E and selenium have a sparing action on the requirement of the other and share the same characteristics [54]. Both contribute to antioxidant activity and maintain cellular health and function. Selenium contributes to intercellular, intracellular, and extracellular activity, while vitamin E preserves cellular integrity by protecting the cellular membrane [50].

Trace Mineral and Vitamin Supplementation Challenges

As discussed, trace minerals and vitamins are essential for proper immune function, cellular health, and hormone synthesis, which are essential for postpartum involution, health of the reproductive tract, and resumption of normal estrous cyclicity after calving. It has been established previously that fresh cows suffering from postpartum diseases such as retained fetal membranes and metritis experience poor reproductive performance and increased days in milk [6]. However, compounding this issue is that approximately one month prior to calving, there is maternal transfer of stored trace minerals from the dam to the fetal tissue. Studies have demonstrated this transfer with copper, manganese, zinc, and selenium, which are the most limiting trace minerals with regard to fetal and neonatal survival and development [55–57]. In addition, transfer of vitamins A and E in colostrum occurs at calving and colostrum is a source of these vitamins for the calf after birth [57, 58]. Maternal transfer of trace minerals is essential for calf health, but this transfer occurs at the cow's expense during a time of decreased DMI and demands on the immune system that occur prior to calving [59]. Further, contributing to the risk of deficiency and disease is the issue of mineral antagonism or negative mineral interactions, which reduces absorption in the gastrointestinal tract as well as antagonistic activity systemically. Excessive sulfur found in dried distillers grains, molasses, and water reduce copper absorption in the gastrointestinal tract through formation of copper sulfide [60, 61]. Selenium and sulfur are physically and chemically similar and when excessive sulfur is present in the ration, competition for absorption can result in reduction of selenium absorption [62]. In addition to sulfur, calcium levels greater than 1% of ration dry matter reduce the absorption of selenium from natural sources [63]. Systemic antagonism of the enzymatic function of copper can occur if excessive consumption of sulfur is combined with excessive consumption of molybdenum, resulting in the formation of thiomolybdate in the rumen that reduces copper absorption in the gastrointestinal tract [64, 65]. In addition, thiomolybdate is absorbed and blocks systemic function of copper and increases biliary excretion of copper from liver stores, resulting in symptoms of copper deficiency [60].

Subclinical deficiencies of trace minerals that occur due to antagonism, maternal transfer, or reduction in DMI prior to calving can persist into lactation, potentially compromising reproductive performance. Nutritionists address the risk of trace mineral deficiencies by providing proper amounts of trace minerals in the ration and reducing potential negative mineral interactions or antagonism, as well as including trace minerals with improved bioavailability such as chelates or organic trace minerals [60]. The study of trace mineral form, function, and supplementation continues to be an active area of research. Recent studies have shown a benefit to health when trace minerals are

provided as an additional supplement or parenterally administered to cows that are provided with a supplemented ration. Such benefits to a cow's reproductive and physical health have been demonstrated with supplementary selenium and vitamin E. In addition, recent studies have shown an improvement in uterine health and reduction in the population of bacteria causing metritis when an injectable trace mineral product containing zinc, manganese, selenium, and copper was administered during the dry period and during early lactation [52, 53, 66, 67].

Summary

Through genetic selection, economic pressure for higher milk production, and maintenance of profitability, today's dairy cow has become a physiologic athlete. However, development of today's dairy cow has resulted in many challenges to reproduction and health. Continually addressing those challenges through research has allowed better understanding of how to preemptively design rations and herd health protocols to allow for a successful lifetime.

Cystic Ovarian Follicles

Jack D. Smith

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

Cystic ovarian follicles (COF) have been recognized as a condition that compromises normal ovarian cyclicity and is a significant disrupter of normal reproduction in cattle. Frequently a cause of subfertility and reduced reproductive performance, it has been recognized in cattle for over 100 years. This condition is most commonly characterized by anovulation and is noted to occur in a number of mammalian species. The condition in cattle results in a major cause of economic loss worldwide, most notably in dairy cattle. Cows in modern dairy production systems are under intense metabolic and environmental stresses that can lead to compromised reproduction, with COF being one of the most common manifestations encountered. The major causes of economic loss attributable to this condition involve: increased days open in the postpartum period leading to extended calving intervals; increased drug and treatment costs associated with its management; increased semen costs attributable to the increase in servicers per conception; and higher culling rates of affected animals [1, 2]. One study in dairy cattle demonstrated that cows with COF took 6–11 days longer to reach first service and took 20–30 more days to conception than control cows, clearly demonstrating the economic impact of this condition [3].

Terminology

Numerous terms and definitions have been used to describe the anovulatory condition of cattle, which is most commonly termed cystic ovarian disease (COD). Other terms that have been used previously to describe the same clinical manifestation include adrenal virilism, nymphomania, ovarian cysts, cystic ovarian degeneration, and cystic ovaries, among others [2]. The classic definition proposed by Roberts [4] was the presence of an anovulatory structure on the ovary more than 2.5 cm in diameter and which has persisted for at least 10 days in the absence of a corpus luteum (CL). Several aspects of the former definitions are relatively arbitrary and do not reflect our current understanding of the condition. Cattle typically ovulate a dominant follicle with an average follicular diameter of 1.6–1.9 cm. The use of a size limit of 2.5 cm thereby excludes all cystic follicles which are smaller than this arbitrary size [5]. Also, many previous definitions stated the requirement that the cystic structure be present for a minimum of 10 days. This requirement should also be questioned as it is known that these structures are dynamic in nature. Evidence shows that both naturally occurring as well as steroid-induced cystic follicles undergo frequent turnover and are replaced by a new and similar structure at another site on the same or opposite ovary. Current management systems would often not allow the cow to be reexamined to fulfill the 10-day duration requirement. Older definitions have also required the absence of a CL. The necessity for the absence of a CL is not universally fulfilled as it is evident that some cysts are not steroidogenic and thus are hormonally inactive and would not necessarily influence the estrous cycle. Such cystic structures can be found in the presence of a functional CL.

Vanholder et al. [5] attempted to more accurately define and describe this anovulatory condition of cattle and its effects on reproduction as "cystic ovarian follicles." COF is defined as the presence of a follicle(s) with a diameter of at least 20 mm, present on one or both ovaries in the absence of any active luteal tissue, and which clearly interferes with normal ovarian cyclicity [5].

Further subclassification of the COF condition into follicular or luteal cyst is based on the degree of luteinization and on progesterone levels in blood or milk. Follicular

cysts are typically thin-walled structures that secrete varying amounts of estradiol. The thickness of the layers of granulosa cells dictates the amount of estradiol present in the intrafollicular fluid. Both cyst types are considered to be different forms of the same condition, with luteal cysts being a follicular cyst in which theca and granulosa cells have undergone some luteinization and are producing progesterone [2]. Follicular cysts do not secrete progesterone, whereas luteal cysts secrete varying amounts of progesterone depending on the degree of luteinization. A single universal threshold level of progesterone used to distinguish follicular cysts from luteal cysts has not been established [5]. The ability to accurately classify each individual cyst as a follicular or luteal cyst remains subject to personal interpretation of the clinical examination and history findings in addition to ovarian ultrasound findings and serum progesterone levels.

Incidence

The incidence of COF in cattle is very dependent on their intended use and their respective management system. The incidence of COF is much greater in dairy cows compared with beef cattle and dairy heifers, where the incidence is relatively low. Utilizing data from a number of studies, the average incidence of COF in lactating dairy cattle is estimated to be near 10–12%, with various studies reporting incidences ranging from 3 to 32% [2]. There are numerous factors that can impact the apparent incidence of COF. The time of diagnosis can easily influence the apparent incidence of COF as it has been shown that as many as 60% of dairy cattle that develop COF recover spontaneously prior to their first postpartum ovulation and may never be diagnosed. Cattle that experience a disruption in normal parturition, fetal membrane release, or any metabolic disease in the postpartum period are at almost two times greater risk of developing COF than normal control cattle.

In beef cattle the incidence of COF is much lower when the cattle are under routine management. It is when the reproduction of beef cattle is intensively managed or manipulated that the incidence of COF begins to rise above that of the general population. Beef cattle used for embryo donation after superovulation appear to develop COF at a much higher incidence than the general population and may approach the incidence rate of dairy cattle.

Pathophysiology of COF Formation

Potential mechanism(s) involved in the pathogenesis of COF have been investigated for over 50 years, but to date many studies have not yet yielded the single definitive cause resulting in the condition of COF. A general consensus is that there is an underlying likely multifactorial dysfunction or neuroendocrine imbalance involving the control mechanisms of the hypothalamic–pituitary–gonadal axis resulting in ovulation failure [1, 2, 6–13]. The precise or primary mechanism(s) leading to ovulation failure remains elusive. A complicating factor in this search is that it is evident that there are multiple factors/pathways/imbalances involved in the pathogenesis of this condition. These factors can be lumped into one of the following: individual genetic factors, phenotypic traits, environmental factors, metabolic and cellular factors, and management factors, which can individually and/or collectively be involved in contributing to this condition [5].

The most widely accepted hypothesis involves the altered release of luteinizing hormone (LH) from the pituitary gland. The preovulatory surge of LH is absent, insufficient in magnitude, or improperly timed, leading to failure of the dominant follicle to ovulate. The dominant follicle continues to grow and becomes large and anovulatory [1, 2, 5, 14]. There does not appear to be a reduction in gonadotropin releasing hormone (GnRH) content in the hypothalamus or a reduction in GnRH receptors in the pituitary [5]. LH content in the pituitary also does not appear to be reduced in cows with COF [5, 15]. Injections of exogenous estradiol to cows with naturally occurring or induced follicular cysts fail to induce an LH surge, although an injection of GnRH in affected cows can induce the release of LH [16–19]. These findings support the belief that there is a functional breakdown in the positive estradiol feedback loop which controls LH secretion. There appears to be disruption in the responsiveness of the hypothalamus to estradiol which leads to resultant ovulation failure. Under normal conditions, preovulatory follicles secrete estrogen that has a positive feedback effect on the hypothalamic–pituitary–ovarian axis, inducing an LH surge which is responsible for ovulation of the dominant follicle [16]. Because of the functional abnormality in the regulation of LH secretion, cows with COF lack an adequate LH surge needed for ovulation, which results in ovulation failure.

In cows with COF, there is also loss of the negative feedback effects of progesterone, leading to relatively high levels of LH pulse secretion. These LH pulses have been observed to be higher than those in cattle with a normal luteal phase. High LH pulses promote continued and excessive growth of the dominant follicle, ultimately leading to the abnormally large preovulatory follicle [16, 20, 21]. Additionally, the period of estradiol and inhibin production by the dominant follicle is protracted, which helps establish long-term dominance of the cystic follicle via suppression of follicle-stimulating hormone (FSH) production by the anterior pituitary [16, 22–25]. When the COF ultimately undergoes regression and no longer produces sufficient estradiol and

inhibin at levels sufficient to suppress FSH, a new follicular wave emerges. Unless the abnormality in the estradiol feedback loop is corrected, the new dominant follicle of the subsequent wave will also become cystic and anovulatory, thereby sustaining or perpetuating the anovulatory condition [16]. This apparent turnover and replacement of the COF condition can be responsible for the protracted anovulation noted in some cows.

There also appears to be an intraovarian component in the pathogenesis of COF. Metabolic hormones, most notably insulin and insulin-like growth factor (IGF)-1, stimulate follicular cell steroidogenesis and proliferation. Growth of dominant follicles is dependent upon IGF-1 helping drive estradiol-17β secretion. Insulin is needed in the promotion of follicular maturation [26]. It is known that cows with COF are often concurrently or were previously exposed to various kinds of insults or stress such as oxidative stress, negative energy balance, dietary restriction, reduced or poor liver function, and low circulating insulin and IGF-1 [26–29].

There has been an association with these stressors and an increase in heat shock protein (HSP) in the ovaries of cows with COF. It is speculated that the altered expression of HSP genes decreases apoptosis in the follicular wall and leads to the delayed regression of cystic follicles [27]. Although the precise relationship between the aberrant amounts of HSP in the ovaries of cattle under stress and the COF condition is not completely understood, it is speculated that there is an association with HSP and an intraovarian component of COF pathophysiology [27].

Several studies have looked at the impact of non-esterified fatty acids (NEFA) on the formation of the COF condition. Often during early lactation when dietary intake is insufficient to meet the need for milk production, NEFA levels are high. High NEFA has been proposed as a contributor in COF due to its effects on follicular growth and development related to its cytotoxic effects on bovine theca cells and their steroidogenesis. The presence of elevated NEFA and the sustained effects on the follicular cells is proposed to be a potential explanation for cases that fail to recover spontaneously and cows that repeatedly develop the condition [30].

Clinical Signs

The clinical sings associated with COF are generally related to altered reproductive behavior and, less frequently, changes in physical characteristics. Most commonly, cows with COF show prolonged periods of anestrus, which is seen in over 80% of affected cows. This is most evident in cattle that develop COF early in the postpartum period [4]. Nymphomania with prolonged periods of persistent and frequent estrus is seen in approximately 10% of cows with COF. It is common for the affected cow to frequently participate in riding activity of estral cows but not stand for mating herself [4]. The presence of an extremely masculine phenotype has also been associated with cows with COF who show prolonged nymphomania [31]. It appears that as the interval from calving to diagnosis of COF increases, the likelihood of observing nymphomania behavior increases [4]. Estrous cycles with sporadic and irregular patterns can also be the primary clinical sign in cattle with COF.

Diagnosis

Transrectal palpation of the reproductive tract has been the primary means of diagnosing COF for many years. The accuracy with which even an experienced clinician can correctly determine the specific type of cyst present is relatively poor. Transrectal ultrasound can be used to more accurately determine the specific type of cyst present. Follicular cysts typically have a thin wall (≤3 mm), whereas luteal cysts typically have a thicker and more echogenic wall (≥3 mm). The follicular fluid is often hypoechoic in follicular cysts, whereas with luteal cysts echogenic strands may be present, creating a cobweb-like appearance [32]. The collective findings of transrectal examination of the reproductive tract including ultrasonography, blood progesterone levels, and the clinical history of the cow will allow the most accurate diagnosis regarding the type of cyst present. It is relatively uncommon for blood progesterone levels to be determined in the diagnosis and management of routine cases in clinical practice.

The accuracy with which a skilled clinician can identify the type of cysts present based on palpation alone is relatively poor [33]. The dynamic nature of both cysts and developing corpora lutea can complicate the diagnosis when palpation alone is used. Farin et al. [34] showed that 10% of cows diagnosed as having cysts based on transrectal examination were found to have a structure consistent with a normal CL when the ovaries were subsequently examined with ultrasound. When ultrasound technology was used the accuracy of a correct diagnosis of cyst type was 74% for follicular cysts and almost 90% for luteal cysts [35]. Progesterone concentrations have been shown to correlate very well with cyst wall thickness, with 3 mm often being the threshold between follicular and luteal cysts [1, 36]. When blood progesterone concentration is combined with both palpation and ultrasound findings, the diagnosis of cyst type approaches 100%. Knowledge of progesterone concentrations could certainly aid in treatment decisions, although most of the currently recommended treatments effectively treat both luteal and follicular cysts, thereby negating the need for knowing this information prior to treatment.

Treatment Strategies

Many techniques, drugs, and strategies have been used in the treatment of COF in cattle over the last hundred years or so. Currently the most effective and most widely used treatments all involve hormonal therapy(s) of some kind which are aimed at causing ovulation of a dominant follicle to occur or to reestablish the responsiveness of the hypothalamus to the positive feedback of estrogen. Older therapies that are no longer recommended include ovariectomy, uterine infusions of antibiotics or antiseptics, and crushing of the COF. Studies in the 1950s showed that when compared with hormonal therapies of the time, manual crushing showed no advantage and there may even be some adverse conditions such as trauma and adhesions associated with its use [37]. Fatal hemorrhage associated with attempts to crush or manually rupture COFs has been reported [38]. This form of treatment, although still found in several texts, should never be used as a primary method of treatment due to the potential side effects as well the availability of safer and more reliable and effective treatments.

GnRH

Hormone therapy aimed at either causing (GnRH) or mimicking (human chorionic gonadotropin) an LH surge can be used to treat follicular cysts. Of these two options, GnRH is generally chosen first due to its low molecular weight and size, which reduces the likelihood of an adverse immune reaction [1, 7]. The standard dose of 100 μg was shown in a pharmacokinetic study to be more than adequate for the production of an LH surge capable of triggering ovulation of a dominant follicle in cows diagnosed with COF [39].

GnRH was first reported in the early 1970s as an effective treatment for follicular cysts in cattle [40]. In this small early study, all treated cows ($n = 5$) were observed in standing estrus within 20–24 days following GnRH treatment [40]. Many subsequent studies have shown the value of treating cows with COF with GnRH products and its use in the management of COF continues today. Across many studies, there have been wide variations in the results observed in the treatment of COF with GnRH alone.

Following an injection of GnRH a surge of LH from the anterior pituitary occurs within two hours [17]. This LH surge acts to cause luteinization of the follicular cyst, which will then generally undergo spontaneous luteolysis in 18–20 days, followed by a normal estrous cycle. However, it is common for the injection of GnRH to cause ovulation of a dominant follicle also present on one of the ovaries at the time of treatment. With this situation, ovulation will occur as well as initiation of a new follicular wave, followed by a normal luteal phase [41]. The subsequent increase in progesterone concentrations from the luteinized cyst lasts for 15–18 days and allows the resetting of the normal hypothalamic–pituitary–ovarian axis, with resumption of the positive feedback of estradiol to the hypothalamus. This leads to resumption of normal cyclicity in 72–85% of cows, with a return to estrus generally within three weeks [2]. However, the interval from GnRH injection to estrus can be reduced with the use of prostaglandins administered 7–10 days after GnRH treatment, causing luteolysis and subsequent estrus.

In one study looking at the effectiveness of a single injection of GnRH for treatment of cows with COF, 72% of cows resumed normal cyclicity within 20 days of treatment compared with 16% of control cows [17]. However, as mentioned above, findings have not been consistent across studies. There was no difference in the period of time between treatment with GnRH alone and resolution of COF or in the period of time between treatment and a CL being observed [42]. These studies highlight the difficulty in evaluating the effectiveness of GnRH alone as therapy for COF because of the high number of cows that appear to recover spontaneously and the variability and confounding factors present in the numerous study designs.

No differences have been observed when comparing synthetic GnRH to GnRH analogs or among different concentrations of GnRH. The typical dose administered in the treatment of COF is 100 μg intramuscularly and any of the commercially available products should assure similar results [43, 44].

Human Chorionic Gonadotropin

Human chorionic gonadotropin (hCG) is a protein hormone that has been used to treat refractory cysts that fail to respond to GnRH. hCG has high LH-like properties that will often cause the cyst or other follicles present to luteinize and subsequently begin producing progesterone [45]. Once luteinized, the cyst can then be treated with prostaglandins to induce regression of the functional luteal structures and reinitiate normal estrous cycles. The most common dosage used is 10000 IU given intramuscularly. Its use has occasionally been noted to stimulate an immune reaction leading to refractoriness, although the importance of this reaction is poorly understood [1]. It is a more costly treatment than GnRH and it has been known to occasionally cause anaphylactic reaction following treatment. For these reasons, it is generally only used when GnRH or other therapies have failed to render a cure.

Progesterone

Use of progesterone as a treatment for COF was proposed over 40 years ago [46]. With the approval of progesterone-impregnated controlled intravaginal drug-releasing devices (CIDRs) for use in lactating dairy cattle in a number of

countries there have been many studies evaluating their effectiveness in the treatment of COF. Treatment with these CIDRs reduces LH secretion, results in regression of the cystic structure, and initiates a new follicular wave following removal of the implant. Progesterone has been shown to reestablish the normal feedback mechanisms involving the hypothalamic–pituitary–ovarian axis and allow cows with COF to resume normal cyclicity. The precise mechanism for how that occurs remains somewhat elusive, but the following model proposed by Todoroki et al. is the current hypothesis. Progesterone released from the CIDR raises circulating progesterone levels to those comparable with levels during the normal luteal phase. This heightened level of progesterone induces atresia of the cystic follicles by lowering the LH pulse frequency. This then allows for relief from the inhibitory effects of elevated estradiol and inhibin produced by the cystic follicle so that emergence of a new follicular wave can occur. Additionally, progesterone prevents excessive growth of the emerging dominant follicle and allows for turnover of follicles at normal intervals by suppressing LH secretion. Progesterone is believed to be able to restore the hypothalamic–pituitary–ovarian axis to produce an adequate LH surge in response to elevated estradiol production by the dominant follicle following removal of the progesterone source [16, 47–49]. The duration of progesterone treatment which is sufficient to reestablish the normal feedback mechanism involving the hypothalamic–pituitary–ovarian axis appears to be as short as three days [50].

Progesterone can be used as the sole treatment for COF. There were comparable pregnancy rates in cows with COF who were treated with the Ovsynch protocol and bred via artificial insemination (AI) versus cows who received a CIDR for seven days with a prostaglandin injection on removal and bred via AI after heat detection, suggesting that CIDRs alone can be effective in treating cows with COF [51]. CIDRs can also be used very effectively in the treatment of COF when combined with the Ovsynch protocol mentioned later in this chapter.

Todoroki et al. [47] studied the effects of using CIDRs for the treatment of superovulated beef-cow donors who were diagnosed with follicular cysts and found favorable results. Over a period of two years, 28 cows were diagnosed with COF and treated with a CIDR for 14 days. After removal of the CIDR all cows exhibited estrus behavior and ovulated between 2 and 10 days following CIDR removal and subsequently formed corpora lutea. In 18 of 28 (64%) treated cows that showed initial recovery, the COF condition did not recur after repeated embryo recovery attempts. However, the COF condition did recur in 10 of 28 (36%) cows after the next embryo recovery [47].

The use of CIDRs in place of traditional prostaglandin for synchronization of estrus after embryo recovery reduced the incidence of follicular cysts in superovulated beef-cow donors [47]. Immediately after embryo recovery, a CIDR was placed in the vagina of each cow and left for 14 days. Todoroki et al. [47] showed that when CIDRs were used in place of prostaglandins for synchronization of estrus after embryo recovery, there was a marked reduction in the number of cows subsequently diagnosed with COF. In year one of the study of 61 donors, of which 22 had a history of COF, only two developed COF. In year 2 of the study, among 54 donors, of which 17 had a history of COF, no cows developed COF. CIDRs proved effective both in the treatment of COF and in lowering the incidence of COF in beef-cow donors, where it was used in place of prostaglandin for synchronization of estrus after embryo recovery.

Progesterone clearly appears to have some healing effects on the functions of the hypothalamic–pituitary–ovarian axis in cows with COF [46–48]. The use of progesterone either alone or in conjunction with other hormonal therapy can be very effective in treatment of cows diagnosed with COF.

Prostaglandins

Prostaglandins are limited to the treatment of luteal cysts as their use has no effect on follicular cysts. Once a follicular cyst undergoes lutenization, it will become a luteal cyst and would then become responsive to prostaglandins [1, 2, 7, 41]. The ineffectiveness of prostaglandin use in the management of follicular cysts emphasizes the importance of accurate diagnosis prior to using prostaglandins as a single modality treatment option. Following prostaglandin treatment of luteal cysts, regression of the cyst occurs, with estrus occurring in 90% of cows by day 8 following treatment [2]. In cases where a determination of the exact cyst type is not made or cannot be determined before initiation of treatment, it is recommended to give prostaglandins concurrently with GnRH. This allows for the most efficient treatment of any cyst that is a luteal cyst while also appropriately treating all follicular cysts. It has also been shown that the simultaneous use of GnRH and prostaglandins at the initiation of the Ovsynch protocol in lactating dairy cows with COF showed improved pregnancy rates over the standard Ovsynch protocol and rates comparable to normal controls when heat detection and AI were used [9].

Ovsynch Protocol

Numerous protocols have been reported involving a series of hormonal injections aimed at treating COF and restoring the cow to normal cyclicity [1, 8, 51–54]. It has been shown that progesterone levels in cows with COF that were treated with a single injection of GnRH are elevated at five days following treatment. This indicates that the Ovsynch protocol can be

used with good results [52]. The classic Ovsynch protocol has been used in the treatment of cows with COF. Pregnancy rates observed following Ovsynch treatment of those cows varied from 17 to 25% [54, 55]. The rationale for and benefit of using the Ovsynch protocol to treat cows with COF is that it should work regardless of the specific cyst type and should provide an opportunity to inseminate the cow without the need for heat detection [8, 51–54]. This flexibility has allowed the Ovsynch protocol to gain popularity because it is familiar to many producers and because of its "one size fits all" usefulness regarding treatment of cows with COF regardless of the specific cyst type.

As mentioned in the section "Prostaglandins," combined treatment with GnRH and prostaglandin increased the number of cows with COF that responded appropriately to an injection of prostaglandin 14 days later. Utilizing both hormones at initiation of the Ovsynch protocol allows for any cow with luteal cysts to be treated in the most efficient manner possible.

Combining the Ovsynch protocol with a CIDR for treating cows with COF is very effective. This combination alters the endocrine state to allow recruitment of a new follicular wave, causing COF turnover and resetting the hypothalamic–pituitary axis, with the added benefit of allowing fixed-time artificial insemination (FTAI). The combination of the additional progesterone provided by the CIDR should assure all cows are exposed to its beneficial effects. Results have shown an increase in pregnancy rates in cows with COF that were treated with Ovsynch plus CIDR (37.5% pregnancy rate) over cows treated with Ovsynch alone (16.7% pregnancy rate) [53].

Additional Therapies

Two reports evaluating the effectiveness of the opioid antagonist naloxone as a treatment for COF have been published [56–57]. It has been shown that stress may be a contributing factor in the pathogenesis of COF in cattle. Endogenous opioid peptides are involved in many responses to stress, including the regulation of various endocrine systems [56]. Endogenous opioid peptides are believed to block the release of GnRH from the hypothalamus as well as the estrogen-induced LH surge [58]. It has been shown that administration of the opioid antagonist naloxone results in elevated LH release in cattle under various stressful states [59]. When naloxone was combined with an injection of the GnRH agonist buserelin in treatment of cows with COF, 77.5% of the treated cows had begun cystic regression, as viewed with ultrasonography, or had begun cycling normally within two weeks after treatment [56]. In a subsequent small study, cows with COF were treated with naloxone and demonstrated improved pregnancy rates (numerical), but the increase was not considered statistically significant [57]. Before this therapy can be recommended a much larger and statistically powerful study is warranted to evaluate naloxone as a treatment for COF in cattle.

Associations

Numerous risk factors have been associated with the formation of COF. The association between high milk production and the incidence of COF has been noted for over 50 years. Most studies show that there is either a positive association with increased milk production and the incidence of COF or no association with increased milk production and the incidence of COF. However, it should be noted that no study to date has shown that as milk production increases, the incidence of COF goes down. As cows are increasingly selected for high milk production and are pushed metabolically to meet their lactation potential, stressors associated with these demands contribute to the formation of COF. Whether the association between milk production and COF formation is a cause-and-effect relationship has not been clearly identified yet.

During early lactation, dry matter intake is often insufficient to meet the nutritional demands of lactation. The ensuing nutritional imbalance results in an increase in NEFA from the mobilization of adipose tissue to ultimately lead to production of ketones (primarily beta hydroxybutyrate), which serve as a key indicator of negative energy balance. High levels of NEFA have been shown to have a detrimental effect on follicular growth and appear to be involved in the development of COF [60]. The use of bovine somatotropin does not appear to be associated with any increased incidence of COF in dairy cattle [61, 62].

A study attempting to identify risk factors associated with postpartum COF formation showed that the condition was most commonly seen in cows calving in the summer months, higher-producing dairy cattle, older cattle, and cows that increased in body condition immediately preceding calving [9]. The presence of COF in the early postpartum period was the single greatest risk factor for the presence of COF at the time of insemination in dairy cattle. The risk of having COF at the time of insemination was 36.6% higher for cows that had developed COF early in the postpartum period [9]. These findings would seem to suggest that treatment of multiparous cows with COF early in the postpartum period would be beneficial, whereas younger cows could be delayed until the end of the voluntary waiting period to allow for spontaneous resolution [9]. Dairy cows that were identified as having had an abnormal puerperium were 1.9 times more likely to develop COF in the postpartum period. Also, cattle that had a 1-unit increase

in body condition score in the prepartum period were 8.4 times as likely to develop COF [8]. Dairy cows that deliver twins were 2.0–2.7 times more likely to develop COF in the postpartum period compared with cows that did not deliver twins, suggesting that delivery of twins may predispose the cow to COF in the subsequent lactation [63, 64].

Metabolic factors that have been shown to be associated with increase in the incidence of COF include overconditioned cattle, reduction in insulin and IGF-1, and increased non-esterified fatty acids [5, 7]. Recent studies have proposed that imbalances in hormones such as insulin, leptin, and adiponectin as well as several metabolites such as glucose, non-esterfied fatty acids (NEFA), and some amino acids have been put forward [65]. Additional factors that have been shown to be associated with COF formation but without a clear causal relationship include heat stress, utilization of bulls with high genetic merit for fat and protein, high stocking rates in barns, and melengestrol acetate use in beef heifers [66, 67].

There is a genetic predisposition for COF in dairy cattle, although the heritability is low at 0.07–0.12 [68, 69]. Certain cow families in the dairy breeds appear to have a higher incidence of COF than their contemporaries. Swedish workers showed that when sires were removed from the breeding pool after producing daughters that developed COF, they could significantly reduce the incidence of COF from 10 to 3% [70]. An aspirational goal would be to select cow families both with high milk production and that show little genetic predisposition to the development of COF. Genetic selection as a means of prevention of COF can be effective. One must weigh the impact of such selection, as often milk production will be selected against as well.

Summary

Efforts to reduce the incidence of common postpartum diseases and stress should be the focus of prevention strategies. Prompt diagnosis with the use of ultrasound should allow for early recognition and the selection of effective treatments. The simultaneous use of GnRH and a prostaglandin should be considered especially when the type of cyst is unknown, as this combination allows for efficient treatment regardless of the cyst type. Efforts moving forward should be focused on minimizing the contributing factors that have been associated with COF formation and treating cows in a prompt time frame to assure they can be available for breeding in a timely manner to avoid the economic losses associated with this condition.

Postpartum Anestrus and Its Management in Dairy Cattle

Divakar J. Ambrose

Livestock Research Branch, Alberta Agriculture and Forestry, and Department of Agricultural, Food and Nutritional Science, University of Alberta, Edmonton, Alberta, Canada

Introduction

Postpartum anestrus refers to a condition where cows have not been observed or reported in estrus for several weeks after calving, often to the end of the voluntary (elective) waiting period, in dairy cattle. While a short period of ovarian inactivity during the immediate postpartum period is normal, extended anestrus in non-suckled cattle such as dairy cows could have negative ramifications on the timely reestablishment of pregnancy [1–4]. Postpartum anestrus has been recognized as a problem by animal scientists for several decades. According to one source [5], anestrus in cattle was first reported as a reproductive problem back in the 1920s [6]. There has been significant interest in the past two to three decades in the understanding and management of postpartum anestrus, both in beef and dairy cows [5, 7–14]. Nevertheless, postpartum anestrus continues to be a challenge to dairy practitioners and farmers alike. This chapter will focus primarily on the problem of postpartum anestrus and its management in dairy cattle, although references to the condition in beef cattle will be made where appropriate.

Fertility of the High-Producing Dairy Cow

The modern dairy cow is an important livestock species with a remarkable ability to produce tens of thousands of liters of milk during her lifetime. Understandably, the profitability of dairy farming largely depends on the reproductive success of dairy herds [15, 16]. However, suboptimal fertility of the modern dairy cow is a problem that afflicts the dairy industry worldwide [17–21], with reproductive failure often being the primary reason for culling dairy cows [22–24]. While the reasons for declining fertility in dairy cattle will remain debatable, it is important to bear in mind that the modern dairy cow is physiologically quite different from her counterparts of past decades [19], calling for new and improved strategies of reproductive management to maintain or enhance reproductive success. An extended period of postpartum anestrus is one among the many factors contributing to poor reproductive efficiency in dairy cattle. Rajala-Schultz and Gröhn [25] showed that if a cow had not been inseminated at all, her risk of culling was 10 times higher than if she had been inseminated at least once. While a deliberate managerial decision to not breed a cow, due to past history, may have directly contributed to this increased culling risk, anestrus could also have increased the risk, emphasizing the importance of detecting cows in estrus and having them bred in a timely manner.

Prevalence and Implications of Postpartum Anestrus

The prevalence of postpartum anestrus in dairy cattle is herd-specific and varies widely from one herd to another. However, typical prevalence rates at the end of the elective waiting period (60–80 days after calving) are in the range 10–30% [26–31], whereas higher rates of up to 59% have been reported in individual herds [19, 28, 30]. In a Canadian study involving 23 herds, milk progesterone concentrations were measured twice weekly in 637 cows to determine the onset of cyclicity, starting approximately from 7 to 90 days after calving [31]. The overall mean interval from calving to first rise in progesterone, indicative of an ovulation, was 32.0 ± 0.7 days. The cumulative percentages of cows initiating cyclicity by 3, 6, 9, and >9 weeks after calving are shown in Figure 34.1.

In a more recent study [32] on 748 Canadian Holsteins from two herds, commencement of luteal activity was determined based on milk progesterone concentrations

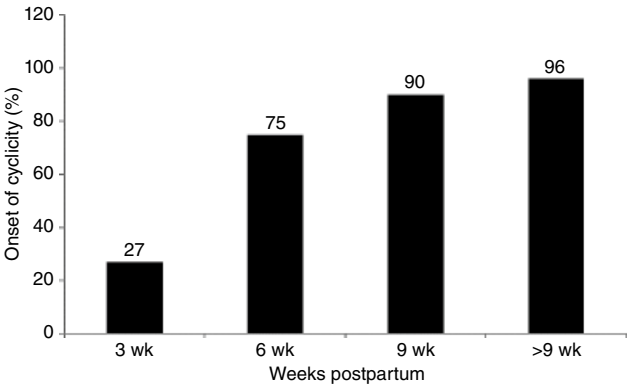

Figure 34.1 Onset of cyclicity (data presented as cumulative percentages) in 637 dairy cows (23 herds) by 3, 6, 9, and >9 weeks postpartum determined based on milk progesterone concentrations quantified twice weekly from 7 up to 90 days postpartum or until first service, whichever occurred earlier. Mean interval from calving to first rise in progesterone (indicative of first ovulation) was 32.0 ± 0.7 days (range 5–113 days). *Source:* [31].

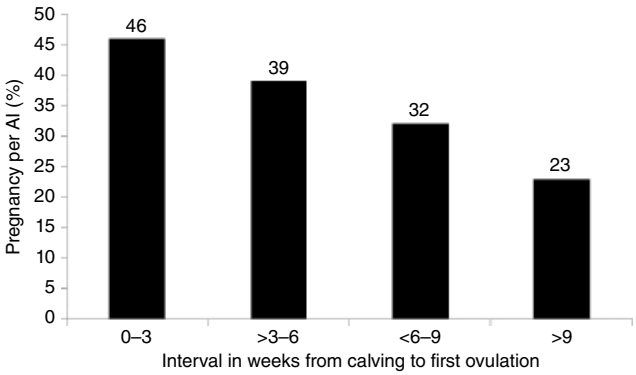

Figure 34.2 P/AI to first service by interval from calving to first ovulation in 637 cows (23 herds) determined based on rise in milk progesterone concentrations quantified twice weekly from 7 up to 90 days postpartum or until first service, whichever occurred earlier. The first rise in progesterone was indicative of ovulation. Cows that had the first rise in progesterone within three weeks after calving had the highest ($P < 0.03$) P/AI to first service. *Source:* [31].

using an automated in-line milk analysis system (Herd Navigator™, DeLaval International, Tumba, Sweden). The proportions of cows determined to have commenced luteal activity earlier than 4, 5, 6, 7, 8, and 9 weeks postpartum were 27, 53, 68, 77, 84, and 89% (cumulative percentages) in the aforesaid study, respectively. Although these collective findings suggest that postpartum anestrus is not necessarily a huge problem because approximately 90% of the cows had initiated cyclicity by 9 weeks – the typical end of the elective waiting period – it is important to note that cows that initiated cyclicity during the early postpartum period had higher pregnancy per artificial insemination (P/AI) at first service (Figure 34.2). Similar findings have been reported by others [1, 2, 4, 27]. Bruinjé et al. [32] found that the proportion of cows commencing luteal activity later than 28 days postpartum was greater among primiparous than multiparous cows (79.1 vs 68.6%; $P < 0.01$); the same trend was evident later in lactation when more primiparous than multiparous cows (13.1 vs 8.3; $P < 0.05$) remained acyclic beyond 63 days postpartum, indicating the influence of parity on anestrus.

The biggest impact of postpartum anestrus is the extension of the interval from calving to conception, which consequently impacts the calving interval. Whereas high-producing dairy cows that fail to return to estrus and conceive soon after the end of the elective waiting period may continue to remain profitable for a period of time, cows with lower production that remain acyclic for an extended period, resulting in delayed conception, are often unprofitable and become potential targets for culling.

Physiological Basis for Postpartum Anestrus and Resumption of Cyclicity

Endocrine Events Leading to Anestrus

During gestation, circulating progesterone and estrogen concentrations remain high, exerting a suppressive effect on the hypothalamic–pituitary axis [33]. Although peripheral progesterone concentrations in late gestation are not much higher than that of mid-luteal or early gestational periods [34, 35], circulating estrogens progressively increase, starting at about 60 days of gestation and reaching 50- to 1000-fold higher concentrations in the days immediately preceding parturition [34, 36, 37]. The sustained long exposure to high concentrations of estradiol, either by itself or in tandem with progesterone, inhibits hypothalamic gonadotropin-releasing hormone (GnRH) secretion, which negatively affects the synthesis of luteinizing hormone (LH), leading to a gradual depletion of pituitary LH reserves. Although the mechanisms for release of LH from the anterior pituitary gland remain intact and functional throughout pregnancy [33], the absence of pulsatile GnRH secretion from the hypothalamus is what appears to negatively impact LH production.

Unlike LH, changes in the concentrations of follicle stimulating hormone (FSH) during late gestation are less remarkable. While mean FSH concentrations do not differ between prepartum and postpartum periods [34, 38], the recurrent rise (surge) and fall of FSH that typically occurs every few days in cyclic and pregnant cows is largely absent [34] or slowed down [38] during the last weeks preceding parturition. Consequently, the associated

follicular wave emergence is also absent during the last 30 days before parturition [38].

Whereas it is possible to restore the pulsatile release of LH under experimental conditions by administering low-dose GnRH injections at frequent intervals (one to two hours), not all cows respond to such treatment. Because of the inconsistent response to such an approach, it is believed that the inhibition of GnRH secretion is perhaps not the only mechanism involved in anestrus [5].

Endocrine Events Leading to the Resumption of Cyclicity

As parturition approaches there is a gradual decrease in progesterone concentrations. In contrast, estrogens keep rising and attain peak concentrations during the last 24 hours prior to parturition [36, 37]. Since almost all circulating estrogens are of placental origin, their concentrations plummet sharply after expulsion of the conceptus, reaching basal levels within one day after calving [36, 37]. In the absence of progesterone and estradiol in the immediate postpartum period, the hypothalamic–pituitary axis is "liberated" from the suppressive effects of these steroids, resulting in the restoration of normal function of the GnRH pulse generator and the resultant pulsatile release of GnRH, which acts on the pituitary to restore a normal pattern of FSH release. Normal FSH surges resume within three days after calving, triggering the emergence of a follicular wave [34]. Whereas early stages of follicle development are gonadotropin independent, FSH support is required for the growth of follicles from 4 to 9 mm and LH pulses are indispensable for continued growth of follicles beyond 9 mm in diameter [39, 40].

During the early postpartum period the LH pulse frequency remains very low, generally less than one pulse every four hours, which later increases to about one to two pulses per hour as GnRH pulsatility increases. The restoration of pituitary function and reaccumulation of LH could take up to three weeks or longer depending on several factors. Thus, when conditions are optimal for pituitary LH reserves to be replenished, normal LH pulsatility is restored, leading to the growth and establishment of dominant follicles capable of producing greater quantities of estradiol. A high concentration of estradiol from the dominant follicle is essential to trigger an LH surge, which is critical for the first ovulation to occur. Although the first ovulation signals resumption of cyclicity, not all cows would resume normal ovarian cycles following the first ovulation; at least some cases could return to anestrus [41].

If cows are challenged with either exogenous GnRH or estradiol during the early postpartum period, not only is LH release greatly diminished due to lack of pituitary LH reserves, but also its bioactivity is lowered [5]. Kisspeptin – a more recently discovered neuroendocrine regulator of reproduction – controls GnRH synthesis in the hypothalamus, and subsequently influences LH release in many species including cattle [42]. Exogenous administration of kisspeptin induced ovulation in seasonally anestrous ewes [43] and both GnRH and LH responses to kisspeptin were greater in anestrous ewes than in cyclic ewes during luteal phase [44]. Although little is known about the direct role of kisspeptin in the cessation of postpartum anestrus in cattle, at least one study has presented evidence to suggest that kisspeptin plays a key role in the resumption of cyclicity after pregnancy-induced anestrus in dairy cows [45].

Fate of the First Dominant Follicle

The fate of the first dominant follicle in the postpartum cow is determined by the pulsatile LH support it receives and by its own steroidogenic capacity to produce estradiol. Depending on these factors, the first dominant follicle may (i) ovulate and form a corpus luteum (CL); (ii) become anovulatory, possibly developing into a cystic follicle; or (iii) regress, making way for a new dominant follicle [46, 47].

Classification of Postpartum Anestrus

Postpartum anestrus can be classified into different types based on either ovarian follicle dynamics or progesterone profiles.

Categorizing Anestrus Based on Ovarian Follicular Dynamics

The classification of anovulatory conditions in cattle based on three functionally critical follicular diameters relating to emergence (~4 mm), deviation (~9 mm), and ovulation (10–20 mm) has been proposed [48]. With the above classification as the basis, four types of anestrus, types I to IV, were described by Peter et al. [13] (Figure 34.3).

In type I anestrus, there is growth of follicles up to emergence but no deviation occurs, resulting in lack of selection of a dominant follicle. This type of anestrus is presumed due to extreme malnutrition, which could exert a negative effect on FSH production, suppressing follicular growth, although other factors could also be involved. Ovaries under this type may be described as either "inactive" or "smooth" as a reference to the lack of palpable ovarian structures during reproductive examinations per rectum. An Israeli study [49] from the 1980s reported an incidence of 8.5% inactive ovaries from 7751 lactations. While type I anestrus is not widely seen in well-nourished dairy cattle in

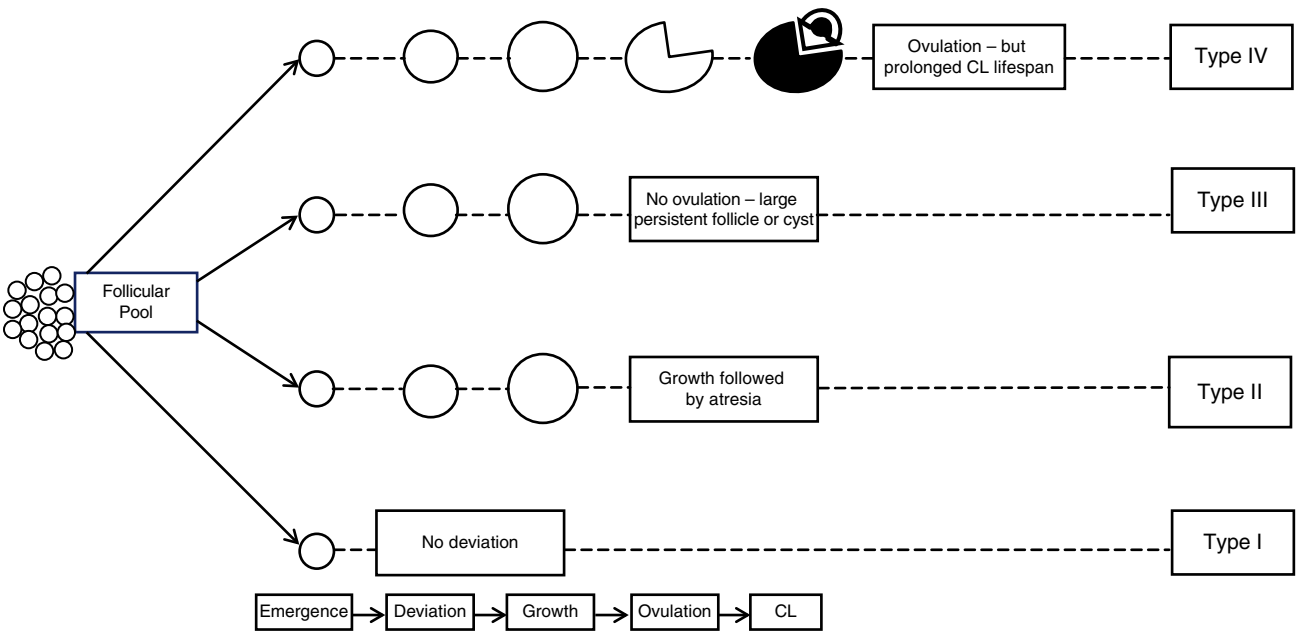

Figure 34.3 Schematic representation of types of anestrous conditions based on ovarian follicular dynamics. *Source:* Modified from [13].

the USA and Canada, this type of anestrus could be more prevalent in regions of the world where balanced energy-dense rations are unavailable to dairy cattle.

In type II anestrus, both follicular deviation and growth occur, followed by regression, in some cases, after a follicle attained dominance. Regression of a dominant follicle is usually followed by the emergence of a new follicular wave, two to three days later. In this type of anestrus, there may be sequential emergence of follicular waves prior to the eventual occurrence of the first ovulation. Up to nine waves of follicular growth have been reported in one study [50].

In type III anestrus, deviation, growth, and establishment of a dominant follicle takes place, but the dominant follicle fails to ovulate, becoming a persistent structure which may either linger as an anovular follicle or continue to grow and develop into a cystic follicle. Anovular follicles are considered different from cystic follicles because in cows with the latter condition there is disruption of the feedback mechanisms in the hypothalamic–pituitary axis [51]. The secretory pattern of LH in cows with cystic ovarian follicle is quite different from that in normal cyclic cows in that mean concentrations of LH, frequency of LH pulses, and amplitude of LH pulses are all higher [52]; in addition, in cows with an actively growing cystic follicle, the estradiol concentration is significantly higher [53, 54]. A cystic follicle that is growing actively usually exerts dominance, suppressing the growth of other follicles. Upon retrospective analysis of data obtained from twice-weekly ovarian ultrasonography (7–35 days after calving), on eight lactating dairy cows that developed cystic ovarian follicles, a first-wave dominant follicle became cystic in seven cows, and a second-wave dominant follicle became cystic in one cow. No other follicle greater than about 5–6 mm diameter was detected on either ovary of cows until the cystic follicle turned over. In five cows, the cyst persisted until (possibly beyond) day 35; in two cows, the initial cystic follicle was replaced by another one; in one cow two follicles from the second follicular wave became dominant around day 30, at which time the original cyst had regressed under 20 mm diameter, giving way for both dominant follicles to ovulate (Divakar J. Ambrose, personal observations).

In type IV anestrus, a dominant follicle ovulates and forms a CL, but the luteal phase is prolonged due to the absence of timely luteolysis followed by CL regression. Aberrant follicular growth patterns resulting in the absence of an estrogenic dominant follicle at the ideal time to trigger luteolysis could be a reason for this condition of persistent CL [48].

Categorizing Anestrus Based on Progesterone Profiles

Cows can also be classified into different categories of anestrus based on progesterone measured in milk or blood at least on a twice-weekly basis. Using twice-weekly measurement of progesterone in milk fat on 334 dairy cows from six herds, Opsomer et al. [55] reported that 51% of the cows had a normal progesterone profile with the first rise in progesterone occurring before 50 days after calving, followed by regular cyclicity. Among the remaining popula-

tion, 21.5% of the cows had delayed cyclicity (anestrus for the first 50 days after calving, characterized by consistently low progesterone during that entire period), 21.5% had prolonged luteal phase (progesterone remained elevated for >20 days without a preceding insemination), 4% had cessation of cyclicity (normal cycles interrupted by at least 14 days of consistently low progesterone concentrations), 0.5% had short luteal phases (characterized by more than one luteal phase, excluding the first luteal phase, that was shorter than 10 days' duration), and 1.5% of the cows had irregular progesterone profiles (atypical profiles, that did not belong to any of the previously described categories).

Factors Contributing to Postpartum Anestrus

The causes of postpartum anestrus in cattle are often multifactorial [5, 8, 10, 12, 13, 47, 56–60] but can be broadly categorized into physiological, nutritional, managerial, environmental, and pathological, as detailed in Table 34.1 (and Figure 34.4). Among the numerous potential contributors, suckling and nutrition (negative energy balance) are considered the most important.

Suckling

Suckling is a major contributor to anestrus in beef cattle [56], but it is generally not considered a cause for anestrus in dairy cattle because of the prevailing industry practice of separating dairy calves from the dam soon after birth.

However, under experimental conditions when identical twin pairs of dairy cows were assigned to either suckling by multiple calves or twice-daily machine milking, the suckled cows had a five- to nine-week longer interval to first estrus after calving than their machine-milked twins. Basal plasma concentrations of LH did not differ between suckled and machine-milked twins, yet GnRH-induced LH release increased progressively in machine-milked cows from weeks zero to six after calving, and the LH response at two weeks after calving was significantly higher in machine-milked cows than in their suckled twins [90]. Estradiol-17β-induced LH release within 24 hours after treatment was delayed by up to 6 weeks in suckled cows compared with their machine-milked twins, indicating that the response of the hypothalamic–pituitary axis to both GnRH and estradiol-17β is impaired by suckling. In another study [91], suckled dairy cows had lower mean LH

Table 34.1 Direct and indirect causes of anestrus in cattle.[1]

Causal factor	Comment
Physiological	
Suckling	Suckling suppresses episodic LH secretion, thereby delaying ovulation [56, 59, 61]. Suckling is a major contributor to postpartum anestrus in beef cattle, but not so in dairy cattle because dairy calves are usually separated from the dam soon after birth
Parity	Parity as a risk factor for anestrus has been reported in numerous studies [32, 55, 57, 62]. Most reports suggest that first-parity cows are at a higher risk of anestrus due to delayed first ovulation. Multiparous cows, particularly those with four or more calvings, are reportedly at a significantly higher risk for anestrus due to prolonged luteal phases. The reason may be that with increasing parity the uterus takes more time to return to its pregravid size, thereby increasing the risk of pyometra and persistent CL [55]
Milk yield	Although high milk production has been identified as a risk factor for anestrus by some researchers [30, 62, 63], others have not found such an association. In one study [30], the probability of anovulation decreased by 2% for every 100-kg increase in the first 305-day mature-equivalent milk projection between 5000 and 9500 kg, and the risk of anovulation did not change as first 305-day mature-equivalent milk production increased above 9500 kg. Similarly, another large study [62] found that cows with lower daily average milk yield in the first 90 days postpartum (32.1 vs 39.1, 43.6, 50.0 kg/day) were at higher risk for anestrus. It is unlikely that high milk production itself is a cause for anestrus; however, the inability to meet energy requirements leading to negative energy balance, a common problem in lactating dairy cows, is the most likely reason
Ratio of increase in milk yield	The ratio of increase in milk yield from the first week postpartum to the week when milk yield reached its peak is reportedly smaller in ovular than in anovular cows [64]
Social or chemical cues	In beef cattle, the interval from calving to resumption of cyclicity is significantly reduced by the presence of bulls [65]. In one study, the exposure to bulls in the early postpartum period had an acute effect on LH release in anestrous dairy cows [66]. Likewise, the presence of other estrous females or exposure to cervical mucus collected from estrous cows can shorten the duration of postpartum anestrus [67], particularly in cows with extended anestrous periods

Table 34.1 (Continued)

Causal factor	Comment
Breed	The influence of breed or type (genetic) differences on the interval from calving to commencement of luteal activity has been reported in dairy [68], beef [57], and crossbred cattle [68, 69]
Nutritional	
Malnutrition	Severe feed restriction will induce anestrus in cattle. In one study [70], non-lactating beef cows placed on a restricted diet formulated for 1% of body weight loss each week became anestrous after 26 weeks and lost 24% of their initial body weight. Estrous cycles resumed about 9 weeks after cows were returned to a diet that was 160% of the maintenance diet given to control cows. Anestrus was associated with a decrease in the frequency of LH pulses
Negative energy balance	Cows in negative energy balance are at a very high risk of anestrus and delayed onset of cyclicity [11]. Elevated circulating concentrations of non-esterified fatty acids are associated with adipose tissue mobilization and indicative of negative energy balance
Body condition and rate of loss of body condition	A body condition score (BCS) of less than 3.0 on a 1–5 scale is commonly an indicator of negative energy balance [55, 62]. Cows with low BCS are more likely to be anestrous and it has been reported that the influence of body condition on the duration of postpartum anestrous period is mediated through differences in LH pulse frequency [71]. Cyclic cows with low BCS tend to have poor P/AI and higher embryonic losses [62, 72, 73]. A higher rate of body condition loss has been associated with extended intervals from calving to resumption of cyclicity or first service [74–76] (Figure 34.4)
Managerial	
Length of previous dry period	Cows having a dry period longer than 77 days were almost three times more at risk of anestrus and delayed ovulation [55]. In contrast, the interval from calving to first ovulation in cows given no dry period (fed a high-energy diet continuously) compared to those given a 56-day dry period (fed a low-energy diet from 56 to 29 days prepartum followed by a moderate-energy diet for the last 28 days) was significantly shorter (13.2 vs 31.9 days) [77, 78]
Increased milking frequency	Increasing the frequency of milking from twice to three or four times daily lengthens the interval from calving to first ovulation by less than a week. When milking frequency is increased from three to six times daily, the interval to first ovulation is lengthened, but still not to the same extent as that of frequent suckling [59]. Therefore increased milking frequency is only a minor contributor to anestrus
Efficiency of estrus detection	Unobserved estrus due to poor estrus detection efficiency can frequently contribute to anestrus [31], exacerbating the severity of the condition
Feed and feeding management	Inadequate dry matter intake is one of major reasons for cows entering a state of negative energy balance [47, 79, 80]. Maximizing dry matter intake through particle size management, frequency of feed delivery (more than one feed), grouping cows by parity/production levels/social order, feed bunk management (e.g. frequent push-ups), discouraging sorting behavior by adding water, and avoiding overstocking are some examples of strategies to improve dry matter intake, thereby reducing negative energy balance
Environmental	
Calving season	Cows calving in the winter have delayed resumption of estrous cycles compared with those calving in the summer [7, 30, 55]. While some of the variations attributed to season are likely due to seasonal differences in management, photoperiod does seem to play a role in the regulation of postpartum cyclicity
Weather	Under extreme hot and humid conditions, cows have reduced expression of estrus [7], which contributes to an increase in anestrus due to subestrus and silent estrus
Social hierarchy and stocking density	Social hierarchy (e.g. presence of dominant cows) could be a factor that has detrimental effects on feed intake, particularly in overstocked barns. It is not uncommon to see "bullying" among cows. The subordinate or the "bullied" cows frequently end up eating leftover feed which may be of poor quality as it is likely to have been sorted through. Such cows are at higher risk for negative energy balance, and thus anestrus [81]

(*Continued*)

Table 34.1 (Continued)

Causal factor	Comment
Housing type	Cows under intensive housing systems compared with those on pasture have a higher risk of anestrus. Tie-stalled cows are more likely to be declared anestrus than cows in other types of housing [57]; one reason is that lactating cows housed in tie-stalls fail to manifest activity changes during estrus [82], likely increasing anestrus due to unexpressed or unobserved estrus
Stall design (cow comfort)	Poorly designed stalls (e.g. lack of lunge space) would limit the frequency of accessing feed bunk/manger, negatively affecting dry matter intake, predisposing cows to negative energy balance and consequently anestrus
Stray voltage	Few studies have examined the effects of stray voltage on reproductive function in cattle. Although no direct evidence of stray voltage on impairment of ovarian function could be found, it is a potential contributor to anestrus, as bothersome stray voltage in and around the feeding area could be a deterrent to feed intake
Pathological	
Uterine inflammation	Cows with acute forms of metritis and those with severe bacterial contamination of the uterus have delayed resumption of cyclic ovarian activity [55, 83]. The mean interval from calving to first ovulation was longer (45 vs 32 days) in cows that were determined to have uterine inflammation (based on higher proportion of polymorphonuclear [PMN] cells at endometrial cytology performed on day 25 postpartum) compared with cows with no uterine inflammation [84]. The cumulative pregnancy (percentage) at 270 days postpartum tended to be lower in cows with high PMN (58 vs 80) than in those with low PMN counts
Persistent corpus luteum	Cows with uterine infections accompanied by abnormal vaginal discharge are at much higher risk for anestrus due to prolonged luteal cycles [55]. However, prolonged luteal phases of >30 days' duration have been reported in cows that were not previously inseminated, even in the absence of any uterine infections [18, 85, 86]
Cystic ovarian follicle (COF)	Though not strictly a pathological condition, cows diagnosed with COF are often anestrous and anovulatory [87]. The precise etiology of COF is still not fully understood, but an aberration in LH secretory pattern is believed to trigger the formation of COF; cows with active COF have increased LH pulsatility, which is essential for continued growth of the cyst [51, 54]
Calving disorders	Dystocia, twinning, and retained placenta could predispose cows to anestrus [30, 55]
Metabolic disorders	Ketosis and displaced abomasum have been associated with delayed cyclicity and anovulation [30, 55], particularly in cows with subclinical ketosis during the first week postpartum [30]
Lameness	The increased risk of anestrus associated with lameness has been reported by many studies [55, 88, 89]
Mastitis	Mastitis by itself has been identified as a risk factor for anestrus [55]. Cows that suffered lameness and mastitis, or lameness and another severe stressor, were at much greater risk for delayed onset of cyclicity [89] than cows with mastitis alone
Other disease	Cows that developed pneumonia during the first month after calving were 5.4 times more at risk for delayed resumption of ovarian activity [55]. Numerous other types of systemic illnesses can contribute to the condition, as sick cows will have reduced dry matter intake, increasing their risk to enter a state of negative energy balance, and thereby anestrus

[1] This list should not be deemed complete and the references are representative citations only.

concentrations than non-suckled controls on day 13 after calving. This decrease resulted from a 60% reduction in the frequency and a 40% reduction in the amplitude of LH pulses. These authors concluded that decreased frequency and amplitude of episodic LH secretion and reduced capacity of pituitaries to respond to GnRH may account for suckling-induced inhibition of postpartum ovulation. For further reading on the effects of suckling on postpartum anestrus in cattle, please refer to reviews on the topic [56, 59, 60] and Chapter 24.

Nutrition

Inadequate consumption of dry matter (i.e. energy) resulting in negative energy balance is an important contributing factor to anestrus in dairy cattle [11, 47, 58]. Soon after calving, the energy needs of the newly lactating cow increase dramatically due to the higher energy requirements associated with milk production, pushing the cow into a catabolic metabolism. Energy balance is the net result of energy intake minus energy expended for maintenance, growth, and milk yield. Although dairy cows rarely enter into a state of

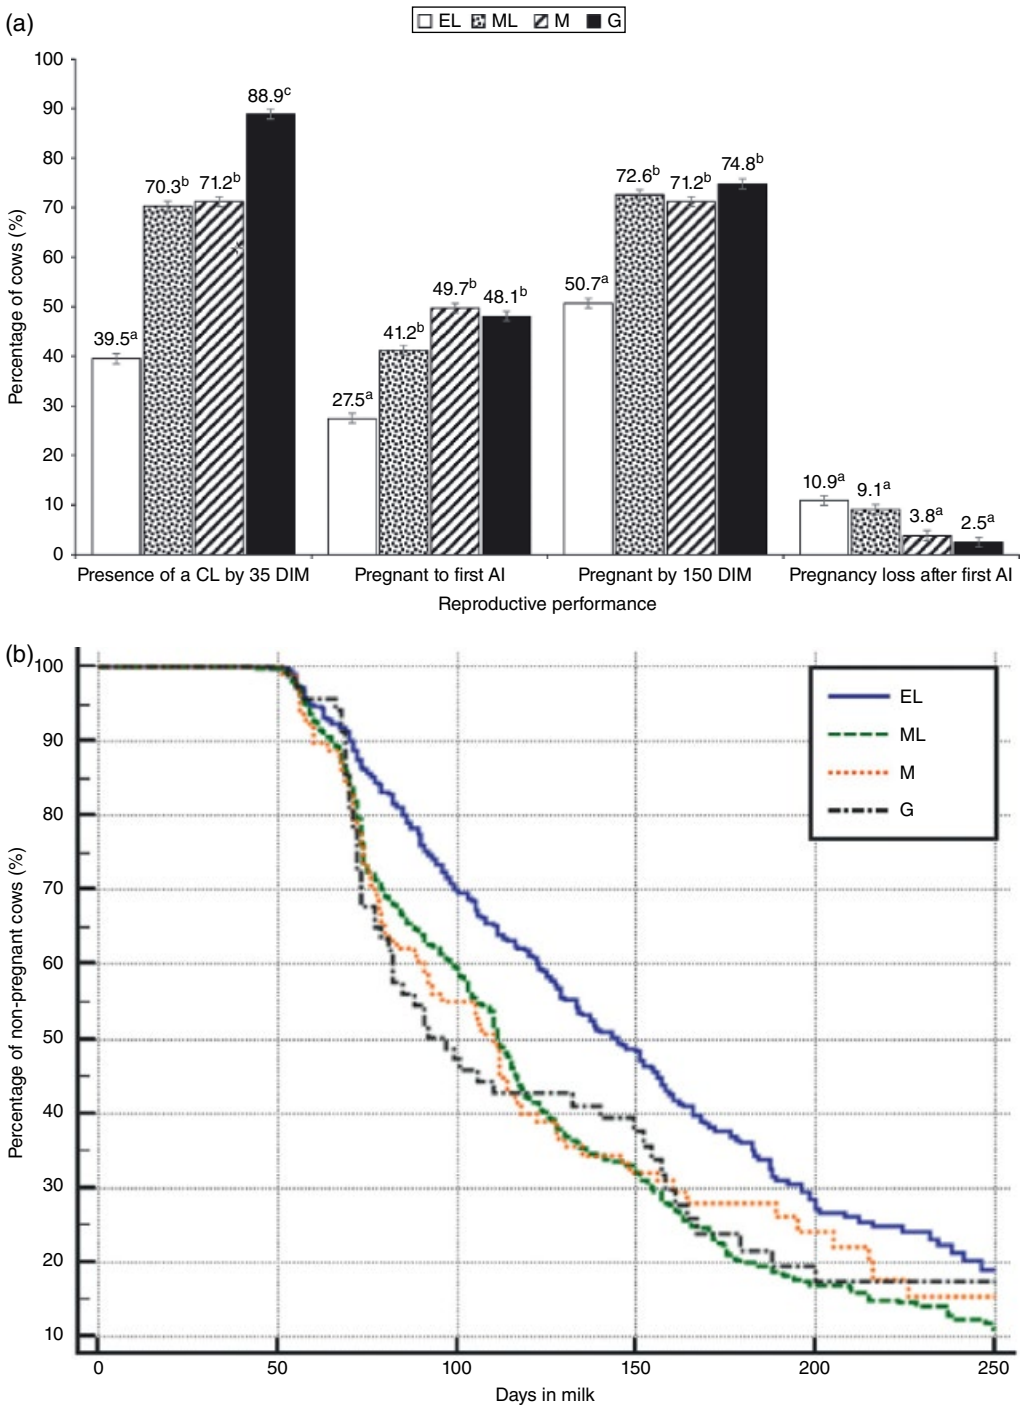

Figure 34.4 Results of a study of 911 lactating dairy cows assessed for BCS on a 5-point scale (1 = thin, 5 = fat) with 0.25-unit increments, at approximately 10 days precalving and 35 days postcalving, and categorized according to BCS change between the two time points. Categories were: lost ≥ 0.75 points (extreme loss: EL; open bars), lost either 0.25 or 0.50 units (moderate loss: ML; dotted bars), no change in BCS (maintained: M; hatched bars), or gained ⩾0.25 units (gained: G; filled bars). (a) Association between postpartum BCS change categories and reproductive outcomes. Transrectal ultrasonography of ovaries was performed at 34.6 ± 4.0 days in milk (DIM) to determine presence of a CL at 30–35 days postinsemination to diagnose pregnancy, and cows pregnant at first examination were reexamined 3–5 weeks later to confirm pregnancy. Pregnancy loss was declared when a cow diagnosed pregnant at first examination was not pregnant at reexamination. Different superscripts within same reproductive performance cluster differed (a, b, c; $P < 0.05$). (b) Kaplen-Meier survival curve showing probability of pregnancy up to 250 DIM by postpartum BCS change categories. Overall hazard of pregnancy differed ($P < 0.01$) between postpartum BCS change categories. Hazard ratio of pregnancy was 0.65 (approximately 35% lower pregnancy risk) for cows in EL category compared with ML category ($P < 0.01$), indicating fewer cows that had extreme loss of BCS were pregnant at 250 DIM compared to those that had moderate loss. Hazard of pregnancy did not differ between cows in ML, M, and G categories. *Source:* From [76], © 2019, Elsevier.

negative energy balance during the dry period, except in the immediate prepartum period when dry matter intake declines, most lactating dairy cows are unable to meet their energy demands after calving and invariably become energy deficient. Physical fill in the rumen is one of the factors limiting maximum dry matter intake in early postpartum dairy cows. Even if dry matter intake is maximized, cows selected for high milk production (e.g. North American Holstein) selectively use all available nutrients for milk production at the expense of body condition [80]. Thus nutrient partitioning prevents cows from ending the catabolic state because all the available glucose is preferentially used up for milk synthesis [92]. Despite the advances made in the understanding of dairy cow nutrition and the availability of high-precision ration-balancing software, meeting all the energy needs of a lactating dairy cow continues to remain a challenge, placing cows in a state of negative energy balance that extends for 10–12 weeks into the postpartum period [11].

Dairy cows that are in negative energy balance have lower blood concentrations of insulin and insulin-like growth factor (IGF)-1. Low circulating concentrations of IGF-1 reduce the negative feedback on growth hormone (GH), resulting in an increase in GH concentrations.

Increased GH increases liver gluconeogenesis and promotes lipolysis (mobilization of adipose tissue), resulting in the release of non-esterified fatty acids (NEFAs). High concentrations of GH and NEFA antagonize insulin action, creating a state of insulin resistance in postpartum dairy cows [79, 92], which diminishes glucose utilization by non-mammary tissues, conserving glucose for milk synthesis. Negative energy balance is strongly associated with the postpartum anovulatory period through decreased LH pulse frequency and low concentrations of blood glucose, insulin, and IGF-1 that collectively limit estrogen production by dominant follicles [11] which is essential for the LH surge, thereby delaying ovulations.

High stocking density that increases competition for feed, poor stall design that discourage cows from getting up frequently to eat, physical barriers that limit free and continuous access to feed, infrequent feed push-ups, excessive sorting by cows that get to the feed first, and inadequate hoof care leading to high prevalence of lameness are indirect causes that can reduce dry matter intake. Furthermore, social hierarchy situations where younger or subordinate animals are intimidated by herdmates, stray voltage, slippery footing, and other deterrents can dissuade cows from comfortably accessing feed, limiting dry matter intake and predisposing cows to enter a state of negative energy balance.

Unobserved Estrus or Silent Estrus

Unobserved estrus is often a major contributor to anestrus, as many of the cows considered anestrous could in fact be cycling normally, yet are never seen or reported in estrus. There are two categories of animals:

1) Subestrus: cows that express poor estrous behavior (e.g. short-duration, low-intensity estrus) and get missed during routine estrus detection.
2) Silent estrus: cows that fail to express any overt signs of estrus.

Both categories of cows may ovulate spontaneously and develop a CL; however, because they were never seen in estrus, they are falsely categorized as "anestrus." Performing more frequent visual detection of estrus (say three to four daily periods of dedicated surveillance) and observing for secondary signs of estrus such as chin-resting, vulva sniffing, licking, tailgating, and partial attempts to mount, rather than strictly for "standing estrus," will increase the probability of detecting estrus in these cows. The first ovulation after calving is rarely preceded by overt estrous behavior; only 10–13% of dairy cows reportedly exhibit standing estrus prior to the first ovulation [41, 93], although this proportion increases significantly in the second and third ovulatory cycles (Figure 34.5).

The level of milk production could also influence the proportion of cows detected in standing estrus at first ovulation [41, 93, 94], with a higher proportion of low-producing cows detected in standing estrus at first ovulation (Figure 34.6).

As previously stated, cows that initiate cyclicity earlier in the postpartum period have better reproductive performance [1, 2, 4, 27, 31, 32]. Therefore it becomes extremely important to assess the ovarian status of postpartum cows at regular intervals to differentiate cases of "anestrus due to unobserved estrus" from those that are "true anestrus." This is discussed in more detail in the section "Managing Anestrus."

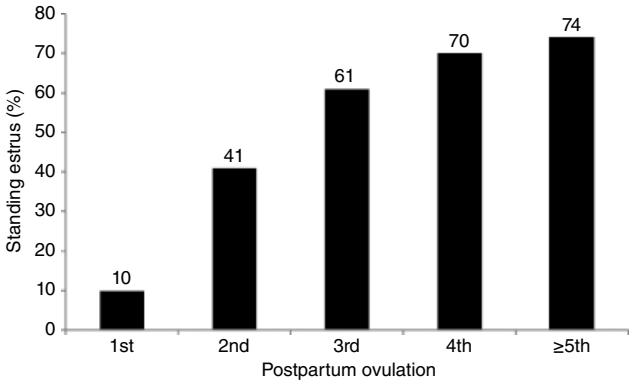

Figure 34.5 Frequency distribution of standing estrus behavior associated with first through fifth or greater postpartum ovulation in dairy cows. Standing estrus was associated with only 10% of first ovulations, but increased progressively at each subsequent ovulation. *Source:* Redrawn from [41].

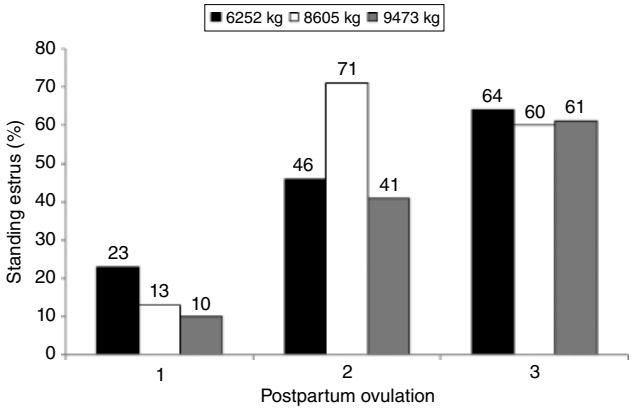

Figure 34.6 Frequency of occurrence of standing estrus and its association with level of milk production at first, second, and third postpartum ovulations. Percentage of standing estrus accompanying first ovulation was higher in cows with lowest annual production level of 6252 kg compared to those with higher production levels. Incidence of standing estrus at second and third ovulations increased substantially in higher-producing cows compared to that at first ovulation. *Sources:* Data are from references [41, 93, 94] for annual milk production levels of 9473, 8605, and 6252 kg, respectively.

Pregnancy

The primary physiological reason for cows being anestrus is the interruption of cyclicity by pregnancy. Although most dairy farmers keep excellent breeding records, it is not uncommon for errors to occur at the time of updating breeding records. The inadvertent transposition of numeric characters during data entry is a common error that can falsely identify inseminated cows as not inseminated, resulting in the occasional case of anestrus due to a "surprise pregnancy." During reproductive examinations, practitioners should always bear this in mind and rule out pregnancy first.

Managing Anestrus

Before planning a course of action to manage anestrus, it is important to assess the prevalence of anestrus at herd level. Anestrous postpartum beef cows, if treated, can recover from anestrus with normal fertility [95], whereas dairy cows treated for anestrus have much lower fertility [96], possibly due to an associated negative energy balance. Therefore every effort should be taken to return the cows to positive energy balance before first insemination.

General Strategies to Diagnose and Minimize the Impact of Anestrus

Some strategies to consider for assessing prevalence of anestrus at herd level are listed here.

1) *Performing body condition scoring* (*BCS*). Assessing BCS of cows will provide an indirect indication of whether cows are meeting their energy needs adequately. Performing BCS of the whole herd, paying particular attention to close-up dry cows, fresh cows, and cows in the breeding group, would be of great value. Close-up dry cows that are in high body condition (BCS >3.5/5) should be considered high risk for metabolic disorders and anestrus. A disproportionately large number of cows beyond 60 days in milk with poor body condition (BCS <3.0/5) should also be considered a problem as the prevalence of anestrus will be higher in those herds. Herdsmen should be educated on the importance of BCS, properly trained in the technique, and encouraged to perform condition scoring every two weeks, or at least monthly, and keep a good record of the scores. Inseminating cows in poor body condition must be avoided and breeding delayed until a threshold BCS is attained, as low BCS cows have low conception risk and a high risk of pregnancy loss. Recent studies [74–76] indicate that an acute loss in body condition in the weeks between calving and breeding time in dairy cows has a greater detrimental effect on fertility than the absolute BCS. This finding further emphasizes the need for systematic recording of BCS at set intervals.
2) *Performing gait* (*locomotion*) *scoring*. In herds where gait scoring is not performed, this should be encouraged, routinely, to identify cows that are showing early signs of lameness. Periodic gait scoring, regular hoof trimming, and the use of foot baths must be encouraged to keep lameness in check. Lame cows will often be the last ones to reach the feed bunks and they are less motivated to leave the comfort of their stall to access feed frequently. As a result, they consume less feed, predisposing them to an increased risk of negative energy balance and anestrus. Grouping cows with even early signs of lameness and feeding them separately would be one strategy to improve dry matter intake in these cows, mitigating negative energy balance.
3) *Improving the efficiency of estrus detection*. The use of tail chalk or tail paint to improve estrus detection efficiency is one of the simplest strategies that could be implemented in herds of any size. Using three different colors to mark fresh cows (to determine cyclicity), cows at the end of the elective waiting period (to be flagged for insemination), and previously inseminated cows (for return service) would provide an efficient yet simple system for systematically detecting cows in estrus. In the breeding group, tail chalk scores should be recorded daily for this system to be effective and fresh chalk applied at least once weekly. Applying tail chalk or tail paint on fresh cows 30–40 days before the end of

the elective waiting period is highly recommended. If tail chalk remains largely intact until the end of the elective waiting period, the cow is probably anestrous. I say probably, because "standing estrus," which is essential for tail chalk to be removed completely, is only exhibited by 50% of lactating dairy cows in estrus [41] at 9–12 weeks after calving.

4) *Using ultrasonography*. Transrectal ultrasonography is an excellent diagnostic tool [97, 98] for the objective assessment of ovaries and must be used wherever practical during routine reproductive examinations. Examining the ovaries by ultrasonography at five to six weeks after calving provides great diagnostic value to identify cows at risk of reduced fertility (P/AI) because a cow that is not cyclic (absence of luteal tissue at ultrasound examination) by five to six weeks is less likely to conceive at first service. Diagnosis of the anestrous condition based on ovarian ultrasonography must ideally involve at least two consecutive examinations performed at an interval of 7–14 days [99]. Although two examinations at a 7- to 14-day interval are preferred, even a single ultrasound examination performed at the initiation of a timed-AI (TAI) protocol (e.g. Ovsynch) not only identifies anestrous cows (no luteal tissue) but also assists with the identification of cows at risk of reduced P/AI (cows with ill-defined CL, such as those at proestrus, estrus, and metestrus phases of their estrous cycle) [100–102].
5) *Monitoring progesterone profiles*. Albeit somewhat expensive, monitoring milk progesterone concentrations can be a reliable approach for assessing the prevalence of anestrus in dairy herds. During the early postpartum period progesterone concentrations will be very low and will continue to remain so until first ovulation occurs. Progesterone will rise following the first ovulation but may decline after a few days as the first luteal phase is often short-lived. The second and later luteal phases are more likely to be of normal duration. Dairy cows relapsing back into anestrus after the first postpartum ovulation has been documented [41]; regular measurement of progesterone can assist in determining the patterns of cyclicity in dairy herds. The Herd Navigator® system (DeLaval International) has the capability to measure real-time milk progesterone concentrations at the point of milking in both robotic and parlor systems. It has been claimed that Herd Navigator detects consistently above 95% of all estrus events including silent heats and is very useful in the detection of postpartum anestrus, pregnancy, and ovarian cysts [103]. A recent study validated the efficacy of this system for pregnancy diagnosis in dairy cattle and concluded that >95% accuracy is attainable if pregnancy determination occurred ≥41 days after insemination [104]. While the Herd Navigator is a welcome addition to the reproductive management tool-kit, it is an expensive technology, adaptable only to DeLaval milking systems.
6) *Measuring blood metabolites*. Elevated concentrations of NEFA, an indicator of negative energy balance [79, 92, 105], and betahydroxybutyric acid (BHBA), an indicator of subclinical ketosis, particularly during the first week postpartum [30] can assist in the early identification of cows at risk for anestrus. Low concentrations of glucose and IGF-1 in blood during the early postpartum period also increase the risk of delayed onset of cyclicity [105].

While clinical management of individual cases of anestrus has its place, a whole-herd approach is often more beneficial. For a practitioner to focus only on anestrous cows presented for reproductive examinations during herd health visits is not always the best approach. Instead, taking a proactive approach of whole-herd assessment is highly recommended, particularly in herds with a history or suspicion of high prevalence of anestrus.

Walking through the barns without disturbing the cows to assess stall comfort and stall design and how those might influence cow behavior would be an essential component of the exercise. A poorly designed stall, such as one with limited lunge space, in a free-stall barn, may discourage cows from getting up to access feed several times a day because of the discomforts associated with frequent getting up and lying down in a poorly designed stall.

It is equally, if not more, important for a dairy practitioner to be fully aware of reproductive management practices of the herd and to have regular conversations with the person in charge of reproductive management and the herdsmen/technicians performing estrus detection and AI. In herds that have frequent staff turnover, it would be prudent to ensure that standard operating protocols for chores such as estrus detection, synchronization treatments, semen handling, and AI are available, prominently posted, and strictly followed. The veterinarian must know who is in charge of estrus detection and how frequently and for how long estrus detection is performed each day. In herds where electronic estrus detection systems are used, the system must be optimized for the herd to minimize false positives (wasted semen and labor) and false negatives (missed breeding opportunity). Complete reliance on electronic estrus detection systems must be discouraged, especially in herds where the system is newly installed.

Nutritional Intervention

Interactions between nutrition and reproductive processes are complex [92, 106] and it is often difficult to precisely study effects of specific nutrients on ovarian function. Excessive energy intake during the close-up dry period can result in changes in metabolism that may predispose cows to decreased dry matter intake and higher circulating NEFA during the immediate peripartal period [79]; therefore monitoring feed intake in close-up dry cows is also quite important.

Specific nutritional or nutraceutical interventions to reduce the incidence of postpartum anestrus may include feeding diets high in starch [107, 108] or daily oral administration of monopropylene glycol [109] during the postpartum period. Adding starch [110] or oilseeds enriched in long-chain fatty acids such as linoleic or linolenic acid [111] during the prepartum period has also reduced the interval from calving to first ovulation. One study [112] reported that cows that consumed an energy-restricted (80% of calculated requirement) diet during the entire dry period had lower NEFA concentrations and higher dry matter intake during the postpartum period than cows consuming 160% of predicted energy requirements during the dry period. Thus, several options exist for dietary manipulations that could mitigate negative energy balance and reduce anestrus. However, results are variable and research findings may not always translate into practical or economic solutions under commercial herd settings.

Therapeutic Intervention

Hormonal treatment to induce estrus or ovulation is a more tangible approach that is well within the realm of a veterinary practitioner. Specific hormone therapy can be administered to either an individual animal or a group of cattle as required. The commonly used hormones for treatment of anestrus are progesterone, estradiol, and GnRH, although equine chorionic gonadotropin (eCG), porcine LH, and human chorionic gonadotropin (hCG) have also been used. In herds where estrus detection efficiency is poor and undetected estrus (subestrus or silent estrus) is the primary suspected cause of anestrus, the use of prostaglandin (PG)$F_{2\alpha}$ followed by intensive estrus detection could be quite effective [113, 114]. Of course, $PGF_{2\alpha}$ could also be used in combination with most of the above hormones in protocols that induce or synchronize estrus and ovulation.

Progesterone

A short period of exposure to high progesterone during the postpartum period is important for expression of estrus and for the establishment of normal luteal function. Treating anestrous cows with progesterone increased LH pulsatility, estradiol concentrations, and LH receptors in granulosa and theca cells of the preovulatory follicle [115]. Thus intravaginal progesterone devices (IVPD) can be quite effective in treating true anestrus. When progesterone is used alone, a treatment regimen for true anestrous cases would constitute insertion of a progesterone device for seven to nine days, removal of the device, and insemination at detected estrus. The insertion of a progesterone-releasing intravaginal device (PRID) (1.55 g progesterone) for seven days and its removal at the end of that period induced cyclicity in 64 of 90 (71%) treated cows in contrast to only 33 of 83 (40%) untreated controls [99]; cyclicity was confirmed by the presence of a CL at ovarian ultrasonography 11 days after PRID removal. For therapy of anestrus at herd level, a 7-day progesterone treatment followed by $PGF_{2\alpha}$ injection at device removal is often recommended to ensure luteolysis in cows that were "silent ovulators" (subestrus) and in those that were falsely categorized as anestrous due to poor estrus detection efficiency (unobserved estrus).

The two brands of IVPD available in the US market are CIDR® 1380 (CIDR; Zoetis, Florham Park, NJ, USA; 1.38 g progesterone) and PRID-Delta® (Ceva Animal Health, Cambridge, Ontario, Canada; 1.55 g progesterone). While PRID-Delta is approved in Canada specifically for treatment of anestrus in dairy cattle, CIDR is approved in the USA to treat anestrous, synchronize estrus, and resynchronize the return to estrus in lactating dairy cows that failed to conceive to the previous insemination. To my knowledge neither product has milk withdrawal requirements. The use of oral progestagens (e.g. melengestrol acetate) is not discussed in this chapter because it is (i) registered as a product to improve growth rate and feed efficiency and suppress estrus, and (ii) it is not approved for use in any animal other than beef heifers intended for slaughter (Veterinary Drug Directorate, Ottawa, Canada).

Estradiol

Estradiol alone may be used for inducing estrus in anestrous cattle, but it is not recommended because the ovulatory response to estradiol is often variable. Furthermore, unless anestrous cows were previously exposed to progesterone, even if estradiol treatment induces estrus and ovulation, the ensuing luteal phase will usually be of short duration. However, using estradiol

to induce estrus after a seven-day exposure to progesterone has been found effective in both beef and dairy cattle and has been widely used in New Zealand for treating anestrous dairy cattle. For example, the use of a CIDR device for six days, followed by an injection of 1 mg estradiol benzoate 24 hours after CIDR removal resulted in 87% of dairy cows being detected in estrus within seven days of estradiol treatment; 79% of cows detected in estrus ovulated and a P/AI of 42% was attained [115]. Estradiol is available in different forms: estradiol-17β, estradiol benzoate, estradiol cypionate, and estradiol valerate. To my knowledge no injectable estradiol preparation approved for use in cattle is commercially available in the USA. Estradiol cypionate (ECP), previously marketed by Pfizer Animal Health in the USA and Canada for use in cattle, was withdrawn in 2005. Prepackaged estradiol cypionate is still available in the Canadian market through a small pharmaceutical company. Estradiol products may be legally dispensed by a compounding pharmacist under veterinary prescription in Canada. Although US practitioners may still be able to obtain ECP or other estradiol preparations through compounding pharmacies, such use is illegal because it constitutes compounding of an unapproved animal drug and extra-label use for purposes not specifically approved by the Food and Drug Administration [116]. Considering prevailing concerns about the use of estrogens in food animals, it would be prudent to choose alternative products for management of anestrus.

GnRH

Exogenous administration of GnRH induces LH release as early as the first week after calving in dairy cows, although the response is significantly higher by the second week [117] (Figure 34.7). If a dominant LH-responsive follicle is present at the time of GnRH injection, there is a high probability of it ovulating, especially when the follicle has not been exposed to progesterone. In our laboratory, four of five lactating dairy cows given 100 µg GnRH in the second week after calving ovulated [117]. Inducing an ovulation in anestrous cows with no prior exposure to progesterone could result in short luteal phases, increasing the chances for cows to revert back into anestrus. In one study [99], 93 of 108 (86%) anestrous cows ovulated in response to a GnRH injection, but 20% of these cows reverted to anestrus. Thus, although GnRH can be used independently to induce ovulations in anestrous dairy cows, one must recognize that short luteal phases and reversion to anestrus are drawbacks associated with this approach.

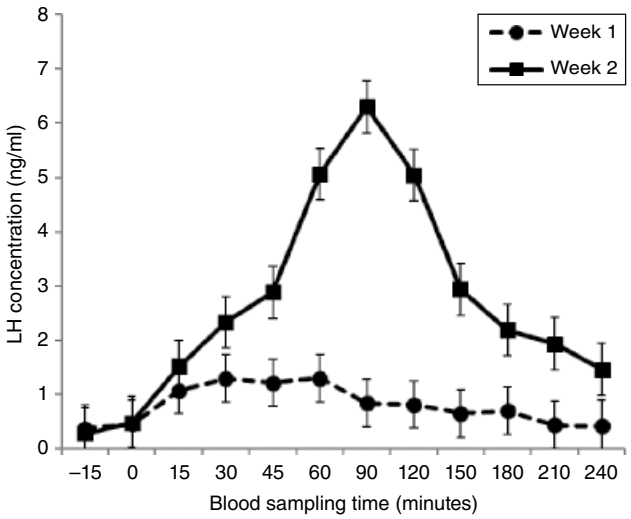

Figure 34.7 GnRH-induced LH release in early postpartum dairy cows when challenged during the first (circles) or second (squares) week postpartum. Cows (n = 10, 5 each week) were given 100 µg gonadorelin acetate intramuscularly (IM) and LH measured in blood samples were collected over four hours. Mean and peak LH concentrations differed ($P < 0.03$) between weeks one and two. A prepartum diet supplemented with oilseeds high in oleic or linoleic acid reduced GnRH-induced LH release in dairy cows during the second week postpartum. *Source:* Redrawn from [117].

GnRH and $PGF_{2\alpha}$ Combination

Using GnRH in combination with $PGF_{2\alpha}$ in a protocol such as Ovsynch [118] followed by TAI (Figure 34.8, A.1) has been effective in the management of anestrous cows. Although the P/AI in anestrous cows following this approach is generally lower than in cyclic controls, several studies [99, 100, 122–125] have reported acceptable P/AI (Table 34.2).

Porcine LH or hCG can be used in lieu of GnRH in the Ovsynch protocol, but these products are significantly more expensive than GnRH. Furthermore, there is limited research on the use of these products in the management of anestrous cattle. In one study [124], replacing the second GnRH injection of the Ovsynch protocol with a commercial preparation of highly purified porcine LH (Lutropin®-V, Bioniche Animal Health, Belleville, Ontario) in predominantly cyclic lactating dairy cows significantly improved P/AI by 14 percentile points (42% vs 28%; $n = 308$). In the same study, when porcine LH was used in lieu of the first GnRH injection of the Ovsynch protocol on a different subset of cows, the ovulatory response to porcine LH treatment was significantly higher than to GnRH treatment (62% vs 44%). Since several studies have reported that cows ovulating in response to the first GnRH treatment of the Ovsynch protocol have higher pregnancy rates after

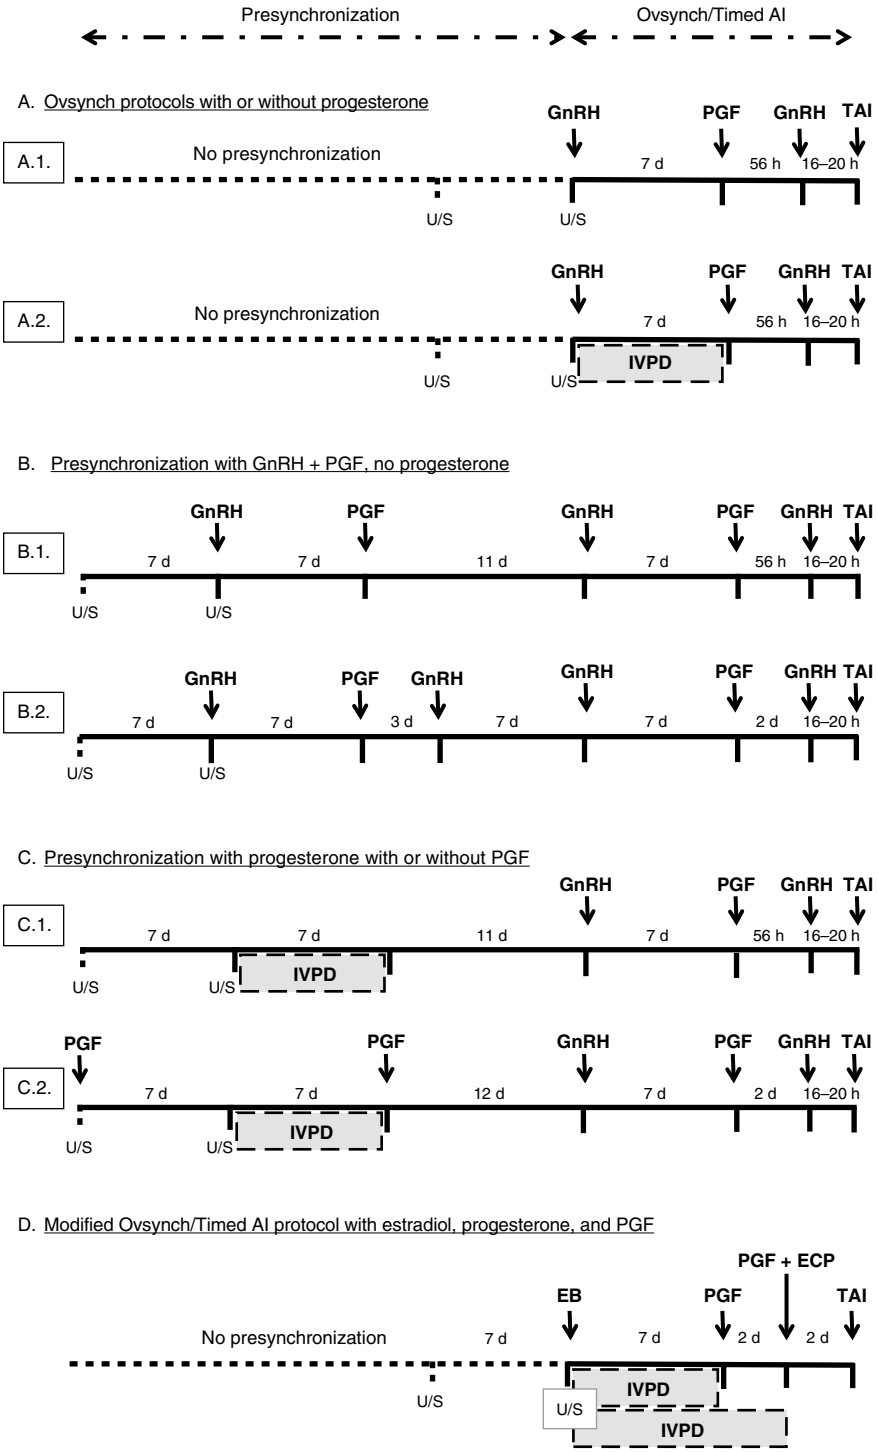

Figure 34.8 Fixed TAI protocols for anestrous dairy cows. A.1 is a standard Ovsynch protocol [118] with no presynchronization or progesterone added. A.2 is a modified Ovsynch protocol that includes an IVPD during the first seven days, with the device inserted at first GnRH and removed at PGFα administration. B.1 and B.2 include presynchronization with either GnRH+PGF (B.1) or GnRH+PGF + GnRH (B.2); in B.1, presynchronizing injections of GnRH and PGF, in that order, are given seven days apart and Ovsynch protocol is started after 11 days [99]. In B.2, two Ovsynch protocols follow back-to-back, with a seven-day interval between end of first and beginning of second protocol (Double-Ovsynch [119]). C.1 involves insertion of an IVPD for 7 days followed by initiation of Ovsynch protocol 11 days later [99]. C.2 [120] is identical to C.1 except that two PGF injections are given 14 days apart, with the IVPD inserted for 7 days starting on the 7th day after initial PGF injection; Ovsynch protocol starts 12 days later. Whether the two injections of PGF given 14 days apart have any value in confirmed anestrus cows was not tested in that report [120]. D [121] is a modified Ovsynch/TAI protocol where 2 mg estradiol benzoate (EB) and 1 mg estradiol cypionate (ECP) replaces GnRH. Two IVPD devices are inserted at EB, with one device kept for 7 days (removed at first PGF) and the second device for 9 days (removed at second PGF/ECP), with TAI occurring 48 hours later. Ovarian ultrasonography (U/S) performed twice, seven days apart, to confirm cyclicity status is important to identify cows that are truly anestrus. Furthermore, confirming ovulation following the first GnRH injection of Ovsynch protocol is highly recommended, where feasible, because anestrous cows that fail to ovulate in response to the first GnRH injection rarely conceive [122].

Table 34.2 P/AI after Ovsynch/TAI in dairy cows classified as anestrous or cyclic.

Percent P/AI			
Anestrous (n)	**Cyclic (n)**	**P**	**Reference**

n/a, Not applicable; only anestrous cows were assigned to the study.

TAI [96, 100, 122], using porcine LH in the treatment of individual cases of anestrus has potential value, where such use is legally permissible.

In this regard, P/AI was greatly enhanced in anestrous cows that ovulated in response to the first GnRH treatment of the Ovsynch protocol (46% vs 6%) than in anestrous cows that failed to ovulate [122]. These results strongly indicate that determining the ovulation response to the first GnRH treatment in anestrous cows, by ultrasonography, would have significant value in increasing the probability of pregnancy.

Using a presynchronization treatment (Figure 34.8, B.1, B.2, C.1, and C.2) prior to the initiation of an Ovsynch protocol has a significant advantage in that it creates a physiologically conducive ovarian environment for optimal response to the Ovsynch protocol. Whereas presynchronization with $PGF_{2\alpha}$ alone will perhaps be of little benefit to anestrous cows, using GnRH and $PGF_{2\alpha}$ at strategic intervals prior to the initiation of an Ovsynch protocol can successfully induce cyclicity in anestrous cows [99, 119]. In this regard, a Double-Ovsynch protocol [119] (Figure 34.8, B.2) has been shown to have significant advantages in managing anestrus. At least three reports [119, 126, 127] indicate that the Double-Ovsynch protocol is very effective in inducing ovulation in cows that were non-cyclic at the initiation of the treatment. The Double-Ovsynch protocol does not typically improve P/AI in multiparous cows when compared to a Presynch-Ovsynch protocol, wherein two consecutive injections of $PGF_{2\alpha}$ are given 14 days apart followed by an Ovsynch protocol started 12 days after the second $PGF_{2\alpha}$ injection. Nevertheless, the Double-Ovsynch protocol significantly improves P/AI in primiparous cows, possibly because the incidence of anestrus is higher in primiparous than multiparous cows. All-in-all, a Double-Ovsynch/TAI protocol appears to be an effective strategy to get a greater proportion of anestrous cows pregnant. A recent meta-analysis [128] has evaluated the efficacy of $PGF_{2\alpha}$ minus vs $PGF_{2\alpha}$ plus GnRH-based presynchronization methods prior to the initiation of Ovsynch in lactating dairy cows, comparing 25 publications involving 21 046 cows, and this may be of further interest to the reader.

Progesterone, GnRH, and $PGF_{2\alpha}$ Combination

The incorporation of an IVPD into a synchronized ovulation program such as Ovsynch (Figure 34.8, A.2) is one approach to improve treatment outcomes (ovulation and pregnancy) in anestrous cows [100–102, 122]. An alternative approach is to use an IVPD as a presynchronization treatment (Figure 34.8, C.1, C.2) before the initiation of the Ovsynch protocol. Figure 34.8 presents some of the treatment options for postpartum anestrus in dairy cattle.

Studies show that anestrous cows subjected to Ovsynch plus TAI, with the insertion of an IVPD for the first seven days of the protocol (Fig. 34.8, A.2), have higher P/AI than that of anestrous cows subjected to the same protocol without progesterone (Figure 34.8, A.1). P/AI are comparable to that of cyclic cows subjected to Ovsynch plus TAI with no progesterone treatment (Table 34.3) [100, 122, 129]. A large field trial (12 herds, 1662 cows) conducted in New Zealand on anestrous dairy cows concluded that therapeutic intervention is the most economic option compared with no treatment, and that including an IVPD in the Ovsynch protocol was most cost-effective, attaining the highest net benefit of NZ$80.40 per cow [130]. A meta-analysis of 21 studies (13 762 cows) [131], evaluating the effect of progesterone supplementation within TAI programs concluded that cows lacking a CL (i.e. anestrous) at the initiation of the TAI protocol had greatly improved P/AI when progesterone was given as a single intravaginal insert. Among the cows without CL, progesterone supplementation increased ($P < 0.01$) P/AI at 32 days by 14% (relative risk = 1.14; 95% confidence interval [CI] = 1.04–1.25) and at 60 days by 16% (relative risk = 1.16; 95% CI = 1.06–1.29) compared to untreated controls. Therefore supplemental progesterone is beneficial when provided to anestrous cows and to those without a CL at the initiation of the TAI protocol, whereby P/AI similar to that of cows in diestrus is attainable.

Although stand-alone PGF treatments in a presynchronization protocol are unlikely to benefit anestrous cows, giving PGF before AI in an estradiol–progesterone-based TAI protocol (Figure 34.8D) increased P/AI in anestrous dairy cows [121]. Here, anestrous cows were given a supplementary PGF treatment two days before TAI, secondary to the

Table 34.3 P/AI in anestrous dairy cows subjected to Ovsynch/TAI with or without insertion of an IVPD for the first seven days of the Ovsynch protocol.

Anestrous No IVPD	Anestrous Plus IVPD	Cyclic No IVPD	Cyclic Plus IVPD	Reference

luteolytic PGF, to determine if PGF given before AI has a role on fertility independent of its luteolytic effects. P/AI was greater (38.8 vs 13.3%) in normothermic (<39.1 °C) anestrous cows that received the supplementary PGF than in hyperthermic (>39.1 °C) cows. The duration of LH surge, the diameter and volume of the preovulatory follicle, and intrafollicular estradiol concentrations were greater in anestrous cows given the supplementary PGF treatment. In a previous report [132], a low-dose natural PGF (10 mg dinoprost) given concurrently with TAI improved conception rates in lactating dairy cows of undetermined cyclic status. Collectively, these results suggest that the improved fertility in cows due to PGF given before or at AI might be related to changes in gonadotropin release and the endocrine milieu of the preovulatory follicle. Other benefits of PGF treatment may come from a further reduction of progesterone (i.e. in cases of delayed or incomplete luteolysis) at AI which increases the probability of pregnancy [133] and through mechanisms independent of luteolysis, discussed elsewhere by Ambrose et al. [132].

The Ovsynch/TAI protocol has also been used successfully in cows with cystic ovarian follicles [53], although the addition of a progesterone device to this protocol did not improve pregnancy [134]. Ovarian responses documented by ultrasonography and pregnancy rates after TAI in cows with cystic ovarian follicles in the above studies [53, 134] are summarized in Table 34.4.

Table 34.4 Ovarian responses to GnRH treatments, based on ultrasonography, and P/AI after Ovsynch/TAI in cows with cystic ovarian follicles in two studies.

Observation	Reference [53]	Reference [132]
Number of cows	18	109
Mean diameter of cyst	33.9 ± 1.5	33.6 ± 6.0
Ovulation of cystic follicle after first GnRH	0/18 (0)	12/109 (11.0)[a]
Ovulation of an existing follicle after first GnRH	8/18 (44.4)	68/109 (62.4)
New follicle developed after first GnRH	18/18 (100)	102/109 (93.6)
Ovulation of new follicle after second GnRH	15/18 (83.3)	91/109 (83.4)
Cows pregnant 32 days after TAI	7/17 (41.2)[b]	45/109 (41.3)

[a] Some of the smaller cystic follicles (25–30 mm range) ovulated.
[b] Only 17 cows were available for pregnancy diagnosis.

Equine Chorionic Gonadotropin

Studies [135–137] have found that including eCG in a progesterone-based protocol in treatment of anestrous cows is beneficial. Anestrous cows that were subjected to GnRH and six to seven days of an IVPD, followed by $PGF_2\alpha$ plus 400 IU eCG at device removal had increased P/AI at first service (defined as cows that conceived within seven days of their finishing the assigned breeding protocol) by 5.4 percentile points (36.0 vs 30.6%; $P = 0.02$) [135]. Another study [137], in which 1906 anestrous cows from 12 herds were assigned to different ovulation synchronization-based TAI programs with or without an IVPD, found that when eCG treatment was added to a protocol that included an IVPD, P/AI was increased by up to seven percentile units. P/AI and 28-day pregnancy rates were increased ($P < 0.01$) in anestrous cows receiving IVPD + eCG treatment vs those that received neither IVPD nor eCG, if they had passed 60 days postpartum at breeding. Mechanistically, eCG improves the development and ovulation rate of the dominant and

preovulatory follicle(s), consequently improving the quality and function of the ensuing CL, with a positive effect on embryo development and survival, particularly in anoestrus cows [138].

Postbreeding Treatments

Because of the higher risk of pregnancy loss in anestrous dairy cows, postbreeding interventions aimed at improving progesterone concentrations during the early phases of embryonic development have been attempted. Insertion of a PRID for 7 days starting at 4.5 days after AI in anestrous dairy cows tended to reduce pregnancy losses (5.6% vs 33.3%; P = 0.10) between 32 and 60 days of gestation, compared with anestrous cows that did not receive a PRID after AI [122]. In another study, giving a GnRH injection five days after TAI increased P/AI in anestrous dairy cows (45.5 vs 31.1%) compared with cyclic cows [139].

Summary

The underlying reasons for postpartum anestrus in dairy cattle are often multifactorial, but negative energy balance is recognized as a major contributor. To maximize reproductive success, cows that are considered to be at higher risk for anestrus should be identified early and managed for increased dry matter intake. Improving estrus detection efficiency would greatly diminish anestrus due to undetected estrus. Assessment of ovarian status by ultrasonography offers great diagnostic value. Where therapeutic intervention is chosen, a progesterone-based Ovsynch protocol, a progesterone-based presynchronization protocol followed by Ovsynch/TAI, or a Double-Ovsynch/TAI protocol are recommended options. Post-AI treatments with progesterone or GnRH also offer increased P/AI. Treatment of anestrous cows by placing them in a TAI program is the cost-effective alternative to no treatment.

Estrus Detection

Roberto A. Palomares

Group for Reproduction in Animals, Vaccinology and Infectious Diseases, GRAVID™ Department of Population Health, College of Veterinary Medicine, University of Georgia, Athens, GA, USA

Introduction

Approximately 90% of dairy producers in the USA rely on artificial insemination (AI) to breed their herds [1]. Low estrus detection efficiency is a major cause of poor reproductive performance in dairy farms, which causes substantial economic losses to the cattle industry [2]. Poor estrus detection results in failure to detect and inseminate cows in estrus (inefficiency), insemination of cows at the incorrect time relative to ovulation, or insemination of cows that are not in estrus (inaccuracy). The ability to detect estrus in dairy cows is affected by many factors including human error and inadequate use of heat detection aids, weather conditions, stress, housing, milk production, and endocrine status [2].

Estrus synchronization (Chapter 37) using hormones can help to reduce the time and effort spent on estrus detection and increase its efficiency. Although ovulation synchronization and timed artificial insemination (TAI) protocols (e.g. Ovsynch, Cosynch) have provided dairy producers the opportunity to breed their cows without the need for heat detection, AI based on estrus detection still plays an essential role in the breeding management of most dairy operations [3]. Moreover, a great proportion of dairy cattlemen inseminate their heifers based on estrus detection, and only a small percentage use TAI protocols for the heifers' breeding program. On the other hand, in most beef farms in the USA, breeding programs are based on natural mating. Less than 7% of beef cattle operations use estrus synchronization, heat detection, and AI [4]. In cow-calf beef operations where their genetic progress is based on AI and embryo transfer (ET), estrus detection in combination with TAI protocols represent the cornerstone of the breeding program. In these beef farms, especial consideration should be given to strategies that maximize the identification of animals in estrus. Adequate estrus detection has a significant impact on overall pregnancy rates after a 70-day breeding season, or the number and quality of embryos produced during the ET program.

In general, estrus detection based on visual observation should be performed by observing the herd for one hour in the morning and one hour in the evening. In addition, the appropriate use of estrus detection aids to complement visual observation helps to maintain continuous monitoring of estrus activity with the final purpose of inseminating cows at the correct time relative to ovulation. Some of the estrus detection aids include but are not limited to heat mount detectors or patches, tailhead markers (e.g. paint, chalk, or paste), and teaser bulls, as well as more sophisticated electronic heat detection devices (pedometers, Heat Watch®, etc.). This chapter will discuss the physiological aspects of estrus expression, factors affecting estrus expression and heat detection, and the main management tools used as estrus detection aids, making emphasis on fundamentals, application, advantages, and disadvantages.

Physiology of Estrus

Estrus or heat is a stage of the estrous cycle when the cow is receptive to the bull. It lasts 12–18 hours and occurs as a result of the effects of hormones on the brain behavioral centers. During estrus, the preovulatory follicle grows and secretes high levels of estradiol, which reaches a threshold and induces a positive feedback on the hypothalamus and anterior pituitary, resulting in an increase in luteinizing hormone (LH) concentration and the primary sign of estrus behavior (i.e. the cow stands to be mounted). Estrus behavior coincides with low progesterone levels, high estradiol concentration, and the preovulatory surges of

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

gonadotropin-releasing hormone (GnRH) and LH that result in ovulation 24–32 hours after the beginning of estrus (during metestrus) [5]. This endocrine profile also induces changes in the reproductive tract leading to secondary signs of estrus, including the presence of a clear vaginal discharge, vulvar edema, vaginal hyperemia, and increased uterine tone. During this time, cervical mucus becomes more abundant, clear, and less viscous, which facilitates sperm transport through the cervix. An increased number of leukocytes, particularly neutrophils in the subepithelial layers of the endometrium, can be identified during estrus. These cells are crucial for phagocytosis of bacteria, dead sperm, and cell debris.

Some cows do not show significant signs of estrus but have silent ovulations. This is a condition commonly occurring in dairy cows during the early postpartum period [6, 7]. In contrast, a less common outcome called anovulatory estrus occurs when a cow shows estrus signs but there is a low LH concentration, absence of LH surge, or low responsiveness to the LH surge by the preovulatory follicle [8]. In a field study, the ovulation failure rate in lactating dairy cows detected in heat was reported to be 6.5% [8].

Signs of Estrus in Cattle

In cattle, the most obvious behavioral estrus activity or "primary sign" is standing immobile to be mounted (Figure 35.1). Thus, standing estrus refers to the period when a cow is mounted by other cows and stays quiet without trying to escape. In dairy cows, the number of standing mount episodes during estrus is highly variable (3–140) [9], with an average of 35 mounts of three to seven seconds each. Conversely, some cows do not express signs of standing heat during their estrus, which represents a challenge for the breeding program [10, 11].

A cow in heat also displays secondary signs of estrus (Figure 35.2). These signs may occur before and after heat. She becomes restless and nervous, with increased physical activity [12], raises her tail, and may have a long string of clear mucous discharge hanging from her vulva or on her tail or hindquarters. She has vaginal hyperemia and a reddened, relaxed, and edematous vulva. A roughened tailhead (with fluffed-up hair) or mud on her back or sides indicates that she has been mounted. A cow in heat follows other cows, bellows more frequently, stands beside them, sniffs their vulva, shows Flehmen response, and rests her head on the back of other cows. The cow may behave disorientated, mounting and being mounted but not standing, licking, rubbing, and having aggressive behavior like head butting.

During estrus, an abundant clear vaginal secretion is normal. If the vaginal discharge is bloody, this is also normal but indicates that estrus ended (one to three days ago) and the cow is in "metestrus" and has already ovulated. At this point, it would be generally too late to inseminate this animal, but she should be observed closely for the next estrus in 19 days. If the secretion is cloudy, milk-white, or purulent, the animal may have a

Figure 35.2 Holstein cows showing secondary signs of estrus: (a) long string of clear mucous discharge hanging from her vulva and a reddened, relaxed, and edematous vulva; and (b) roughened tailhead indicating that she was mounted. *Sources:* Images courtesy of Drs. Roberto Palomares (a) and Antonio Landaeta-Hernandez (b).

vaginal, cervical, or uterine infection. This condition could reduce the odds of conception.

There may be several cows showing sexual behavior at the same time (especially when synchronization protocols are used), so that it can be difficult to sort out which ones are in heat and which ones may be coming into heat soon. Cows attempting to mount other cows are also part of the so-called sexually active group (SAG). The mounting animals in this group are not necessarily in heat but they may come into heat soon. This behavior results from increasing estradiol concentration (e.g. during proestrus) or social dominance.

An observational study was performed monitoring 200 Holstein–Friesian cows to describe the chronological sequence of estrus behavior in cattle [13]. Visual observation was performed in 3-hour blocks continuously between 04:00 and 24:00 hours and Heatime® neck collars were used as detection aid. The duration of standing to be mounted was 4.7 ± 1.5 hours (range 0.25–18.3 hours). Sniffing the vulva of another cow, chin resting on the rear part of another cow, and being chin rested upon by another cow were the most frequently observed behaviors, with not accepting a mount being the least frequent. The duration between the first and last observed estrus behavior was 14.0 ± 1.9 hours (range 8.5–28.8 hours) [13]. Cows with secondary signs of estrus behavior should be carefully monitored for standing behavior. In dairy cattle, a decrease in feed intake and milk production for no apparent reason may occur during the estrus period. In beef cows, a reduction in milk production during estrus can also be noticed by observing their bawling hungry calves in the pasture.

Factors Affecting Estrus Expression and Detection

The estrus expression intensity and the possibility to detect it can be affected by numerous factors including breed, postpartum period, parity, milk yield, health status, nutrition, weather conditions, stress, hormonal treatment, bull presence, housing, and herd size.

Breed

Estrus behavior including duration (hours) and intensity (mounts per hour) of sexual receptivity is more pronounced in *Bos taurus (8–18 hours)* than *Bos indicus (6–12 hours)*. In addition, a field study showed that cows of dark-colored breeds had greater sexual behavior than white- or red-haired cows [14].

Postpartum Period

The hypothalamus sensitivity to estradiol varies during the postpartum period. Some ovulations occurring during the early postpartum period often occur with mild or no estrus behavior. This is a condition commonly occurring in dairy

cows during the early postpartum period [6, 7]. This might be due to a refractory effect on estradiol caused by high estrogen levels at late pregnancy and parturition. Postpartum anestrus or delayed resumption of ovarian cyclicity is a major factor affecting reproductive performance in beef and high-producing dairy cows [15]. Several studies performed in large commercial dairy farms have demonstrated that approximately 20% (7–41%) of the lactating cows remain in anestrus and anovulation at the end of the 60-day voluntary waiting period (VWP) [16, 17].

Milk Production

High-producing dairy cows had lower estradiol levels and shorter estrus compared with low-producing cows [18]. The higher metabolic rate of estradiol and progesterone observed in high-producing dairy cows has been associated with reduction in duration and intensity of estrus behavior. Nevertheless, reports showed no correlation between estrus expression and level of milk production [19].

Nutrition and Body Condition Score (BCS)

Subnutrition and poor body condition score (BCS) can negatively affect estrus behavior [20]. There may be confounding effects of the diet on the intensity of estrus behavior in lactating Holstein cows. A field study in France demonstrated that there was an increase in the odds of estrus detection based on "mild" secondary signs (instead of standing heat) in cows receiving a high diet (65% corn silage, 5% hay, and 30% concentrate containing soybean, barley, beet pulp, wheat, corn, and minerals) when compared to cows given a low diet (85% grass silage and 15% concentrate). This could be explained by a possible effect of increased milk production in cows consuming high diet decreasing the intensity of estrus behavior [10].

Parity and Lactation Number

There is a contrasting effect of parity on primary and secondary signs of estrus behavior. The length and intensity of the primary estrus sign (standing to be mounted) increases with parity [14]. A multiparous cow expresses "standing estrus" more accurately (during a longer period) than primiparous cows. In contrast, primiparous cows show greater walking and mounting activity during estrus compared to multiparous cows; and this physical activity decreases with each additional lactation [15, 21–23].

Health Status (Lameness and Mastitis)

Although lameness has been associated with delayed resumption of postpartum ovarian cyclicity in cattle, a report showed that follicular development and maturation is similar in lame cows compared with normal animals [24]. Clinical lameness is commonly related to decreased expression of estrus behavior in dairy cows [25]. This reduction in estrus intensity could be due to reduced physical activity and mounting behavior. That is, a lame cow has shorter episodes of standing, mounting, and walking activity during estrus [26]. Alternatively, the reduced estrus behavior in a stressed lame cow might be a consequence of lower progesterone concentrations before estrus and decreased LH secretion, as previously reported [27]. It is also possible that a lame cow stands to be mounted when she is not in estrus since escaping when mounted might increase the pain. Hockett et al. [28] reported that cows with clinical mastitis may have variable reproductive outcomes. They may show normal estrus behavior and ovulation or have decreased LH pulses, lack of LH surge and estrous behavior, low estradiol concentrations, and ovulation failure [28]. In addition, a study showed that subclinical mastitis disturbs the steroidogenic function of small follicles, and these effects are then carried over to preovulatory follicles [29].

Weather and Stress

Several studies have reported significant effects of season on estrus behavior [10, 30, 31]. The effect of heat stress on gonadal steroid production has a significant impact on sexual behavior in cattle. It is well known that the length and intensity of estrus behavior can be dramatically affected by heat stress. A study in beef cows showed that during summer, cows received fewer mounts, with longer intervals between mounts, when compared with winter and spring. Time of ovulation after the onset of estrus was not influenced by the season [32]. Extreme environmental conditions such as heavy rain or high humidity may also lessen or inhibit estrus behavior [10, 30–32]. In addition, there is a variation in estrus activity during the day. Cows increase their mounting and standing behavior during the night and early morning (e.g. from 7 p.m. to 7 a.m.), when the temperature is lower [33].

Housing and Flooring

Duration and intensity of estrus behavior is greater when cattle are kept on dirt compared to concrete, slippery surfaces [34, 35]. Furthermore, the use of rubber mats to cover a concrete floor improved the expression of estrus [36]. In addition, estrus detection is less efficient in cows under tie-stall barn conditions compared with cows observed continuously under free stall barn conditions. Interestingly, barn-housed cattle displayed greater number of mounts during estrus than pasture-managed cattle, which spend a

significant amount of time grazing [37, 38]. It is highly recommended that barn-managed cows be turned out twice daily (morning and afternoon) to be observed during one hour each time.

Presence of a Bull

The presence of a bull has a positive effect on the resumption of post-calving ovarian cyclicity, shortening the interval to first estrus and ovulation via pheromone secretion [39–42]. The presence of the bull may increase the probability to identify cows in heat. However, Landaeta-Hernandez et al. [43] demonstrated that duration of estrus, total mounts received, and intensity of estrus were not affected by the presence of the bull. Moreover, a bull commingling within the herd can inhibit the cow–cow mounting activity [44].

Hormonal Treatments

In general, it is believed that duration of estrus behavior is not different between animals showing prostaglandin (PG) $F_{2\alpha}$ induced estrus versus spontaneous estrus [22]. However, reports showed that duration of natural estrus appears to be longer than estrus induced by $PGF2_{2\alpha}$ (15.3 vs 13.3 hours) [45]. Another study revealed that treatment with progestogens appears to result in higher frequency of heat detection compared to treatment with $PGF_{2\alpha}$ [46]. It is important to emphasize that after hormonal treatments, farm employees are more aware of signs of heat during visual observation.

Population Density

The larger the number of animals in the herd, the greater the sexual interactions among them. When the herd size is increased, the odds of creating cattle SAG is greater. SAG refers to the number of cows in estrus or close to being in estrus interacting and displaying sexual behavior at the same time [47]. A large number of cows in heat at the same time improves the intensity of estrus expression and, therefore, the efficiency of detection [10, 12, 19, 22, 48]. However, excessive number of cows in a small area (overcrowding conditions) might make non-estrous cows stand when they are mounted, resulting in an erroneous heat detection.

Visual Observation as a Method for Estrus Detection

Visual observation is the method most commonly used for estrus detection. The observer's experience, frequency and length of observation, and the time of the day have a significant impact on the estrus detection efficiency.

Heat detection based on visual observation should be performed by observing groups of cows during one hour in the morning and one hour in the evening. Cattle should be observed during their normal activity of social interaction as they move to from housing, feeding, or pasture areas.

Development of observation skills for heat detection requires focus, consistency, and time. The observer must identify the primary sign of estrus (the cow stands to be mounted) without overlooking other secondary signs such as the presence of a clear vaginal discharge, vulvar edema, and increased physical activity. The personnel should be aware also that some cows show short-length estrous signs, while other cows do not show any sign of estrous behavior.

In dairy operations, cows can be observed as they are moved to and from the milking parlor. It is important for the cows to be able to express their sexual behavior to be on dirt, and always avoid observation on slippery concrete floors or floors with standing water. Normally, cattle are unwilling to mount or be mounted when they are on unstable ground surfaces. In beef farms, heat detection often requires observation in the pasture, feeding area, or holding pens. It is critical to not interfere with the cows' social interaction when performing the visual observation. It is common to observe nursing bull calves (approximately five to six months old) following the cows in heat and trying to mount them.

Heat detection efficiency based on visual observation of standing heat varies considerably among herds, from less than 50% to around 90% [49–51]. A significantly high heat detection rate (94%) was reported when visual observation was done twice a day for one hour each, at early morning and late evening. Increasing the observation frequency has a positive impact on the detection efficiency. In a field study using visual observation of both standing and mounting behavior three times per day during 30 minutes each, the heat detection rate improved to 90% [51]. It is highly recommended to encourage the personnel in charge of heat detection by providing a financial incentive (e.g. for each pregnant cow). This has an immediate and direct impact on estrus detection efficiency. Keeping both manual (e.g. notebook) and automated computer-based records of estrus and AI facilitates the anticipation of upcoming heats.

Artificial Insemination Based on Estrus Detection

AI based on heat detection is centered on the AM–PM rule. That is, if a cow shows estrus behavior in the morning, she should be inseminated in the evening. If she shows estrus activity in the evening, she should be inseminated the next morning. Since cows ovulate 24–32 hours after the beginning of estrus, AI performed approximately 8–12 hours

after estrus detection allows sperm to be in the uterus and uterine tubes for enough time to undergo capacitation before being able to fertilize the oocyte. A great proportion of cattle will show estrus behavior overnight. Therefore it is recommended to observe and inseminate cows as late as the light allows in the evening and as early as possible in the morning, especially during the warmest months (July and August). The use of hormonal protocols for estrus–ovulation synchronization permits personnel to combine heat detection plus AI (using the AM–PM rule) and TAI.

In farms where management conditions and heat detection systems allow to identify accurately the beginning of estrus behavior, cows should be inseminated using the AM–PM rule. In contrast, in those farms with low pregnancy rate and poor heat detection, it is recommended to inseminate the cows immediately after they have been detected standing to be mounted [30]. In previous studies an optimal pregnancy rate was achieved when AI was performed from mid-estrus until a few hours after the completion of standing behavior [52, 53].

The efficiency of heat detection affects not only the total number of cows eligible to be inseminated, but also the timing of insemination relative to ovulation and subsequent fertility. For instance, in a previous study, pregnancy rate decreased from 66.2 to 45.4% when AI was performed at 8–18 hours and >30 hours after heat detection, respectively [54]. The timing of AI influences the resulting pregnancy rate by affecting the fertilization rate and embryo quality. A trial demonstrated that performing early AI during standing heat behavior was associated with lower fertilization rates but adequate embryo quality. In contrast, inseminating 24 hours after the onset of estrus resulted in high fertilization rate but low embryo quality. A middle time of AI around 12 hours (6–16 hours) after the onset of estrus (AM–PM rule) resulted in an adequate balance between fertilization rate and embryo quality [55]. This effect was associated with the number of accessory sperm trapped in the zona pellucida. In addition, insemination timing relative to ovulation has an effect on the offspring's gender [54]. The percentage of male offspring is higher with late AI (10 hours before ovulation). In contrast, early AI (20 hours before ovulation) seemed to favor the proportion of female offspring [56].

When AI is based on heat detection, extra caution should be considered for cows previously diagnosed pregnant and showing signs of standing heat. Performing AI in a pregnant animal can cause embryonic mortality or abortion.

Estrus Detection Efficiency

Insemination risk has a great impact on reproductive performance in dairy operations. The number of cows inseminated will depend on the personnel's ability to detect estrus, which can be monitored by multiple parameters of estrus detection efficiency. An essential requisite for assessing estrus detection efficiency is having reliable records of the cows identified in estrus and inseminated (including dates and timing), their pregnancy diagnosis, and calving dates. Farms with severe estrus detection problems have low pregnancy risk, high percentage of repeat breeding, and prolonged intervals from calving to first service and conception. These farms may have a great proportion of cows inseminated when they are not in heat (heat detection inaccuracy), many cows in heat that are not inseminated (heat detection inefficiency), and, commonly, many cows inseminated too early or too late relative to estrus and ovulation.

Ideally, 80–85% of cows should be detected in estrus during the VWP (by 60 days postpartum). Therefore the percentage of anestrous cows should be lower than 15–20%. Farms with adequate estrus detection generally have a calving to first service interval of 71–76 days, most of the cycling cows (>70%) have an inter-estrus interval (IEI) of 18–24 days, and their personnel detect more than 70% of cows in heat.

In farms with inaccurate heat detection, there is a high percentage (>15%) of cows with too short (e.g. less than 17 days) or too long (e.g. 30 days) IEI, many cows are diagnosed pregnant to a service earlier than the last recorded, and a high percentage of cows calve before the calving due date. Inaccuracy of heat detection can be confirmed by determining the progesterone concentrations in milk in a representative number of cows (n = 20) on the day of AI. In these farms with inaccurate heat detection, more than 5% of the samples will have high progesterone concentration (>1 ng/ml), indicating the animals were not in estrus when they were inseminated. In farms with inefficient heat detection, cycling cows are routinely missed before the first insemination, so that the calving to first service interval is prolonged (e.g. 90 days). Furthermore, a high proportion of cows (>15–20%) have an IEI two or three times longer than the expected average of 21 days for cycling cows (e.g. 36–44 or 54–66 days). Moreover, in this case scenerio, the pregnancy risk at diagnosis is lower than 85%, indicating that many estrous cows have been missed between the AI day and the day of pregnancy diagnosis.

Several equations have been created to calculate the estrus detection efficiency (reviewed by Roelofs et al. [30]). These parameters are used to determine the proportion of cows detected in estrus relative to the number of cycling cows during a certain period of time. Some of these methods include percentage of heats detected during and after the VWP and heat detection index, which is calculated utilizing the number of cows detected in estrus, the IEI, the number of days to first service, and the VWP, as determin-

ing endpoints. Another approach includes calculation of the ratio between cows with normal IEI (18–24 days) and cows with prolonged IEI (36–48 days), which should be 4 : 1. Currently, numerous cattle management computer softwares are commercially available and provide a complete evaluation of the reproductive performance, including estrus detection indexes based on the mentioned variables. The information reported by the software will depend on the data collected and recorded from the herd by the personnel, so that continuous monitoring, data collection, and software updates are crucial for accurate reports.

Estrus Detection Aids

Several technologies have been developed for producers to improve estrus detection efficiency by providing continuous monitoring of behavior. These heat detection aids do not substitute for visual observation but have been designed to complement it. The following are the most common estrus detection aids currently used in cattle production.

Rump-Mounted Alert Patches

These include pressure-sensitive heatmount detectors (e.g. Kamar®) which are glued onto the tailhead to assist in identifying females showing standing estrus behavior (Figure 35.3). These patches usually contain a small vial of fluid with a smaller vial of color that breaks when pressure is applied by mounting activity. Animals with an activated (e.g. red color) heatmount detector are considered to be in estrus. In addition, there are self-adhesive heat detection patches with a silver scratch-off surface (e.g. Estrotect®). When the animal standing is mounted, the bright signal layer underneath is shown for easy identification.

Tailhead Markings

Marking the cow's tailhead with chalk, color wax, crayon, or paint (Figure 35.4) helps to identify animals that were mounted. In this case, the paint is rubbed off or smeared down the sides of the tailhead onto the rump, indicating that the cow has been ridden by another cow. This method has the advantage of being less expensive than the rump-mounted alert patches.

Chin-Ball Marker

The chin-ball marker (Figure 35.5) comprises a metal ink reservoir with a large ball bearing held by a harness which is placed under the marker animal's chin. As the marker animal mounts and dismounts the cow in heat, a characteristic mark is left on the cow's back and rump. The paint reservoir usually holds enough paint for about 25 cows, depending on mating behavior. Usually chin-ball markers are used with teaser bulls or testosterone-treated cows.

Teaser Animals

Teaser animals refer to animals that can identify and mount a cow in standing heat but cannot naturally breed her. A "teaser" bull is a bull that has been surgically altered, so that he cannot perform intromission during the mounting activity (Chapter 21). Several techniques can be utilized for this purpose including vasectomy, caudal epididymectomy, penile deviation, and penectomy. In addition, androgenized cows can be used as teaser animals.

A combination of these techniques can be used, such as vasectomy plus penile deviation. An additional benefit of using teaser bulls in beef herds is that their presence stimulates the resumption of cows' postpartum cyclicity, reducing the calving to first estrus interval. One of the disadvantages of using teaser bulls is that they can have a preference for specific cows and miss other cows that are in heat. In addition, some teaser bulls will lose their libido over time once they notice they are not able to breed the cows when they mount them. It is also important to pick teaser bulls that have a docile temperament, as these bulls are separated from the cows before AI.

Vasectomy

Vasectomy consists of removing a section of the ductus deferens from the spermatic cord. The testes and penis continue functioning normally, but transport of spermatozoa to the urethra is interrupted. The sexual activity of the bull remains unaltered and he will detect cows in heat as well as an intact bull but he will not be able to impregnate them. As this method does not prevent penetration, it does not control transmission of venereal diseases in the herd.

Caudal Epididymectomy

This surgical technique involves resection of the epididymis tail (Figure 35.6) to prevent sperm from reaching the ductus deferens and ejaculation. Similar to vasectomy, the disadvantage of this procedure is that the bull continues to penetrate cows and can transmit venereal infections from one cow to another.

Penile Deviation

Penile deviation is commonly done using a surgical technique that translocates the penis and sheath from their natural position to the fold of the flank. This method allows normal erection but not vaginal intromission (Figure 35.7). An alternative technique consists in the resection of a portion (5 cm) of the dorsal ligament of the penis. With this

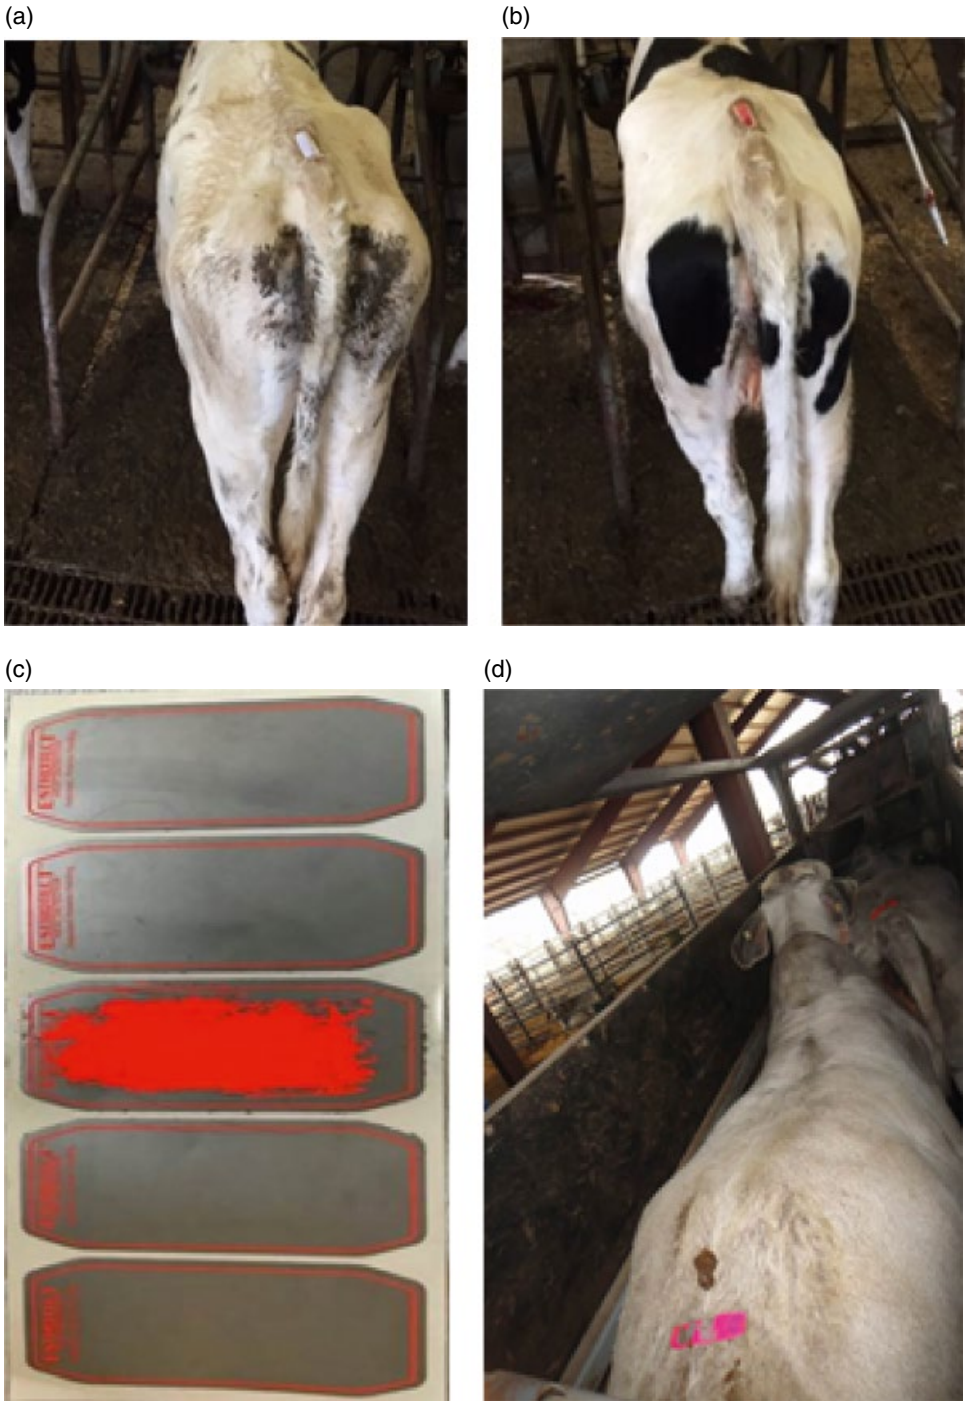

Figure 35.3 Rump-mounted alert patches. Holstein heifers showing pressure-sensitive heatmount detectors (Kamar®) glued onto the tailhead to assist in identifying females showing standing estrus behavior. (a) The heatmount detector is not activated, indicating that this heifer has not been mounted. (b) Heifer showing an activated (red color) heatmount detector, which indicates that she was mounted. Roberto Palomares (a–c) and Juan C. Gutierrez-Añez (d).

technique the penis is deviated ventrally during the erection, preventing vaginal penetration. This surgery is faster and simpler than lateral penile translocation and results in a lower risk of postoperative complications compared to penile translocation. However, this technique has not been fully accepted by practitioners since incomplete resection of the penile dorsal ligament results in partial deviation of the penis and vaginal intromission. The advantage of these techniques is that the possibility of transmission of venereal diseases is usually very low unless the bull becomes

skilled and discovers a way to breed the cow. The main disadvantage is that the bulls can become frustrated and lose their libido.

Penectomy

This technique consists of removing two-thirds of the penis and exteriorizing the remaining end, suturing it to the tissues between the anus and the scrotum. The disadvantage of this procedure is that libido is usually reduced; however, it helps in preventing venereal infections. Ethical issues and animal welfare concerns about this technique might exist and should be considered before using it.

Figure 35.6 Caudal epididymectomy.

Androgenized Animals

This method is based on extra-label systematic injections of testosterone (200 mg intramuscularly (IM) every other day for three weeks) or implant (testosterone plus estradiol) to a cull open cow (not intended for breeding) or freemartin heifer or steer to maintain consistent aggressive sexual behavior. Cows injected with testosterone propionate are usually sexually active, mounting other cows in heat within a few days after treatment. These animals can be equipped with a chin-ball to enhance their efficacy. The benefits of this method are that the cost is relatively low, the androgenized animals cannot spread venereal diseases, and they can be sold for harvest later after the breeding season. It is crucial that these animals be free of feet and leg problems

(e.g. lameness), have a large body frame, and are dominant, to actively display sexual behavior mounting cows in estrus.

Electronic Heat-Detection Systems

In general, dairy farms have tended to increase their herd size and production and intensified their management during recent years. However, labor has become less available, affecting negatively the efficiency of heat detection. Electronic technologies have been developed to enhance heat detection in dairy cattle by providing continuous monitoring of behavior using tri-axial accelerometers and wireless telemetry. These technologies include electronic rump-mounted devices, and pedometry and radiotelemetric devices that monitor the number of steps and mounting activity. Other electronic equipment that consider additional measures (e.g. milk and skin temperature, electronic noses, rumination) have been developed for this purpose, but are currently under investigation and their efficiency and applicability are still being tested.

Automated Activity Monitoring System (AAMS)

In cattle, increased physical activity is considered a secondary sign of heat. The increase in physical activity in cows has been reported as high as 400% in winter and 175% during summer [57]. Automated activity monitoring systems (AAMS) can continuously monitor physical activity in cattle and register fluctuations in their motion (e.g. head movements). This technology has been implemented with great acceptance in the USA and Europe in the last few years in an attempt to help reduce the labor of visual observation and maintain a continued surveillance.

The system utilizes tri-axial accelerometers in a tag attached to the animal (e.g. a neck collar or ear tag) that constantly determine acceleration forces related to gravity to assess specific variation in physical activity associated with estrus behavior (Figure 35.8). Data are recorded for certain periods of time (e.g. two hours) and transmitted to a transceiver unit (generally at the milking parlor). This device transfers the information to a software installed on an on-farm computer. The individual cow's activity is graphed and, using a mathematical algorithm, an activity index is calculated by the software indicating the variation from average activity in the same time period during a longer time frame (e.g. the last seven days).

Three studies developed at commercial dairy farms using AAMS in cows managed in a free stall barn revealed that approximately 70% of the cows were identified as having increased physical activity [58–60]. In addition, 95% of cows documented to be in estrus by the system ovulated. Further, 35% of the cows not detected in heat by the system ovulated. The results of these studies suggest that AAMS were efficient in detecting cows in estrus but did not detect increased activity in anestrous cows or cows having silent ovulations without heat [58–60]. Similarly, LeRoy et al. [61] performed a study to determine the capability of AAMS to detect estrus for first AI, the accuracy of detection, and the optimum interval from the estrus alert to insemination. Activity monitors identified over 80% of animals for insemination between 55 and 80 days in milk (DIM), but intervention such as TAI would nevertheless be required for the remaining undetected cows. This study suggested that primiparous cows should receive AI 0–8 hours after being detected in estrus by AAMS to optimize pregnancy risk. In contrast, no difference was found in pregnancy risk for the multiparous cows in which AI was performed up to 24 hours after the AAMS alert [61].

A trial compared different AAMS in evaluating steps, motion, neck activity, lying behavior, feeding, rumination, and rumen and vaginal temperature for estrus detection. The study considered visual observation four times a day for heat detection and temporal progesterone profile as a reference standard. Only 56% of cows that ovulated were observed standing by visual observation. The evaluated devices were capable of detecting estrus at least as efficiently as visual observation. The devices were able to detect 15–35% more cows in heat than visual observation [62]. This study recapitulated previous results, indicating that activity patterns increased on the day of estrus. Further, this study and others [63, 64] indicated that decrease in rumination and eating time might also be considered as predictors of estrus in dairy cows [62]. Likewise, another trial using a 3D-accelerometer integrated into an ear tag (SMARTBOW®) for the detection of cows in estrus

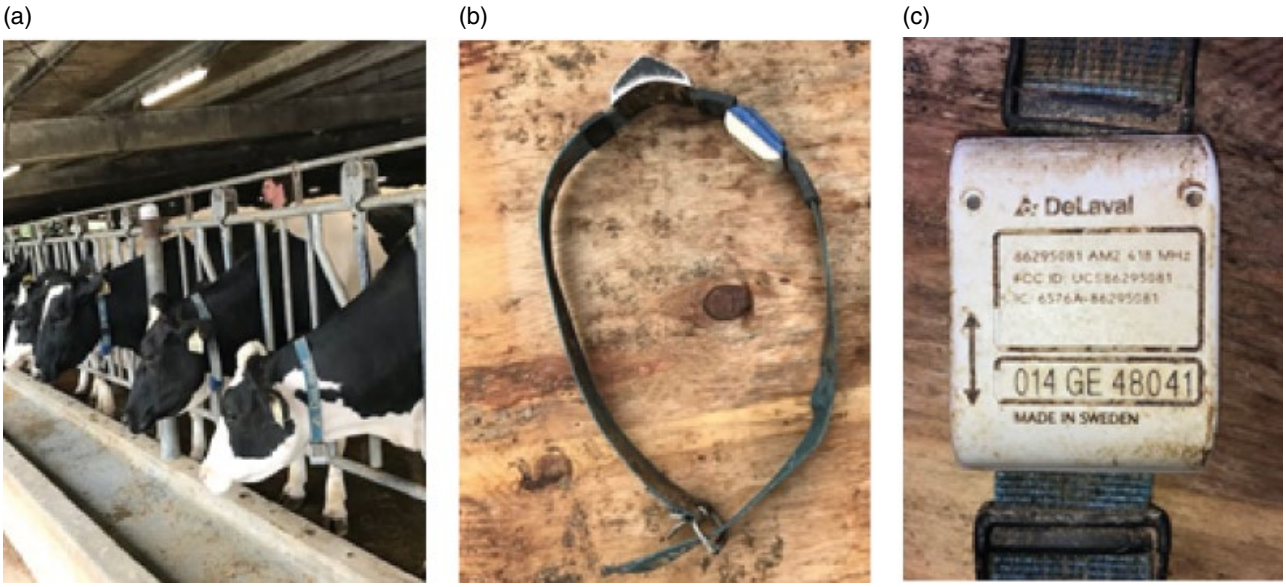

Figure 35.8 (a–c) Automated activity monitoring system (AAMS). Holstein cows wearing activity meters (DelPro™, DeLaval®) attached to neck collars which determine specific variation in physical activity associated with estrus behavior. *Source:* Image courtesy of Dr. Roberto Palomares.

(gold standard: estrus that resulted in pregnancy after AI) demonstrated that the system was appropriate for automated heat detection of multiparous, indoor-housed dairy cows, showing values of sensitivity, specificity, positive and negative predictive values, accuracy, and error rate of 97, 98, 96, 94, 96, and 2%, respectively [65].

AAMS can also determine the duration of the increased physical activity during estrus, which has been reported to be 16.1 ± 4.7 hours (range 4.0–28.0) [58]. These values are similar to the estrus length reported for cows monitored for signs of standing to be mounted (13.4 hours). However, it is important to highlight that secondary signs of estrus behavior increase significantly a few hours (~2 hours) before the onset of standing estrus [59]. Another aspect to consider when using AAMS is that the confined housing conditions in most dairy operations are not appropriate for cows to exhibit full estrus activity, limiting the behavioral indicators used by producers to detect cows in heat. Changes in patterns of lying and standing times at estrus would be a potential parameter for estrus detection in cows within tie-stalls [66]. The evaluation of automated devices using accelerometers revealed an overall increase in total daily standing time during estrous days and longest lying periods on the day after estrus [66, 67]. These studies have also shown that there is a great variation in standing–lying patterns among cows [66, 67].

An eventual goal of these systems is to determine the timing of AI relative to behavioral estrus and ovulation in order to improve overall pregnancy rates. Studies using AAMS revealed that the mean interval from AI to ovulation when inseminating based on the increased physical activity was 7.9 hours [58], which apparently provides enough time for sperm capacitation before fertilization [68]. Another study using AAMS in lactating Holstein cows showed that animals with higher estrous expression had longer intervals from activity alert to ovulation, less ovulation failure, and greater pregnancy rate [69]. Unfortunately, there is a great variation in the interval from onset of activity (and subsequent AI) to ovulation among cows [58]. This variability has a negative impact on pregnancy outcomes. Therefore, in order to minimize the negative effects of this variation, AAMS should be programmed to generate two lists (one list every 8–12 hours) of cows to be inseminated. Another limitation of AAMS is related to the presence of anestrus–anovulatory cows (~20% of the cows in a herd) which fail to be detected with increased activity and are submitted to an ovulation synchronization protocol (e.g. Ovsynch), resulting in poor pregnancy per timed artificial insemination (P/TAI).

The use of AAMS to detect cows for AI in combination with ovulation synchronization and TAI protocols represents a current challenge for herd managers and is becoming a promising tool for systematic AI programs in dairy operations. A study to evaluate the reproductive efficiency of lactating dairy cows managed for first service using a Presynch-Ovsynch TAI protocol with or without detection of estrus using an AAMS reported no improvement in overall pregnancy risk when the presynchronized cows were inseminated based on increased activity and not included for the TAI protocol [59]. A study comparing pregnancy

outcomes in dairy cows inseminated based on AAMS with hormone intervention versus cows inseminated using only a TAI protocol showed no significant differences in pregnancy outcomes between these two management strategies, indicating that AI in cows using AAMS can achieve a level of reproductive performance comparable to TAI [70]. Veronese et al. [71] reported that the use of AAMS for reproductive management of dairy heifers was not advantageous compared with Kamar and did not result in significant improvement in reproductive parameters. The implementation of these systems by herd managers may be affected by hesitancy about their benefits, being unfamiliar with available technology, the excessive information without clear relevance for management [72], the high initial investment, future technology improvement, and availability of future technical support [73].

Pedometers

The number of steps per hour by a cow in estrus is approximately two- to four-fold greater compared with a cow in diestrus [74]. Pedometers are electronic devices that are attached to a cow's leg to count her steps, as an indicator of her physical activity (Figure 35.9). The resulting step count is compared with her baseline count when she is not in estrus. The cow is considered in estrus when her count exceeds the baseline values. When this happens the system sends a signal to the receiver, reporting the event. The efficacy of pedometers is variable (49–90%), since it depends on the housing conditions [75]. Pedometers are more efficient detecting cows in estrus when animals are housed in free stall barns and their benefit is limited in tie stall-housed cows, where they are not able to display increased walking behavior. In farms where animals are moved excessively these systems can provide inaccurate and unreliable results.

Figure 35.9 A cow wearing a pedometer attached to her right rear leg to count her steps, as an indicator of her physical activity. *Source:* Image courtesy of Dr. Antonio Landaeta-Hernandez.

HeatWatch

The HeatWatch® system is an electronic radiotelemetric, pressure-sensitive device that consists of a sensor-transmitter fixed in a cloth tag that is attached to the cow's tailhead region which determines the pressure applied by a mounting cow (Figure 35.10). The transmitter sends a signal to a receiver wired into a computer where the data are stored and analyzed. The transmitters are coded so that each mounted animal sends a unique animal-identifying signal to the computer. The system reports the animal's identification, date, time, and duration of the mounting activity, and which cow is ready to be bred. The HeatWatch® system is very helpful when visual observation for heat detection is inefficient. A disadvantage of this technology is that it has high investment costs and there can be some problems when cows are located under sheds or trees or if there are hills which may inhibit signal reception.

Body and Milk Temperature

During estrus there is a noticeable increase in body and rectal temperature [76]. This variation might be associated with greater physical activity during estrus [30]. However, the specific physiological mechanism involved in the temperature change during the cow's estrous cycle remains unknown.

Thermal infrared (IR) scanning of the cow's posterior body surfaces (gluteal region, vulvar, perineal, and inguinal areas) has been used to detect temperature changes related to ovulation. A trial reported differences of 0.2 °C. The ovulation detection sensitivity was 80%, with high false positive and negative rates [77], not being recommended as an accurate method for routine heat detection. A study in dairy cows using IR thermography and behavioral biometrics showed that variations in radiated temperature from the vulva, muzzle, eye, neck, cheek, and withers as well as tail movements before ovulation were associated with estrus indicators in tie stall-housed cows. The authors stated that this could be used as non-invasive estrus alerts in multiparous cows housed in a tie stall system [78].

Milk temperature may also increase (e.g. 0.3–0.4 °C) on the day of behavioral estrus and has been shown to be a potential alert for estrus detection.

Figure 35.10 (a) and (b) Brahman cows wearing HeatWatch patches (blue and orange) over the tailhead. These cows are in a dry-lot area so that there is close proximity to the receiver for the electronic transmitter. *Source:* Images courtesy of Juan C. Gutierrez-Añez.

Since there is so much variation among animals and body fluids' temperature can be affected by several confounding factors (e.g. season, stress, disease), these methods are not currently considered accurate and reliable for estrus detection.

Vaginal Mucus Electrical Resistance

It is well known that vaginal mucus viscosity and electrical resistance decrease during proestrus and estrus [79]. Previous studies using a conductivity measuring device showed a high variation in vaginal mucus conductivity among cows, suggesting that it is not an accurate or reliable method for estrus detection. Moreover, the tools initially developed were expensive and labor intensive, because cattle needed to be tested frequently to detect the reduction in electrical resistance. In a study evaluating the vaginal conductivity and temperature in 17 female cattle using a wireless vaginal sensor system, 16 of 17 estruses were correctly detected. The interval from detection to ovulation was similar to that observed with standing estrus, suggesting that estrus can be identified in real-time using this new technology [80].

Electronic Nose

Pheromonal odor secreted from the perineal glands near the vagina is a determinant for the bull to identify cows in heat [81]. Efforts have been made to identify chemical compounds associated with estrus [82]. A study was performed to test automatic differentiation between estrous and non-estrous cows using an integrated measurement system consisting of a breath sample device. The results showed sensitivity and specificity combinations of 0.83 and 0.86, respectively, suggesting a potential for automated detection based on breath sampling [83].

Summary

Estrus expression and its detection are multifactorial traits. Estrus detection efficiency depends on the observer's experience, frequency and length of observation, and the method(s) used as detection aid(s). Selection of the estrus detection aid method(s) depends on herd management, cost, labor, efficacy, and usefulness. Detecting cows in heat and inseminating them at the appropriate time relative to the time of estrus behavior and ovulation is vital to achieve an adequate pregnancy rate. Currently, the integration of visual observation with detection aid methods (especially electronic technology) can help enhance estrus detection efficiency in dairy and beef herds. Regardless of the methods utilized in each farm, it is important to frequently monitor estrus detection operating procedures (and retrain personnel), maintain a systematic data collection (e.g. estrus, AI, and calving dates), consistently transcribe the information to the computerized systems, and obtain "useful" reports about reproductive performance that can be interpreted by the herd manager and the veterinarian.

Artificial Insemination

Ram Kasimanickam

Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, WA, USA

Introduction

Artificial insemination (AI), the introduction of sperm into the female reproductive tract by means of an instrument, is the oldest assisted reproductive technology [1]. The use of AI in domestic animal reproduction was originally pioneered for sanitary reasons. However, once frozen semen became readily available, the economic advantages of improved fertility and accelerated genetic progress became evident. Since then, AI has become the method of choice for rapidly spreading preferred animal genetics. Numerous bulls have produced hundreds of thousands of insemination doses and offspring. Furthermore, reduced numbers of sperm per insemination dose without compromising fertility has greatly increased the number of inseminations and offspring from genetically superior sires. Several important developments, including novel sperm diluents, new AI techniques, protocols for synchronizing estrus and ovulation, and the availability of gender-selected semen, have further increased the use and importance of AI as an assisted reproduction technique.

Achieving high fertility with AI requires excellent management of all phases of the AI program; it truly requires a team approach. In that regard, personnel responsible for semen collection, processing, and delivery must all correctly perform their tasks, as any deficit will reduce fertility success. Furthermore, the innate fertility of bulls and cows is of vital importance.

Large commercial AI centers generally have protocols and quality control procedures in place to ensure that good-quality semen is marketed. However, once the semen has been sold, fertility depends on the ability of others to correctly handle and thaw the semen and to correctly inseminate cows at the proper time. The primary objective of semen handling is to conserve fertilizing competency, which is accomplished by minimizing exposure of sperm to deleterious conditions. Damage to sperm during cryopreservation, storage, and thawing has been attributed to cold shock, ice crystal formation, oxidative stress, membrane alteration, cryoprotectant toxicity, and osmotic changes [2]. Knowledge of semen tank management, proper thawing and semen handling techniques, and sanitary insemination in the correct location at the correct time are critical and should be periodically reviewed.

Semen Tank Management

Frozen semen is stored in a specialized tank containing liquid nitrogen. These tanks have a rugged outer jacket (aluminum or stainless steel) and an inner compartment that contains liquid nitrogen. The space between the inner and outer jackets is insulated and under extreme vacuum. The lid is attached to a hard foam cylinder that protrudes into the neck of the tank to insulate liquid nitrogen and frozen semen from outside temperatures, thereby minimizing evaporation. However, the tank is not airtight; the liquid nitrogen releases gas as the temperature fluctuates (if the tank was tightly sealed, it might explode). Recent technical progress in design and construction has resulted in user-friendly good-quality semen tanks, including those with extended holding intervals (6–12 months). It is noteworthy that holding intervals vary according to tank model and the frequency with which it is opened. It is essential that the nitrogen content is routinely monitored and additional nitrogen added as required.

With newer semen tanks, maintenance of very low liquid nitrogen temperatures in the inner chamber is possible due to high-quality solid insulation material and vacuum. Regardless, all tanks are susceptible to damage from mishandling. The inner chamber containing liquid nitrogen is actually suspended from the outer shell by the neck tube.

Table 36.1 Fluctuating temperatures in the neck of a typical semen storage tank.

Location in neck of storage tank	Temperature (°C)
Top of neck	2.2 to 12.2
2.54 cm from top	−15 to −22.2
5.08 cm from top	−40 to −46
7.62 cm inch from top	−75 to −82
10.16 cm from top	−100 to −120
12.7 cm from top	−140 to −160
15.24 cm from top	−180 to −192

Source: Adapted from [3].

Consequently, any abnormal stress on the neck tube caused by substantial force or an excessive swinging motion can crack the tube, resulting in vacuum loss. Puncture of the outer shell will also lead to vacuum loss. Welding the tank exterior should be avoided, as this could also cause vacuum loss. Since vacuum is the major insulating component of the tank, vacuum loss causes an increase in temperature within the inner chamber and rapid evaporation of nitrogen. Accumulation of heavy frost at the top of the tank indicates rapid evaporation of liquid nitrogen and tank failure. Although semen can be stored at −196 °C indefinitely with minimum liquid nitrogen, a minimum depth of 5 cm should be maintained.

Semen storage tanks should be stored away from direct sunlight in a cool, clean, dry, dust-free, and well-ventilated environment. Tanks should be elevated on a wooden pallet and never stored directly on a concrete floor (to prevent corrosion on the bottom of the tank). Furthermore, tanks should not be stacked on top of each other. The tank should be placed in an area where it can be observed frequently to detect excessive evaporation of liquid nitrogen. The tank should not be laid horizontally and rolled. Storing the tank on a wooden or plastic dolly with wheels facilitates movement of the tank. Tanks should be properly secured during transportation in a vehicle to minimize damage or spillage.

Frozen Semen Storage

Most semen is packaged in 0.25- or 0.5-ml straws (sex-sorted semen is consistently in 0.25-ml straws). The straw is placed in a goblet with four other straws from the same bull. Two goblets are packaged onto a metal cane that has the bull's code number printed on top. Canes are stored in canisters in a semen tank. Storage and handling of 0.5- and 0.25-ml straws are similar.

Maintenance of low temperatures is the key to successful storage of frozen semen. During cooling and freezing, microenvironments are created within the semen straw. Each chemical component of extended semen freezes or solidifies at a different temperature. Water begins to freeze as temperatures are decreased below 0 °C, forming ice crystals that remain somewhat unstable at temperatures above −80 °C [3]. This instability is thought to be caused by recrystallization of the ice. Also, as water is converted to ice, sperm are exposed to the remaining concentrated solution of salts and other components of the extender which freeze at temperatures considerably below the freezing point of water. Instability of ice and concentrated solutions are harmful to sperm. Dehydration during cryopreservation has an important impact on sperm; dehydration decreases the risk of intracellular ice crystal formation, but excessive dehydration is also detrimental [4]. Adjusting the osmolality of the diluents is critical, as it influences water fluxes during cryopreservation [4]. Fortunately, cryoprotective agents and optimized freezing programs help minimize sperm damage. However, semen must be kept well below critical temperatures where the recrystallization of ice begins to occur (−100 to −80 °C). Temperatures fluctuate dangerously from the low to upper third of the neck of the tank [3] (Table 36.1). Furthermore, stored semen can be exposed to adverse high temperatures when removed from the tank for thawing, when transferring semen from tank to tank, and when handling semen within the neck when trying to locate and thaw a specific straw. In addition, other semen straws in goblets and canisters are also exposed to high temperatures. The thermal response of semen in 0.5-ml straws when raised to 5 cm from the top of the tank and exposed to an environment temperature of 22 °C (ambient room temperature) and 5 °C (refrigerated room temperature) is shown in Table 36.2. The time to reach critical ice recrystallization temperature (−100 to −80 °C) is approximately 10–20 seconds for both temperatures at half or full capacity. Thermal injury to sperm is permanent and cannot be corrected by returning semen to liquid nitrogen. To assure maintenance of sperm viability, canes and canisters should be raised into the neck of the tank and kept below the frost line only for five to eight seconds. If necessary, the canister should be lowered back into the tank for cooling and subsequently brought back to the neck of the tank.

The number of sperm per straw is variable, with some reduction in number common for high-demand elite bulls and substantially lower numbers for sex-sorted semen. Higher dilutions (2 million sperm per 0.25-ml straw) did not affect the proportions of linearly motile spermatozoa, membrane integrity or stability, or chromatin integrity immediately after thawing compared with a low dilution

Table 36.2 Thermal response of semen straw exposed to refrigerated and ambient temperature (temperature observed in the upper portion of the semen storage tank).

		At full capacity[a]								At half capacity[b]							
		At 5 °C				At 22 °C				At 5 °C				At 22 °C			
Tank capacity (l)	Normal working duration (days)	5 s	30 s	60 s	120 s	5 s	30 s	60 s	120 s	5 s	30 s	60 s	120 s	5 s	30 s	60 s	120 s
10	45	−180	−82	−52	−31	−180	−77	−47	−28	−180	−79	−46	−32	−180	−67	−46	−25
20	120	−180	−80	−54	−34	−180	−75	−44	−28	−180	−80	−47	−32	−180	−63	−41	−24

47.5	76	−180	−90	−58	−37	−180	−70	−40	−22	−180	−85	−42	−28	−180	−58	−35	−18

At 5 °C, the tank was stored in a refrigerated room and measurements were recorded; at 22 °C, the tank was stored in a room at ambient temperature and measurements were recorded.
[a] Full capacity means the semen tank was filled with liquid nitrogen to full capacity (e.g. 10 l of LN_2 in a 10-l tank).
[b] Half capacity means the semen tank was filled with liquid nitrogen to half capacity (e.g. 5 l of LN_2 in a 10-l tank).

rate (15 million sperm per 0.25-ml straw). Further, there was no difference in pregnancy rate between dilution rates [5]. Regardless, it is well known that some bulls require more sperm per insemination dose to maintain fertility. Furthermore, due to very low numbers per insemination dose, the fertility of sex-sorted sperm is almost inevitably decreased.

Tips to Minimize Thermal Injury

- Develop a semen inventory system and mount it on a wall near the tank. Try to keep semen from one bull on each rack. Label canister and goblets with bull number/name. Such systems prevent unnecessary searching and exposure of semen to dangerously high temperatures in the neck of the tank.
- Organize rapid transfer of semen between tanks. Involve two people and arrange the tanks side by side. If possible, fill the tanks with nitrogen before transfer. Raise canisters only to a level necessary to locate the rack of semen to be transferred.
- When preparing to thaw semen, raise the canister into the lower portion of the neck where the specific goblet of semen can be grasped, then lower the canister further into the neck. Secure the goblet as low as possible in the neck, thus protecting other straws from thermal injury. If straws cannot be easily removed, bend the top tab of the goblet (45° angle) to improve access.
- Use forceps to remove the straw and to transfer it to the thaw bath. As soon as the straw is retrieved, quickly lower the rack of semen and canister into the body of the tank.

Semen Thawing Method

Various methods for thawing semen in straws have been recommended, including a variety of water bath temperatures and thawing periods, shirt pocket thawing, air-thawing, and thawing in the cow. Regardless, it is recommended that all persons on a farm use the same method to thaw semen. The National Association of Animal Breeders recommends a semen straw be immersed in a water bath at 30–35 °C for 40 seconds. The thawing time for straws should be a minimum of 30 seconds [6]. Thawed semen should be inseminated within 15 minutes after thawing and drastic decreases in post-thaw temperature must be avoided [7].

In pocket thaw methods, the initial pocket temperature was 30 ± 1 °C. However, one minute after pocketing, the temperature decreased to approximately 19 ± 1 °C, which could have adverse effects on sperm parameters. Semen in straws began to liquefy approximately three minutes after pocketing, with thawing completed by five minutes [7]. The results of semen viability assays after pocket thaw differed widely among experiments. The rate of thawing in a shirt pocket could be quite variable depending on the ambient temperature and the insulating effect of different types and thicknesses of clothing. Furthermore, the thaw rate was much slower for pocket-thaw compared with a water bath [7]. More rapid thaw rates result in higher post-thaw viability compared with the pocket-thaw method [7]. However, a recent study claimed that irrespective of improved *in vitro;* semen quality with a fast thaw rate, these semen quality measures did not increase *in vivo;* fertility compared with a pocket-thaw method [8]. If frozen semen is prepared to permit flexible thawing, the thaw method used, whether pocket or warm water thaw, should not affect conception under commercial conditions [8]. Although some sire and extender (egg-yolk citrate vs non-heated whole milk extender) combinations seem to be tolerant to thaw procedures, other combinations are more sensitive, resulting in reduced post-thaw sperm survival, conception rates, or both, in response to thaw methods [9].

Concurrently thawing multiple straws of semen can facilitate efficiently breeding a large number of cows without compromising semen quality or conception rates. Despite several reports that more than one straw can be safely thawed, caution must be employed while preparing multiple guns, because it is paramount to follow proper procedures for straw preparation and thermal protection and to always work within skill and time constraints. An experienced inseminator can thaw multiple straws of semen and prepare insemination guns to breed up to four cows within 20 minutes, without an adverse effect on conception [10]. Another study concluded that, on average, conception rates differed between professional AI technicians and herd inseminators. However, elapsed time from initial thaw to completion of fourth AI and sequence of insemination (first, second, third, or fourth) had no effect on conception rate within the inseminator group [11]. Oliveira et al. [12] concluded that sequence of insemination after simultaneous thawing of 10 semen straws can differently affect conception rates at timed AI, depending on the sire used. Regardless of number of straws thawed simultaneously, it is vital that straws are agitated immediately after immersion to prevent straws from clumping together, resulting in a decreased rate of thaw.

Semen Handling After Thawing

Mixing water and semen will cause irreversible sperm injury. Hence, on removal of the straw from the water bath, the straw should be dried (typically with a paper towel)

before it is cut. If the straw is defective (e.g. perforated), it should be discarded.

Prevention of cold shock is critical for post-thaw semen handling. Cold shock inflicts irreversible injury to sperm and is caused by rapid post-thaw decrease in temperature; this occurs when semen is thawed and then subjected to cold environmental temperatures before being inseminated. Cold shock decreases motility and fertilizing competency due to irreversible changes in the sperm plasma membrane. The severity depends on the rate and duration of temperature drop. The most obvious sign of cold shock is loss of motility which is not regained on warming the semen. There is also a decrease in the rate of fructose breakdown by the sperm and a decrease in oxygen uptake and in adenosine triphosphate (ATP) concentrations, which can now be no longer synthesized and used to supply energy. Cold shock caused an influx of sodium (186.2 ± 9.3 vs 140.7 ± 10.2 mg/100 g wet weight) into sperm, as well as an efflux of potassium (101.6 ± 6.8 vs 155.4 ± 9.6 mg/100 g wet weight) and magnesium (8.1 ± 0.2 vs 11.8 ± 0.5 mg/100 g wet weight) from the sperm [13]. The higher total calcium concentrations in bovine seminal plasma than in sperm are primarily due to a much higher concentration of complex calcium in seminal plasma. The concentration of protein-bound calcium was approximately the same in spermatozoa and seminal plasma, whereas concentrations of ionized calcium were lower in seminal plasma than in spermatozoa. Cold shock significantly increased the concentration of total calcium in spermatozoa, with a corresponding decrease of total calcium in the seminal plasma, due to a decreased content of ionized calcium in the seminal plasma and a simultaneously increased content of complex and protein-bound calcium in spermatozoa. In contrast, there was no increase of calcium in spermatozoa following slow cooling.

Cold shock occurs most frequently when breeding is performed in cold weather and especially when a warm water bath is used. The high surface to volume ratio of a straw makes it vulnerable to cold shock. Saacke [14], using the 0.5-ml French straw, measured the effect of static ambient temperatures (21, 4, and 16 °C) on the rate of temperature drop in semen after thawing during preparation of the inseminating rod (Table 36.3). The temperature drop was only 3–6 °C for an ambient temperature of 21 °C; furthermore, warming the rod was effective in countering temperature drop. However, during preparation at 4 and 16 °C ambient temperatures, the drops were 15 and 20 °C, respectively, and preparation of the AI gun for insemination at these two temperatures only postponed the temperature drop. Clearly, precautions against cold shock must be implemented during preparation of inseminating guns in a cool environment.

Tips to Prevent Cold Shock in Cold Weather

- Perform semen thawing and loading of the AI gun in a sheltered heated area located close to the animal to be bred. Then insulate the AI gun by tucking within clothing or in an AI gun warmer and carry it to the breeding chute.
- Perform preparation of the AI gun and breeding in a sheltered heated area.
- Utilize an AI gun warmer. An AI gun warmer is a portable, heated, temperature-controlled carrying case that maintains multiple loaded AI guns at 35 °C.

Table 36.3 Temperature of semen (°C) in 0.5-ml French straws after water bath thaw at 35 °C during preparation of an AI gun at 21, 16, and 4 °C.

	Preparation at 21 °C		Preparation at 16 °C		Preparation at 4 °C	
Stage of preparation[a]	Warmed[b]	Unwarmed[c]	Warmed	Unwarmed	Warmed	Unwarmed

[a] Preparation of AI gun from thaw to tuck took approximately one minute.
[b] The AI gun was warmed by rubbing rapidly with the hand (warmed) or was maintained at ambient temperature (unwarmed).

Semen Straw Retrieval, Thawing, and Handling Tips

In order to obtain optimal results, frozen semen should be handled and thawed carefully. Insemination equipment should be kept clean and dry (including straw trimmers, which often become heavily soiled). A thermometer should be routinely utilized to monitor the temperature of a water bath, especially when several straws are thawed concurrently. The thermometer should be periodically checked for accuracy (at least every six months).

On retrieving straw from the semen tank, shake the straw gently to remove excess liquid nitrogen that may be retained in the cotton plug and promptly place in 35 °C water to thaw for at least 45 seconds. The thawing should be timed with a watch. While the semen is thawing, prewarm the barrel by stroking it vigorously with a clean paper towel or by placing it close to your body for several minutes in advance of loading. After thawing is completed, remove the straw from the thaw water and wipe it completely dry with a paper towel, and protect the straw from sunlight and rapid cooling. The straw should be held with the crimp upright and gently tapped so that the small air space is adjacent to the crimp. Place the cotton plug end of the straw into the AI gun. Only clean sharp scissors or a straw cutter should be used to cut the straw, perpendicular to the long axis, approximately below the crimped seal to attain a good seal with the AI gun sheath. Slide the plastic sheath over the straw and gun and firmly attach the sheath and gun together. Inspect the straw end of the gun to ensure a proper seal between sheath and straw. The loaded insemination gun is wrapped in a clean paper towel or in a plastic sheath cover to provide both thermal and hygienic protection and the gun is tucked inside clothing or a gun warmer for transport to the animal. The interval from removing the straw from the tank to AI should not exceed 15 minutes.

Insemination

Higher fertility requires proper insemination methods. Several insemination methods have been developed for AI in cattle: uterine body insemination, bilateral cornual insemination, deep uterine horn insemination, and intrafollicular insemination. The most common approach is to use a rectovaginal technique to deposit semen in the uterine body, immediately anterior to the internal os of the cervix. Uterine body and cornual insemination require skill to pass the insemination rod through the cervix. Various training programs are available. For example, many AI studs offer intensive three to five day training schools or provide instructions for individuals on the farm. Most agricultural colleges devote a whole course or part of a course to the technique of AI. However, the intensity of training and specific recommendations given to the participants varies considerably among training programs.

Developing the skill to pass the insemination rod through the cervix should not be the only objective of an AI training program. Along with mastering cervical penetration, the importance of sanitation must be emphasized and skills perfected to consistently identify the proper site of semen deposition and accurately deposit the semen. In addition, trainees should obtain a working knowledge of reproductive anatomy and appreciate the essentials of a sound reproductive management program. Failure to understand the anatomical and functional relationships of various tissues and organs of a cow's reproductive system may lead to insemination errors.

The loaded AI gun is placed in a sanitary plastic cover for protection from vaginal contamination (Figure 36.1). The cow should be adequately restrained, with care to minimize stress (as increased blood cortisol concentrations will supress a luteinizing hormone surge). The palpating arm is introduced into the rectum and the cervix located and firmly grasped (Figure 36.2). The vulva is cleaned with a paper towel, the covered AI gun is inserted into the vagina without contacting the lips of the vulva, and the AI gun is passed through the vagina to the external cervical os (Figure 36.3). Care should be taken to avoid the urethral orifice, vaginal fold, and vaginal fornix. To avoid the possibility of entering the urethral opening (on the floor of the vagina), insert the inseminating rod into the vulva at an angle of 30–40°. The fornix of the vagina tends to stretch rather easily when the AI gun is pushed forward and beyond the cervix. This may give the false impression that progress is being made in advancing the rod through the cervix when really it is above, below, or to either side of the cervix (Figure 36.4). However, one should be able to feel the rod within the vaginal fold (Figure 36.5). When the rod is within the cervix, its tip cannot be felt. The sanitary cover is punctured (Figure 36.6) and the instrument is advanced through the cervix into the base of the uterine body. There are approximately three misaligned cervical rings through which the rod must pass; the rod is advanced by manipulating the cervix and keeping consistent firm pressure on

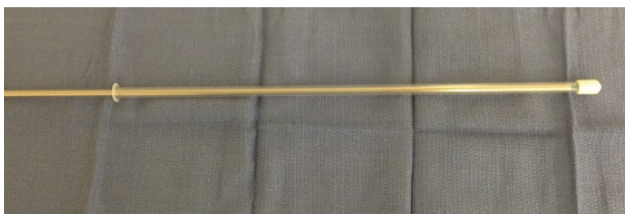

Figure 36.1 AI gun with protective sheath.

Figure 36.2 Locating and grasping the cervix.

Figure 36.3 Locating the external os of the cervix.

the instrument (Figure 36.7). Care should be taken to avoid catching the tip of the rod on cervical folds. The goal for semen deposition is within the uterine body. Since the uterine body is quite small, accurate AI gun placement is paramount. Generally, this site is identified by feeling the internal os of the cervix and the tip of the AI gun as it passes through the internal os and enters the uterine body (Figure 36.8). The tip of the gun should be positioned so that it is approximately 1 cm anterior to the internal os (Figures 36.9 and 36.10); this can be verified with the tip of the index finger of the hand within the rectum. Once the inseminating rod is correctly positioned, the cervix should

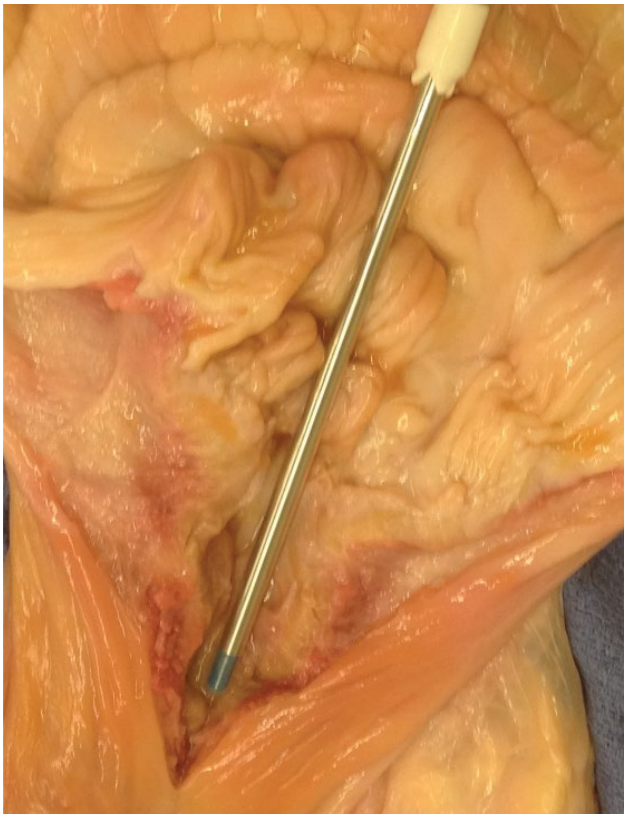

Figure 36.10 Semen deposition site (uterine body).

be held parallel to the long axis of the cow and semen is deposited over a period of approximately five seconds. Slow delivery maximizes the amount of semen delivered from the straw and minimizes the flow of semen unequally into one uterine horn. During the process of semen deposition, one must ensure that the fingers of the palpating hand are not inadvertently blocking a uterine horn or misdirecting the flow of semen in some manner. Care should be taken to avoid pulling the AI gun back through the cervix while depositing the semen. If the cow moves during semen deposition or if the rod slips, reposition the rod to assure proper placement.

Even though the standard recommendation is to deposit semen in the uterine body, bicornual insemination results in no change in fertility [15, 16] or improved fertility [17]. Andersson et al. [18] reported similar pregnancy rates for ipsilateral (to the ovary with the preovulatory follicle) cornual insemination with a lower insemination dose (2 million sperm) compared with uterine body insemination with normal dose (15 million sperm); however, fertility was reduced for lower doses inseminated in the uterine body or bilateral cornual insemination compared with higher dose insemination. It should be noted that anterior cornual insemination did not increase sperm retention rate compared with uterine body insemination. Although factors controlling sperm transport and retention are complex, it is clear that retrograde transport of sperm occurs regardless of site of deposition.

Verberckmoes et al. [19] in Belgium developed a novel AI device (Ghent device) for semen deposition near the uterotubal junction in cattle. The site of semen deposition on fertility was tested with insemination of 12 million sperm deposited in the uterine body using conventional techniques (control) or insemination with a reduced sperm dose (4 million sperm) deposited in the same manner as the control or bilateral deposition near the uterotubal junction using the Ghent device. The authors concluded that neither sperm dosage nor site of semen deposition influenced pregnancy rates.

Intrafollicular insemination is defined as direct introduction of a low-volume (0.06 ml) sperm suspension into a preovulatory follicle. This technique has been recommended as an alternative procedure to the usual deposition of semen into the uterus in cows of low fertility [20]. Even though the results are comparable to intrauterine insemination in a small group of cows, further study is needed to determine its application.

Several methods have been explored to enhance sperm transport following insemination, including administration of prostaglandin (PG)$F_{2\alpha}$ at the time of insemination and clitoral massage immediately after insemination. Administration of a $PGF_{2\alpha}$ analog at the time of insemination improved fertility in heifers compared with non-treated controls, but not in cows [21]. Cooper et al. [22] reported no improvement in pregnancy rates when a five-seconds clitoral massage was done after insemination.

Timing of Insemination

Proper detection of estrus is critical to the success of AI. Standing estrus, or "heat," is the most reliable indication that a cow is in estrus. Studies have shown that a dairy cow displays an average of seven episodes of estrus (stands to be mounted by other cows) [23]. In addition, cows in estrus show estrus activity at any time of the day and hence it is vital that visual observation should be performed several times per day. Increased frequency of visual observation increases the proportion of cows detected in estrus. Several heat detection aids have been developed to assist producers in detection of estrus, including tail paint, Estrus Alert® and Kamar® patches, pedometers, and radio-telemetric systems. A combination of visual observation and one or more of the detection aids increases the effectiveness of estrus detection compared with visual observation or detection aids alone.

Ovulation usually occurs approximately 28–32 hours after the onset of estrus in dairy cows [24]. Optimal fertility of ova is projected to be between 6 and 12 hours after ovulation [25]. The viable lifespan of sperm in the reproductive tract is estimated at 24–30 hours [26, 27]. Given these limitations, the window of opportunity is very short for a successful fertilization.

For several years, researchers have investigated the optimal time to inseminate cows relative to the stage of estrus. Early work led to the establishment of the "a.m.–p.m." recommendation and based on this guideline cows in estrus during morning hours should be inseminated during the afternoon hours, and cows in estrus in the afternoon should be bred the following morning. However, large field trials indicate that maximum conception rates may not be achieved using the a.m.–p.m. rule. The decreased frequency of estrus detection may affect success when AI is performed based on the a.m.–p.m. rule. Highest conception rates for AI occurred between 4 and 12 hours after the onset of estrus in dairy cows [28].

Summary

Accurate insemination technique requires technical and management skills. The level of success ranges from excellent to frustratingly low. Technical skill includes concentration, attention to detail, a clear understanding of reproductive anatomy, and the ability to identify the site of deposition and proper position of the insemination rod. Management skill includes proper semen storage and semen tank management. With scrupulous efforts and attention to detail, the AI program can be successful with farm inseminators. However, successful AI programs depend on not only proper skill and management but also appreciable knowledge regarding risks and pitfalls. Periodic evaluation of AI parameters, such as number of services per conception and conception rate, should be done, with corrective measures taken as required, which may include seeking professional help. Herd inseminators should periodically attend a retraining course to review their techniques and be updated regarding new developments and recommendations regarding AI technique.

Pharmacological Intervention of Estrous Cycles

Ram Kasimanickam

Department of Veterinary Clinical Sciences, College of Veterinary Medicine, Washington State University, Pullman, WA, USA

Introduction

Reproductive competence is a major aspect affecting the production and economic success of dairy and beef cattle operations. For herds using artificial insemination (AI), detection of estrus (submission rate) and calving rate are the two major determinants of inter-calving interval. The economic consequences of low efficiency and poor accuracy in the detection of estrus are the main reasons why cattle reproduction research programs focus on developing practical breeding protocols. The important requirements for any effective estrous synchronization protocol are predictable and high estrus and ovulation responses during a specified interval, followed by a higher pregnancy rate to a single insemination carried out in a predetermined time [1]. To achieve better control of the estrous cycle in cattle it is necessary to synchronize emergence of new follicular waves, ensure a luteal phase, terminate the luteal phase, and synchronize ovulation.

Ovarian Follicular Dynamics

Growth of ovarian follicles in cattle occurs in distinct wave-like patterns during the estrous cycle, during pregnancy, and in certain anestrous conditions [2]. Each follicle wave has a lifespan of 7–10 days (range 6–12 days, depending on two vs three waves per cycle and 18 vs 24 days length of cycle) as the follicle progresses through the different stages of development, namely emergence, selection or atresia, and dominance and atresia or dominance and ovulation. Emergence of a new follicular wave is supported by a transient (one to two days) increase in follicle-stimulating hormone (FSH) coinciding with the emergence of a follicular wave. Peak FSH concentrations occur just before wave emergence, and then subsequently decline over several days; concurrently, follicles grow and reach approximately 8.0 mm in diameter [3, 4]. On average, these follicles grow at a constant and comparable rate and then this group of growing follicles is divided into a single dominant and several subordinate follicles. Typically, deviation begins when the diameter of the largest follicles reaches 8.0 mm [3, 4]. The time difference is approximately eight hours in cattle [5]. Once functional dominance is established, the selected dominant follicle continues to grow, while the remaining follicles that emerged during the same follicular wave cease growth and become atretic. Selection of the dominant follicle occurs during declining FSH concentrations; however, the dominant follicle continues to grow (despite FSH at nadir concentrations) until it either ovulates or undergoes atresia [6]. During the final stages of selection of the dominant follicle, there appears to be a transition from mainly FSH to luteinizing hormone (LH) dependency [6]. The selected dominant follicle uniquely expresses mRNA for LH receptors in granulosa cells, which are likely the key to allowing its continued growth under LH stimulation [6, 7]. Estrogen-active dominant follicles are largely LH-dependent; positive feedback of estrogen releases a large amount of gonadotropin-releasing hormone (GnRH), resulting in an LH surge and ovulation of the dominant follicle [6, 7]. Conversely, if the dominant follicle fails to ovulate, the consequences are continued growth of the dominant follicle dependent on increased LH pulse frequency which, if prolonged, can lead to persistence of the dominant follicle [8]. Therefore hormonal treatments that modify both FSH and LH clearly affect the fate of a follicular wave. Manipulation of the follicle wave, in turn, may alter systemic hormonal concentrations, the intrafollicular environment, and the oocyte. Thus, a dominant follicle capable of ovulation is present only at specific times during each wave. Therefore the interval from exogenously induced luteolysis and/or withdrawal of a progestagen treatment to

estrus and ovulation depends on the stage of the follicle wave at luteolysis and/or at progestagen withdrawal (whichever occurs last if this does not occur at the same time); cattle with a selected dominant follicle will be in estrus within two to three days, whereas in those in which follicular growth is at the preselection stage, estrus will occur three to seven days later [9–12].

To achieve maximum synchrony of onset of estrus in a synchronization program, it is necessary to have a recently selected dominant follicle present at the end of treatment. Therefore new wave emergence must be synchronized, because both the stage of the follicular wave and the duration of dominance affect the duration of the follicular phase and the interval from treatment to estrus. Synchrony of estrus is optimal when the duration of dominance is either less than 4 days (short) or more than 10–12 days (very long). Further, duration of dominance of the preovulatory follicle can affect fertility. When the duration of dominance of the ovulatory follicle exceeds 10 days, there is a dramatic decline in pregnancy rate [10–12], primarily due to aged oocytes with premature activation. Therefore it is desirable to precisely control follicular dynamics (and in particular new wave emergence) to both minimize the variation in timing of onset of estrus and ensure high pregnancy rates.

Pharmacological Control of New Wave Emergence

The method for controlling follicular wave emergence is based on two principles (Figure 37.1): (i) emergence of a new follicular wave is primarily FSH-dependent; and (ii) an estrogen-active dominant follicle is largely LH-dependent. Thus, the negative feedback effects of progestagens and estrogens can be used to synchronize follicle wave emergence by suppression of FSH and/or LH. However, the extent to which follicles are dependent on gonadotropins during various stages of follicular wave development is poorly defined. Further, details of local mechanisms that play key roles in regulating the sequential progression of follicles through sequential physiological stages of the wave are not well defined. This makes it difficult to develop a simple exogenous hormonal treatment that gives predictable new wave emergence in all animals treated, irrespective of the stage of the follicle wave and stage of estrus at treatment [9, 13].

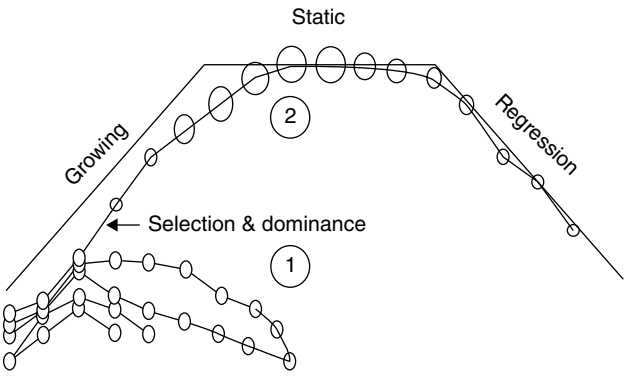

Figure 37.1 Phases of follicular wave. A follicular wave consists of growing, static, and regression phases. The growing phase includes recruitment, and selection and dominance and atresia of subordinate follicles; the static phase includes preparation of ovulation or regression; and the regression phase includes regression of the dominant follicle and preparation for the subsequent wave.

The induction of new follicle wave emergence using exogenous hormonal treatments requires (i) consistent termination of an existing follicle wave, (ii) predictable induction of a transient increase in FSH to induce emergence of a new wave, and (iii) normal growth of the dominant follicle after selection. The primary dependence of the follicle wave progression on gonadotropin support has resulted in the use of steroids to suppress FSH and LH and thus terminate the existing wave. However, it should be realized that FSH and LH are differentially regulated [6]. In the case of FSH, the dominant follicle is the key regulator of the recurrent increases or decreases that occur during the wave. In contrast, although progesterone concentrations are important in regulation of LH pulse frequency, there are changes in LH pulse frequency that occur during the luteal phase which are difficult to clarify by changes in peripheral progesterone or estradiol concentrations. An alternative non-steroidal approach is the administration of GnRH to induce endogenous LH and FSH surges that cause luteinization or ovulation of an existing dominant follicle, thereby inducing emergence of a new wave [14].

Use of GnRH

Functional removal of the dominant follicle or cohort follicles by inducing either ovulation or luteinization using exogenously induced gonadotropin release is a practical approach for induction of a new follicular wave. Administration of GnRH induced an immediate LH and FSH surge, the magnitude of which was independent of progesterone concentration or stage of the follicle wave [15]. However, the effect of GnRH on the existing follicle wave is dependent on the presence or absence of a dominant follicle. GnRH administered after dominant follicle selection caused it to ovulate, with emergence of a new wave 1.5–2.0 days later [14]. However, when GnRH was administered before selection, it had no effect on

progression of the existing follicular wave. In all cows treated after dominant follicle selection, the induced gonadotropin surge was followed by a transient increase in FSH (but not LH) which was associated with new wave emergence [15]. Therefore GnRH synchronizes new wave emergence only when administered in the presence of a functional dominant follicle, whereas if given before dominance it would appear not to affect the subsequent progress of that wave, presumably because of lack of LH receptors on the granulosa cells of such growing follicles. The dichotomy of GnRH effects on progression of the follicle wave is a constraint that needs to be considered when using it as a treatment to synchronize new wave emergence at the start of either progesterone or prostaglandin ($PGF_{2\alpha}$) synchronization regimens [16]. The subsequent use of $PGF_{2\alpha}$ to cause regression of the induced corpus luteum (CL) is mandatory when GnRH is used to synchronize follicle waves. In addition, not only the stage of development of the dominant follicle [17] but also the stage of the estrous cycle [18] at the time that GnRH is administered affects results. If GnRH is administered when the dominant follicle is pre- or post-dominance, ovulation may not occur and a new follicular wave will not emerge [17]. An alternative is to ensure that a viable growing dominant follicle is present at the time of GnRH treatment. In that regard, cattle will respond most consistently when GnRH is administered between days 5 and 12 of the estrous cycle [18, 19].

Use of Estradiol

Even though combined treatment with progestin and estradiol has been utilized for decades, knowledge of the physiological effects and mechanisms of action of exogenous estradiol and progesterone on follicles is a prerequisite to the development of improved methods of controlling the estrous cycle. Estradiol suppresses the growing phase of the dominant follicle; suppression is more profound when given in combination with progesterone [20]. The mechanism responsible for estrogen-induced suppression of follicle growth appears to involve suppression of both FSH and LH [21]. Further, it exerts its negative effect on both the hypothalamus and pituitary. Studies have focused on the effects of short-term estradiol and progesterone treatments, either alone or in combination at the time of pre-follicle wave emergence, on LH and FSH, progression of the follicle wave, and changes during follicle wave development [1]. The period of elevated FSH associated with wave emergence was shortened by approximately 10 hours following estradiol, progesterone, or a combination of estradiol and progesterone treatments, compared with control. Frequency of LH pulses was reduced following progesterone treatment and was further reduced in response to a combination of estradiol and progesterone treatments. This steroid combination also significantly reduced pulse amplitude. The emergence of the follicle wave and selection of the first dominant follicle of the cycle were delayed approximately 1.5 and 2.5 days, respectively, by the combination of estradiol and progesterone treatment. Intrafollicular estradiol concentrations were suppressed in the largest follicle following combination estradiol and progesterone treatment, whereas under estradiol treatment they were unchanged. However, they were suppressed in smaller follicles following both estradiol and combination estradiol and progesterone treatments. Therefore suppression of LH pulses by the combination estradiol and progesterone treatment is important for suppressing follicular estradiol in the largest follicle, whereas suppression of FSH alone may be sufficient to reduce follicular estradiol concentrations in smaller follicles.

In estrous synchronization protocols, estradiol is usually administered at the initiation of the protocol, concurrent with insertion of a progestin-releasing device. The combination of estradiol and progestin was used to determine if suppression of follicle growth would induce new wave emergence at a consistent interval after treatment regardless of the phases (i.e. growing, static, or regressing phases) of follicle development at which treatment was initiated. The use of estradiol-17β in progestin-implanted cattle was followed consistently by the emergence of a new wave, on average 4.5 days later [9, 16]. Once the estradiol was metabolized, there was an FSH surge and a new follicular wave emerged [22, 23]. The administration of 2.5 or 5 mg estradiol-17β (or 2 mg estradiol benzoate or estradiol valerate) in progestin-implanted cattle at random stages of the cycle was followed by the emergence of a new follicular wave approximately four days later, with little variability [24–26].

The mechanism of action of estradiol would appear to be through FSH and LH, causing follicle atresia followed by synchronous release of FSH and emergence of a new follicle wave. Hence, in general, estradiol has been the hormone treatment used most successfully to synchronize follicle wave emergence in cattle. However, the use of estradiol is prohibited in an increasing number of countries, so alternatives must be sought. Similarly, the use of GnRH or LH to induce ovulation, and to remove the suppressive effects of a dominant follicle on FSH, result in a surge in FSH and a new follicle wave at a predictable time thereafter. Therefore synchronization of follicle wave emergence is likely to be through FSH release, which may involve manipulation of ovarian (follicular) metabolic pathways or feedback mechanisms to the hypothalamic–pituitary axis.

Controlling the Lifespan of the Corpus Luteum

Shortening the Luteal Phase (Premature Luteolysis)

Luteolysis is initiated by estradiol from the developing preovulatory follicle, which triggers the release of hypophyseal oxytocin, which in turn stimulates release of a small quantity of uterine $PGF_{2\alpha}$. $PGF_{2\alpha}$ then initiates a positive feedback loop involving release of additional luteal oxytocin and $PGF_{2\alpha}$ of both luteal and uterine origin [27]. Oxytocin stimulates synthesis and secretion of $PGF_{2\alpha}$ from the uterus. It has recently been proposed that release of luteal $PGF_{2\alpha}$ amplifies the luteolytic signal in an autocrine or paracrine manner [27, 28]. $PGF_{2\alpha}$ causes decreased blood flow to luteal parenchyma and morphological changes that reduce both the number of small steroidogenic luteal cells and the size of large luteal cells. In addition, it is involved in intracellular signaling that facilitates apoptosis of large luteal cells and stimulates intraluteal production of $PGF_{2\alpha}$, thereby resulting in the demise of the CL [29, 30].

Since the discovery of $PGF_{2\alpha}$ as the luteolytic agent in cattle [31, 32], it has been the most commonly used treatment for elective induction of luteal regression and/or synchronization of estrus [33]. The injection of $PGF_{2\alpha}$ causes immediate regression of the CL after approximately day 5 of the estrous cycle: progesterone concentrations decline rapidly to basal levels within 24 hours, and LH pulse frequency increases, causing a significant increase in estradiol from the dominant follicle and the induction of estrus and ovulation. Despite rapid luteolysis, the interval from treatment to the onset of estrus is variable and dependent on the stage of the follicle wave at treatment. Animals with a functional dominant follicle are typically in estrus within two to three days, because the dominant follicle at the time of induced luteolysis ovulates shortly (Figure 37.2a); however, animals at the pre-dominance or regression phase of the wave will require four to six days to form a dominant follicle and hence have a longer and more variable interval to onset of estrus (Figure 37.2b).

$PGF_{2\alpha}$ fails to effectively induce luteolysis during the first five or six days following estrus. Lack of responsiveness was due to lack of $PGF_{2\alpha}$ receptors in immature CL, but recent work has demonstrated the presence of $PGF_{2\alpha}$ receptors in the CL as early as two days after ovulation [34]. However, it appears that the mature CL may possess a positive feedback loop that results in intraluteal $PGF_{2\alpha}$ production that may continue the process of luteolysis initiated by a single treatment of exogenous PGF [35]. It should be noted that although luteolytic response was variable when a single dose of $PGF_{2\alpha}$ was given on days 5 or 6 of the estrous cycle, two doses of prostaglandin analog (12 hours apart) consistently induced luteal regression (95–100%) at two to five days after estrus [36, 37].

Extending/Simulating a Luteal Phase with Exogenous Progesterone

Development of intravaginal progesterone delivery devices, such as the progesterone-releasing intravaginal device (PRID, 1.55 g), controlled intravaginal releasing device [CIDR, 1.38 g (US) or 1.9 g (Canada)], and Cue-Mate (1.56 g) intravaginal progesterone device (IPVD), has facilitated the use of progestagens for synchronization in cattle. In general, for all progesterone-based synchronization treatments, a high proportion (up to 85%) of cows exhibit estrus 36–72 hours after removal. This higher degree of estrous synchrony allows for fixed-time AI (FTAI) between 48 and 84 hours after removal, with hormonal induction of ovulation using GnRH or estradiol. Alternatively, cows may be observed for estrus and inseminated once after detection of estrus.

Estrous synchronization systems that include progesterone in the protocol have three primary advantages. First, maintaining the concentration of progesterone at greater than threshold level (>1 ng/ml) suppresses the LH surge and estrous behavior. Treatment with progesterone for 14 or 21 days resulted in a high estrus response within three days after progesterone removal [38]. However, conception rates following prolonged progesterone treatment are 10–15% below those of cows treated with progesterone for shorter duration. The reason for low conception is that intravaginal progesterone releasing devices result in progesterone concentrations that are lower than those of the luteal phase, and LH pulse frequency and peripheral estradiol concentrations are elevated. Consequently, the dominant follicle continues to receive gonadotropin support beyond the time where either ovulation or atresia would have occurred. Ultrastructural changes in the oocyte within the persistent dominant follicle are believed to reduce fertility of treated cows [10, 39]. Fertility concerns for progesterone-treated cows have led to development of short-term protocols (seven to nine days) for progesterone use. Progesterone is also typically combined with follicular synchronization so that a newly developing dominant follicle is present during progesterone supplementation. Progesterone supplementation is an effective method for treating anestrus, which affects approximately 20% of beef cows at the start of the breeding season [40, 41]. Furthermore, in US dairies, 28% of primiparous cows and 15% of multiparous cows had not ovulated by 60 days after calving [41]. Thus the second primary advantage for progesterone in estrous synchronization protocols is that

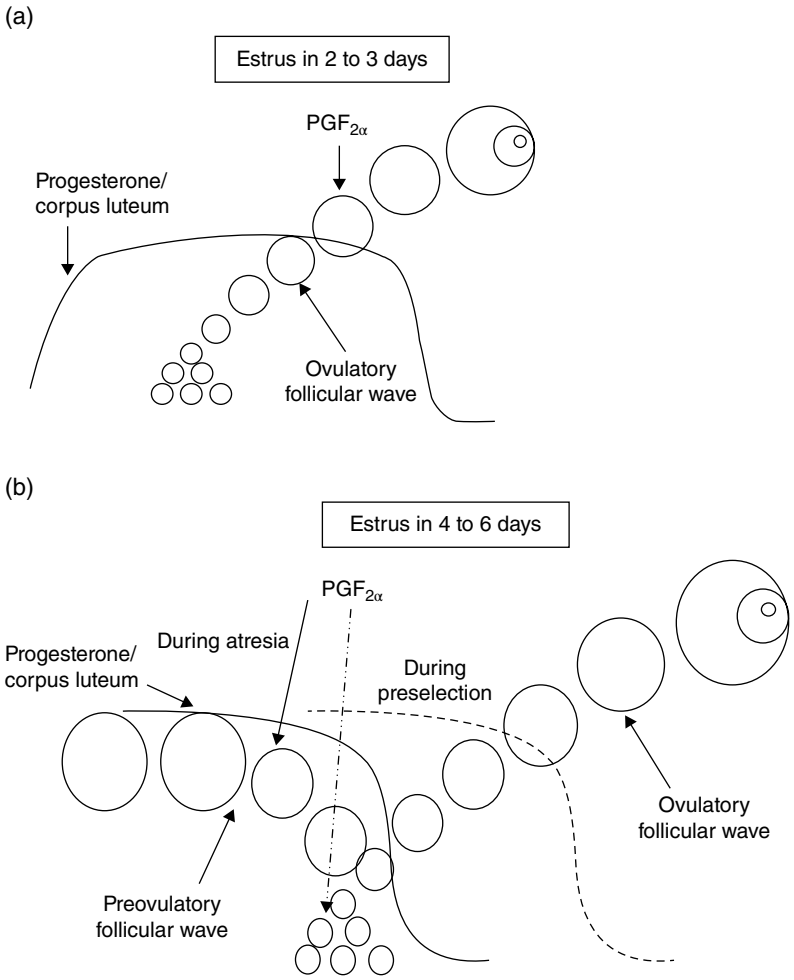

Figure 37.2 Interval from $PGF_{2\alpha}$ administration to estrus. (a) Animals with a functional dominant follicle are in estrus within two to three days because the dominant follicle at the time of induced luteolysis ovulates soon thereafter. (b) Animals at the pre-dominance or regression phase of the follicular wave will require four to six days for a dominant follicle to reach preovulatory diameters and hence have a longer and more variable interval to onset of estrus.

anestrous cows are responsive when progesterone is used. Progesterone supplementation in an anestrous cow decreases LH initially, but then increases LH pulsatility [42, 43]. The increase in LH pulsatility increases dominant follicle development. Progesterone also primes the hypothalamic center for estrous expression and the LH surge. Removal of the progesterone is followed by estrus, ovulation, and a normal-length luteal phase in a large percentage of treated cows [42]. Treatment of cystic ovarian disease is the third advantage of progesterone supplementation. Approximately 10% of US dairy cows are affected [44]. Abnormally high LH pulsatility and absence of an LH surge are characteristic endocrine features of the disease [44–46]. Progesterone supplementation decreases LH pulsatility in cystic cows. The decrease in LH pulsatility after progesterone treatment is followed by turnover of the cystic (dominant) follicle. Development of a new dominant follicle is normal and ovulation occurs after progesterone withdrawal [45–47].

Induction of Ovulation

Prior to the preovulatory LH surge in cyclic cows, the frequency of LH pulses gradually increases to one pulse per hour in response to endogenous GnRH pulses. In cyclic cows a single dose of exogenous GnRH induces LH release. Therefore a single injection of GnRH induces an LH surge and ovulation when given at approximately days 10–18 after calving in dairy cows and days 21–31 after calving in beef cows [41]. A single injection of GnRH combined with 48-hour calf removal also induces ovulation in beef cows. A single injection of human chorionic gonadotropin (hCG) 500–3000 IU induces ovulation in dairy and beef cows. Further, because of its positive feedback effect on the

surges of FSH and LH, exogenous estradiol has been used to induce ovulation in cows. It should be noted that the GnRH-induced CL in postpartum cows usually has a shorter lifespan than a spontaneously formed CL. Further, administration of GnRH prior to complete uterine involution results in pyometra in postpartum dairy cows. Therefore a single injection of GnRH during the early postpartum period is not very useful in practice.

Synchronization of Estrus

Prostaglandin Protocol

The mechanism of action of prostaglandin is luteolysis, and thus the application of a prostaglandin program is restricted only to cycling cows with a functional mature CL. The administration of a luteolytic dose of $PGF_{2\alpha}$ (25 mg) or its synthetic analogs (e.g. 500 µg cloprostenol) causes regression of the CL in most stages of diestrus, thereby inducing estrus in over half (55–65%) of a cycling herd (Figure 37.3a). A second injection given 11–14 days later should result in synchronized estrus of the herd because the cows that responded to the first injection will be on day 6–15 of diestrus, with the majority being on days 7–9 (Figure 37.3b). A 100% response is not realistic, even if every cow in the group was known to have a mature CL at the time of the second injection. This is partly because not all mature corpora lutea, at least in lactating dairy cattle, are lysed by $PGF_{2\alpha}$. For example, approximately 25% of the cows that were on day 6 respond, approximately 33% of those that were on day 7 respond, and fewer than 100% of those that were on days 8–16 of the cycle respond. Many prostaglandin-controlled synchronization programs have been developed (Figure 37.3). The selection of a program best suited to a herd depends on a variety of factors including efficiency of estrus detection on the farm, palpation skills of the attending veterinarian (Figure 37.3c), cost of treatment, availability of labor, and the objectives of the program. Further, these programs involve intramuscular injections of a single luteolytic dose of $PGF_{2\alpha}$. Various doses and injection sites have since been compared involving the ischiorectal fossa (one luteolytic dose) and vaginal submucosa (half a standard luteolytic dose). Administration of half a standard luteolytic dose submucosally in the vagina or injection of a single luteolytic dose of $PGF_{2\alpha}$ into the ischiorectal fossa was as efficacious as intramuscular administration [48].

Progesterone Protocols

Fourteen-Day Treatment

In this protocol, cows are supplemented for 14 days usually using an IVPD or oral progestin (melengestrol acetate, MGA) (Figure 37.4). Since ovulation is inhibited for up to 14 days, the follicle that ovulates following this protocol is aged (from a persistent follicle) and hence has reduced fertility. Therefore $PGF_{2\alpha}$ is given 19 days following progesterone/progestin removal. The animals are observed for two to four days following treatment with $PGF_{2\alpha}$ and inseminated at observed estrus using the a.m.–p.m. rule. This injection of $PGF_{2\alpha}$ regresses the CL that forms after the

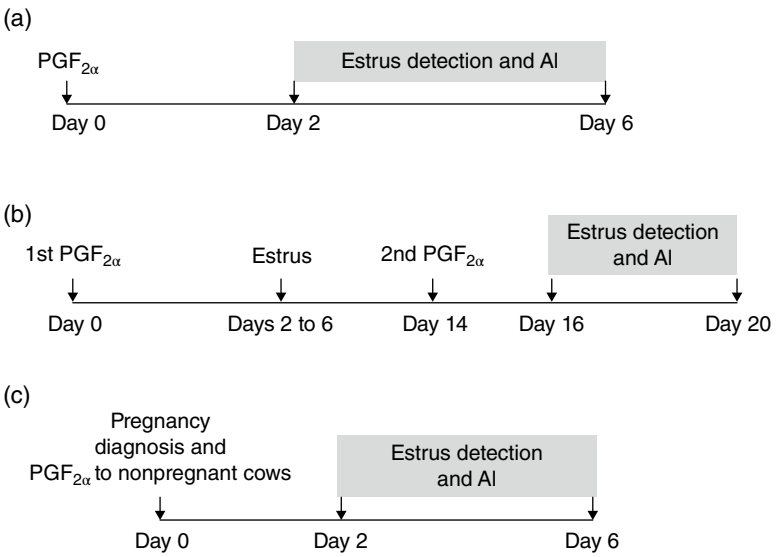

Figure 37.3 Synchronization of estrus using $PGF_{2\alpha}$. (a) Single $PGF_{2\alpha}$ program. (b) Double $PGF_{2\alpha}$ program. (c) Administration of $PGF_{2\alpha}$ to non-pregnant cows at pregnancy diagnosis. Note that under field conditions, the pregnancy examination is performed by a veterinarian to avoid iatrogenic pregnancy loss.

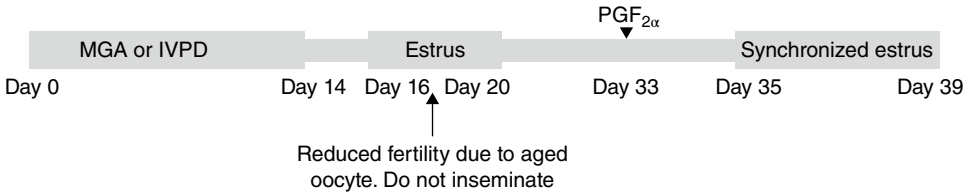

Figure 37.4 Estrus synchronization protocol with progesterone supplementation for 14 days using an IVPD or MGA and $PGF_{2\alpha}$.

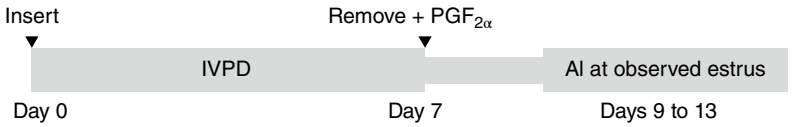

Figure 37.5 Estrus synchronization protocol with progesterone supplementation for seven days using an IVPD and $PGF_{2\alpha}$.

ovulation of a persistent follicle, and an estrus with good fertility will occur. This type of synchronization protocol with longer duration of progesterone treatment (14–17 days [49] and 14–19 days [50, 51]) has become a commonly used method of synchronizing estrus in replacement beef heifers. MGA, an orally active progestin [52], is capable of inhibiting estrus and ovulation in heifers when consumed at 0.5 mg/head daily for 14 days in a supplement carrier. Usually MGA is mixed with grain or a protein supplement and fed to cattle. The MGA program is usually a cost-effective synchronization program. It is important to ensure that all animals enrolled receive the recommended dose. Recently, a 14- to 16-day IVPD–$PGF_{2\alpha}$ protocol was evaluated for synchronization of estrus in replacement beef heifers in an attempt to replace the oral MGA program [53, 54]. This has the potential to improve synchrony of estrus compared with other protocols currently available. Progesterone has been shown to effectively presynchronize estrus [49, 54, 55] in replacement beef heifers and induce ovulation in heifers that did not reach puberty before administration of treatments [56].

Seven-Day Exposure

In this synchronization program, progestin, usually an IVPD, is used for seven days (Figure 37.5). Progesterone from the device mimics the progesterone produced by the CL and inhibits estrus and ovulation. When ovulation is inhibited for seven days, all cycling animals are expected to have a CL that is at least seven days old at $PGF_{2\alpha}$ treatment. Therefore all animals with a CL will respond to $PGF_{2\alpha}$. Animals in which a CL had regressed during the seven-day period will show standing estrus following removal of the progestin. Estrus is observed two to six days after removal of progesterone; those detected in estrus are inseminated using the a.m.–p.m. rule (cows first detected in estrus in the morning will be inseminated the same evening and cows first detected in estrus in the evening will be inseminated the next morning).

Use of GnRH in a Seven-Day Protocol

Progesterone exposure will not synchronize follicular waves. However, exogenous GnRH at the start of progesterone treatment will synchronize follicular waves. The normal duration of a follicular wave is 7–10 days; therefore if a mature follicle is present at the initiation of the protocol, that follicle will persist (and ovulate an oocyte with reduced fertility). Initiation of a new follicular wave at the beginning of the protocol by administering GnRH will reduce the occurrence of any persistent follicle forming. Furthermore, the progestin that is present between the GnRH and $PGF_{2\alpha}$ injections will virtually eliminate the chance of animals exhibiting signs of standing estrus before the $PGF_{2\alpha}$ injection (Figure 37.6). The animal is inseminated at observed estrus following progesterone removal.

Synchronization of Ovulation

Synchronization of ovulation involves a combination of GnRH and $PGF_{2\alpha}$, with or without progesterone supplementation during the course of the treatment. These protocols facilitate insemination at a predetermined (fixed) time without the need for detection of estrus. Several protocols have been successfully employed with acceptable pregnancy rates.

GnRH–$PGF_{2\alpha}$–GnRH Protocol

The protocol involves an injection of GnRH at a random stage of the estrous cycle, followed by an injection of $PGF_{2\alpha}$ seven days later. A second injection of GnRH follows the $PGF_{2\alpha}$ injection by 48 hours. The method is designed to be used with timed insemination 16 (range 8–24) hours after the last GnRH injection (Figure 37.7a; Ovsynch) [14]. This synchronization system results in a tight synchrony of

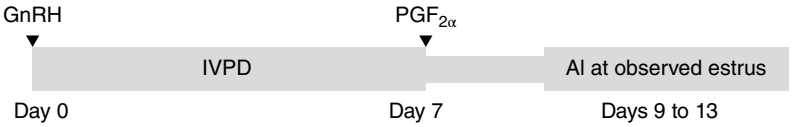

Figure 37.6 Estrus synchronization protocol with progesterone supplementation for seven days using an IVPD, GnRH, and $PGF_{2\alpha}$. Note that the addition of GnRH is to initiate a new follicular wave. GnRH is replaced with estradiol-17β or estradiol benzoate plus progesterone.

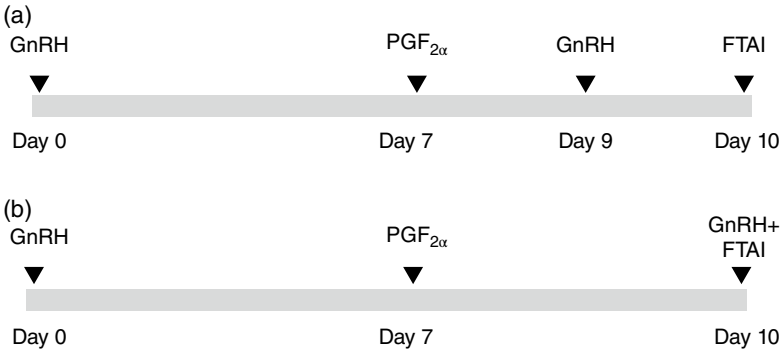

Figure 37.7 Ovulation synchronization protocol using GnRH–$PGF_{2\alpha}$–GnRH for a predetermined timed insemination (FTAI). (a) Ovsynch protocol. (b) CO-Synch protocol. Note that the first GnRH is replaced with estradiol-17β or estradiol benzoate plus progesterone and the second GnRH with estradiol-17β or estradiol benzoate. The concurrent administration of GnRH at the time of insemination in the CO-Synch protocol is preferred in beef farms as it reduces number of handlings.

estrus, allowing breeding at an appointed time without detection of estrus. The first injection of GnRH causes either ovulation or luteinization of all dominant or large growing follicles. As a result, a new follicular wave is initiated in all cows by approximately three days after the injection. Therefore all the females in the group have growing follicles of about the same stage of development. In addition, GnRH stimulates development of luteal tissue from the cells that were previously the dominant follicle. The $PGF_{2\alpha}$ injection lyses the CL resulting from the initial GnRH injection. Furthermore, the final GnRH injection serves to increase the synchrony of ovulation within a group of cows. The success of the first injection of GnRH to synchronize follicular growth is very good in cows, but less so in heifers. The CO-Synch protocol is similar to the Ovsynch protocol, except that the second injection of GnRH is given concurrent with AI (Figure 37.7b). This has a huge advantage in beef synchronization regimens because the CO-Synch regimen requires one less handling.

Presynch Protocol

It is evident that stage of estrous cycle at initiation of the Ovsynch protocol influences the success of synchrony of the follicular wave. Initiation of the protocol too early (e.g. one to four days after ovulation) or too late (e.g. 13–20 days after ovulation) reduced synchrony. Furthermore, if the first GnRH treatment was given when the dominant follicle was pre- or post-dominance, ovulation may not occur and synchronous emergence of a new follicular wave will not occur [17]. An alternative is to ensure that a viable growing dominant follicle is present at the time of GnRH treatment. Cattle will respond most consistently when GnRH is given between days 5 and 12 of the estrous cycle [18, 19]. Consequently, several protocols have been employed to align cows at days 5–12 of the estrous cycle at initiation of an Ovsynch or CO-Synch protocol, including presynchronizing cows before Ovsynch using two injections of $PGF_{2\alpha}$ administered 14 days apart, with initiation of the timed AI protocol 11 days [57], 12 days [19], or 14 days [58] later (Presynch-Ovsynch). Another protocol, designated G6G, starts with an injection of $PGF_{2\alpha}$, which is intended to induce luteolysis of functional corpora lutea, and a GnRH injection two days later, intended to induce an ovulation. Collectively, the two injections of G6G are intended to initiate a new estrous cycle. The Ovsynch is scheduled to start six days after the GnRH injection in order for the cow to be on day 6 of a new estrous cycle and very likely to have a functional dominant follicle, capable of ovulating in response to the first GnRH of Ovsynch. Further, use of two injections of $PGF_{2\alpha}$ to presynchronize estrous cycles was not effective for anovular cows [19]. Presynchronization protocols that induce production of a CL before initiation of the Ovsynch protocol are likely to improve fertility in anovular cows. A protocol that involves induction of cyclicity in anovular dairy cows is the use of an Ovsynch protocol to presynchronize and induce cyclicity in cows before the use of a breeding Ovsynch protocol, termed Double-Ovsynch [59].

Addition of Progesterone in GnRH–$PGF_{2\alpha}$–GnRH Protocol

Progesterone supplementation between the first GnRH and $PGF_{2\alpha}$ for seven days in Ovsynch (Figure 37.8a) and CO-Synch (Figure 37.8b) protocols enhances estrus/ovulation synchrony and conception in cows and heifers. These protocols are advantageous in anestrous cows and heifers and in cows with cystic ovaries. Several protocols are available for use, modified from the above-mentioned protocol. Recently, progesterone supplementation between the first GnRH and $PGF_{2\alpha}$ for five days in CO-Synch protocol (Figure 37.8c) has been evaluated. The objective is to shorten progesterone treatment to five days and to increase the proestrus phase (the interval from $PGF_{2\alpha}$ to the second GnRH) to 72 hours [60, 61]. This approach increased AI pregnancy rates up to 15% in beef cows [40, 41]. Because of the shortened interval from the initial GnRH to $PGF_{2\alpha}$ in the five-day IVPD protocol, and variability in luteolysis in some cows when a single dose of $PGF_{2\alpha}$ is given on day 5 of the estrous cycle, all cows should receive a second dose of $PGF_{2\alpha}$ treatment approximately 6–12 hours after the first $PGF_{2\alpha}$ given at CIDR withdrawal [62, 63].

Addition of Equine Chorionic Gonadotrophin

Equine chorionic gonadotropin (eCG) is added to the synchronization treatment protocols as a means of increasing follicular development. The utilization of eCG in breeding protocols improves reproductive efficiency in seasonally calving, anestrous cattle. Addition of 400 IU eCG at progesterone device removal resulted in 74% pregnancy in a 49-day breeding season [64]. Inclusion of eCG in 6 or 7 days of the GPG/P4 protocol increased pregnancy in a 28-day breeding (58.6 vs 52.3%) and decreased median days to conception in anestrous dairy cows [65]. In South American pasture-based lactating beef and dairy lactating anestrous cows, addition of eCG increased pregnancy rates by 10–15% after FTAI compared with the same protocol without eCG [66–68].

Split-Time AI

A proportion of females undergoing estrus synchronization do not express estrus prior to FTAI. To account for these non-estrous females, all cows and heifers are administered GnRH at FTAI to ensure that ovulation is induced. However, pregnancy rates are on average 27% lower among females that fail to express estrus prior to FTAI [69]. Researchers at the University of Missouri developed an alternative approach to manage timed insemination of cows and heifers that have not expressed estrus prior to FTAI. This approach, known as "split-time AI" (STAI), delays insemination of non-estrous females until 20–24 hours after the scheduled timed AI. AI

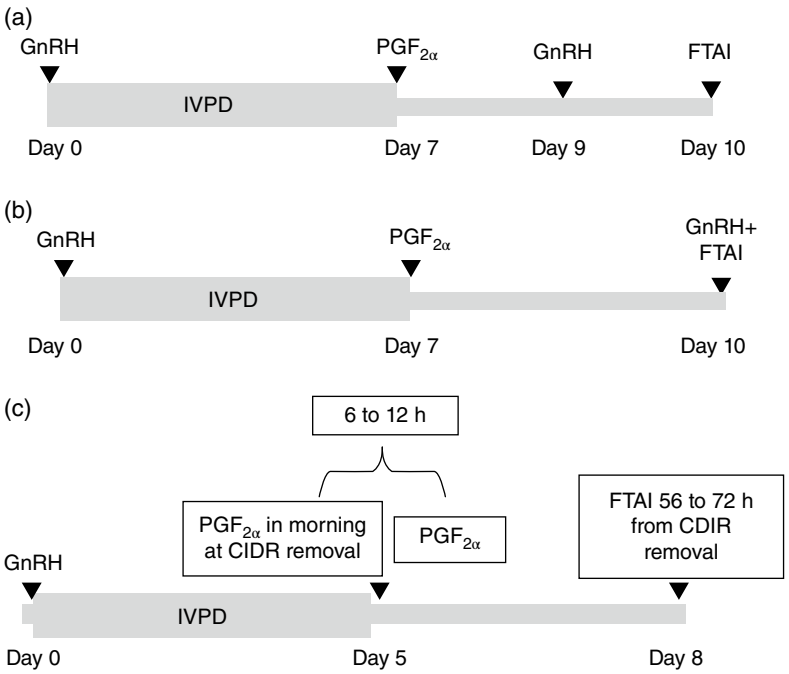

Figure 37.8 Ovulation synchronization protocol using GnRH–$PGF_{2\alpha}$–GnRH with addition of progesterone for a predetermined timed insemination (FTAI). (a) Ovsynch with IVPD. (b) CO-Synch with IVPD. (c) Five-day CO-Synch with IVPD. Note that the first GnRH is replaced with estradiol-17β or estradiol benzoate plus progesterone and the second GnRH with estradiol-17β or estradiol benzoate. The addition of progesterone is considered advantageous in anestrous cows and prepubertal and peripubertal heifers. Concurrent administration of GnRH at time of insemination in CO-Synch + IVPD protocol is preferred on beef farms as it reduces the number of handlings.

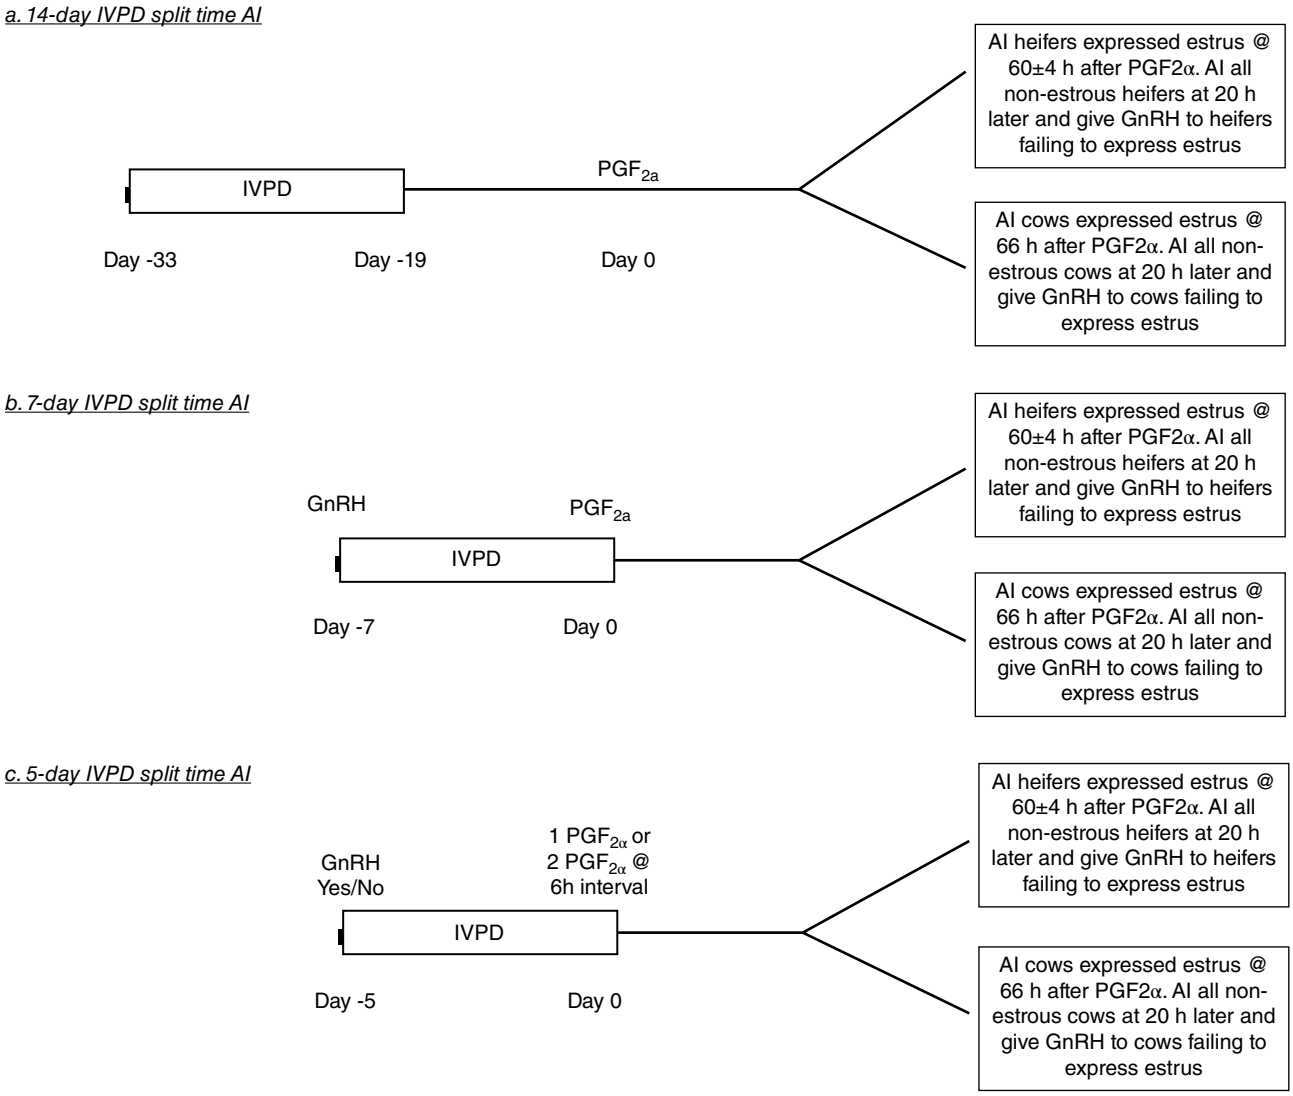

Figure 37.9 STAI protocol using GnRH–$PGF_{2\alpha}$–GnRH with addition of progesterone for a predetermined timed insemination (FTAI) for cattle expressing estrus and delayed AI for cattle that failed to express estrus. (a) Fourteen-day STAI with IVPD. (b) Seven-day STAI with IVPD. (c) Five-day STAI with IVPD. Note that due to the shortened interval from initial GnRH to $PGF_{2\alpha}$ in the five-day IVPD protocol and variability in luteolysis, when GnRH is administered at the time of IVPD all beef females should receive a second dose of $PGF_{2\alpha}$ approximately 6–12 hours after the first $PGF_{2\alpha}$ given at IVPD withdrawal on day 5, and when GnRH is not administered at the time of IVPD all dairy females should receive one dose of $PGF_{2\alpha}$.

pregnancy rates can be optimized through use of a STAI approach following administration of the 14-day IVPD-$PGF_{2\alpha}$ or 5-day CO-Synch protocol for heifers and the 7- or 5-day CO-Synch + IVPD protocol for mature cows (Figure 37.9). Estrus detection aids applied at the time of $PGF_{2\alpha}$ administration allow producers to determine the estrous status of females and inseminate at the optimal time. STAI improved timed AI pregnancy rates among beef replacement heifers following the 14-day IVPD-$PGF_{2\alpha}$ protocol [70] and among mature beef cows following the 7-day CO-Synch + IVPD protocol [71, 72]. Typically, 30–50% of mature cows and 20–40% of heifers fail to express estrus prior to 66 hours after prostaglandin following the 7-day CO-Synch + IVPD and 14-day IVPD-$PGF_{2\alpha}$ protocols, respectively. Results from the University of Missouri study showed that 55% of both heifers and cows that had failed to express estrus by 66 hours after $PGF_{2\alpha}$ went on to express estrus by the time delayed AI was performed. The pregnancy rates of non-estrous females were improved 16 percentage points by delaying insemination by 20–24 hours [70, 72]. Further, in addition to offering improved pregnancy rates compared to FTAI, STAI allows for a reduction in the use of GnRH. Since administration of GnRH was not found to be required for cows or heifers with activated estrus detection

patches at AI [73], insemination can be performed without GnRH administration for cows and heifers that have expressed estrus prior to the standard time of appointment breeding, as well as for cows and heifers that expressed estrus prior to the delayed time point.

Summary

Estrous and ovulation synchronization protocols now exist to successfully achieve acceptable fertility after applying insemination at observed estrus or at a predetermined time without estrus detection. Further, success is achieved in females that may not be cycling at the onset of treatment. Initiation of fertile ovulation in peripubertal heifers and acyclic cows is likely the primary manner in which producers may improve fertility in response to estrous synchronization and timed AI protocols. Use of IVPD-based synchronization before insemination of cows and heifers enhances fertility more effectively than other hormonal synchronization interventions. Development of synchronization protocols that reduce the factors associated with reducing synchrony of estrus and/or ovulation will provide cattle producers with efficient and effective tools for improving genetics in their operations. Since location, pasture difference, diet, breed composition, body condition, postpartum interval, climate, and geographic location may affect the success of synchronization protocols, these variables should be kept in mind to enhance the success of synchronization.

Examination for Pregnancy: Rectal Palpation

David Christiansen

Department of Pathobiology and Population Medicine, College of Veterinary Medicine, Mississippi State University, Starkville, MS, USA

Introduction

Pregnancy diagnosis is an invaluable tool to the cattle producer who is trying to maintain maximum profitability. In the case of the beef cattle herd, a significant portion of the cost of producing calves is due to the feeding and care of the pregnant dam particularly during the winter months. Cows that are open (not pregnant) will add to the cost of maintaining the herd while not providing income in support of the producer. Similarly, in dairy cattle, a cow that fails to become pregnant in a timely fashion will ultimately produce less milk for the dairyman, thus adding cost but not enhancing income. A pregnancy test that would identify pregnant and open cows before they return to estrus, thus allowing intervention and rebreeding by the subsequent estrus, would help minimize the calving interval and thereby maximize profit especially in a program utilizing artificial insemination. In addition, the ideal pregnancy test would be minimally invasive, simple to perform requiring little investment in equipment, supplies, and time, yield quick results allowing cow-side decisions to be made by the producer, and have high sensitivity and specificity. Finally, in many herds the capability to estimate the stage of gestation, the gender of the fetus, and the presence of pathologic conditions of the reproductive organs can be very helpful.

Currently there are three reliable methods of diagnosing the pregnancy status of a cow: transrectal palpation, transrectal ultrasound examination, and endocrine testing (Table 38.1). While none of these meets all the criteria for the ideal test, each has its advantages and disadvantages. The producer and veterinarian must carefully consider each test and determine which provides the most benefit for the conditions at hand. Of these methods, transrectal palpation is the most commonly utilized and meets the most criteria under the most circumstances.

The diagnosis of pregnancy by transrectal palpation is a skill that can readily be acquired and honed to great sensitivity and specificity with good understanding of normal anatomy and physiology of the cow. A good understanding of pregnancy and fetal development also allows the examiner to accurately estimate the stage of pregnancy with experience. A thorough discussion of normal anatomy, physiology, and pregnancy can be found in previous chapters. With this understanding and practice, one can achieve very consistent results approaching 100% accuracy as early as day 30–35 of pregnancy. Transrectal examination of the reproductive tract begins with identification of the cervix which is fibrocartilagenous and firm (sometimes described as feeling somewhat like a chicken neck) and serves as the landmark for the reproductive organs. In the non-gravid or early pregnant uterus, it typically is found within or just at the brim of the pelvis. In multiparous cows and as pregnancy progresses, it may be found pulled more cranial and ventral. It is important to remember that the cervix is relatively mobile and one may have to sweep the pelvic canal and work over the brim of the pelvis until it is found. Once identified, the cervix may be grasped and used to retract the body, horns, and uterus caudally to allow better access to and examination of these structures. Then you can follow the cervix cranially to the body of the uterus and identify the bifurcation of the horns. At this location, the ventral intercornual ligament (see Figure 22.6) can be used to retract the horns and lay them along the floor of the pelvis to facilitate thorough palpation of each horn. Just beyond the tip of each horn, the ovaries can be palpated. As pregnancy progresses, the size and weight of the fetus and fetal fluids will make retraction of the cervix and uterus impossible and they will have to be examined in place.

The definitive diagnosis of pregnancy is based on the identification of structures that can only occur if the cow is

Table 38.1 Comparison of different methods of pregnancy diagnosis.

Criteria	Endocrine testing	Ultrasound examination	Transrectal palpation
Allows intervention prior to first estrus after breeding	Yes	No	No
Minimally invasive	Minimal to moderate	Yes	Yes
Simple to perform, little investment/cost	Moderate to high	Moderate	Simple, minimal cost
Results available quickly	Minutes to days	Instant	Instant
Estimates stage of gestation	No	Yes	Yes
Gender determination	No	Yes	No
Identifies pathologic conditions of reproductive tract	No	Yes	Yes
Sensitivity/specificity	Varies (see Chapter 39)	Excellent	Excellent

indeed pregnant; if none of these can be identified, the cow should be considered not pregnant or the diagnosis deferred. Four such structures can be readily palpated and are considered the cardinal signs of pregnancy. They are chorioallantoic (membrane) slip, the amniotic vesicle, placentomes, and the fetus. A diagnosis of not pregnant should not be made until complete palpation of the body and both uterine horns is performed.

In addition, other changes in the reproductive tract can be palpated that are considered supportive of a positive diagnosis of pregnancy. These include the inability to retract the cervix, fluid within or fluctuance of the uterus, enlarged diameter and asymmetry of the uterine horn(s), and enlargement and fremitus (a buzzing sensation) of the middle uterine artery.

Figure 38.1 Slipping of the chorioallantoic membrane. *Source:* Courtesy Maarten Drost, VISGAR.

Cardinal Signs of Pregnancy

Membrane Slip

Membrane slip can be palpated routinely by 30–32 days of pregnancy in the gravid horn (as early as 28 days in heifers as one gains experience) and in both horns by day 50–60 of gestation. Following identification of the cervix and retraction of the uterus, each horn can be grasped gently between the fingers and thumb and lifted slightly (Figure 38.1). If pregnant, a distinct popping sensation can be felt as the membrane slips from the grasp within the uterine walls. At 32 days of pregnancy it gives the impression of a thread and by day 45 a small string slipping from the fingers in the gravid horn. By day 60 it is palpable in both horns as a somewhat larger string and by day 75 is approaching the feel of a piece of yarn slipping from the fingers. Membrane slip is most commonly used up to day 90 of gestation.

Amniotic Vesicle

The amniotic vesicle is a very turgid, fluid-filled sack surrounding and protecting the embryo proper during early gestation. It can be palpated as a small knot or bump within the uterine horn approximately 6–7 mm in diameter by 32–35 days (5 weeks) of gestation. By 6 weeks of gestation it will be 1.5 cm in diameter and at 7 weeks it will be 3.5–5 cm in diameter. By 8 weeks, the vesicle will be 6–7 cm and will be losing its turgidity, generally allowing for palpation of the fetus proper around day 60. As this occurs, the vesicle itself will become more difficult to identify and can generally no longer be used to determine pregnancy.

Fetus

As the fetus becomes palpable around day 55–60, it will be approximately 5–6 cm in length and can be felt floating in the fluid of the gravid horn by carefully cupping the horn with the fingers and sliding them along the length of the

pregnant horn. Alternatively, the wall of the uterus may be lightly tapped by the fingers, creating a wave of fluid and causing the fetus to bump back against the fingers (referred to as ballottement). As the pregnancy advances, fetal parts may more readily be identified such as the head, feet, and legs, allowing the beginner to be more comfortable with the diagnosis. By three months of pregnancy, the uterus and fetus will reach sufficient size and weight to cause it to drop over the brim of the pelvis and into the abdominal cavity and by four to five months of pregnancy the fetus may descend into the abdomen far enough to make palpation of the fetus itself difficult or impossible, particularly in large, deep-bodied cows. Usually by the seventh month the fetus has grown large enough that it will be readily accessible and can once again be used to determine pregnancy status.

Placentomes

Placentomes (occasionally referred to as buttons by lay personnel) are made up of the maternal caruncle and fetal cotyledon. With experience they may be palpated as early as 75–80 days of gestation as soft pea-sized swellings or bumps on the internal uterine wall, but are a bit more firm and readily palpated by day 90. At this time they are about the size of a dime and will reach about the size of a half dollar by the time the cow is five months pregnant. During mid-gestation as the fetus becomes more difficult to reach, placentomes may become the best method to definitively diagnose pregnancy. At least three should be identified, ensuring that the ovaries are not mistaken for placentomes.

Supportive Signs of Pregnancy

As pregnancy advances to 60 days and beyond, the weight of the fetus and fetal fluids pulls the cervix cranially over the edge of the pelvis and into the abdomen. It becomes increasingly difficult at this time to retract the uterus into the pelvic canal; thus, if the cervix feels "heavy" and relatively immobile, pregnancy can immediately be suspected and the palpator can search for the cardinal signs found in more advanced pregnancy such as the fetus and placentomes. This can save time and effort that would be required to find the more subtle membrane slip or amniotic vesicle.

Fluid within or fluctuance of the uterus is sometimes used in early pregnancy (as early as 28 days) to make a presumptive diagnosis of pregnancy, but the owner must clearly understand that it is presumptive only and should be confirmed at a later date. The wall of the pregnant uterus at this time thins significantly, resulting in a structure that feels much like a partially filled water balloon. This fluid, along with the developing fetus, results in an enlarged diameter of the gravid uterine horn, and later, as the pregnancy progresses, both uterine horns. This asymmetry early in gestation and the enlarged uterine horn(s) are highly suggestive of a pregnant cow.

With the development of the fetus and growth of the feto-placental unit, there must be a corresponding increase in blood delivery to the uterus. This requires considerable enlargement of the uterine arteries, and by four to five months of gestation not only can the increased diameter of the artery supplying the gravid horn be appreciated but fremitus (a buzzing or vibrating sensation) as well. The uterine arteries originate from the aorta just caudal to the internal iliac artery and are freely movable as they traverse the broad ligament, allowing them to be readily differentiated from the internal iliac arteries (see Figure 22.11).

Misdiagnosis and Differential Diagnoses

Failure to properly determine the pregnancy status of a cow is most commonly a result of an incomplete examination and inexperience. This can be exacerbated by the desire for speed and fatigue. Therefore it is important – especially when first learning to diagnose pregnancy – to develop a systematic routine for the examination to be followed at all times and to allot adequate time for the procedure, with additional time for rest if needed to prevent fatigue from becoming a deleterious factor. It should be reiterated that in the absence of one of the four cardinal signs of pregnancy, a definitive diagnosis should not be made and the temptation to base a decision on supportive signs of pregnancy must be resisted. Indeed, these signs are not considered definitive indications of pregnancy because they may be induced by other conditions. Adhesions from a number of disease processes may fix the cervix and uterus in location. Fluid in the uterus may be the result of a pyometra or mucometra, rather than fetal fluid. Along with causing fluctuance of the uterus, this fluid may make the cervix and uterus difficult to retract in addition to causing asymmetry and/or enlargement of the uterine horns. Physometra (air within the uterus) may also cause asymmetry and enlargement of the uterus. Typically, however, in these cases the uterine walls do not thin as they would in pregnancy, yielding somewhat more tone to the feel of the uterus. Tumors may also make the cervix difficult to retract and cause asymmetry of the horns. These pathological conditions may cause enlargement and – albeit rarely – fremitus of the middle uterine arteries. Fremitus and uterine artery enlargement may also persist for a short time following delivery of a calf.

The uterus is a site of predilection for tumors caused by bovine leukemia virus, and in addition to altering the

supporting signs of pregnancy, these and other tumors may be difficult to differentiate from a fetus. With careful palpation it can be noted that this mass has no identifiable fetal parts such as the head or legs and is not floating within the normal fetal fluids but is in intimate contact with the endometrium. Similarly, a mummified or macerated fetus can be palpated as a mass within the uterus, and, although fetal parts may be identified, once again there is no amniotic or allantoic fluid surrounding the fetus. The uterine walls are contracted down around the remnant of the fetus and it is not freely movable with the uterine lumen. In addition, a macerated fetus often has a characteristic grinding or crepitus upon palpation, believed to be the body parts and bones rubbing against one another during manipulation. Cows having an enlarged cervix may occasionally be misdiagnosed as pregnant by the inexperienced examiner as the cervix may approach softball size and be very firm, feeling a bit like the fetal head or pelvis. The postpartum uterus is also enlarged, may be asymmetric, and may lead one to suspect pregnancy. However, the uterine walls will be very thick, the cardinal signs cannot be identified, and often rugae (ridges or folds of the surface of the uterus as it begins to shrink and involute following parturition) may be palpated.

Various structures not associated with the uterus may also occasionally be mistaken for pregnancy. The dorsal sac of the rumen can extend near or into the pelvic canal, particularly in a cow restrained in a hydraulic squeeze chute, and is sometimes mistaken for a large fetus by the beginner. It should be noted that it is much more "doughy" than the fetus. The right kidney may be bumped and may feel somewhat similar to ballotting a fetus; however, it is located more dorsally than a calf would normally be. The bladder is also sometimes mistaken for a fluid-filled uterus and must be differentiated from a pregnancy. Finally, tumors or other masses may be misdiagnosed as a fetus. With care and patience, a thorough examination of all of these will allow the clinician to determine that these are not associated with the reproductive tract and that the cardinal signs of pregnancy are not associated with these structures.

Determining the Stage of Gestation

Once a cow has been determined to be pregnant, both the cardinal and supportive signs of pregnancy can be utilized to make a determination as to the stage of her gestation. This determination can be very accurate (within a few days) during the first trimester of pregnancy, as fetal development through this time is relatively consistent regardless of breed or other genetic and environmental factors. Fetal development begins to vary a bit among individuals through mid-gestation and relatively more during the final trimester. Indeed, in the final trimester as the fetus goes through rapid growth, the examiner often has no precise way of predicting the size of the calf at birth. As birth weight may vary from less than 25 kg to more than 50 kg, depending upon breed and maternal and paternal factors as well as environmental factors, estimation of gestation length at this time becomes somewhat less precise than earlier in gestation. However, if the cattle are from a purebred operation or dairy farm, the examiner can have a reliable frame of reference from which to work. In a commercial herd, the size and type of the dam and any information about the type and breed of bulls being used will be helpful in achieving the highest degree of accuracy possible. The fingers and hand can be measured and used to evaluate the size of the structures being examined to further enhance the degree of accuracy.

Early in gestation, the size of the amniotic vesicle, the magnitude of the membrane slip, and the diameter of the horn can be used to determine the stage of gestation. As the pregnancy approaches 60 days and the fetus becomes palpable, it becomes another tool that can be used along with horn diameter. The size (Table 38.2) of either the fetus (Figure 38.2) or the nose to crown length of the head (Figure 38.3) may also be utilized.

By 4.5–5 months of pregnancy, the uterus is pulled deep into the abdomen of the cow and the fetus itself often may not be palpated. The development of placentomes by around day 75–80 provides another aid. While the size of the placentomes is very useful, just their presence combined with the inability to reach the fetus places the cow in mid-gestation. Placentome size is most consistent just anterior to the cervix. The diameter of the uterine artery(ies) may also be measured reliably at this time and the advent of fremitus ipsilateral to the pregnant horn indicates a pregnancy of about four months. Bilateral fremitus is usually present by about six months of pregnancy. As the fetus reaches seven months of age, it will begin ascending once again, allowing feet, legs, and head to be examined. It is important to note that at this time the placentomes become more variable in size and less reliable indicators of gestation length. See Table 38.2 for a list of pertinent structures and where they may be located at different stages of gestation as well as their approximate sizes as pregnancy develops.

Risks Associated with Transrectal Palpation

Although palpation per rectum is a relatively non-invasive procedure, it is not without some concerns. These include the possibility of disease transmission and causing damage

Table 38.2 Size of various reproductive organs and fetal structures that can be used to help determine the stage of gestation.

Gestation length (days)	Amniotic vesicle size (cm)	Membrane slip	Fetal body length (cm)	Fetal size	Placentome size	Fetal nose to crown length	Horn diameter	Uterine artery findings and diameter
30	0.6–0.7	Thread in gravid horn					Slightly asymmetric	3–4 mm
40	1.2–1.5	Small string in gravid horn					Slightly enlarged, asymmetric	
50	5–6						6 cm	
60	8–8.5	String in both horns	5.5–7	Mouse			7 cm	3–4 mm
70			10			1.5 cm		
80			14		Pea	3.5 cm		
90		Large string in both horns	15–16	Rat	Dime	5.5 cm	8–10 cm	
100			18–20			7.5 cm		
110			24–25			9 cm		
120			27–28	Small cat	Nickel–quarter	10.5 cm	15 cm	Fremitis on side of pregnant horn, 6 mm
150			36–38	Big cat	Half dollar		18 cm	Fremitis on side of pregnant horn, 9 mm
180			47–50	Beagle	Variable			Fremitus both horns, 10–12 mm
210			62–64	Springer Spaniel				
240			73–80	Doberman				
270			85–105	German Shepherd				10–15 mm

to the embryo or fetus especially during early gestation. The diseases most frequently mentioned are bovine leukosis virus (BLV) and bovine virus diarrhea (BVD). Studies of both have met with mixed results. BLV has been shown experimentally to be spread when blood from infected cattle was repeatedly introduced rectally to non-infected cattle [1]. However, the same researchers in another study showed no transmission of the virus in a commercial dairy when the same glove was used on multiple cows versus using a new glove for every cow. In this same report, they demonstrated transmission of BLV in a university-owned teaching herd apparently from the use of common gloves. In this instance, it seems likely that more blood and trauma from inexperienced palpators and repeated palpations contributed to the seroconversion of these cows [2]. Conversely, in a small study, Kohara et al. [3] demonstrated seroconversion in three of four steers palpated a single time with a common glove following palpation of a positive cow. In addition, BLV negative cows palpated twice weekly for nine weeks with obstetric sleeves which were first used for aggressive palpation (to the point there was mucus and blood on the sleeves) of two BLV positive cows resulted in all the negative cows developing BLV antibodies [4]. Thus, it may be prudent to change or wash a sleeve if there is blood on the palpation sleeve prior to examining the subsequent cow in herds in which BLV is a concern.

Lang-Ree et al. [5] tied 10 BVD negative heifers side by side with no partition between them. They then palpated a persistently infected (PI) heifer and using the same sleeve palpated the first three heifers in the line. With a new sleeve, they again palpated a PI heifer and examined heifers 5–7. Again changing to a new sleeve, heifers 9 and 10 were palpated following the same procedure. All eight of the palpated heifers showed mild clinical signs of BVD and seroconverted within two weeks of the examinations. In addition, the virus was isolated from five of the eight palpated heifers. Blood was not observed at any time on the sleeve following palpation of the PI heifer. Heifers 4 and 8 (not palpated) remained asymptomatic and seronegative even though they were kept in close proximity with the others [5]. Consequently, in herds to be examined for pregnancy which are at high risk for having a PI cow, the clinician may want to take extra precautions to reduce the chance of transmitting the virus and inducing clinical signs or, more importantly, a PI calf (editor's note: see Chapter 62 for management of PI-BVD animals).

Early embryonic death resulting from transrectal palpation has also been studied with variable results. Older studies seemed to indicate some level of iatrogenic abortion during early pregnancy diagnosis. Females palpated at or before 45 days of gestation had higher incidence of embryonic mortality than females examined later in gestation [6]. Similarly, fetal loss was greater in females palpated 35–51 days after insemination than in females palpated 52–70 days post-insemination [7]. Decreased pregnancy rates were observed in females palpated twice between 42 and 46 days post-breeding as compared to females initially diagnosed pregnant by progesterone testing and first

palpated at 90 days post-breeding [8]. Vaillancourt et al. [9], on the other hand, found that though the rate of embryonic death was greater in females examined before 50 days of gestation, there was no conclusive indication that the increased embryonic loss was due to pregnancy diagnosis by fetal membrane slip. Conversely, Thurmond and Picanso [10] found that females palpated early in the gestational period from 28 to 42 days had a significantly lower probability ($P < 0.0001$) of early embryonic death compared with females palpated later in the 28–42 days interval. In two other studies, there was no significant difference ($P > 0.05$) in the incidence of embryonic death in females that underwent transrectal palpation and those that were not palpated [11, 12]. In a series of studies, Romano and colleagues demonstrated no deleterious effects of pregnancy diagnosis by membrane slip [13] or by palpation of the vesicle [14] versus ultrasound controls; and then in a comparison study on pregnancy loss, calving rates, and abnormalities in newborn calves, neither a difference between the two methods of diagnosis nor the control group which was diagnosed by transrectal ultrasound was identified [15]. A number of confounding factors have likely contributed to the differences in these studies. These include natural embryonic and fetal loss and the lack of a reliable, non-invasive test with which to make the original pregnancy diagnosis. As these tests have improved, the degree of normal embryonic and fetal loss has become better understood, thus allowing for better design and evaluation of the more recent studies. In addition, one must take into consideration the number of examinations and stress placed on cattle in studies compared with normal production scenarios. As these factors may contribute to the varying results of these studies [13, 16], it is likely that the more recent studies are more reliable and that routine transrectal palpation does not significantly contribute to early embryonic death or fetal demise when performed within normal management programs.

Summary

The cost of carrying open cows is significant to the beef producer, and for dairy producers it is important to minimize the calving interval for each cow to maximize profitability. Rectal palpation is currently the most commonly utilized method of diagnosing pregnancy in cattle. With experience it can be performed rapidly, with very good accuracy and relatively inexpensively, to determine not only pregnancy status but also stage of gestation. Indeed, Kasimanickam et al. [17] showed a very small error rate when trans-rectal palpation was used to separate cows that were 70 days pregnant by fixed time artificial insemination (FTAI) from cows that were bred by a bull turned in two weeks following the FTAI, and demonstrated increasing accuracy with the experience of the individual performing the examination. This kind of capability allows the producer the opportunity to make crucial management decisions such as culling or knowing when to dry a cow off based upon these findings. However, data gathered by the National Animal Health Monitoring System indicate that pregnancy diagnosis by palpation was utilized in only 10.8% of beef cattle operations with less than 50 cows, 25.8% of operations with 50–99 head, 41.2% of operations with 100–199 head, and 58.3% of farms with 200 or more cows [18]. On the other hand, about two-thirds of all dairy operations (67.0%) performed pregnancy examinations monthly or more frequently. The majority of large operations (75.0%) performed pregnancy examinations weekly or every two weeks, while 50.2% of small operations performed examinations on a monthly basis and 69.3% of mid-size operations performed examinations once or twice a month [19]. Thus, there is a significant opportunity for veterinarians with expertise in pregnancy diagnosis and pregnancy staging by rectal palpation to provide a valuable profit-building service to their clients and the effort to develop this skill is well worth the investment.

Examination for Pregnancy: Biochemical Tests

Amanda Cain Dempsey

DeKalb Animal Clinic, Smithville, TN, USA

Introduction

Prompt accurate diagnosis of pregnancy or non-pregnancy is critical for efficient livestock management, especially in the dairy industry where profitability relies largely on the reproductive efficiency of the cow herd [1]. Early identification of non-pregnant cows, particularly if they can be identified before the next expected estrus, is vital for maintenance of a desirable calving interval in both beef and dairy herds.

Traditionally, producers have relied heavily on transrectal palpation and/or transrectal ultrasound to diagnose pregnancy. Both of these methods require specialized training and technical skill and are usually performed by a veterinarian. Neither can diagnose pregnancy prior to the estrus immediately following breeding. Moreover, many geographical areas are experiencing a shortage of large animal practitioners. This, coupled with the desire to identify non-pregnant animals as early after insemination as possible, has made the pursuit of reliable biochemical methods of pregnancy testing more attractive [2]. A number of biochemical tests for pregnancy in the bovine are currently available. These tests detect pregnancy-associated hormones or the presence of pregnancy-specific molecules in maternal circulation and are marketed as viable alternatives to transrectal palpation and transrectal ultrasonography. However, unlike transrectal palpation and transrectal ultrasound these tests by themselves cannot currently be used to closely estimate the stage of gestation.

When diagnosing pregnancy via transrectal palpation, reproductive structures are felt for positive signs of pregnancy. Most large-animal veterinarians can accurately diagnose pregnancy as early as 30–35 days after insemination, but the level of accuracy is highly dependent on the expertise of the veterinarian and generally increases when examination is delayed to 40–50 days after breeding [3]. Concerns over early embryonic mortality as a result of transrectal palpation, particularly via fetal membrane slip, have been expressed and have been the subject of multiple studies. The risks associated with transrectal palpation for diagnosis of pregnancy are fully addressed in Chapter 38.

Through transrectal ultrasound, pregnancy can be consistently and accurately diagnosed as early as 25 days after insemination. Maximum sensitivity in diagnosing a pregnancy is reached at day 26 and day 29 in heifers and cows, respectively [4, 5]. For this reason, transrectal ultrasound is often used as the "gold standard" when evaluating other means of pregnancy diagnosis. Although 25 days after insemination provides a diagnosis earlier than transrectal palpation, transrectal ultrasound still does not allow diagnosis of non-pregnancy before the next expected estrus, and, like transrectal palpation, requires that the veterinarian has a great deal of technical skill in order to yield consistently accurate diagnoses. Furthermore, this method of pregnancy determination requires substantial inputs to purchase and maintain necessary equipment, and these costs must be passed on to the producer.

The ideal pregnancy test would accurately diagnose both pregnancy and non-pregnancy a short time after fertilization, and have excellent sensitivity (the female that tests pregnant is indeed pregnant), specificity (the female that tests non-pregnant is indeed open), and accuracy (the proportion of true results). Furthermore, the ideal pregnancy test would be non-invasive in that there would be no risk of causing embryonic or fetal death through testing. In addition, it would be minimally expensive, require little or no technical skill, and could be quickly and easily performed chute-side. An ideal pregnancy test for the bovine would be very similar to the human chorionic gonadotropin (hCG) test for pregnancy in women.

The hCG test is a simple enzyme-linked immunosorbent assay (ELISA) that detects the presence of hCG protein in

Bovine Reproduction, Second Edition. Edited by Richard M. Hopper.

Companion website: www.wiley.com/go/hopper/bovine

the urine of pregnant women. It can easily and inexpensively be performed in the home, requiring virtually no technical skill. Commercially available hCG tests boast extremely high accuracy (>99%), and some can be performed as early as 8–10 days after conception [6]. Unfortunately, cows and heifers do not produce hCG or any analogous molecule that could be tested in a comparable fashion. Instead, tests have been developed to ascertain the presence of certain pregnancy-associated molecules such as elevated progesterone concentration, pregnancy-associated glycoproteins (PAGs), early pregnancy factor (EPF), and interferon-stimulated genes (ISG) [2]. Additionally, as technology and scientific knowledge of early pregnancy advance, there are a number of other molecules that may one day be used as pregnancy biomarkers in the bovine.

An important distinction that producers should be mindful of when opting to utilize biochemical methods to determine pregnancy status is that progesterone, PAG, EPF, and ISG assays are more accurate in detecting non-pregnant females than in correctly identifying pregnancy. Consequently, endocrine-based pregnancy tests often have excellent specificity (>90%) but slightly less desirable sensitivity. This is of significant economic importance because females in intensive production scenarios that are falsely identified as open will often be administered prostaglandin in an attempt to initiate a new cycle and reduce time to next insemination. This injection of prostaglandin will, of course, induce abortion in pregnant females, and since the average cost of a pregnancy loss in a dairy female in the USA is estimated at $555, there is significant incentive to minimize the incidence of iatrogenic embryonic and fetal loss [7].

Similarly, another confounding factor when attempting to identify pregnancy soon after fertilization is natural pregnancy loss. Bovine fertilization rates are usually high (>90%) and therefore the main contributor to reproductive wastage is embryonic or fetal death [8, 9]. Early embryonic death, occurring prior to day 17 of pregnancy, accounts for 20.5–43.6% of loss when coupled with frequency of failure of fertilization [10]. However, late embryonic death, which represents loss from approximately 17 to 42 days of gestation, is estimated to be, on average, 12.8% in dairy cows and approximately 6.5% in beef females [11–13]. It has been estimated that pregnancy losses from fertilization to term in high-producing dairy cows may approach 60% [13]. When critically evaluating the reliability of endocrine tests performed early in gestation, it is customary to confirm pregnancy diagnosis by transrectal palpation or ultrasound days or weeks after the initial test was performed. This creates a window in which embryonic or fetal loss can occur, thus skewing the data by incorrectly labeling some results as false positives as the female was indeed pregnant when first tested but lost the pregnancy before the confirmatory pregnancy evaluation.

Progesterone Concentration

Serum and milk progesterone levels steadily increase following ovulation as a functional corpus luteum (CL) grows and develops. In non-pregnant females, progesterone declines as the CL regresses and the cow returns to estrus. In pregnant females, however, progesterone levels should remain elevated during the period of the next expected estrus as the CL continues to produce progesterone in order to maintain the pregnancy.

Progesterone concentration testing functions on the premise that serum and/or milk progesterone concentration will remain elevated at the time of the next expected estrus if the female were pregnant. If the female is open, progesterone concentration will decrease to baseline as the CL regresses and a new dominant follicle develops [3] (see Chapters 24 and 25).

Discrepancies in progesterone testing may be largely caused by natural variation between individuals in luteal lifespan and estrous cycle length as progesterone levels remain high while a CL is present during diestrus [14]. Furthermore, embryonic mortality between the time of progesterone testing and pregnancy confirmation via transrectal palpation or transrectal ultrasound examination may contribute to perceived test error [3].

A potential drawback to the use of progesterone testing in production settings is that the breeding or insemination date must be known in order to obtain reliable results from a single sample, and therefore the applicability of progesterone testing is somewhat limited [2, 3]. Typically, a milk or serum sample is taken 21–24 days after breeding and is analyzed using either radioimmunoassay (RIA), ELISA, or, less frequently, latex agglutination (LA). A number of progesterone ELISAs for serum and milk are available to producers and are marketed as cow-side tests.

Progesterone testing is very reliable for identifying non-pregnant females, as cows with blood progesterone levels less than 1 ng/ml 21 days after insemination cannot be pregnant, but it is less reliable for positively diagnosing pregnancy because of natural variations in estrous cycle lengths between individual animals [2]. Detection rates of 95–100% have been reported in detecting non-pregnancy. Pregnancy was correctly identified 68–97% of the time, with study designs varying in the day of gestation the test was performed, the standard it was compared against, and the type of assay used (ELISA, RIA, or LA) [15–20].

Pregnancy-Associated Glycoproteins

Ruminant trophoblasts release proteins as part of maternal recognition of a viable conceptus. These pregnancy-associated glycoproteins (PAGs) are aspartic peptidases and have not

been found to be proteolytically active. The first PAG to be discovered was pregnancy-specific protein B (PSPB), formerly known as PAG 1. This protein is produced by trophoblast binucleate cells in the bovine placenta around the time of implantation, though its exact role in pregnancy maintenance is not yet fully understood. It can be found in maternal circulation from the time of implantation throughout gestation, often persisting well into the postpartum interval [21, 22].

As its name suggests, PSPB is a pregnancy-specific molecule and is not found in the serum of virgin heifers or open cows, thus demonstrating that the protein is produced solely as a response to a conceptus and not in response to luteal activity during the estrous cycle [23]. Unlike equine chorionic gonadotropin (eCG) and hCG, PSPB is not detectable in urine, and it is only found in milk during intervals when PSPB is at very high concentration in plasma, for example shortly after parturition [21]. For additional information regarding the origins and characterization of PAGs, specifically PSPB, see the review article by Wallace et al. [24].

An RIA capable of reliably detecting PSPB in maternal serum as early as 24 days after conception was developed by Sasser et al. [23] in 1986. A then-unique advantage of PSPB testing was that, unlike progesterone assays, insemination dates are not needed to confirm pregnancy in PSPB testing as the protein is pregnancy specific and present throughout gestation, peaking around the time of parturition [23].

In addition to the RIA test, there are several commercially available ELISAs for bovine PAGs including PSPB. Currently available tests include BioPRYN™ (Biotracking, Moscow, ID, USA), Bovine Pregnancy Assays (IDEXX Laboratories Inc., Westbrook, ME, USA), and DG29 (Conception Inc., Beaumont, Quebec, Canada). These assays are marketed in both the USA and abroad as convenient and inexpensive pregnancy tests for use by both producers and veterinarians, and furthermore are marketed as being as accurate as transrectal ultrasound examination. They can be used as early as 28 days after insemination in both cows and heifers and use similar concentrations for the determination of pregnancy or non-pregnancy as earlier RIA tests [24–26]. According to the manufacturers, samples (blood or milk) may be submitted to labs and results will be reported to producers the same day that samples are received, or kits are available that allow the assay to be run on farm in as little as 30 minutes. When verified contemporaneously with transrectal ultrasound near the end of the late embryonic period, PAG ELISAs yielded accuracies for pregnancy detection ranging from 89 to 100% [27–31], and on-farm rapid visual test kits were found to have equal sensitivity and accuracy as traditional PAG ELISAs [32].

The usefulness of PAGs in pregnancy diagnosis can be detrimentally affected by the relatively long half-life of some PAGs. For example, PSPB can be detected in maternal blood up to 80–100 days after calving; therefore producers must be cautious when using PSPB assays to detect pregnancy in cows bred early in the postpartum period [23, 33]. In addition, this long half-life may result in false-positive tests for pregnancy following pregnancy loss. Finally, this test does not have the advantage of diagnosing non-pregnancy prior to the cow's first estrus following breeding.

Early Pregnancy Factor

EPF is an immunosuppressive hormone that can first be found at detectable levels in the maternal system 24–48 hours after successful fertilization and persists for at least the first half of gestation [34]. EPF acts as an immunomodulator protecting the antigenically foreign conceptus from maternal rejection [35]. It is produced by maternal tissues during the preimplantation stage in response to the presence of a conceptus. After implantation has occurred, however, the embryonic tissue assumes responsibility for EPF production. Only a viable conceptus that has reached the blastocyst stage is capable of producing EPF. Furthermore, EPF dissipates rapidly after the death or removal of the conceptus. Unlike some PAGs, including PSPB, EPF has never been detected after parturition [34]. The combination of these attributes makes EPF potentially very useful for pregnancy determination and recognition of embryonic fetal death.

Before the discovery of EPF and development of a test to determine its presence, it was impossible to detect a pregnancy prior to implantation except through invasive surgery. Although diagnosing pregnancy so soon after insemination seems appealing, the high frequency of early embryonic mortality makes this test less useful. Producers opting to use EPF to diagnose pregnancy early in gestation should retest all positive females at a later date to confirm the presence of a viable conceptus.

A producer-oriented assay for EPF would be a very valuable tool for the detection of fertilization and pregnancy in cows during the first four weeks of gestation as the unique properties of EPF make it particularly useful in intensive production scenarios. It is detectable within 48 hours of fertilization and, unlike PAGs, disappears rapidly on removal of the embryo or fetus, and therefore can be assayed accurately even in cows inseminated early in the postpartum interval that may have residual PAGs in circulation. Furthermore, an EPF assay would be far less likely than a PAG assay to yield a false-positive result due to previous pregnancy loss [36]. Most importantly, however, an EPF test can accurately determine the pregnancy status of a female well before her next expected estrus [34].

The first and currently the only reliable test for EPF is the rosette inhibition test (RIT) in which EPF, in the presence of a complement, works to cause an increase in the effects and titers of antilymphocyte serum in decreasing the

formation of rosettes between lymphocytes and heterologous red blood cells [34]. The RIT for EPF is very accurate and extremely useful in identifying non-pregnant females. Unfortunately, the RIT is time-consuming and difficult to maintain, and therefore it is not practical for regular use on commercial operations [3].

A producer-oriented test to detect the presence of EPF was previously available in the USA. This test, the early conception factor (ECF) lateral flow assay, was marketed as a cow-side test for non-pregnancy and reportedly could detect EPF in milk or serum 48 hours to 20 days after fertilization [37]. However, concerns regarding the accuracy of the ECF test performed early in gestation were raised, and the ECF test is no longer commercially available. Ambrose et al. [38] reported that ECF specificity on 7, 14, and 21 days after insemination ranged from 38 to 51%. Data from other studies corroborate these findings and conclude that the ECF lateral flow assay cannot correctly identify open cows with the degree of precision needed by most commercial dairy operations [39–41]. However, the development of a more reliable assay for EPF could revolutionize early bovine pregnancy diagnosis, especially in the dairy industry.

Interferon-Stimulated Genes

In cattle, the molecule primarily responsible for the maternal recognition of pregnancy is interferon (IFN)-tau. It is secreted by conceptus trophectoderm cells and acts in a paracrine manner on uterine endometrium to inhibit pulsatile secretion of prostaglandin (PG)$F_{2\alpha}$, thereby effectively inhibiting luteolysis and successfully maintaining the pregnancy [42]. Unlike the molecules of maternal pregnancy recognition in some other mammalian species (i.e. hCG in humans and eCG in mares), IFN-tau is present only in very low concentrations in the maternal periphery and therefore cannot currently be directly tested for in serum or milk. Thus, maternal IFN-tau concentration itself cannot be used in diagnosing early pregnancy in the bovine [43].

In addition to its role in interrupting the signal transduction pathway that regulates the release of $PGF_{2\alpha}$, IFN-tau induces the upregulation of multiple differentially expressed ISGs on maternal leukocytes. Among these ISGs are myxovirus resistance gene 1 and 2 (Mx1 and Mx2) and interferon-stimulated gene 15-kDa protein (ISG15), a ubiquitin homolog [43–46]. ISG15 mRNA expression on maternal white blood cells follows a similar pattern to IFN-tau release, first being expressed around day 14 after conception, peaking between day 17 and 18, and declining from day 21 to day 26 [47]. However, unlike IFN-tau, ISG15 is detectable in the maternal periphery in early pregnancy and could potentially be useful in diagnosing non-pregnancy before the next expected return to estrus. Because of variability between individual females' white blood cell composition and differences in IFN-tau concentrations between conceptuses, ISG15, like most other molecules of biochemical pregnancy diagnosis, is more useful in detecting open cows than in affirmatively diagnosing pregnancy.

Though results generated in laboratories for the use of ISG15 in identifying non-pregnant females, especially heifers, have been promising, thus far a consumer-oriented test for ISG15 mRNA upregulation has not been developed, and real-time polymerase chain reaction (PCR) must be used to detect ISG15 mRNA in maternal serum [43, 48]. Furthermore, serial blood tests are necessary to achieve maximum accuracy (>99.9%) when using ISG15 mRNA to identify non-pregnant cows and heifers. Accuracy in detecting non-pregnant cows from a single blood collection (day 18) was 89% in a 2006 study conducted by Han et al. [48]. Further complicating the potential application of ISG15 as a means to early pregnancy determination is ISG15 activation as a response to interferon throughout the course of a viral infection. If relying solely on ISG mRNA expression levels for pregnancy detection, virally infected open females may be falsely diagnosed pregnant [48]. Though ISG15 mRNA is currently not feasible for use in early pregnancy determination in commercial operations, with refinement and further scientific advances this innovative new technology may one day be adapted for widespread use in diagnosing pregnancy and predicting embryonic mortality.

Emerging Research

In addition to the previously described pregnancy-associated molecules, which have been well tested and reviewed in scientific literature, there are a number of other peripheral indicators of pregnancy that may one day be useful for commercial pregnancy diagnosis in the bovine. As our knowledge of early gestation and early maternal responses to conception increases, more biomolecules with potential applications in pregnancy determination will be uncovered. As with existing biochemical pregnancy tests, these new and emerging tests will endeavor to detect the presence of a conceptus prior to the female's next expected estrus so that she may be rebred, if necessary, as quickly as possible.

Among the most promising molecules for potential future use in early bovine pregnancy determination are circulating nucleic acids (CNAs). CNAs are cell-free DNA/RNA molecules circulating in the blood and have been used as biomarkers in both diseased and healthy humans and animals for a number of years. In humans, CNAs are primarily used in the diagnosis of certain tumor diseases and other disorders. During human pregnancy, CNAs are often used to screen for genetic abnormalities such as chromosomal aneuploidy [49]. Unlike human fetuses, bovine

Table 39.1 Summary of biochemical indicators presently used for the diagnosis of pregnancy in the bovine.

Molecule	Type of test	Producer test available?	Days of gestation effective	Significant drawbacks
Progesterone	RIA, ELISA, LA	Yes	21–285	Must know breeding date to use reliably in early gestation
PAGs	RIA, ELISA	Yes	28–285	Long half-life may skew results in females bred before 90 days postpartum
EPF	RIT	No	2–140	No producer test
ISG15	RT-PCR	No	14–26	No reliable producer test; virally infected females may have false positives

trophoblasts have no direct contact with maternal blood, and therefore exchange of fetal genetic material occurs less readily than it does in humans. However, it has been demonstrated that "transplacental leakage" of bovine fetal DNA into the maternal circulation can, and often does, occur in spite of the epitheliochorial placenta structure, though the mechanisms responsible for this exchange have not yet been elucidated [50, 51]. Other studies have demonstrated that CNAs can be used to accurately (100% for male calves, 91% for female calves) determine calf sex after day 30 of gestation [51, 52]. Mayer et al. [49, 53] have recently characterized the differences in CNA composition between pregnant and open cows at day 20 of gestation, finding multiple sequences present exclusively in the serum of pregnant females. Although this particular application of CNA technology is still in its infancy, these findings indicate that it may one day be feasible to use CNAs to identify pregnant cows and heifers as early as 20 days after breeding.

Another promising class of biomarkers for potential use in early pregnancy diagnosis is microRNA (miRNA). MiRNAs are short, non-coding RNA molecules which are heavily involved in gene expression and may be found in virtually every bodily fluid, making them ideal for minimally invasive sampling [53–56]. At this point in time, numerous miRNAs have been identified as unique to individual disease or physiological states, including pregnancy [56–58]. Further studies are needed to elucidate the role of miRNAs in bovine early pregnancy and to determine which miRNA molecules would be most reliable in the diagnosis of pregnancy [59].

Summary

Intensive reproductive management systems make early and accurate pregnancy determination a necessity in the cattle industry, especially on commercial dairy operations. Though producers have traditionally been limited to transrectal palpation and transrectal ultrasound for pregnancy diagnosis, a variety of biochemical pregnancy tests are rapidly becoming available. A summary of the tests discussed in this chapter and their attributes is provided in Table 39.1. All of these tests have the potential to diagnose pregnancy or non-pregnancy earlier than traditional methods (transrectal palpation and transrectal ultrasound) while still maintaining a comparable level of accuracy. However, on their own, they do not have the capability to closely stage the pregnancy and may require some knowledge of the breeding or artificial insemination (AI) date.

Currently, only EPF or ISG15 would allow producer intervention (i.e. prostaglandin administration) prior to the first estrus after insemination. Unfortunately, RIT and real-time PCR, respectively, are required to accurately detect these molecules in maternal peripheral circulation. Both of these tests require expensive equipment and are difficult to run outside of a laboratory environment. Thus, the practicality of using these compounds for bovine pregnancy determination is currently limited. Producers and veterinarians should work together to make decisions regarding which pregnancy testing method to use based on the individual needs of each operation.

Ultrasound Evaluation of the Female Reproductive Tract

Jill Colloton

Bovine Services LLC, Edgar, WI, USA

Introduction

When O.J. Ginther [1] published *Ultrasonic Imaging and Animal Reproduction: Fundamentals* in 1995, field veterinarians began using ultrasound technology for reproductive examinations in the bovine. With the advent of small machines designed to be carried on the operator's person, the use of ultrasound has become mainstream. Many texts and other resources have been published describing the use of ultrasound for bovine reproductive examinations [1–6]. The goal of this chapter is not to reiterate those resources, but to expand on them.

Pregnancy Diagnosis

It is theoretically possible to identify a conceptus by ultrasound as early as 21 days after breeding [7], but that is usually not practical in field conditions. One proficient ultrasonographer tested his ability to accurately diagnose open versus pregnant cows beginning at 24 days after breeding [8]. The negative predictive value (diagnosis of not pregnant) was 89% at 24 days in adult cows. In other words, 11% of cows diagnosed open were found to be pregnant when rechecked at 32 days. By 26 days this ultrasonographer was able to identify open cows correctly in 99% of cows examined. In heifers he was able to achieve the same level of competency at 24 days after breeding.

Bovine ultrasonographers are advised to perform a similar analysis of their skills to identify their competence at various stages after insemination. The time it takes to perform examinations and the number of rechecks required at various stages should also be taken into consideration. Note the large difference in the amount of fluid and size of the embryo between 26 days (Figure 40.1a) and 28 days (Figure 40.1b). Note that the 26-day embryo is difficult to visualize against the uterine wall. The 28-day embryo, on the other hand, is 1 cm in length and easily seen within the uterine fluid. Embryonic development occurs very rapidly, so waiting just a couple of days can improve accuracy and speed of pregnancy examinations. It is of no value to the producer if early pregnancy examinations do not lead to immediate management decisions.

Ovarian structures are helpful aids in pregnancy diagnosis. It can hasten the examination to know if a corpus luteum (CL) is present and, if so, on which side. Two corpora lutea indicate the potential for twins. A pregnancy with the CL contralateral to the embryo or fetus is very high risk for pregnancy loss. A small or poor-quality CL may indicate low progesterone levels that could lead to pregnancy loss. A cavitary CL is of no concern unless the cavity is so large and the rim of luteal tissue so small that total luteal volume is low. In cases of poor-quality or contralateral corpora lutea, treatment with gonadotropin-releasing hormone (GnRH) may produce an accessory CL to improve progesterone levels. Examination of ovarian structures is discussed further in later sections of this chapter.

The producer should understand that early diagnosis of open cows is critical for quick rebreeding of those animals, but that pregnant cows diagnosed before day 60 should be checked again after placentation is complete (see section "Embryonic and Fetal Viability"). This is especially important for lactating dairy animals due to their higher risk of late embryonic and early fetal death.

Embryonic and Fetal Aging

Ultrasound is far superior to manual palpation for staging pregnancies up to about 120 days in gestation. With ultrasound, embryonic or fetal size is measured rather than the size of the amniotic sac or total amount of pregnancy fluid. Embryonic and fetal growth is very consistent

regardless of ambient temperature or breed, whereas the amount of fluid can vary.

Two methods can be used to determine the gestational age of the embryo or fetus. First, direct measurements of the embryo or fetal structures can be taken and correlated to age using a gestational aging chart [9, 10]. Trunk diameter is the widest part of the ribcage at the level of the umbilicus. Braincase diameter is the maximum diameter of the skull just caudal to the eyes. Head length is measured from the top of the cranium to the tip of the nose. Crown–rump length is measured from the tailhead to the crown of the skull. Of these measurements, only crown–rump length has a simple formula for a portion of gestation. Until approximately 50 days of gestation embryonic or fetal age can be calculated thus:

$$\text{Length of the embryo fetus in millimeters} + 18 = \text{embryonic or fetal age in days}$$

For measurements of other structures, or for fetal ages greater than 50 days, one must use fetal aging charts or an ultrasound unit that is equipped with software to measure and calculate gestational age.

The second method is to visually evaluate embryonic/fetal development. Sandra Curran and colleagues have studied when various structures first appear (Table 40.1) [7]. This author finds that in field conditions these structures are most easily seen at the high end of Dr. Curran's range. Using embryonic/fetal size and knowledge of development,

experienced ultrasonographers learn to "eyeball" age quite accurately without referring to charts or software.

After approximately 120 days of gestation fetal aging is less accurate. It is difficult to reach and measure fetal structures. Also, fetal size begins to vary among animals with the same breeding dates. Other measurements, such as fetal eye diameter, placentome size, or uterine artery diameter, are too variable among animals to provide accurate estimates of fetal age.

Embryonic and Fetal Viability

Lactating dairy cattle experience considerable pregnancy loss, particularly before 60 days of gestation when placentation is not yet complete. Losses in lactating dairy cattle are approximately 3.6 times greater than in pregnant heifers [11] and often are 10–12% from day of initial pregnancy diagnosis to 90 days [12]. Hypotheses for this high rate of loss include reduced progesterone levels due to high milk production [13], a history of postpartum disorders [14], insemination by certain bulls [15], twinning [16], and heat stress [17]. Regardless of cause, it is critical for producers to understand pregnancy loss and the need to reconfirm pregnancies diagnosed prior to about 60 days of gestation.

Fetal viability is easily assessed with ultrasound. Beginning at about 24 days of gestation, the fetal heartbeat can be seen [7]. The heart rate should be at least 130 bpm in early gestation, increasing to about 190 bpm by 60 days [2]. It can be difficult to identify the beating heart if the cow or the fetus is moving. For this reason, it is advisable to recheck pregnancies when no heartbeat is seen but all else appears normal.

The amniotic and chorioallantoic fluids should be clear and anechoic until at least 70 days of gestation. If the fluid is cloudy before 70 days and there is no heartbeat, the embryo or fetus can safely be assumed to be dead. Separated chorioallantoic membranes may also be seen in cases of late embryonic or early fetal death, often appearing to be floating in the pregnancy fluids. Compare the normal 35-day pregnancy in Figure 40.2a with the dead 40-day twin pregnancy in Figure 40.2b. Note the clear fluid and normal fetal development in the live fetus versus the flocculent fluid and unformed fetuses in the dead twins. Movement, other than a beating heart, is difficult to detect before 50 days because the limbs are not well developed yet.

After 70 days the fluids of pregnancy may begin to appear cloudy in normal pregnancies, but by that stage fetal movement can easily be appreciated. Separation of the chorioallantoic membrane is difficult to appreciate at this stage due

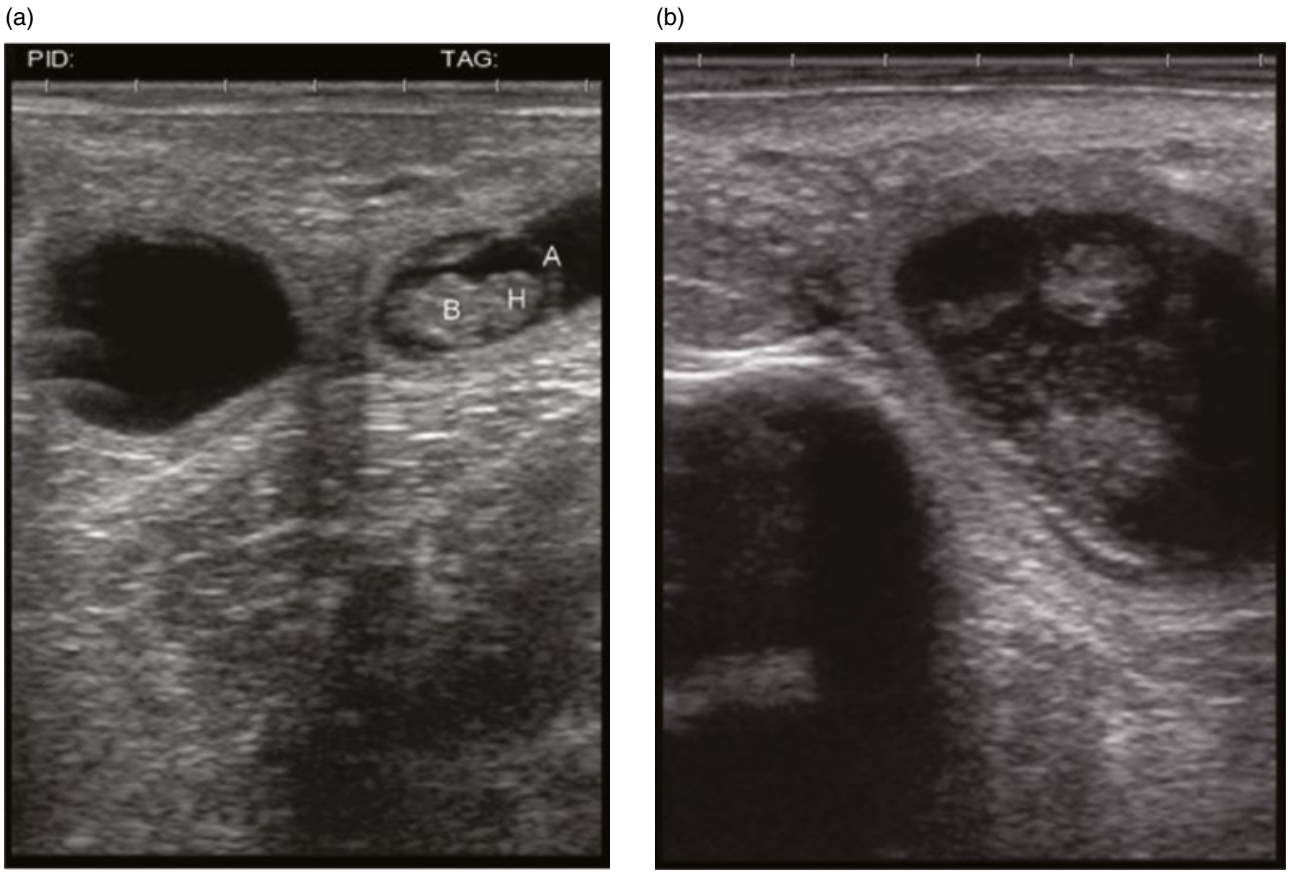

Figure 40.2 (a) Normal 35-day pregnancy: amniotic vesicle (A), head (H), body (B). (b) Dead 40-day twins.

to elongation and folding of all the placental tissues. Dead fetuses often are very heterogeneous, with many areas of high echogenicity that do not correspond to normal bony anatomy. There may also be fluid in the peritoneal cavity. Compare the dead 65-day fetus in Figure 40.3a with the normal 60-day fetus in Figure 40.3b. Fetal mummies (Figure 40.4) are easily identified by echogenic bony remnants, nearly complete lack of intrauterine fluid, lack of fetal movement, and lack of heartbeat.

In the absence of prostaglandin treatment and CL regression, dead embryos and fetuses can persist for weeks [18]. In these cases there are usually still palpable cardinal signs of pregnancy such as membrane slip or amniotic vesicle (AV). With ultrasound, however, they can be quickly identified without additional examinations and treated with prostaglandin. In most cases, expulsion of the dead embryo/fetus and uterine contents will be complete within 48 hours after prostaglandin administration.

In some cases, fetal distress can be identified before death. A heart rate of less than 130 bpm is cause for reevaluation at the next visit. Mild separation of chorioallantoic membranes or abnormal fluid in the presence of a live fetus is also cause for follow-up. A live fetus smaller than expected may be cause for concern, but is usually due to incorrect recording of breeding date. Twin fetuses are not smaller than singletons until late in gestation. Fetal anomalies are at higher risk of loss throughout gestation and, in many cases, it is desirable to abort these abnormal pregnancies intentionally (see section "Embryonic and Fetal Anomalies"). As discussed at the beginning of this section on "Pregnancy Diagnosis," a contralateral or poor quality CL is also reason to recheck the pregnancy at the next opportunity.

Twins

High twinning rates are often seen in dairy herds and, less commonly, in beef herds. The primary mechanisms for twinning appear to be correlated to high milk production in dairy cattle [19] and to genetic propensity in certain strains of beef cattle [20]. In dairy cattle there also appears to be a higher risk of twinning in cows with a history of cystic ovarian disease [16]. In any case, twinning can lead to more pregnancy loss [16, 21], more dystocia, more periparturient disease, reduced future reproductive performance [22], freemartinism, and a higher risk of early culling for the dam [23].

Despite these risks it is generally not recommended to abort twin pregnancies. The possibility of failing to produce another pregnancy or of producing another set of twins makes it preferable to monitor and manage the cow carrying twins. This can include additional examinations to identify pregnancy loss, drying the cow off early to compensate for probable early calving, feeding a higher energy ration to improve body condition, providing extra monitoring and assistance at calving, and being alert for periparturient metabolic disease. In order to provide these management techniques it is important to the producer to know which animals are carrying twins. Manual palpation is not an accurate method for diagnosis of twins [24]. However, a careful ultrasonographic examination can identify most cases.

Because over 95% of twins in cattle are dizygous [25], it is helpful to examine the ovaries for two or, occasionally, more corpora lutea. Approximately 60% of pregnant cows with two corpora lutea will have twins [26]. When twins are suspected a thorough examination of the entire uterus should be performed. It is imperative to follow the tract in a systematic fashion to avoid inadvertently counting a single fetus twice. Triplets are rare but should be considered when three or more corpora lutea are present (Figure 40.5).

During examination of the uterus a twin line (TL) may be seen (Figure 40.6). This line represents the confluence of the chorioallantoic membranes of each fetus. It can be distinguished from the AV because it moves away from the fetus rather than encircling it. It should also not be confused with the umbilicus, which is not readily visible prior to 45 days and which is much thicker after that. A TL may be seen with either ipsilateral or contralateral twins. In some cases it is not seen due to the angle of examination. In later pregnancy the TL is difficult to identify because all the placental membranes are elongated and folded within the uterus. Twin pregnancies also tend to have more fluid than single pregnancies and often extend beyond the pelvic brim sooner. However, the only cardinal sign of twin pregnancy is the presence of two fetuses.

Twin pregnancies, particularly if ipsilateral, have higher rates of loss (Figure 40.2b) throughout gestation, but especially in the first 60 days before placentation is complete. This loss may be 3.1–6.9 times higher than that for singleton pregnancies [15, 27]. However, one unpublished study (A. Scheidegger, personal communication, 2005) indicates that loss of contralateral twins may be more likely in mid gestation. In either case, recheck examinations are warranted to identify cases of loss.

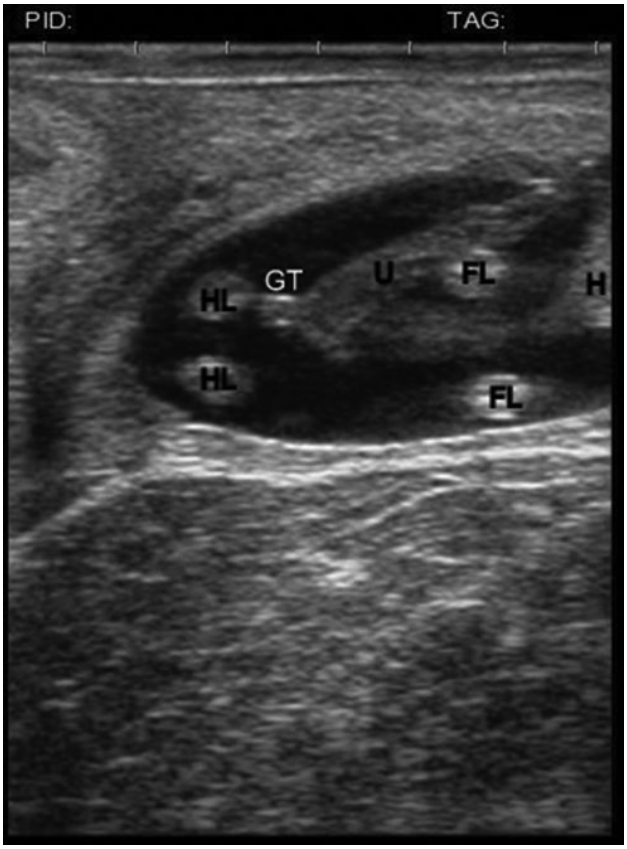

Figure 40.7 A 73-day male fetus: head (H), forelimbs (FL), hindlimbs (HL), genital tubercle (GT), umbilicus (U).

Spontaneous reduction of twin embryos has been documented [16, 21], most commonly in the late embryonic or early fetal stages. Depending on the study, 8–24% of twins reduced to a single fetus. The varying incidence is probably due at least partly to different days after insemination for initial and follow-up examinations. CL reduction often occurs in the ovary ipsilateral to the uterine horn suffering embryo reduction. Attempts to manually reduce twins in cattle have been, at best, only marginally successful [28]. In the future these results may be improved upon by ultrasound-guided needle aspiration of earlier embryos, as is done successfully in mares.

Fetal Gender Determination

Ultrasonographic gender determination of the bovine fetus was first described by Curran et al. [29] in 1989. It was found that the relative location of the genital tubercle (GT), which will become the penis in the male and the clitoris in the female, could be used to determine fetal gender beginning at day 55 of gestation. By this stage the GT has reached its final location immediately behind the umbilicus in the male (Figures 40.3b and 40.7) or immediately under the tail in the female (Figure 40.8). Until about 80 days of gestation the GT usually appears as a highly echogenic bilobed structure in both genders, but may appear mono- or trilobed.

After 70 days of gestation the skin of the prepuce or vulva begins to cover the GT [2]. At this point the adult term for the male or female external genitalia replaces the term "genital tubercle." By about 80 days the skin of the prepuce or vulva has developed enough to reduce the bright bilobed appearance of the genital structure, as shown in Figure 40.9. Also by this time the scrotum and mammary glands can be detected with most field ultrasound units. The scrotum may appear as three bright lines representing the lateral walls and median raphe or it may appear as a soft tissue sac. Teats appear as bright dots and may resemble the scrotum when it presents as three bright lines. High-quality ultrasound units can detect teats on bull fetuses, especially after about 90 days. Figure 40.10 shows teats on the same 98-day bull fetus shown in Figure 40.9. For these reasons it is not advisable to diagnose fetal gender based on presence of a scrotum or teats without visualizing the GT, penis, or vulvar structures.

After 90 days the uterus may be over the brim of the pelvis and difficult to reach for gender determination in some animals. In others it may be possible to reach the fetus at 120 days or even later; 60–80 days is the ideal time

Figure 40.8 A 65-day female fetus: tail (T), genital tubercle (GT), hooves (H).

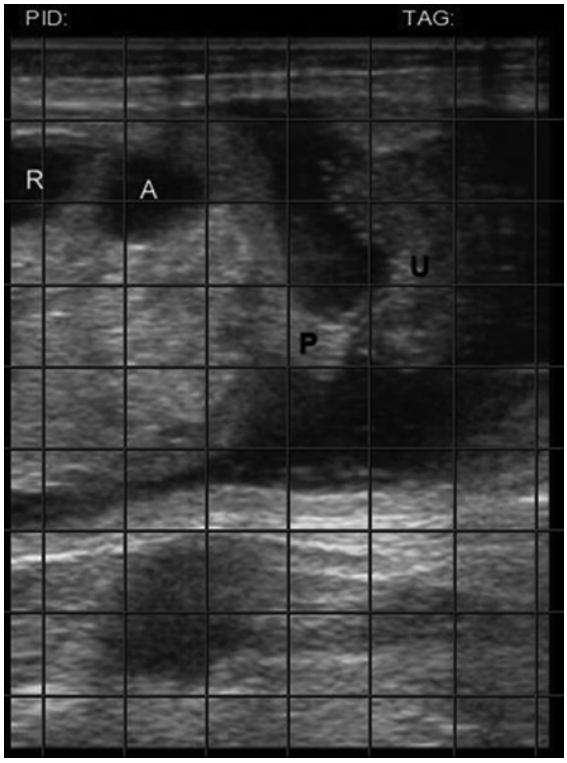

Figure 40.9 A 98-day male fetus demonstrating penis covered by prepuce: rumen (R), abomasum (A), penis (P), umbilicus (U).

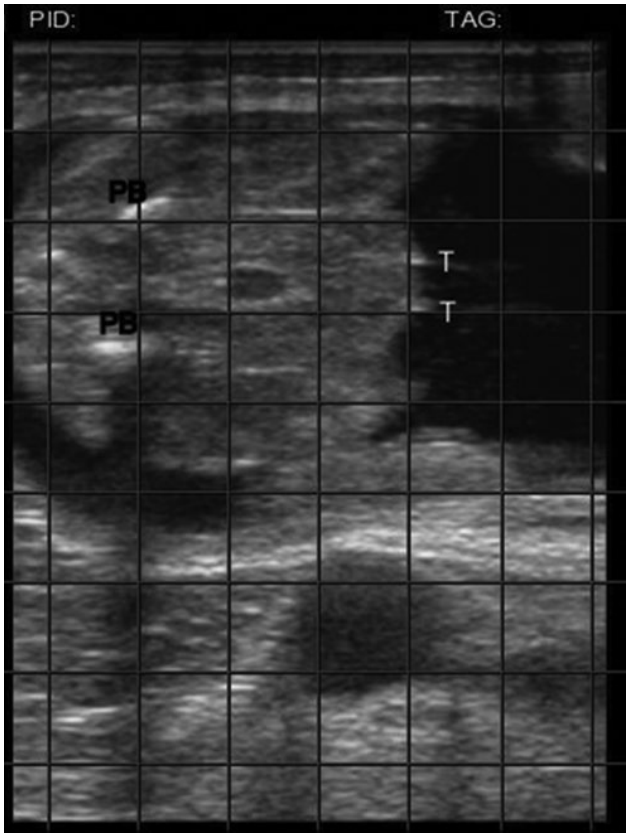

Figure 40.10 A 98-day male fetus demonstrating teats: teats (T), pelvic bones (PB).

for gender determination. At this stage the fetus is easily reached, small enough to orient the location of structures, and the GT is not obscured by skin.

Knowledge of fetal anatomic landmarks helps to locate the GT. The large tortuous umbilicus is easily identified (Figure 40.7) and the area immediately behind it can be examined for presence of a male GT. The fluid-filled anechoic rumen and abomasum (Figure 40.9) are also in the region of the male GT. The "V" shape of the ribcage permits easy identification of cranial and caudal aspects of the fetus. The head is easily identified by its echogenic bony structure.

The most common error in fetal gender diagnosis occurs because the operator does not appreciate how much the genital structures protrude from the body wall. For example, in a precise cross-sectional examination of a female fetus only the monolobed tailhead and female GT will be seen because they protrude away from other pelvic and hindlimb structures. Similarly, in the case of a male in precise longitudinal plane, only the male genital structure and the umbilicus will be seen. Therefore it is important not to stop short when scanning the fetus for gender determination.

It is also easy to move too quickly when scanning for fetal gender. There is no gap between the umbilicus and male GT

by 60 days of gestation. Likewise, there is very little space between the female GT and tailhead by that stage. Very slow, small movements are critical to avoid passing through these structures before the eye can appreciate them.

Other errors occur when another structure or artifact is mistaken for the GT. Legs sometimes occlude the umbilical area and the bones in cross-section can resemble the GT. Specular reflections in the umbilical cord can be mistaken for a male GT. Figure 40.11 shows the female GT to the right of the image, along with two less-distinct bright lines in the abdominal region where the male GT would be found. These lines are a specular reflection artifact between the fluid vessels and the walls of the umbilicus (see section "Artifacts" for further explanation). A cross-section of the tail can be mistaken for a female GT. When in doubt it is wise to examine both the umbilical region and the perineal region to confirm gender.

Finally, one must develop a quick eye to accurately identify landmarks and the GT. Because the cow and the fetus are moving it is usually not possible to isolate the structures for prolonged viewing. Training videos such as Brad Stroud's *Bovine Fetal Sexing Unedited* are valuable for training the eye to detect fetal gender quickly and accurately [30].

Normal Uterine and Ovarian Structures Throughout the Estrous Cycle

Proestrus

In proestrus the uterus becomes more heterogeneous as blood flow increases [31]. Anechoic mucus begins to accumulate in the lumen about three days before ovulation. One, or sometimes more, large (16–20 mm) follicles will be present. The CL is usually still visible but is becoming smaller and more heterogeneous.

Estrus
