Chapter 34

Circadian Rhythms

Vincent M. Cassone
Department of Biology, University of Kentucky, Lexington, KY, USA

Vinod Kumar
Department of Zoology, University of Delhi, Delhi, India

Biological circadian rhythms and the clocks that control them are fundamental properties of all freely living organisms studied in any detail. These are expressed by organisms ranging from cyanobacteria to humans with highly conserved formal properties. Among animals, the molecular details of biological clocks are highly conserved as well. The conserved nature of these rhythms and clocks likely derive from the fact that they are all adaptations to a single selective pressure—the daily change from night to day and the abiotic and biotic rhythms that accompany it. Biological clock function is particularly apparent in birds, partly due to the fact that they share with us a primarily diurnal lifestyle, but also because time of day and time of year pervades all aspects of avian physiology.

34.1 ENVIRONMENTAL CYCLES

34.1.1 Light Cycles

Although we all know that the cycle of day to night derives from the rotation of the Earth on its axis approximately every 24 h, we experience this process through the apparent rise of the sun on the eastern horizon (dawn), its traverse across the sky, its setting in the west (dusk), and subsequent night. The most salient feature of the *solar day* is the dramatic change in visible and invisible light intensity, polarization, and wavelength spectra. Daylight intensity can be measured in a variety of radiometric and photometric ways, extending beyond the scope of this chapter. One can gather the scale of daily change in lux (lx), the International System of Units (SI) measure of illuminance, or the intensity of white light as perceived by the human eye. These values range from 120,000 lx in the brightest sunlight to 400 lx at dusk or dawn on a clear day to 0.0001 lx under overcast, moonless night sky. This vast range in intensity may go unperceived consciously, because our and birds' visual systems adapt to changes in intensity. However, as discussed in this chapter, changes in absolute intensity and timing of illumination are detected and processed by the circadian clock. In addition to intensity, the wavelength of ambient light changes due to diffraction of shorter wavelengths at dawn and dusk, resulting in the perception of reddish hues at sunrise and sunset.

34.1.2 Temperature

Due to the daily changes in solar illumination, the atmosphere and surface of the Earth undergo daily changes in temperature that generally rise as the day progresses but vary dramatically due to latitude, season, and local conditions such as urban growth, proximity to bodies of water, desertification, and variations in land use (Geerts, 2002). The daily temperature range (DTR) is highly variable at different latitudes. For example, at the equator, the DTR is 8 °C in the summer and 9 °C in the winter. In contrast, at 40° latitude in North America, the DTR in summer is 18 °C in the summer and only 10 °C in the winter. Proximity of oceans also ameliorates daily temperature ranges. For example, in July in Australia, the DTR increases from 6 °C on the coast to 17 °C 150 km inland. These changes are clearly important for natural ecosystems as well as agricultural activity—perhaps being as important as the mean temperature itself. There is increasing evidence that, in addition to the gradual increase in mean global temperatures, the daily temperature ranges have changed as well, decreasing the daily range 0.4 °C from 1950 to 1993.

34.1.3 Other Physical Cycles

Other physical characteristics vary over the day as a derivative of the diurnal solar cycle. These include daily changes

Sturkie's Avian Physiology.

in barometric pressure, characteristics of the magnetic field, and, in many locations, precipitation. Pressure variations derive from the thermal energy arising from the heating of the upper atmosphere that moves in a westward wave the speed of the Earth's rotation (Hardy et al., 1998). These variations depend upon latitude, altitude, and season. Aspects of the Earth's magnetic field also vary in intensity and inclination depending on the time of day, as the solar wind emanating from the sun interacts with the magnetosphere on a regular 24 h cycle.

34.1.4 Rhythms in the Biotic Environment

Because daily cycles in many aspects of the physical, abiotic environment are so pervasive, it should not be surprising that nearly all free-living organisms have evolved adaptations to the changing environment. Thus, in addition to daily changes in abiotic factors, birds' biotic environment is also changing on a daily basis. The presence of food, competitors, predators, parasites and potential mates may be present at one time of day and absent another (Bradshaw and Holzapfel, 2010). Hence, birds, like nearly all organisms on Earth, have evolved an internal biological clock that synchronizes patterns of many aspects of behavior, physiology, biochemistry and molecular biology to external time (Pittendrigh, 1993) and coordinate internal processes to temporally maximize efficient processes within (Navara and Nelson, 2007).

34.2 CIRCADIAN RHYTHMS

34.2.1 Formal Properties

The internal biological clock shares fundamental formal properties among most living organisms through the expression of endogenously generated circadian (*circa* = approximately; *dian* = a day) oscillations that entrain to local time through the process of entrainment. Rhythmic processes cannot be identified as circadian unless they are experimentally observed to persist when the organism in question is placed in constant environmental conditions of either constant darkness (DD) or constant dim light (dimLL). (Constant high light (LL) may have other effects, frequently abolishing circadian rhythms altogether and/or damaging photoreceptive elements in the system (Aschoff, 1979).) In this scenario, organisms will repeatedly express patterns of behavior, physiology, or biochemical processes with a period, τ, of close to but rarely exactly 24 h (Figure 34.1). These endogenously driven rhythms must then be entrained to the relevant environmental cycle, typically the light:dark cycle (LD) of day and night, such that the internal phase, φ_i, of the organism's clock corresponds appropriately to the external phase, φ_e, of the LD cycle. Thus, a diurnal bird's locomotor activity pattern entrains to the LD cycle so that activity onset φ_i corresponds approximately to dawn φ_e, maintaining a stable phase relationship, ψ_{ie}. Conversely, a nocturnal bird's ψ_{ie} would be approximately 12 h later than that of a diurnal bird.

34.2.2 Stability and Lability of Circadian Rhythms

In DD, the circadian τ of diurnal birds is generally longer than 24 h, while τ in owls and nightjars tends to be shorter than 24 h (Aschoff, 1979). However, there is quite a bit of inter- and intraspecific variability in τ and even consistent changes within an individual. For example, many house sparrows, *Passer domesticus*, will express a τ of less than 24 h upon transfer from an LD cycle to DD (see Figure 34.1). However, birds' τ gradually lengthens over several days to weeks, depending on the individual, eventually stabilizing with a τ of approximately 25 h. This is a phenomenon known as Eskin's knee, because the actogram, described by Dr. Arnold Eskin in late 1970s (Menaker et al., 1978), appears bent as a knee. Once stabilized, the τ remains stable until environmental factors change.

The major environmental factor affecting τ in birds is ambient light. If diurnal birds are experimentally maintained in dimLL rather than DD, birds' τ will shorten, and as illuminance is increased, τ decreases until at constant illuminances of approximately 50–100 lx, circadian patterns of locomotor activity are lost (Aschoff, 1979); birds are arrhythmic. Nocturnal birds such as owls and nightjars are more highly variable than are diurnal birds. On average, however, their τs lengthen (increase) with increasing illuminance. Other environmental factors have not been studied in as much detail as has light, although birds' circadian patterns appear to be relatively insensitive to altered constant temperatures, as circadian patterns in all organisms tend to be temperature compensated with a Q_{10} of 0.8–1.1 (Pittendrigh, 1993).

34.2.3 Entrainment

A biological clock with a τ that is different from 24 h would not be a particularly useful clock if it could not confer a sense of internal time relative to external, sidereal time, or the time it takes the Earth to rotate relative to the vernal equinox, the solar day. Thus, organisms sense environmental cues called Zeitgebers (German for "time givers"), interpret them, and then adjust their internal time to external time through the process of entrainment. The formal properties of entrainment vary, depending on the Zeitgeber and on the process being measured.

Photic entrainment. The major Zeitgeber for nearly all organisms is the daily change in light intensity, and light affects circadian rhythms in birds profoundly. Photic entrainment in birds is of two types: parametric entrainment

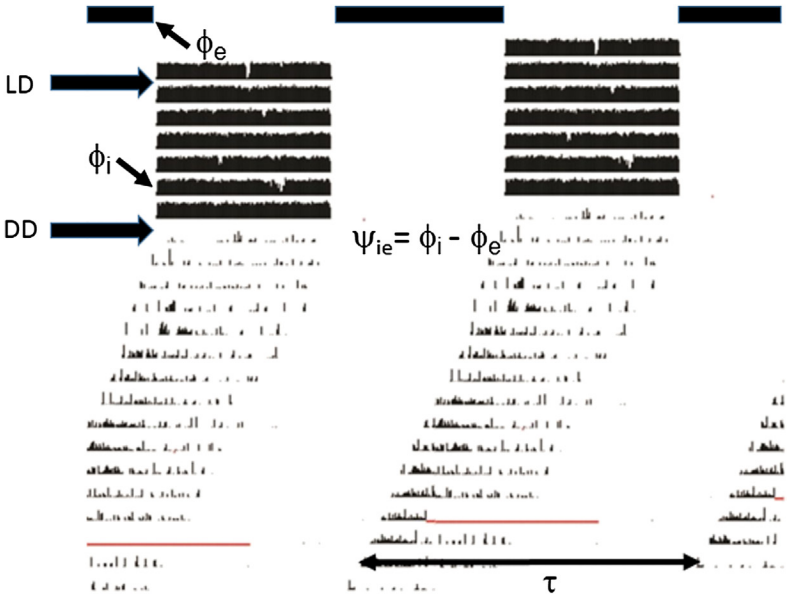

FIGURE 34.1 Actogram of locomotor activity from a single zebra finch, *Taeniopygia guttata*. The top bars indicate the times during which lights are off (black) versus on (white). These are plotted in a 48 h timespan in order to "double-plot" the data. The time off lights on, φ_e, indicated by the arrow, is a phase reference determined by the investigator. The internal phase, φ_i, is determined to be the activity onset. The relationship between φ_i and φ_e is called ψ_{ie}. This relationship may change depending on the time of year and physiological condition of the bird. The internal period, τ, is indicated here as the average interval between activity onsets.

and nonparametric entrainment. Nonparametric entrainment entails the process by which the internal clock is differentially sensitive to the Zeitgeber depending on the time of day rather than the amount (the parameter) of the Zeitgeber present (Aschoff and Pohl, 1978). This process is similar to other organisms in that their circadian system is relatively insensitive to light during the subjective day. If a house sparrow is free-running in DD and she is illuminated for 15–30 min during her subjectively diurnal activity (subjective day), no or little effect on her φ_i will occur. However, if she is illuminated in the beginning of her subjective night, when she is inactive, light will change her φ_i ($\Delta\varphi$) by delaying her activity onset ($-\Delta\varphi$). If she is illuminated during the late subjective night, her subsequent activity onset will be advanced ($+\Delta\varphi$). Through this process, birds' φ_i is maintained in a stable phase relationship (ψ_{ie}) with external time (φ_e). In diurnal birds, however, because they are active during times of great illumination, parametric entrainment can also contribute to the maintenance of an advantageous ψ_{ie}. Because diurnal birds tend to express a τ greater than 24 h and illumination shortens τ, illumination of increasing intensity (a parameter) during the day under natural conditions decreases the amplitude of $\Delta\varphi$ required to maintain a stable ψ_{ie}. This is an underappreciated process that may even be relevant to human circadian organization (Roenneberg et al., 2010).

Nonphotic entrainment. Several nonphotic factors entrain birds' circadian clocks. Homoeothermic animals, such as the vast majority of birds, do not synchronize to daily patterns of ambient temperature, although tissue cultures from avian tissues entrain to cycles of high and low temperature (Barrett and Takahashi, 1995; Csernus et al., 2005). Further, ambient temperature can affect the rate by which birds entrain to novel light cycles (Rensing and Ruoff, 2002).

The presentation of food at a particular time of day can synchronize locomotor rhythms in many species of birds, and the data have suggested that birds, as in mammals, possess both light-entrainable oscillators and experimentally separable food-entrainable oscillators underlying food-seeking behavior. House sparrows maintained in dimLL entrain both locomotor and feeding patterns to the period of the feeding cycle, such that locomotor behavior occurs prior to the time of day at which food is presented (Hau and Gwinner, 1992). In domestic pigeons, *Columba livia*, presentation of food every 23.5 h to birds on a 24 h LD cycle results in an uncoupling of food-associated anticipatory changes in body temperature (Tb) and O_2 consumption with activity associated with LD (Rashotte and Stephan, 1996). Similarly, for Svalbard ptarmigan, *Lagopus mutus hyperboreus*, and Indian weaver birds, *Ploceus phillipinus*, food entrainment is coupled to birds' entrainment to the light cycle, suggesting in both species the food-entrainable oscillator is coupled to the light-entrainable pacemaker (Reierth and Stokkan, 1998; Rani et al., 2009).

There is a very little evidence for social cues influencing circadian patterns in birds. Daily presentation of taped sounds recorded from an aviary entrains circadian

locomotor rhythms of house sparrows maintained in dimLL (Menaker and Eskin, 1966). These data suggest that birdsong and/or calls may influence the circadian clock.

34.3 PHOTORECEPTORS

Because light is the major Zeitgeber involved in circadian entrainment to LD and an environmental factor that strongly influences τ under constant environmental conditions, the pathways by which light influences clocks provide profound clues to the mechanisms underlying biological clocks. Intuitively, we might think that these photoreceptive processes are the exclusive domain of retinal photoreceptors, but this would be the furthest from the truth. Although the retinae participate in photic entrainment and/or parametric responses to light, they are minor participants.

34.3.1 Encephalic Photoreceptors

In addition to photoreceptors in the lateral eyes shared by all vertebrate classes, it has been known for some time that nonmammalian vertebrates express functional photopigments within the brain that are critical for entrainment of both circadian rhythms and circannual cycles (Okano and Fukada, 2000). Early studies by Benoit in the 1930s showed that domestic ducks, *Anas platyrhynchos*, that had been blinded (enucleated) continued to exhibit reproductive responses to changing photoperiod (Benoit and Assenmacher, 1954). Work by Menaker and colleagues in the 1960s and 1970s in passerine birds clearly showed that the eyes are not necessary for circadian entrainment (Menaker, 1968; Menaker and Underwood, 1976). In a classic series of experiments, Menaker's group demonstrated that enucleated house sparrows could entrain to a series of LD cycles of dimmer and dimmer illuminances. Once birds were no longer capable of entrainment, they showed that the responsible photoreceptor resided inside the head by simply plucking feathers, and entrainment was reinstated. They then blocked entrainment by injecting India ink beneath the scalp (Menaker and Underwood, 1976).

Subsequent research has now identified at least four distinct structures within the brain that are functionally photoreceptive, containing several opsin-based photopigments and photoisomerases (Nakane and Yoshimura, 2010; Peirson et al., 2009; Bailey and Cassone, 2004) (Figure 34.2). These include the pineal gland, which expresses a pineal-specific opsin, pinopsin (Bailey et al., 2003; Okano et al., 1994; Max et al., 1995), as well as melanopsin (OPN4) (Bailey and Cassone, 2005; Bailey et al., 2003; Chaurasia et al., 2005) and iodopsin (OPN1) (Masuda et al., 1994; Natesan et al., 2002) and whose photoreceptive function will be discussed further below. In addition, neurons within the preoptic area express vertebrate ancient (VA) opsin (Halford et al., 2009; Davies et al., 2010, 2012), and project to the

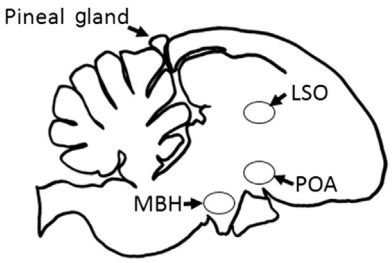

FIGURE 34.2 Schematic of a sagittal view of an avian brain. The general locations of extraocular photoreceptors are delineated in the pineal gland, the lateral septal organ (LSO), preoptic area (POA), and mediobasal hypothalamus (MBH).

tuberal hypothalamus, while the tuberal hypothalamus itself expresses a plethora of photoreceptive cells that appear to be divergent among avian species. In Japanese quail, *Coturnix coturnix*, cerebrospinal fluid-contacting neurons in the mediobasal hypothalamus (MBH) express both OPN4 and neuropsin (OPN5) (Nakane et al., 2010). In house sparrows, neurons within the arcuate nucleus express rhodopsin (OPN2) itself, in addition to OPN4 and OPN5 (Wang and Wingfield, 2011). Finally, the lateral septal organ expresses rhodopsin-like immunoreactivity (Wada et al., 1998). It is not clear whether each of these photoreceptive organs and/or their photopigments subserve mutually exclusive physiological processes or whether these overlap in their functions. In addition to opsin-based photopigments, birds express flavin-based cryptochromes (Bailey and Cassone, 2005; Chaurasia et al., 2005; Kubo et al., 2006). Although cryptochrome is the major photopigment responsible for photoentrainment in *Drosophila* (Emery et al., 1998), the multiple cryptochromes expressed by vertebrates have not been established as photoresponsive molecules.

34.3.2 Pineal Gland

The avian pineal gland emerges from the epithalamus of the diencephalon and extends to the dorsal surface of the brain, where it resides nestled between the two cerebral hemispheres and the cerebellum (Figure 34.2). There, the gland's narrow stalk extends to the skull itself, enlarges in its distal aspects, and attaches to the dura mater. There is considerable variability in pineal structure among birds (Quay, 1965; Menaker and Oksche, 1974). For example, nocturnal owls, shearwaters, and petrels exhibit only a vestigial or rudimentary pineal complex (Quay, 1965), whereas diurnal birds express well-developed pineal glands of differing overt anatomy. According to Menaker and Oksche (1974), avian pineal glands can be categorized as saccular (passerine birds), tubulofollicular (columbiform and anseriform birds), and lobular (galliform birds). At the cellular level, pineal glands comprise at least four classes of celltypes. The photoreceptor-like pinealocytes express outer segments reminiscent of retinal photoreceptors of a sensory

ciliated type with a characteristic 7:0 microtubule configuration, although these are reduced in size and frequently coiled (Oksche et al., 1972; Menaker and Oksche, 1974). These cells, as stated above, express several opsin-based photopigments as well as flavin-based cryptochromes, as well as phototransduction signaling molecules (Masuda et al., 1994; Bailey et al., 2003), clearly indicating that pinealocytes are directly photosensitive. This will be discussed further below. In addition, pineal glands contain interstitial cells that include ependymal and astrocytic neuroglia as well as leukocytes and leukoblasts (Oksche et al., 1972), as well as neurons that project to the epithalamic habenular complex (Sato and Ebisawa, 1988). Finally, the pineal gland is vascularized and contains endothelial capillary cells (Oksche et al., 1972).

34.3.3 Retina

It is axiomatic that the retinae are photoreceptive, but their role as photoreceptors in avian circadian entrainment is less clear. In mammals, which do not possess extraocular photoreceptors (Doyle and Menaker, 2007), circadian entrainment is predominantly mediated by intrinsically photoreceptive retinal ganglion cells, expressing melanopsin (OPN4; Panda, 2007). These cells project directly to circadian pacemakers in the hypothalamic suprachiasmatic nuclei (SCN). In birds, as stated above, the eyes are not necessary for circadian entrainment to LD cycles, since enucleated house sparrows and several other species entrain to LD cycles. However, that is not to say that the eyes are not involved. Multiple layers of the retinae of domestic chicks, *Gallus gallus domesticus*, express OPN4, including retinal ganglion cells (Bailey and Cassone, 2005; Chaurasia et al., 2005), similar to the situation in mammals.

Employing a retinal degenerate chick model developed by Semple-Rowland (Semple-Rowland and Cheng, 1999; Guido et al., 2010), Guido and colleagues have shown that the chicks possessing only inner retinal photoreceptors are capable of entraining feeding rhythms to an LD cycle (Valdez et al., 2009, 2013). When encephalic photoreceptors are covered with a blackened hood, the chicks expressed a free-running rhythm with a 24.5 h τ. When the birds were enucleated, hooded birds free-ran, but illumination of the skull reestablished entrainment. The picture that emerges is that multiple photoreceptors in the brain, the pineal gland and the retina redundantly contribute to photic entrainment in birds (Doyle and Menaker, 2007; Guido et al., 2010).

34.4 PACEMAKERS

As we will see below, the capacity to express circadian rhythms is widely distributed among tissues and cells in multicellular organisms (Bell-Pedersen et al., 2005). However, certain tissues have been designated "pacemakers" because of their capacity for sustained circadian rhythmicity and their importance for circadian organization. In birds, these structures are the pineal gland, the retinae, and the hypothalamic SCN, whose mutual interactions are critical for overt circadian organization.

34.4.1 Pineal Gland and Melatonin

Searching for the location of the intracranial, extraretinal photoreceptors, Gaston and Menaker (1968) surgically removed the pineal gland (PINX) from house sparrows (Figure 34.3). Although the birds retained their ability to entrain to LD, they became arrhythmic when placed in DD, demonstrating that the pineal gland is necessary for self-sustained circadian rhythmicity. However, the data also showed that the pineal gland is part of a system of circadian clock components, because PINX sparrows could anticipate the time of lights on in an LD cycle and because birds only gradually became arrhythmic over 5–15 days following transfer from LD to DD (Gaston and Menaker, 1968; Binkley et al., 1971; Ebihara and Kawamura, 1981; Lu and Cassone, 1993a; Wang et al., 2012). Further, the effect of PINX is not universal among avian species. PINX of European starlings, *Sturnus vulgaris*, results in a range of behavioral changes ranging from arrhythmicity akin to those seen in house sparrows to slight disruption of behavioral locomotor rhythmicity (Gwinner, 1978; Gwinner et al., 1987). Circadian rhythms of locomotor behavior in columbiform and galliform birds are little or not affected at all by PINX (Ebihara et al., 1984; Underwood and Siopes, 1984).

Even so, the pineal gland represents both the capacity for rhythmicity and time of day. In an elegant experiment, Zimmerman and Menaker (1979) transplanted pineal glands from two groups of house sparrows into the anterior chambers of the eye of PINX, arrhythmic sparrows maintained in DD. The first group of donor birds were entrained to an early LD cycle, with lights on at midnight, while the second set of donors were entrained to a late LD cycle, with lights on at 11 AM. Transplantation restored circadian rhythms to both groups of recipients within one day. Moreover, birds that received pineal glands from early donors exhibited an early φ_i , while the recipients of late donor pineal glands exhibited a late φ_i. Thus, the pineal gland is not only necessary for circadian rhythmicity in these birds, but it contains a correlate that confers time of day to recipient birds.

That hormone was known even then to be the indoleamine melatonin from earlier work of Lerner and later of Axelrod, Klein, and their co-workers (Klein et al., 1997), who explored the biochemical basis for melatonin biosynthesis in the pineal gland of the chick, *Gallus domesticus* (Figure 34.4). Research from a large number of investigators have shown that pinealocytes—the photoreceptive, secretory cells of the avian pineal gland—take up the amino acid tryptophan, which is converted to 5-hydroxytryptophan

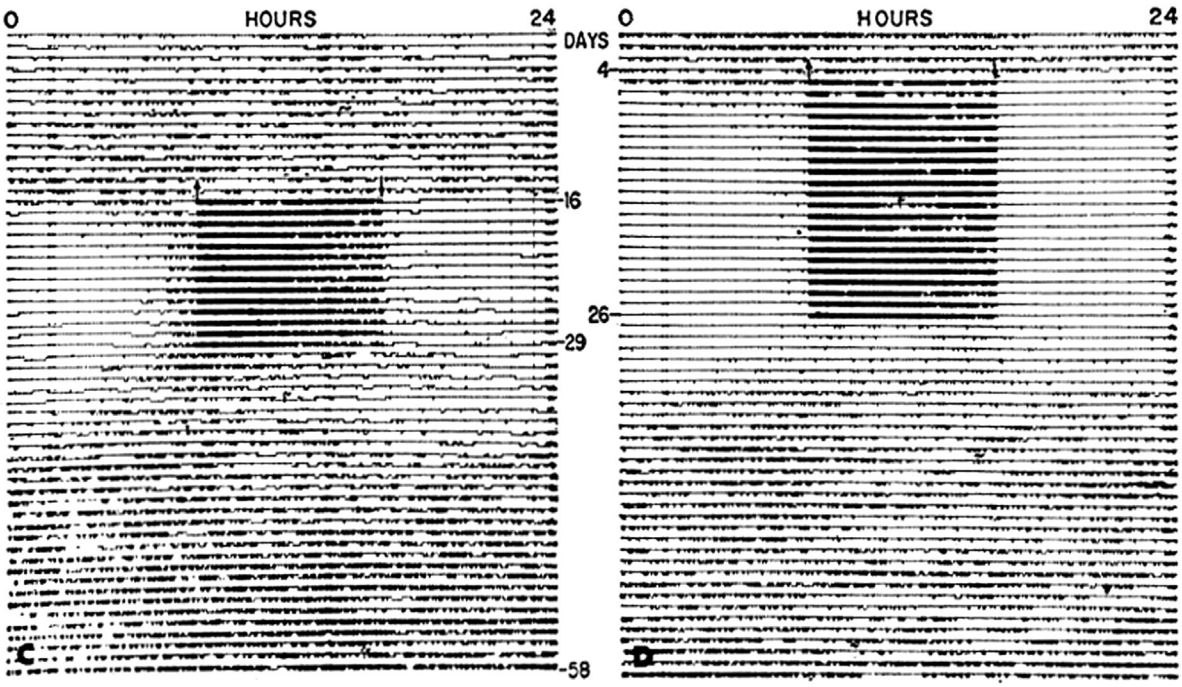

FIGURE 34.3 Effects of pinealectomy on locomotor activity rhythms in house sparrows. Birds are arrhythmic in constant darkness (DD) but are able to entrain to light:dark (LD) cycles (small arrows up and down, respectively). When birds are released into DD again, they take 5–15 days to become arrhythmic again. *From Gaston and Menaker (1968).*

by tryptophan hydroxylase (TrH; EC 1.14.16.4; Chong et al., 1998) and then decarboxylated to produce serotonin (5HT) by aromatic L-amino acid decarboxylase (AAADC; EC 4.1.1.28). During the night in LD and subjective night in DD, 5HT is converted to *N*-acetylserotonin (NAS) by arylalkylamine (or serotonin)-*N*-acetyltransferase (AANAT; EC 2.3.1.87; Bernard et al., 1997). NAS is then converted to melatonin by hydroxyindole-*O*-methyltransferase (HIOMT; EC 2.1.1.4; Bernard et al., 1991). The genes encoding each of these enzymes have been isolated, cloned, and sequenced in several avian species. In chicks, at least, TrH, AANAT, and HIOMT are regulated by both the molecular clockworks within the pinealocytes and directly by light at the transcriptional, translational, and posttranslational levels, so that the enzymatic regulation of pineal melatonin is a dynamic, rhythmic process (Klein et al., 1997).

Rhythmic administration of melatonin to PINX house sparrows, European starlings, and zebra finches, *Taeniopygia guttata*, or to EX/PINX pigeons (Chabot and Menaker, 1992; Lu and Cassone, 1993b; Gwinner et al., 1997; Heigl and Gwinner, 1995; Cassone et al., 1992, 2008; Wang et al., 2012) restores a daily pattern of locomotor behavior (Figure 34.5). Activity typically decreases following melatonin administration and rebounds following the daily dosage, suggesting that melatonin induces a soporific state and/or sleep, which it may well do. In addition, however, the synchronization of locomotor behavior by rhythmic melatonin administration represents entrainment of circadian clockworks in the PINX bird because melatonin administration in a T-cycle different from 24 h results in systematic changes in the phase relationship (ψ) of melatonin to the onset of locomotor activity (Figure 34.5; Chabot and Menaker, 1992; Gwinner et al., 1997). Further, administration of three different behaviors—locomotor behavior, call, and song—by a single melatonin regime results in entrainment at differential rates (Wang et al., 2012).

Further, constant administration of melatonin has profound effects on overt rhythmicity (Gwinner and Brandstatter, 2001). Subcutaneous implants of beeswax (Turek et al., 1976) or Silastic (Hau and Gwinner, 1995; Abraham et al., 2000) containing crystalline melatonin change τ at low concentrations and abolishes rhythmicity altogether at higher dosages. Interestingly, constant melatonin decreases the times taken to reentrain to food cycle (Hau and Gwinner, 1995) or LD cycle (Abraham et al., 2000). This is similar to the effect of PINX itself (Kumar and Gwinner, 2005), punctuating the view that it is the rhythm of endogenous melatonin that preeminently affects circadian organization and that this effect acts through the entrainment of downstream oscillators (Cassone and Westneat, 2012).

Avian pineal glands contain the circadian clockworks and photoreceptors to generate circadian patterns of melatonin biosynthesis *in vitro* as well as *in vivo*, which can be entrained to LD cycles directly (Binkley et al., 1978; Brandstatter et al., 2000; Natesan et al., 2002). Pineal tissue and pinealocyte cultures express circadian patterns of AANAT activity (Binkley et al., 1977; Deguchi, 1979),

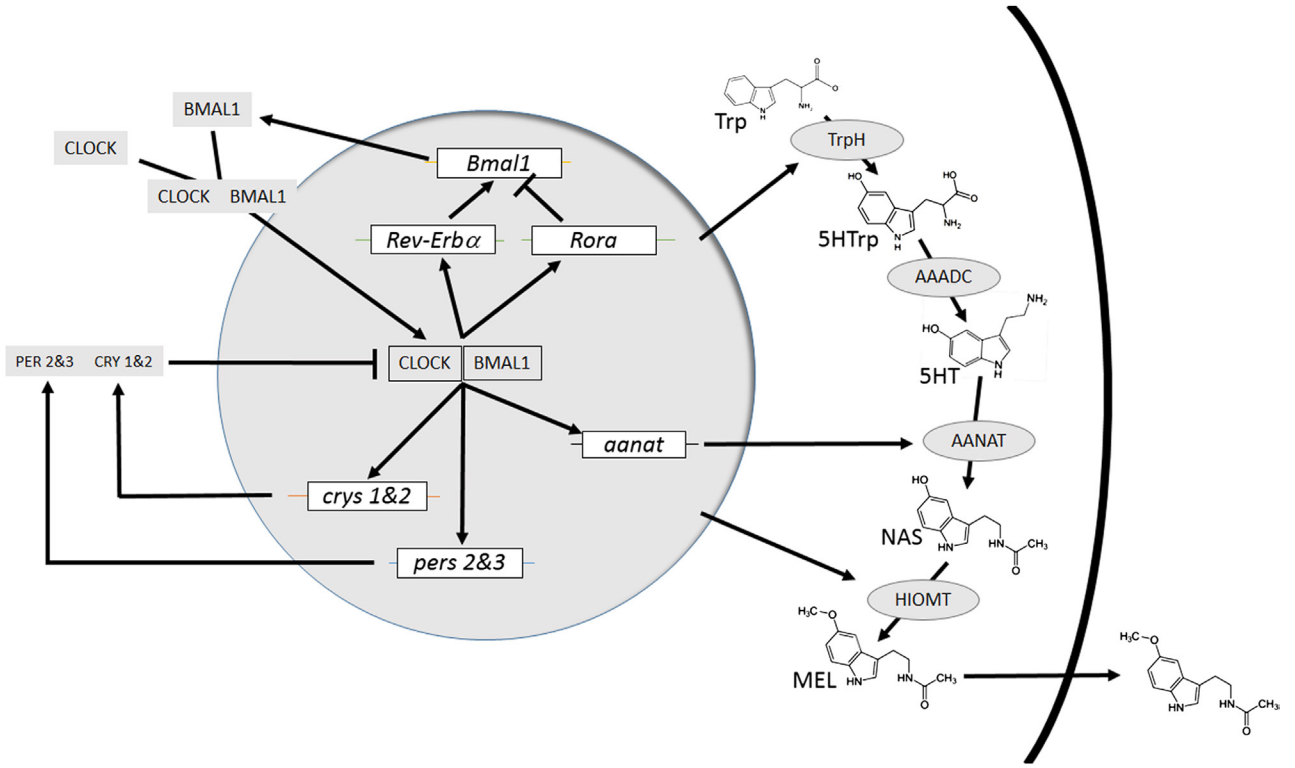

FIGURE 34.4 Schematic of the molecular clockworks regulating circadian patterns of melatonin biosynthesis in a pinealocytes or retinal photoreceptor. Positive elements CLOCK and BMAL1 enter the nucleus and activate expression of genes whose promoters contain an E-Box. Among these are the negative elements *periods 2* and *3* (*per2* and *per3*) and *cryptochromes 1* and *2* (*crys1* and *crys2*), *Rev-Erbα* and *Rora*, which form a secondary loop regulating *Bmal1* transcription, and output, clock-controlled genes such as arylalkylamine-*N*-actyltransferase (*aanat*). The *pers* and *crys* are translated, form heterodimers with other components, such as the casein kinases, and reenter the nucleus to interfere with CLOCK/BMAL1 activation. Melatonin biosynthesis pathways are indicated on the right. Amino acid tryptophan is converted to 5-hydroxytryptophan (Trp) by tryptophan hydroxylase (TrpH). Aromatic amino acid decarboxylase (AAADC) then converts 5-hydroxytryptophan (5HTrp) to 5-hydroxytryptamine (5HT; serotonin). Then, during the night, AANAT converts 5HT to *N*-acetylserotonin (NAS), a substrate for hydroxyindole-*O*-methyltransferase (HIOMT), which produces melatonin (MEL) itself. Presumably, melatonin diffuses out of the cell at this time, although a release mechanism may exist.

gene expression (Karaganis et al., 2008), and melatonin efflux (Figure 34.6; Takahashi et al., 1980), such that levels are high during the night and low during the day in LD. These rhythms persist for 4–10 days in DD before damping to arrhythmicity. Exposure to light has three effects on cultured pineal rhythms: light inhibits melatonin biosynthesis, light increases amplitude and decreases damping, and light phase-shifts the clock within pineal cells (Zatz et al., 1988).

34.4.2 Retinae

Interestingly, the photoreceptors in the retinae of the lateral eyes also synthesize and release melatonin in many vertebrate species (Underwood et al., 1984). In fact, in Japanese quail and domestic pigeon, *C. livia*, the retinae release almost as much melatonin into the systemic circulation as does the pineal gland and removal of this source by enucleation or retinectomy in addition to PINX results in arrhythmic circadian locomotor behavior, similar to the effects of PINX alone in passerine birds (Ebihara et al., 1984, 1997; Underwood and Siopes, 1984). Thus, the variability of the effects of PINX among birds may in part be due to this retinal component in some species, and that it is not the pineal per se but rhythmic melatonin that is important for circadian locomotor behavior.

34.4.3 Suprachiasmatic Nuclei

In birds, two sets of structures have been associated with SCN function: the medial suprachiasmatic nuclei (mSCN) and the visual suprachiasmatic nuclei (vSCN) (Cassone and Moore, 1987; Cantwell and Cassone, 2006a,b). These structures are connected via neuronal projections and are contiguous in terms of their cellular populations, especially in the distribution of astrocytes. The vSCN, but not the mSCN, expresses metabolic rhythmicity and electrical activity such that levels are high during the day and low during the night (Cassone, 1988; Lu and Cassone, 1993a,b; Juss et al., 1994; Cantwell and Cassone, 2002). Further, the vSCN, but not the mSCN, receives retinohypothalamic (RHT) input (Cassone and Moore, 1987; Cassone, 1988; Cantwell and Cassone, 2002, 2006a,b), and the vSCN, but not the mSCN, contains melatonin receptor binding (Rivkees et al., 1989;

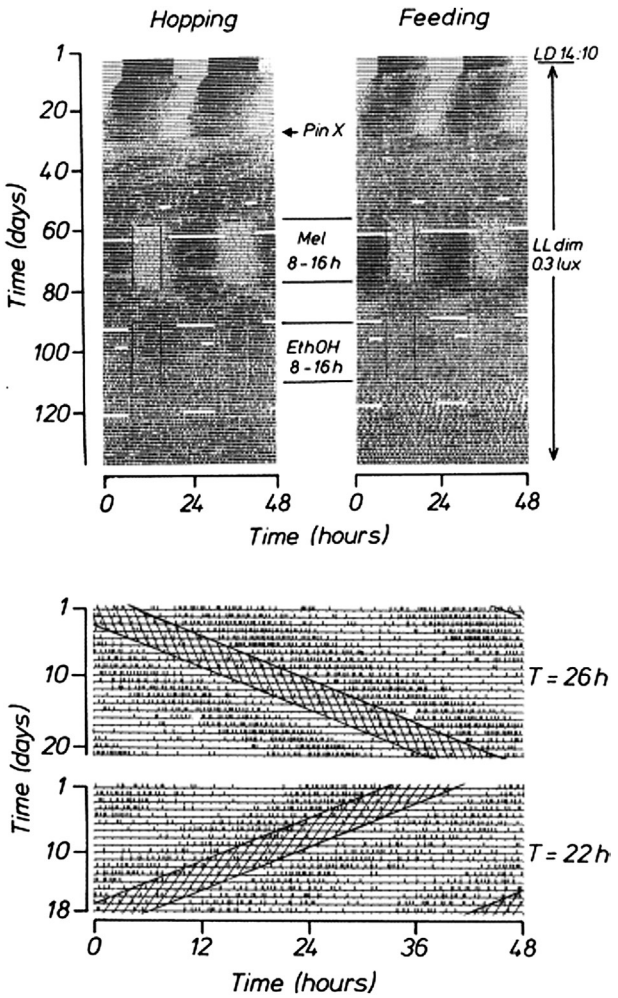

FIGURE 34.5 Effects of rhythmic administration of melatonin to house sparrows. Top: Actograms of perch-hopping and feeding behavior of house sparrows maintained in DD. Birds become arrhythmic in both behaviors following pinealectomy (PINX) and daily rhythms of behavior are reestablished with melatonin administration. Bottom: This synchronization is entrainment rather masking because locomotor activity maintains a systematic phase relationship with the administration of the hormone. When melatonin is presented every 26 h, activity occurs after the administration, whereas a melatonin cycle every 22 h results in behavior that anticipates the melatonin. *From Gwinner et al. (1997).*

Cassone et al., 1995). Administration of melatonin to chicks and house sparrows decreases glucose utilization within the vSCN (Lu and Cassone, 1993b; Cantwell and Cassone, 2002). Finally, light activates *c*-fos expression in the vSCN, but not in the mSCN (King and Follett, 1997). In quail, only the mSCN expresses clock gene rhythmicity (Yoshimura et al., 2001; Yasuo et al., 2002), while in the house sparrow, both structures rhythmically express the expression of the "clock gene" *per2* (Abraham et al., 2002, 2003). Importantly, lesions directed at the mSCN in Java sparrows, *Padda oryzivora*, and house sparrows result in arrhythmicity similar to that observed following PINX (Ebihara and Kawamura, 1981; Takahashi and Menaker, 1982). However, it is not clear whether these lesions also affected vSCN integrity.

34.5 SITES OF MELATONIN ACTION

34.5.1 Melatonin Receptors

In the 1980s and 1990s, high affinity melatonin receptor binding using the radiolabeled agonist 2[^{125}I]-iodomelatonin (IMEL) revealed high densities of IMEL binding in retinal, retinorecipient structures and visual integrative structures in the avian brain as well as peripheral tissues (Figure 34.7; Dubocovich and Takahashi, 1987; Rivkees et al., 1989; Cassone et al., 1995). Binding affinity studies indicated kDs in the pM range with high specificity for melatonin itself. Brain structures that bind IMEL included retinorecipient structures in the SCN of the circadian system, the ventrolateral and dorsal geniculate nuclei of the thalamofugal visual pathway, the optic tectum of the tectofugal pathway, and the nucleus of the basal optic root (nBOR) or the accessory optic pathway. In all species, integrative structures of the tectofugal pathway such as nucleus rotundus (Rt) and the ectopallium (Ep) also bind IMEL (Rivkees et al., 1989; Cassone et al., 1995). In some but not all species, hyperpallial structures, including the visual Wulst, are sites of IMEL binding. In male passerine birds but not females, structures associated with bird song learning and control also revealed high affinity IMEL binding (Gahr and Kosar, 1996; Whitfield-Rucker and Cassone, 1996).

Reppert and colleagues were able to isolate and clone genes encoding two high affinity melatonin receptors; these were designated the Mel_{1A} and Mel_{1C} receptors (Reppert et al., 1995). Independent work isolated partial sequences encoding an ortholog of the Mel_{1B} receptor in the same year (Liu et al., 1995). Subsequent work has confirmed in birds that there are at least three melatonin receptors, the Mel_{1A}, Mel_{1B}, and the Mel_{1C} receptors (Reppert, 1997). All three melatonin receptor subtypes represent 7-transmembrane domain, GTP-binding protein structures, and all three are in the G_i GTP-binding protein category, although some cross-talk with G_q has been documented (Reppert, 1997). The distributions of these three receptor subtypes are not uniform in chicks, zebra finches, and house sparrows. The Mel_{1A} receptor predominates in central nervous neurons and peripheral tissues (Natesan and Cassone, 2002; Karaganis et al., 2009), whereas the Mel_{1B} receptor is expressed in inner retinal neurons and photoreceptors as well as other central nervous neurons (Natesan and Cassone, 2002). In passerines, the Mel_{1B} receptor is the major receptor subtype in song control nuclei, but the other two are expressed as well (Jansen et al., 2005; Bentley et al., 2012). The Mel_{1C} receptor, on the other hand, predominates in nonneuronal elements of the central nervous system (Reppert et al., 1995; Adachi et al., 2002). Culture studies with chick astrocytes (Adachi et al., 2002) show 95–100% diencephalic astrocytes express the Mel_{1C} receptor, while an overlapping 5–10% expresses Mel_{1A}. Astrocytes do not appear to express Mel_{1B}.

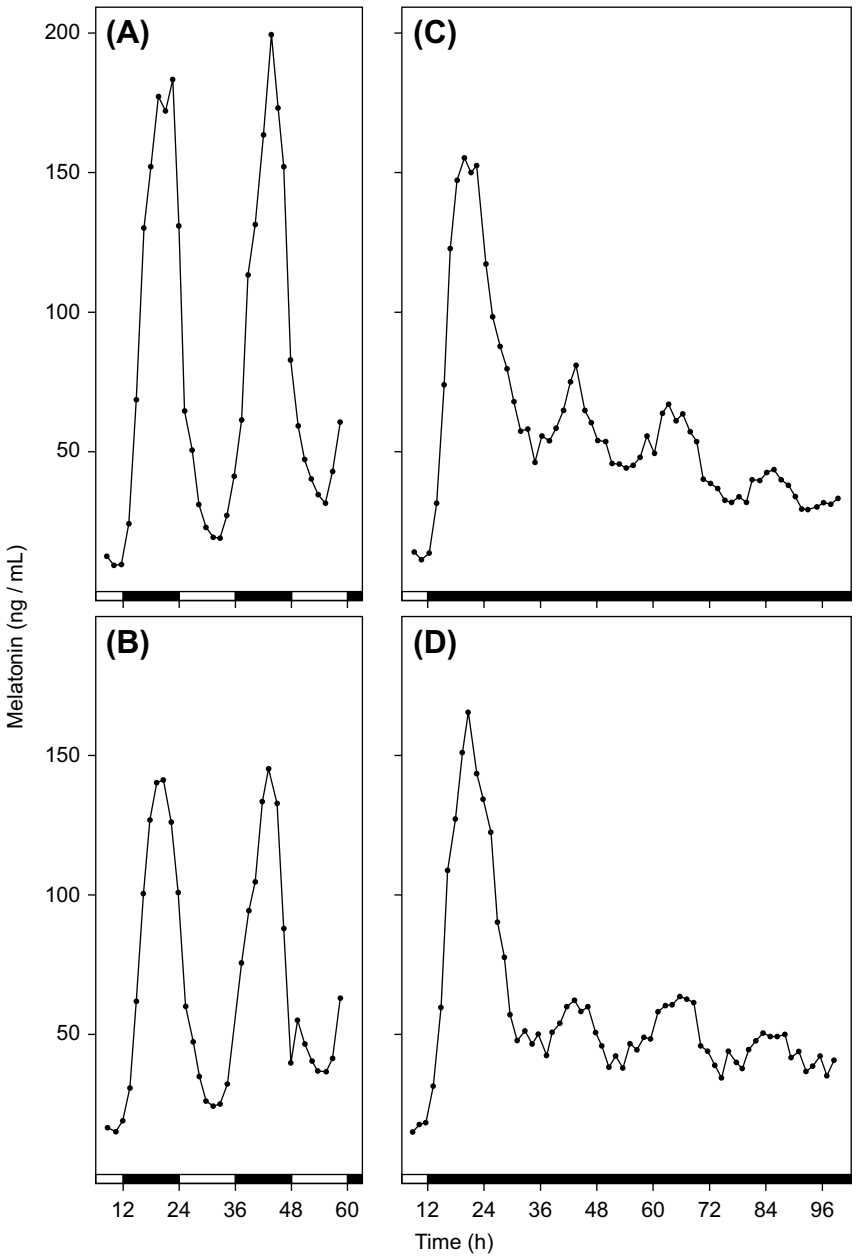

FIGURE 34.6 Melatonin rhythms from cultured chick pineal glands. Melatonin is released during the dark phase in glands maintained in LD *in vitro* (left). These rhythms continue in DD for several days at a lower amplitude but eventually damp out. *From Takahashi et al. (1980).*

34.5.2 Mechanisms of Action

As 7-transmembrane domain receptor proteins in the G_i GTP-binding protein group (Reppert, 1997), the melatonin receptors collectively act via inhibition of adenylyl cyclase activity in cells that express the receptors. There is some evidence for downstream cross-talk with other signaling pathways, however. For example, calcium signaling among chick astrocytes is mediated by a Mel_{1C} melatonin receptor through IP3-depending processes (Peters et al., 2005). In addition, there is evidence that melatonin may act via a receptor-independent and/or by receptor molecules as yet undiscovered. However, these have not been described in birds.

34.6 AVIAN CIRCADIAN ORGANIZATION

Overt circadian rhythms in birds are controlled by multiple circadian pacemakers that are entrained by multiple photoreceptive elements in the central nervous system. The relative importance of these pacemakers varies among the few species studied, but in each, the core of the circadian system can be identified as the pineal gland, the retinae, and the SCN (mSCN and vSCN). Early analyses of the interactions of circadian pacemakers and photoreceptors suggested a hierarchical relationship in which the pineal gland imposes and/or entrains rhythmicity and phase on downstream processes or oscillators respectively. The discovery of SCN and

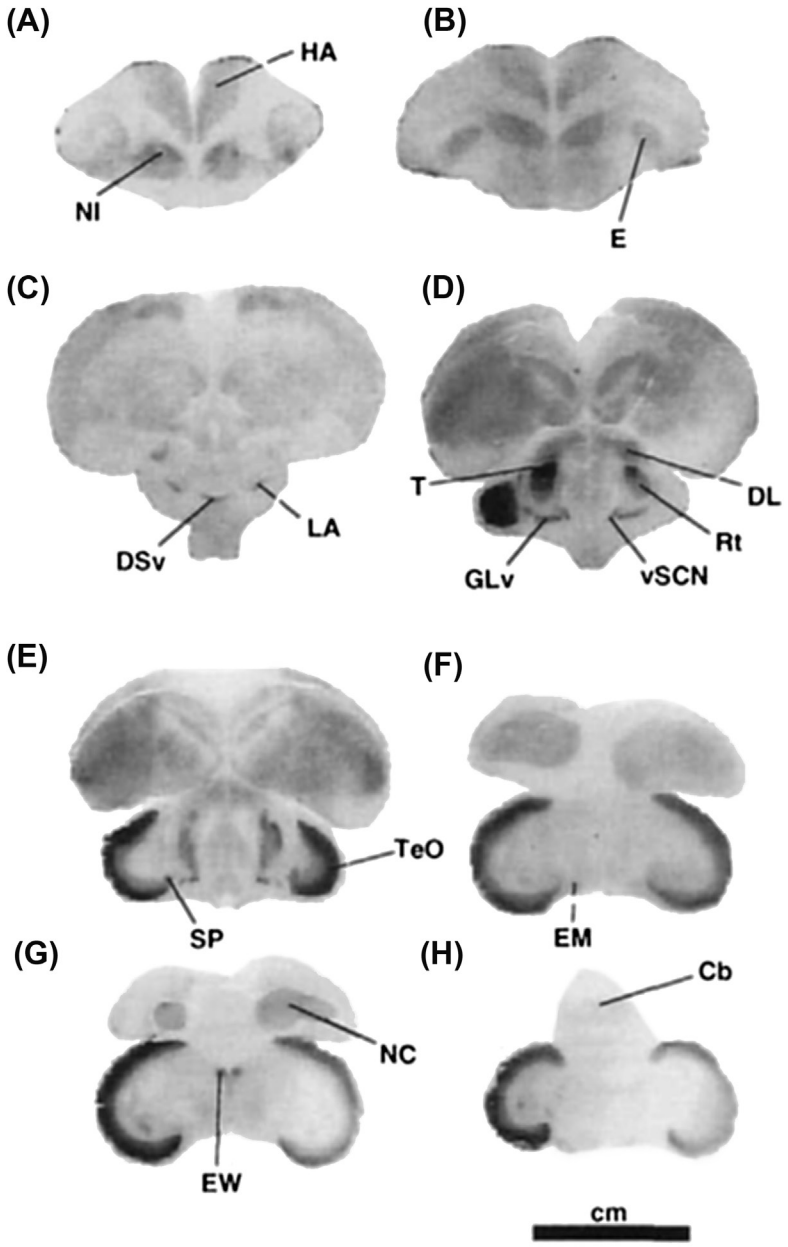

FIGURE 34.7 Melatonin receptor binding in the brain of the ring-necked pheasant, *Phasianus colchicus*. Video digitized images of autoradiographs depicting 2[^{125}I]iodomelatonin binding (IMEL) at 50 pM from the rostral (A) to caudal (H) extents. Densest binding is present in retinorecipient and integrative structures of the circadian (vSCN), tectofugal (optic tectum (TeO), *nucleus rotundus* (Rt), and ectopallium (E)), thalamofugal (lateral anterior nucleus (LA) and dorsolateral nucleus (DL) in the thalamus and the hyperpallium anterior (HA)), and accessory optic (ectomammillary (EM; also called nucleus of the basal optic root) and nucleus of Edinger-Westphal (EW)) visual pathways. *From Cassone et al. (1995).*

retinal pacemaker activity suggested a more complex relationship (Figure 34.8).

There is little doubt that the pineal gland and/or rhythmic melatonin secretion is important for circadian organization, but it is clear it is part of a more complex system of structures and process we shall call avian circadian organization or the avian circadian system. Although PINX indeed does abolish circadian locomotor, Tb, brain metabolism and singing behavior rhythms in oscine passeriform birds, there is compelling evidence for other pacemakers in the system delineated above. First, PINX birds entrain to LD cycles and typically commence locomotor and singing behavior before dawn (Gaston and Menaker, 1968; Menaker et al., 1978; Gwinner et al., 1994; Wang et al., 2012), indicating some capacity for time-keeping. Secondly, when PINX house sparrows, zebra finches and other fringillid passerine birds (sparrows and finches) are transferred from LD to DD or dimLL, they express 5–10 days of damped activity that

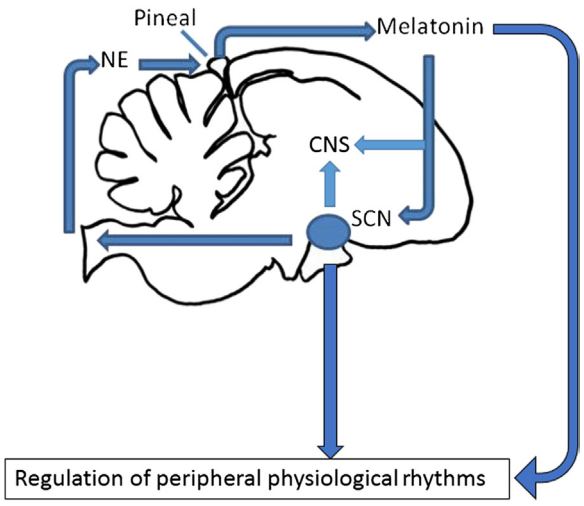

FIGURE 34.8 Neuroendocrine loop model for avian circadian organization. Pacemakers in th pineal gland and SCN interact via mutual inhibition to maintain a stable antiphase relationship. Each pacemaker can affect downstream oscillators and processes independently or in concert in the CNS and periphery. *Modified from Cassone and Westneat (2012).*

gradually descend into arrhythmicity (Figure 34.3), suggesting a remnant pacemaker underlying rhythmic behavior. Thirdly, sturnid passerines (e.g., starlings) and columbiform birds (e.g., pigeons) express a variable response to PINX, with some birds becoming arrhythmic, others disrupted, and still others unaffected (Gwinner, 1978; Ebihara et al., 1984; Gwinner et al., 1997). Finally, as stated above, timed melatonin administration differentially entrains different behaviors in zebra finches (Wang et al., 2012).

At least one of the sites of melatonin action in synchronizing circadian locomotor rhythms is the vSCN. The vSCN express melatonin receptors (Rivkees et al., 1989; Reppert et al., 1995), and melatonin affects the vSCN physiologically. When intact house sparrows are placed in DD and injected with 2DG at different times during the subjective day to map metabolic activity, the vSCN expresses a rhythm in 2DG uptake for at least 10 days in DD (Lu and Cassone, 1993a). However, when PINX birds are similarly placed in DD, 2DG uptake rhythms in the vSCN decline in amplitude and damp to arrhythmicity at the same rate as does locomotor activity (Lu and Cassone, 1993a). When PINX birds are administered melatonin on a daily basis, locomotor activity and vSCN 2DG uptake rhythms are both reestablished (Lu and Cassone, 1993b). Further, injection of melatonin during the late subjective day acutely decreases vSCN 2DG uptake (Cantwell and Cassone, 2002).

Conversely, although it is certain the avian pineal gland contains patent circadian oscillators and photoreceptors to establish overt circadian rhythms in melatonin secretion *in vivo* and *in vitro* (Binkley et al., 1977; Deguchi, 1979; Takahashi et al., 1980; Kumar and Follett, 1993; Csernus et al., 2005; Karaganis et al., 2008), these rhythms are not self-sustained *in vitro* in DD (Figure 34.6). Cultured pineal glands express rhythms of melatonin biosynthesis and secretion such that melatonin levels are high during the night and low during the day in LD, but the amplitude of this rhythm declines in DD, such that the rhythm damps to arrhythmicity in 2–8 days (Cassone and Menaker, 1984; Csernus et al., 2005).

In vivo, the avian pineal gland is innervated by postganglionic sympathetic nerves (Ueck, 1979), and receives daily and circadian input through release of norepinephrine (NE) during the day and subjective day (Cassone et al., 1986). This rhythm of NE turnover is dependent on the vSCN because surgical destruction of the vSCN, but not the mSCN, abolishes the circadian NE turnover rhythms (Cassone et al., 1990). When the pineal gland of domestic hens is denervated of its sympathetic innervation *in vivo*, plasma melatonin rhythms dampen within 4 days (Cassone and Menaker, 1983), similar to the situation of pineal glands *in vitro*. Administration of NE to chick pineal glands *in vivo* and *in vitro* has two effects on pineal melatonin rhythms: (1) NE inhibits melatonin biosynthesis, and (2) NE increases amplitude and decreases damping, but does *not* phase-shift the pineal circadian clock (Cassone and Menaker, 1983; Zatz and Mullen, 1988).

To account for these observations in house sparrows, at least, Cassone and Menaker (1984), Cassone (1990) proposed the neuroendocrine loop model for avian circadian organization (Figure 34.8). In this scenario, pineal and SCN pacemakers are damped circadian oscillators. We do not know if this damping is due to individual cells within these structures themselves damping or whether these cells are self-sustained oscillators that drift out of phase from one another. Light inhibits the output of the pineal gland oscillators through photoreceptors within the gland themselves, and light activates SCN output as well as possessing the capacity to phase-shift the clocks within each. During the night and subjective night in DD, pineal oscillators secrete melatonin and influence a wide array of downstream processes and structures. Among these are the vSCN, which are inhibited by melatonin. However, because the pineal is an endogenous oscillator, its output declines as dawn and subjective dawn in DD approach, disinhibiting SCN (vSCN and mSCN) output. The SCN in turn are active during the day and subjective day in DD, affecting a wide array of downstream processes and structures. Among these are the circadian rhythm in sympathetic outflow in NE turnover in the pineal gland at least, which are high during the day and low during the night. There, NE inhibits the biosynthesis and release of melatonin until, because the SCN are circadian oscillators, their output diminishes, and pineal oscillators are disinhibited. This mutually inhibitory relationship of SCN and pineal oscillators maintains stable phase relationships and enable each pacemaker to affect downstream processes singularly or in concert. Gwinner (1989)

suggested that the relationship between pineal and SCN oscillators conveyed an "internal resonance" in which each oscillator increased the amplitude of its partner. This idea is not mutually exclusive from the neuroendocrine loop model. Indeed, it is clear that application of NE to chick pineal glands increases the amplitude of melatonin output *in vivo* (Cassone and Menaker, 1983) and *in vitro* (Zatz and Mullen, 1988), even as it inhibits melatonin output. The pineal gland releases rebounding high levels of melatonin release following cessation of the NE administration.

Where do the retinae fit into this scheme? For columbiform and galliform species whose retinae secrete melatonin rhythmically, at least part of their role is to serve as a "second (and third) pineal gland" (Menaker, 1985), secreting melatonin during the night, presumably influencing SCN and other downstream oscillators in parallel with pineal output. In addition, inner retinal photoreceptors and circadian oscillators may directly influence circadian patterns of visual perception and activity through retinohypothalamic and other visual pathways (Guido et al., 2010). It is clear, however, that the retinae are the predominant pacemakers in galliform birds, but the nature of this function is not apparent at this stage (Steele et al., 2006).

The mechanism by which this system influences downstream processes is not at all clear at this stage. However, new and exciting data pointing to distributed capacities for rhythmicity are becoming available, and these are described below. First, however, we must explore the molecular aspects of avian circadian clocks.

34.7 MOLECULAR BIOLOGY

The idea that behavior and other complex processes derive from genes and their expression arises from early mutational analyses in search of mutants and the identification of the genes underlying the process. Among the early entrants in this study was the analysis of mutations affecting circadian rhythms in *Drosophila* (Konopka and Benzer, 1971; Rosbash et al., 2007).

34.7.1 Identification, Characterization, and Localization of Molecular Clockworks in Birds

Circadian rhythms are regulated by a highly conserved set of genes, collectively called "clock genes," whose products are believed to dynamically interact to elicit rhythmic patterns of transcription, translation, biochemical and physiological processes, and behavior (Reppert and Weaver, 2002; Bell-Pedersen et al., 2005; Rosbash et al., 2007). In animals ranging from *Drosophila* to humans, the central core of this gene network can be broadly characterized as "positive elements" *clock* and *bmal1* and "negative elements" *period 1* (*Per1*), *period 2* (*per2*), *period 3* (*per3*), and the cryptochromes *cryptochrome 1* (*cry1*) and *cryptochrome 2* (*cry2*).

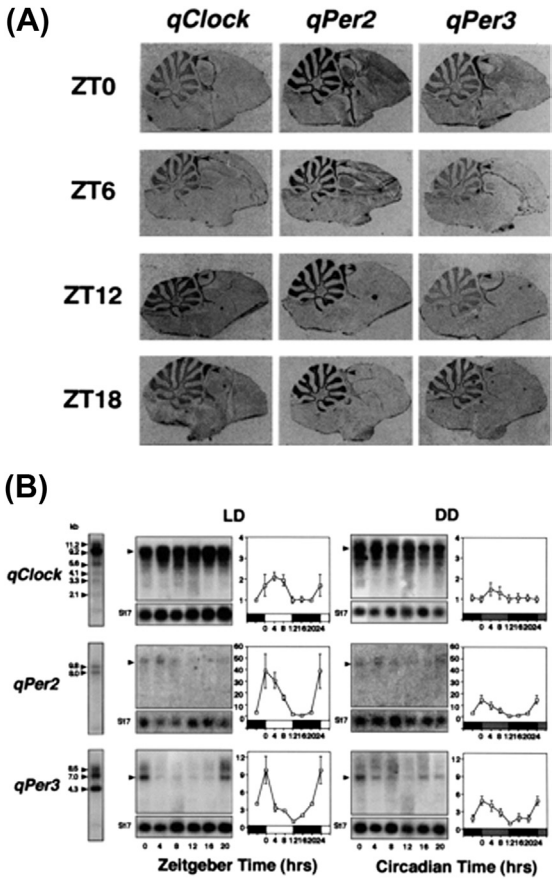

FIGURE 34.9 Circadian expression of clock genes in the (A) pineal gland by *in situ* hybridization and (B) retinae by northern blot analysis in the Japanese quail. In both tissues, *clock* is expressed during the day, whereas *per2* and *per3* are expressed in the late night. *From Yoshimura et al. (2000).*

In contrast to mammals, birds do not express *per1* and have been shown to only express only *per2* and *per3* (Figure 34.9; Yoshimura et al., 2000; Yasuo et al., 2002; Bailey et al., 2003, 2004). *Clock* and *bmal1* are transcribed and then translated in the cytoplasm, where they dimerize and reenter the nucleus and activate transcription of the negative elements through the activation of E-box promoter elements (Figure 34.4; Haque et al., 2010). The *pers* and *crys* in turn are transcribed and translated in the cytoplasm, where the PER proteins are targeted for proteosomal proteolysis by a series of protein kinases, most notably casein kinase 1ε (CK1ε) and CK1δ. This process slows the accumulation of the cytoplasmic PER and thereby increases the period of the molecular cycle. In the cytoplasm, PER and CRY proteins form oligomers that reenter the nucleus and interfere with the CLOCK/BMAL1-mediated activation. A secondary cycle involving two genes containing E-box promoters, *Reverbα* and *rorA*, amplify the cycle by activating and inhibiting *bmal1* transcription respectively. Disruption and/or knock-out of these genes' action has profound effects on the expression of circadian rhythms in animals in which

these technologies are possible (i.e., mice and *Drosophila*) ranging from changes in period to arrhythmicity.

34.7.2 Peripheral Oscillators in Avian Circadian Clocks

Although clock genes are expressed by cells within pacemaker tissues (Yoshimura et al., 2000; Yasuo et al., 2002; Bailey et al., 2002, 2003, 2004), it was surprising to find rhythmic expression of clock genes in other parts of the brain as well as in peripheral tissues, such as heart, liver, lungs, and gonads (Chong et al., 2003; Helfer et al., 2006; Karaganis et al., 2009; Zeman et al., 2009). To determine whether pacemakers in the pineal and eyes were responsible for peripheral clock gene rhythms, Karaganis et al. (2009) showed that PINX or EX of chicks decreased the amplitudes of clock gene expression and changed the φ_1 of rhythms in *cry1*, *per3*, and *bmal1* rhythms but did not abolish them. It is not clear whether combined PINX and EX would abolish these rhythms, but at this stage, one must conclude the peripheral oscillations persist and are only modulated by the pineal and retinae.

34.7.3 Prospects for Transgenesis and Molecular Manipulation of Avian Clocks

At this stage, no stably transformed birds are available for circadian biology. However, there are now many reports of development of transgenic reporter and knock-out lines of chickens (Poynter and Lansford, 2008; Nishijima and Iijima, 2013). Clearly, this is the line of future research in this field. Even so, some progress has been made with viral transductions in avian retina models (Semple-Rowland et al., 2010). Further, application of microRNA vectors associated with CLOCK and BMAL1 expression affect AANAT expression in chick retina (Haque et al., 2010). Thus, it is possible to manipulate the avian circadian clock at the molecular level. The proof now will be in the pudding.

34.8 CONCLUSION AND PERSPECTIVE

Biological clocks in birds are critical components of their physiology and behavior (Cassone, 1990; Gwinner and Brandstatter, 2001). Early research studying avian circadian organization was critical in the understanding of structure–function relationships in the central nervous system. Indeed, the identification of the pineal gland as a "master pacemaker" conveyed a sense that the system was hierarchically organized. However, as the properties of the pineal gland's function became clearer and the identification of new pacemakers in the hypothalamus and retinae made the system appear more complex, it became clear that the avian circadian clock is a system of multiple circadian pacemakers in the SCN, the pineal gland, and in at least some species the retinae. Each of these were entrained to environmental light cycles by photoreceptors in the retinae, the pineal gland, and the brain. These were in turn thought to interact to accomplish a self-sustained oscillation that drove rhythmic processes downstream. The advent of molecular biological techniques revealed that even this distributed system of pacemakers act via entrainment of downstream oscillators rather than via direct action. It remains to be seen how molecular oscillations in the brain and peripheral tissues are coupled to physiological output, but this is the physiology of circadian clocks in the future.

Chapter 35

Circannual Cycles and Photoperiodism

Vincent M. Cassone
Department of Biology, University of Kentucky, Lexington, KY, USA

Takashi Yoshimura
Laboratory of Animal Physiology, Graduate School of Bioagricultural Sciences, Nagoya University, Furo-cho, Chikusa-ku, Nagoya, Japan, Avian Bioscience Research Center, Graduate School of Bioagricultural Sciences, Nagoya University, Furo-cho, Chikusa-ku, Nagoya, Japan

In addition to the effects of daily patterns on physiology and behavior, birds are also very sensitive to annual patterns in the abiotic and biotic environments. This is particularly true for species of birds in circumpolar and temperate zones, but annual cycles of avian physiology are also evident in subtropical and tropical zones of the Earth. In all cases, these annual cycles derive primarily from annual changes in solar irradiance due to the axial tilt of the Earth's rotation and the elliptical orbit of the Earth around the sun, resulting in seasons (Pianka, 1978). In addition, long-term trends in climate, such as global climate change, whether human-derived or astronomical, may have significant effects on avian physiology (Lockwood, 2010).

35.1 ANNUAL CYCLES

35.1.1 Abiotic

35.1.1.1 Photoperiod

Seasons result from the annual revolution of the Earth around the sun and its axial tilt (Figure 35.1). When the Earth's axial tilt is parallel with the trajectory of the Earth's movement relative to the sun, all surfaces receive equal amounts of solar irradiance—12 h of light and 12 h of darkness per 24 h day (LD 12:12); these days are the equinoxes, occurring on March 20 and September 22. The duration of the day phase is the photoperiod, whereas the duration of the night phase is the scotoperiod. In the northern hemisphere, this is the vernal equinox (the beginning of spring), while in the southern hemisphere, it is the autumnal equinox (the beginning of autumn).

As the Earth progresses in its orbit from March to June, the axial tilt exposes the northern hemisphere to more direct and longer durations (photoperiod) of solar illumination. Conversely, the southern hemisphere undergoes less direct and shorter photoperiods until June 21 of each year, when the Earth's axial tilt points the northern hemisphere toward the sun, perpendicular to its orbit. This is the solstice. In the northern hemisphere, it is the longest day, while in the southern, it is the shortest, corresponding to the beginning of summer and winter, respectively. As the Earth then progresses from June to September, the seasons progress to the autumnal equinox in the north and the vernal equinox in the south on September 22. As the Earth progresses from September to December, the Earth's axial tilt once again becomes perpendicular to the Earth's orbit. However, this time, the axial tilt exposes the southern hemisphere to direct light and longer photoperiods, creating the southern summer solstice and conversely plunging the northern hemisphere into the winter solstice.

On Earth, a major result of these astronomical progressions is the annual change in photoperiod, which is in turn dependent on latitude (Figure 35.2). In contrast to the situation in the laboratory in which lights are turned on and off in a timed square-wave, described below, natural photoperiod depends on the definition of global illuminance one defines as twilight, in which the zenith angle of the sun ranges from 85° as in civil twilight (the sun is just below the horizon) to 105° as in astronomical twilight (the sun is 12° below the horizon). At the equator, photoperiod at civil twilight remains static at LD 12:12 throughout the year, but as latitude increases toward the poles, the annual change in photoperiod increases in amplitude. At the Tropics of Cancer and Capricorn (23.4378°), the photoperiod at summer solstice is approximately LD 14:10, while the winter solstice is LD 10:14. At more temperate New York, NY, USA (43.5°), the photoperiod at summer solstice is approximately LD 15:9 with a winter solstice of LD 9:15, while the range of photoperiods above the Arctic Circle (66.6°) is from LD 24:0 to LD

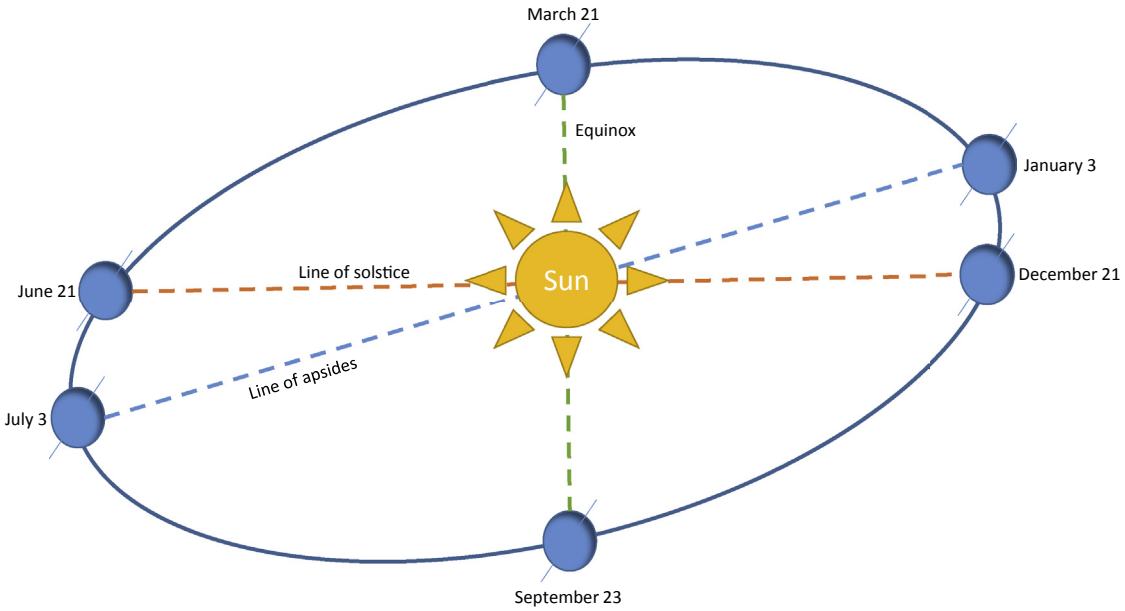

FIGURE 35.1 **The astronomical basis for the seasons on Earth.** Earth's rotation on its axis orients the poles asymmetrically toward or away from the sun depending on the time of year.

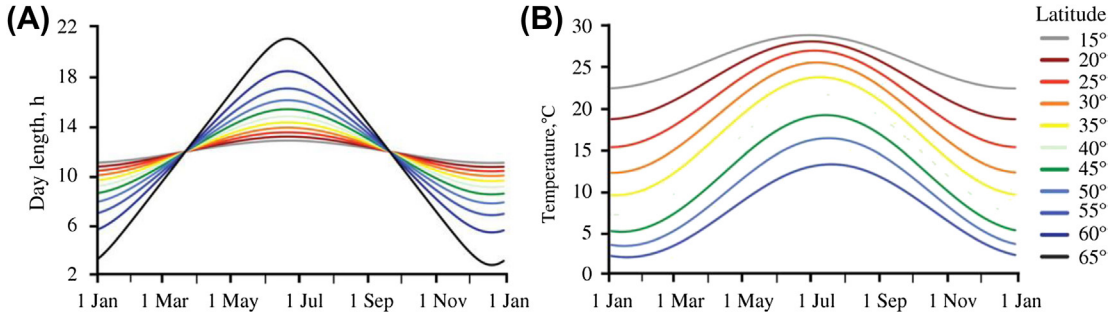

FIGURE 35.2 (A) Annual changes in photoperiod depend upon the latitude in which the amplitude of photoperiodic change is greatest at higher latitudes. (B) Similarly, the seasonal changes in ambient temperature are also dependent on latitude. However, the average temperature at lower latitudes is higher than at higher latitudes. *From Wilczek et al. (2010).*

0:24. Thus, as latitude increases from the equator to the poles, the range of photoperiod dramatically increases over the year.

35.1.1.2 Temperature

One of the major consequences of changing photoperiod as seasons progress is a parallel change in ambient temperature (T_A). Average annual ranges in T_A (ΔT_A), the differences between the coldest month from the hottest month of the year (Glickman, 2000), increase with increases in latitude such that ΔT_A is 0 at the equator to 40 °C at 90° latitude in the northern hemisphere and 31 °C in the south. The principal cause of the asymmetry in ΔT_A between north and south is that a higher percentage of Earth's surface is covered by ocean in the south, absorbing much of the heat. Earth's elliptical orbit in part moderates this difference, because the Earth is closest to the sun in January (Figure 35.1) during the southern summer and northern winter.

In addition to latitude, altitude can dramatically affect T_A as well as ΔT_A. T_A decreases on average 6.4 °C/km altitude, a phenomenon defined as the lapse rate (Glickman, 2000). The lapse rate depends on several variables, however, especially humidity, which decreases lapse rate. For example, an average dry lapse rate is 10 °C/km altitude, while wet lapse rates average 5.5 °C/km altitude. Other abiotic factors that affect T_A and ΔT_A include urbanization, proximity to coasts (continentality), and precipitation.

35.1.1.3 Precipitation and Wind

In addition to annual cycles of photoperiod and temperature, precipitation patterns can also provide temporal cues to birds and other organisms (Pianka, 1978; Glickman, 2000). This is especially the case in subtropical and tropical zones, which experience predictable wet and dry seasons. The intertropical convergence zone results from the Coriolis effect from the

Earth's rotation as well as the evaporation of oceanic water in equatorial areas. Variation in the intertropical convergence zone affects rainfall in many equatorial regions, resulting in predictable wet seasons and dry seasons in subtropical and tropical zones as opposed to the cold and warm seasons at higher latitudes. For example, in tropical Queensland, Australia, precipitation ranges from 65% humidity and 400 mm rain/month the wet season (December–March) to only 17% humidity and 25 mm rain/month in the dry season (June–October). In West Africa, the rainy season extends from April to July, while the dry season falls between October and March. The absolute times of wet and dry seasons are not as predictable globally as is photoperiod, because other factors such as wind direction, mountains, and other physical barriers affect them. However, they tend to be locally predictable, such that many organisms' reproductive processes are synchronized to these abiotic factors.

35.1.2 Biotic

Due to the fact that many abiotic factors vary depending on time of year, it is not surprising that aspects of birds' biotic environment are equally variable. These factors include, but are not limited to, presence and absence of food, competitors, predators and mates. As a consequence, selective pressures for systems to tune physiological processes accurately to the timing of these biotic factors are very high (Pianka, 1978).

35.2 ANNUAL CYCLES OF BIRDS

Birds' life history strategies must adapt to and predict these changing environmental factors. These life history strategies can be complex and species-specific, and the timing of the processes will determine a bird's survival and fitness, perhaps more than any other vertebrate taxon. For an individual and species to survive, time must be allocated to each essential process such as reproduction, migration, molt, and other processes that may interfere with each other (King, 1974). These processes are coordinated such that life history stages are timed to an appropriate time of year relative both to the external environmental conditions described above and among the diverse processes that are coordinated. For example, annual patterns of breeding, migration, body mass, and multiple molt patterns in long-distance migratory birds such as red knots (*Calidrus canutus*) and ruffs (*Philomachus pugnax*) are orchestrated such that each stage of the species' annual cycle occurs at the appropriate time (Helm et al., 2012, Figure 35.3). Thus, birds exhibit hyperphagia and fatten up in anticipation of the vernal migration from southern hemisphere wintering grounds to northern hemisphere breeding grounds, where courtship, sexual behavior, and reproduction occur. Multiple molts occur to replace flight feathers following migratory stints, while breast molt occurs as incubation pads are prepared for incubation of young. Phenological analyses (the study of the temporal aspects of recurrent natural phenomena and their relation to weather and climate of annual cycles; Lincoln et al., 1998) of multiple species of birds indicate similarly complex life history cycles. Obviously, transequatorial migrants, such as ruffs and red knots, exhibit more complex cycles, but these temporal programs are common among avian species.

35.3 CIRCANNUAL RHYTHMS

35.3.1 Circannual Rhythms in the Laboratory

How do birds synchronize their internal biological processes to prevailing environmental cycles? As with circadian rhythms, many physiological and behavioral rhythms in birds exhibit circannual rhythms (Gwinner, 2003). Circannual rhythms can only be demonstrated in the laboratory. Typically, birds are maintained continuously in equatorial photoperiods (LD 12:12) for several years. Under these conditions, many birds will express a free-running rhythm of approximately 1 year (hence, circannual), with periods of slightly less than or more than 365 days. As an example, circannual rhythms of testicular activity and molt in a single African stonechat, *Saxicola torquata axillaris*, maintained in captivity for up to 12 years in LD 12:12 persisted with a period, τ, of approximately 9 months until the bird died, presumably of old age (Figure 35.4; Gwinner, 2003). The expression of circannual rhythms is a widespread phenomenon among avian species, especially among species that experience transequatorial migration (Rani and Kumar, 2013), but circannual patterns are highly variable among species and among individuals within species (Hazlerigg and Loudon, 2008).

The mechanisms by which circannual rhythms are generated, however, are not known. System-level and molecular aspects of circadian clocks appear to interact with the expression of circannual rhythms, but they do not appear to be necessary. For example, pinealectomy (PINX) or constant light (LL), which abolishes circadian patterns of perch-hopping in the spotted munia, *Lonchura punctulata,* as well as other species of oscine passerine birds does not affect circannual patterns of testicular growth and regression or premigratory fattening (Pant and Chandola-Saklani, 1992). Conversely, PINX of migratory white-crowned sparrows, *Zonotrichia leuchophrys*, abolishes both circadian patterns of perch-hopping behavior and circannual patterns of nocturnal migratory restlessness, or *Zugunruhe* (see below; McMillan, 1970). At the molecular level, studies focusing on allelic differences in C-terminal polyglutamine repeats in the CLOCK protein in breeding and migratory patterns of barn swallows, *Hirundo rustica*, suggest a negative selection on "deviant" genotypes (Caprioli et al., 2012; Saino et al., 2013). Even so, other studies in several different swallow species in the genus *Tachycineta* failed to show similar associations (Dor et al., 2012).

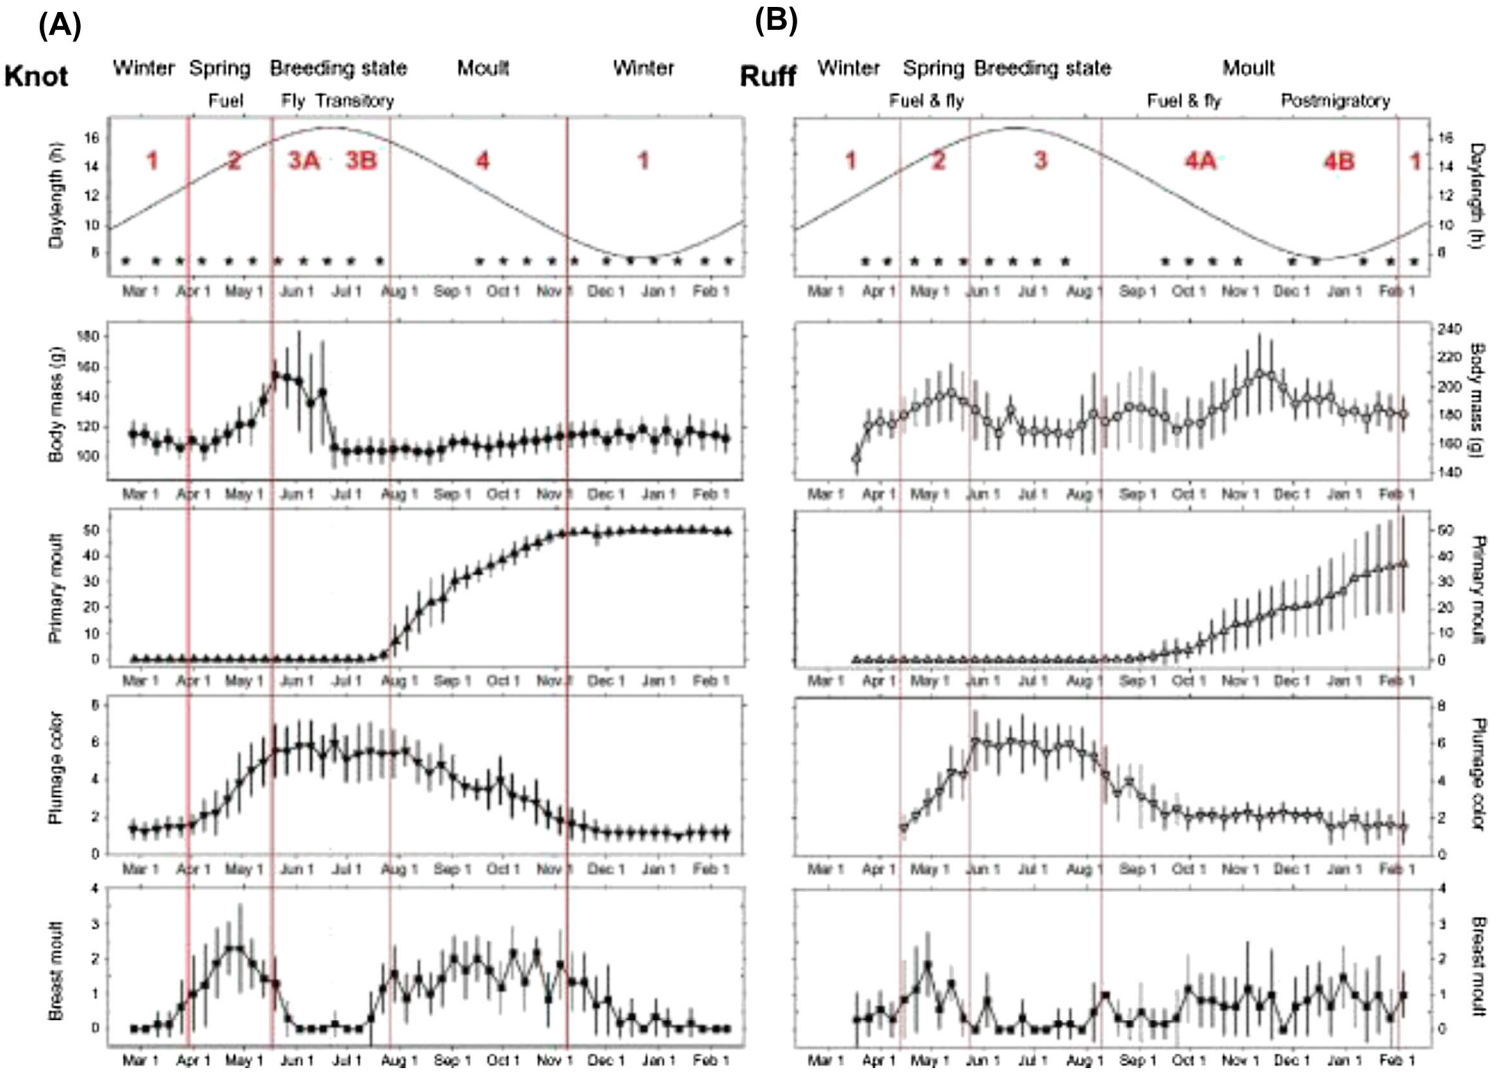

FIGURE 35.3 **The complex annual life histories of two species of wading birds.** (A) The knot, *Calidrus canutus*; and (B) the ruff, *Philomachus pugnax*. Annual changes in body mass, vernal and autumnal molt, and plumage coloration occur in coordinated fashion in species-specific fashion. *From Helm et al. (2012).*

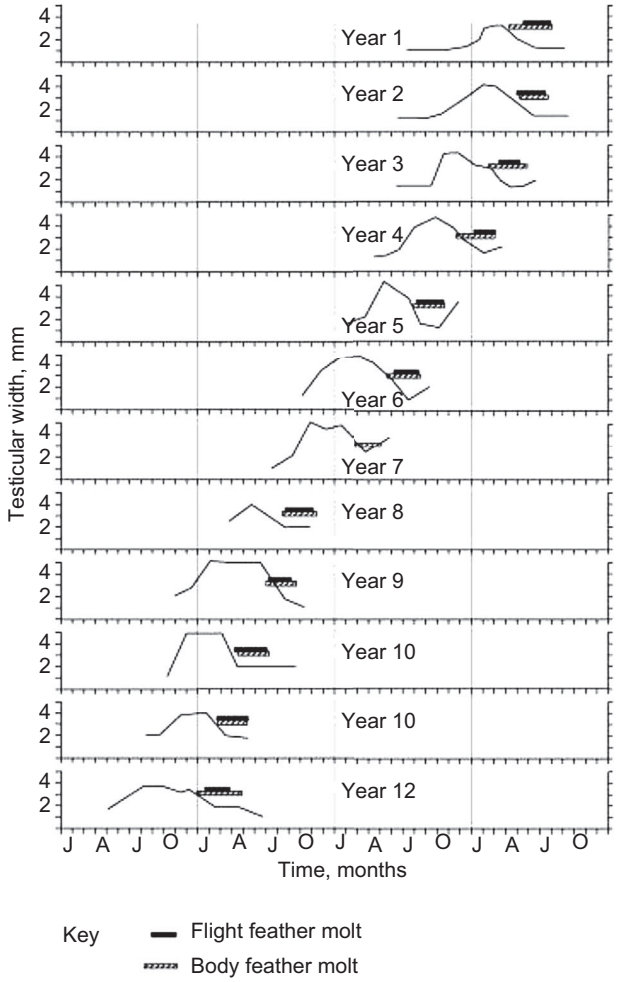

FIGURE 35.4 Circannual cycles of a single African stonechat, *Saxicola torquata axillaris*, of testicular size and molt through 12 consecutive years maintained in constant LD 12:12. *From Gwinner (2003).*

35.3.2 Synchronization of Circannual Rhythms to Environmental Cues

The expression of circannual patterns whose τ are different from 365 days in laboratory conditions but exactly 365 days under natural conditions suggests that, like circadian rhythms, circannual rhythms must be synchronized or entrained to prevailing environmental cues (Gwinner, 2003; Rani and Kumar 2013). In most cases, alternating cycles of increasing and decreasing photoperiod synchronizes or entrains circannual rhythms of birds within a limit of entrainment. For example, exposure of European stonechats, *Saxicola torquata rubicola*, to alternating photoperiods of high amplitude (LD 16:6 to LD 10:14) entrain circannual patterns of testicular width and molt to 12 and 6 months in duration, respectively, but lower amplitude cycles of LD 13:11 to LD 11:13 were unable to entrain these processes to the 6 month cycle. There is little evidence of other Zeitgebers entraining circannual rhythms in birds, although periodic presentation of novel food has transitory effects on circannual cycles in African stonechats (Gwinner and Scheirlein, 1998; Scheuerlein and Gwinner, 2002).

35.4 PHOTOPERIODISM

35.4.1 Effects of Photoperiod on Avian Physiological Function

Aside from the entraining effects of photoperiod on circannual cycles, changes in photoperiod have direct effects on many annual cycles in birds, although it is not clear that these are necessarily mutually exclusive. In fact, it has been known for some time that seasonally breeding, temperate-zone birds time reproduction and migration in a clock-like fashion in response to changing photoperiod (Rowan, 1926). Birds living in temperate-zone latitudes generally restrict breeding to the spring and summer, maximizing the likelihood that young will be hatched during times at which food is plentiful (Gwinner, 1989, 2003). The vast majority of seasonally breeding birds are long-day breeders; that is, they begin sexual maturation, courtship, and mating as the photoperiod transitions from the winter solstice to longer and longer days. There is one well-documented short-day breeding species, the emu, *Dromaius novaehollandiae*, which breeds as the photoperiod shortens (Blache et al., 2001).

The exact photoperiod that induces or suppresses reproductive function in birds is species-, latitude-, and function-specific, called the *critical photoperiod*. This is the minimum photoperiod that induces or suppresses a seasonally regulated process (Figure 35.5). For example, annual testicular growth is induced earlier and by shorter photoperiods in the temperate zone European starling than in the Nearctic-breeding white-crowned sparrow (Dawson, 2008). This corresponds to the likelihood of food availability occurring later in the season at higher versus lower latitudes at a species level. Similarly, within species (especially those that are widely distributed), critical photoperiod tends to be longer in individuals of the same species residing at higher latitudes than at lower latitudes (Dawson, 2013). Thirdly, the critical photoperiod that induces or suppresses different functions, such as reproduction, molt, metabolism, and migration, usually differ among these processes. Obviously, molt while migration would be disadvantageous for any bird.

Subtropical and tropical birds are not immune to these changes, as the breeding seasons of these species are commonly timed as well (Scheuerlein and Gwinner, 2002; Rani and Kumar, 2013). Although the amplitude of photoperiodic change is much reduced at these latitudes (Figure 35.2), there are nonetheless many seasonal signals to which birds can synchronize reproductive and other processes. For example, the spotted antbird, *Hylophylax naevioides*, lives in Panamanian rainforests around 9°N, experiencing a very low-amplitude photoperiodic change. These birds breed in

the rainy season (May–December), when insect prey are abundant (Wikelski et al., 2000). Although the rainy season occurs regularly from year to year, there is significant variation in its inception and duration (Hau et al., 2000). When male antbirds are experimentally transferred from LD 12:12 to LD 13:11, testes volume increases dramatically, while birds maintained in LD 12:12 do not, demonstrating these birds do respond to photoperiodic changes. Conversely, birds maintained in the equinoctial photoperiod stimulated with an additional dietary supplement of live crickets exhibit larger testes than birds maintained on the standard insectivorous diet of mealworms only (Hau et al., 2000). The scenario suggests that slight changes in photoperiod prime the birds' reproductive system to respond to the increase in diet necessary to raise young (Hau, 2001). This is just one example of what is likely a wide array of adaptations to temporal changes in the subtropics and tropics. Because avian biodiversity is 5 times the level in the tropics than in Nearctic regions, the variability in these adaptations is likely just as diverse.

In seasonally reproducing, long-day birds, gonadal activity and gonad size regress and become inactive as the photoperiod decreases, whereas gonads recrudesce, becoming more active in response to increased photoperiod (Figure 35.5(A)). If birds are maintained in long photoperiods for long periods of time, their reproductive systems become insensitive to the photostimulatory effects of long photoperiods and spontaneous regress (Figure 35.5(A)). This process

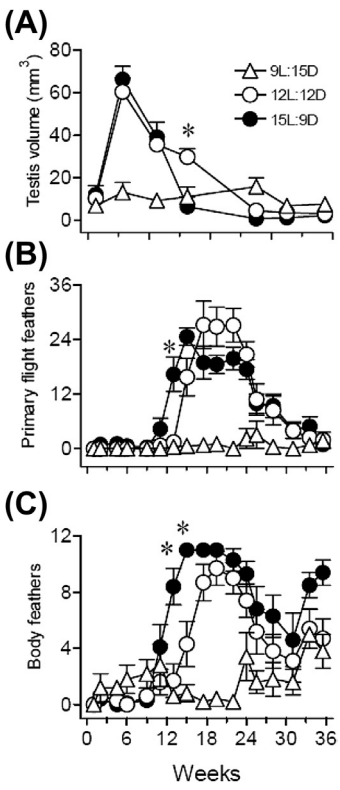

FIGURE 35.5 The effect of differing photoperiods on (A) testes volume, (B) primary, and (C) body molt in captive spotted munia, *Lonchura punctulata*. *From Rani and Kumar (2013).*

is called photorefractoriness, and birds remain photorefractory until they are placed in short days for some time to make them photosensitive again. Similarly, other photoperiodically regulated processes wax and wane depending on the photoperiod, although the absolute time at which they occur may differ from gonadal function (Figure 35.5(B) and (C)).

35.4.2 Role of Photoreceptors

Multiple photoreceptors are involved in circadian entrainment, and these photoreceptors reside in the retinae, pineal gland, and at least three encephalic sites: lateral septal organ (LSO), preoptic area (POA), and tuberal hypothalamus/mediobasal hypothalamus (MBH) (Foster and Hankins, 2002). As with circadian entrainment, the retinae are not necessary for photoperiodic responses (Benoit and Assenmacher, 1954; Menaker, 1968; Menaker and Keatts, 1968; Menaker and Underwood, 1976), although there is some species variability. In the house sparrow, *Passer domesticus*, and American tree sparrow, *Spizella arborea*, removal of the eyes, the pineal gland, or both has no effect on gonadal responses to increases or decreases in photoperiod (Menaker et al., 1970; Wilson, 1990). However, enucleated Japanese quail, *Coturnix coturnix japonica*, exhibit normal photoperiodic responses to increases in photoperiod in egg-laying in females and enlargement of the cloacal gland in males, similar to the situation in sparrows. Still, termination of reproductive activity by exposure to short photoperiods requires that birds experience long days at or before the time of blinding (Homma et al., 1972). Because Japanese quail and house sparrows also differ in the role played by retinal melatonin in circadian organization (Cassone and Menaker, 1984; Underwood and Siopes, 1984), it is not clear if this difference is due to differences in photoreceptors *per se* or due to differences in circadian organization (see below).

Local illumination of the MBH or LSO leads to gonadal growth (Benoit, 1935; Benoit and Assenmacher, 1954; Homma et al., 1979). Nomographic analyses of the action spectra for photoperiodic responses suggest a rhodopsin-like photopigment, with a peak sensitivity of 480 nm to ultraviolet wavelengths (Foster et al., 1985). More recently, several genes encoding rhodopsin superfamily photopigments have been identified in the brains of several avian species, corroborating this view. These include melanopsin (OPN4), vertebrate ancient opsin (VA opsin), neuropsin (OPN5), and rhodopsin itself (OPN2) (Silver et al., 1988; Bailey and Cassone, 2005; Chaurasia et al., 2005; Halford et al., 2009; Nakane et al., 2010; Kang et al., 2010; Wang and Wingfield, 2011). OPN5 is expressed in CSF-contacting neurons within the periventricular organ (PVO) of the Japanese quail (Figure 35.6; Nakane et al., 2010). OPN4-immunoreactivity and mRNA is widely expressed in the brain of the turkey, *Meleagris gallopavo*, including the preoptic area, suprachiasmatic region (mSCN and vSCN) of the hypothalamus, lateral septal region, *pars distalis* of the *adenohypophysis* and the premammillary nucleus (PMM) just dorsal of the PVO (Kang et al., 2010).

35.4.3 Role of Circadian Clocks in Photoperiodic Time Measurement

The role of the circadian clock in annual cycles has been known for some time (Bünning, 1969; Follett et al., 1992; Menaker and Eskin, 1967). Although there are differences among species of birds and between birds and other taxa, neither the absolute length of the photoperiod, length of the scotoperiod (the duration of the dark phase) or their ratio is the proximal causes of gonadal induction. Rather, it is the circadian phase (φ) at which light impinges on photoreceptive elements that causes reproductive changes. For example, male Japanese quail, *Coturnix japonica*, and white-crowned sparrows, *Zonotrichia leucophys*, which are maintained in LD 6:18 will exhibit regressed testes. However, if the last hour of the 6 h photoperiod is extended each long night to a specific "photoinducible phase", φ_{pi}, usually 11–12 h following the onset of the short photoperiod, reproductive activity is commenced. Thus, birds exposed to LD 6:18 or L5: D1: L1: D17 (a single 1 h light pulse interrupting the night) will retain regressed gonads, but if the 1hr pulse occurs 5 h later (L5:D6:L1:D12), gonads will recrudesce (Menaker and Eskin, 1967; Follett et al., 1974; Sharp, 2005). The same total amount of light (and dark) is present for each 24 h, but the effect is dramatically different. It is the *timing* of light coinciding with an internal process that induces or prevents reproductive activity, suggesting a circadian clock underlies photoperiodic time measurement. Nanda and Hamner (1958) had shown this to be the case in plants through an elegant series of experiments in which soy bean plants exposed to a 6 h photoperiod coupled with scotoperiods of varying lengths that were multiples of a 24 h cycle (e.g. LD 6:18; LD 6:42 or LD 6:66) did not flower. However, when plants were exposed to 6 h photoperiods followed by scotoperiods of lengths that did not resonate with 24 h (e.g. LD 6:6; LD 6:30 or LD 6:54) flowering was observed. Similar studies in several species of birds showed that seasonal changes in both gonadal recrudescence and regression are regulated by a circadian clock (Follett et al., 1974, Follett and Pearce-Kelly, 1991; Kumar et al., 1996).

These and other observations have led to two competing models for a role of circadian clocks in photoperiodic time measurement (Figure 35.7). In one, the "external coincidence model" proposed by Bünning (1969) suggests that light has two complementary roles. First, light entrains the circadian clock with a stable ψ_{ie} such that the photoinducible phase, φ_{pi}, is also maintained with a stable ψ approximately 11.5 h following the beginning of the photoperiod (lights on). When light coincides with the φ_{pi} either because the photoperiod is long under natural conditions or through exposure to an experimental light pulse, the reproductive axis is induced.

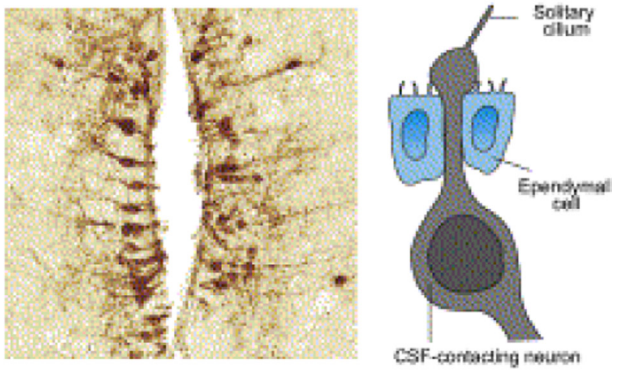

FIGURE 35.6 Expression of neuropsin (OPN5) in the periventricular organ of the mediobasal hypothalamus in the Japanese quail, *Coturnix coturnix*. *From Yoshimura (2013).*

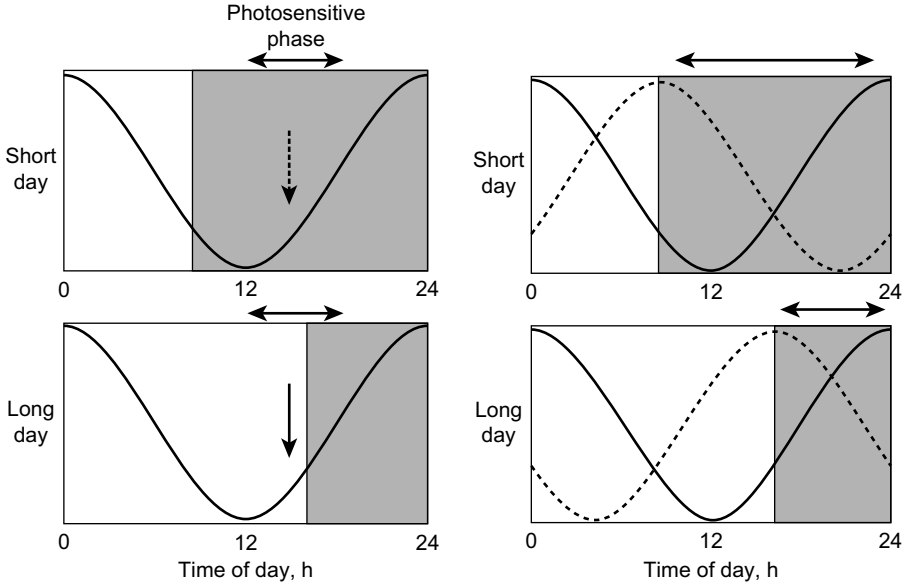

FIGURE 35.7 The difference between the external coincidence (left) and the internal coincidence (right) models for photoperiodic induction. In the case of external coincidence, light (1) entrains the circadian system to a stable phase relationship to the photoperiod and (2) stimulates or inhibits a process such as gonadal induction at a particular photoinducible phase. In the internal coincidence model, at least two circadian oscillators entrain to the photoperiod, and the phase relationship between these two oscillators induces or suppresses the seasonally controlled process. *From Yoshimura (2013).*

The competing notion, the "internal coincidence model" proposed by Pittendrigh (1993) stems from the observation that many circadian systems behave as if they are composed of at least two oscillators, one entrained to dawn and the other to dusk. In the internal coincidence model the phase relationship between the dawn oscillator and the dusk oscillator, ψ_{dawndusk}, induces seasonal changes in reproduction. As we will see below, each of these models has support from different experimental systems in birds. However, until specific structures and/or molecules become associated with these models, they are essentially untestable at the physiological level.

35.4.4 Role of Circadian System Structures (or Lack Thereof)

As stated in Chapter 31, the avian circadian system is comprises the pineal gland, the suprachiasmatic nuclei, the retinae and photoreceptors in the retinae, pineal and brain (Cassone and Menaker, 1984). These structures mutually interact to elicit circadian patterns of a broad array of processes and to entrain them to LD cycles. In view of the fact that photoperiodic time measurement relies on circadian rhythmicity, one might expect that these structures are critical for photoperiodism as well. Intriguingly, in spite of the fact that the rhythmic production of melatonin is critical for the expression of circadian locomotor rhythms in birds, melatonin does not affect seasonal changes in primary reproductive function in these species. As in mammals, pineal melatonin levels faithfully reflect the length of the scotoperiod both in vivo and in vitro (Binkley et al., 1977; Brandstätter et al., 2000). However, PINX and/or EX of several species of birds has little effect on seasonal changes in gonad size or activity (Siopes, 1983; Bentley, 2001; Kumar et al., 2002). Moreover, administration of exogenous melatonin of different durations has little effect on primary reproductive function (Cassone et al., 2008). This corresponds to the relative absence of melatonin receptor activity in the tuberal hypothalamus and hypophysis (Cassone et al., 1995), in stark contrast to the situation in seasonally reproducing mammals, where IMEL binding and melatonin receptor expression in pars tuberalis is a major site of melatonin action (Goldman, 2001).

Circadian clock function has been localized within the mediobasal hypothalamus (MBH) itself of Japanese quail controlling photoperiodic time measurement for reproductive function (Yoshimura, 2010, 2013). Earlier studies had shown that lesion of the MBH blocked testicular recrudescence in response to lengthening photoperiods (Sharp, 2005) and illumination of this area had resulted in excitation of the tuberal hypothalamus and testicular growth (Foster et al., 1985; Meddle and Follett, 1997). As stated above, the MBH of quail and the PMM of turkeys have been shown to express both OPN4 and OPN5 in cerebrospinal fluid (CSF)-contacting neurons (Kang et al., 2010; Nakane and Yoshimura, 2010; Nakane et al., 2010). Noting that PINX or EX or even SCN lesion had little effect on photoperiodic regulation of gonadal function, rhythmic expression of the clock genes *per2*, *per3*, *clock*, and *Bmal1* were identified in the MBH, suggesting that this structure contains the circadian pacemaker associated with photoperiodic time measurement (Yoshimura, 2010, 2013).

35.5 NEUROENDOCRINE REGULATION OF PHOTOPERIODIC TIME MEASUREMENT

35.5.1 Photoperiodic Control of Gonadotropins and Prolactin in Seasonal Reproduction

The circadian pacemaker presumably residing in the MBH controls seasonal changes in the release of gonadotropin releasing hormone (GnRH) and vasoactive intestinal polypeptide (VIP) via the hypothalamohypophysial portal system (HHPS), which in turn regulate the synthesis and release the gonadotropin luteinizing hormone (LH) and prolactin (PRL), respectively (Sharp et al., 1998). GnRH neurons predominate in the preoptic area and anterior hypothalamus and project to the median eminence (Saldanha et al., 2001; Teruyama and Beck, 2001), whereas the VIP neurons are found throughout the basal hypothalamus. The GnRH cells, at least, are in direct contact with terminals arising from rhodopsin-immunoreactive cells, presumably extraocular photoreceptors in the lateral septal organ (Saldanha et al., 2001). The VIP cells project throughout the hypothalamus but also innervate the capillaries in the median eminence (Teruyama and Beck, 2001). GnRH- and VIP-immunoreactive terminals are more dense and in closer proximity to median eminence during long photostimulatory photoperiods than in short photoinhibitory photoperiods.

In long-day breeding birds, lengthening photoperiods induce an increase in the release of GnRH from terminals in the median eminence into the HHPS. *Ex vivo* hypothalamic explants from male Japanese quail release GnRH in culture in response to long photoperiods (Perera and Follett, 1992). GnRH in turn induces the synthesis and release of LH, which remains high during the breeding season. However, when photoperiod decreases, LH levels also decrease. In addition, in long-day breeders, continued exposure to long days induces photorefractoriness, in which birds fail to respond to photostimulatory photoperiods, and LH levels decline (Sharp, 2005).

Lengthening photoperiod also presumably increases the release of VIP from median eminence terminals into the HHPS, although this has not been demonstrated directly. Even so, administration of VIP potently induces the synthesis and release of PRL by the adenohypophysis in several species of passerine, galliform, and columbiform species (Maney et al., 1999; Kosonsiriluk et al., 2008). The rise in PRL is typically delayed relative to LH, declining only after LH declines. Immunization of European starlings, *Sturnus vulgaris*, against VIP delays and attenuates the decline in LH levels during photorefractoriness (Maney et al., 1999).

35.5.2 Role of the Thyroid in Avian Photoperiodism

Thyroidectomy induces gonadal recrudescence in starlings and Japanese quail (Follett and Nicholls, 1985; Dawson et al., 1986), and injection of T3 into the MBH induces quail gonadal growth (Follett and Nicholls, 1985; Yoshimura et al., 2003). Using differential subtractive hybridization, Yoshimura's group found type 2 iodothyronine deiodinase (*Dio2*) to be induced in the MBH by a light pulse associated with long-day induction. *Dio2* encodes an enzyme that catalyzes the conversion of inactive thyroxine (T4) to active triiodothyroine (T3) (Nakao et al., 2008a,b). Later, they showed that type 3 iodothyronine deiodinase (*Dio3*), which inactivates T3, was induced in the MBH by exposure to short days. The scenario they envision is that photoperiod is perceived by photopigments in the MBH, which entrain a circadian oscillator within the MBH. In long days, the circadian clock induces *Dio2*, while short days induce *Dio3*. These two gene switches fine tune local thyroid hormone concentration within the MBH. Although precise mechanisms of thyroid hormone action remain unclear, it is proposed that locally activated thyroid hormone causes morphological changes in neuro–glial interaction between GnRH nerve terminals and the endfeet of the glial processes in the median eminence that regulates or modulates the seasonal GnRH secretion (Figure 35.8; Yamamura et al., 2004).

35.5.3 Role of Gonadal and Neural Steroids

As stated previously, the reproductive systems of long-day breeders recrudesce as the photoperiod lengthens in response to gonadotropin activation. The exact timing of these is species and gender specific. For example, in European starlings, seasonal testes growth begins more than a month earlier than does female follicle formation (Williams, 2012). As testes recrudesce, Sertoli cells synthesize and secrete estrogens, such as estradiol, while Leydig cells synthesize and secrete androgens such as testosterone, androstenedione and dehydroepiandrosterone. Ovarian granulosa cells begin to synthesize and secrete estrogens from androgens generated by adjacent thecal cells. These gonadal steroids induce gender-appropriate seasonal growth and maturation of primary and secondary sexual characteristics (Adkins-Regan, 2012). In males, many of the genomic effects of testosterone are mediated by estrogens generated by local conversion by aromatase. When photoperiod decreases, LH also decreases, and the steroidogenic capacity of the gonads decline in parallel.

Among structures that annually recrudesce and regress are brain structures associated with reproductive behavior (Figure 35.9; Balthazart et al., 2009, 2010). The medial preoptic nucleus (POM) within the POA of Japanese quail has been well established as a structure involved in male sexual behavior (Ball and Balthazart, 2004; Balthazart and Ball, 2007), in which the size

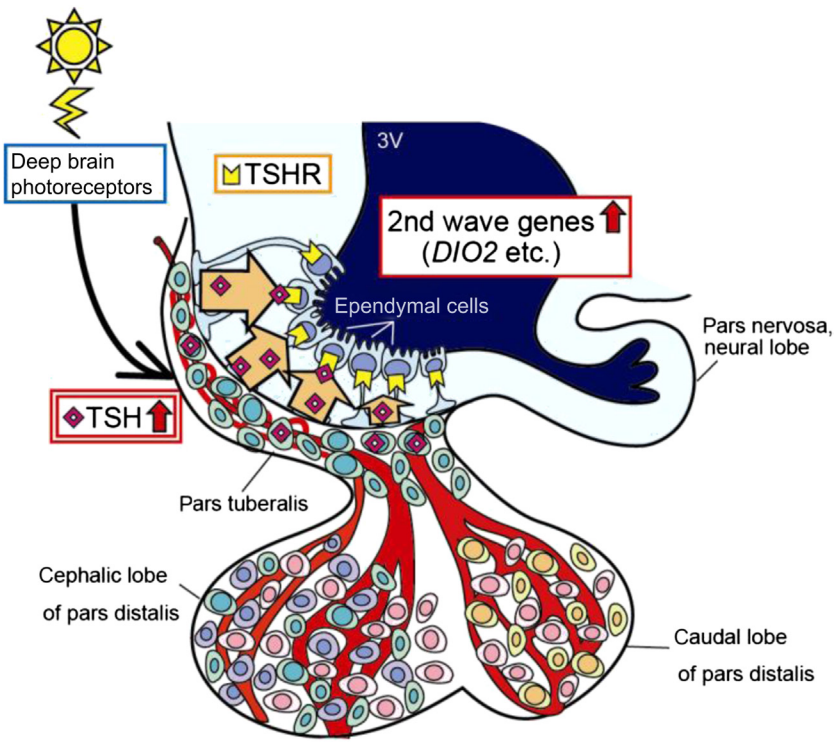

FIGURE 35.8 Schematic of the quail tuberal hypothalamus. Extraocular photoreceptors induce an increase in TSH signaling in the pars tuberalis, which in turn induce changes in ependymal cells or tanycytes. These cells affect the ability of neuroendocrine signals entering the hypothalamohypophysial portal system. *From Yoshimura (2013).*

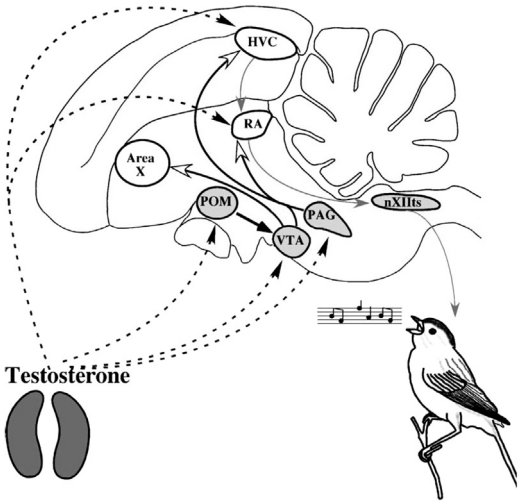

FIGURE 35.9 Schematic of the effects of testosterone on brain structures associated with reproduction and song. Steroid receptors residing in preoptic, brainstem, and forebrain structures mediate primary reproductive behavior as well as bird song. *From Ball and Balthazart (2004).*

of POM is greater in males than in females (Viglietti-Panzica et al., 1986; Ball and Ketterson, 2008). In male quail, the POM increases in volume during the spring and decreases in the fall (Thompson and Adkins-Regan, 1994). Castration of these birds abolishes this pattern, and administration of testosterone, mediated by aromatase-induced estrogens, increases POM volume through increases in cell size and dendritic branching within 2 weeks of administration. In contrast to the situation involving song control (see below), there is no evidence that POM growth involves *de novo* neurogenesis.

However, the gonads and adrenal glands are not the only sources of biologically active steroid hormone (Tsutsui et al., 1999; Schlinger and Remage-Healey, 2012). The brains of many species of birds express the enzymes capable of neurosteroidogenesis, biosynthesis of biologically active steroid hormones by the brain (Tsutsui et al., 1999). In the Lapland longspur (*Calcarus lapponicus*) and song sparrow (*Melospiza melodia*), for example, the hypothalamus, hippocampus, and ventral telencephalon express aromatase, which converts androgens to estrogens, and 5-β-reductase, which deactivates testosterone (Soma et al., 1999, 2003). This suggests that the avian brain can convert circulating gonadal steroids into biologically active estrogens. However, there is growing evidence that the brain can also synthesize steroids from circulating cholesterol (Schlinger et al., 2008; Schlinger and Remage-Healey, 2012).

35.5.4 Mechanisms of Photoperiodic Regulation of Bird Song

The song control system of oscine passeriform birds is a specialized network of brain nuclei involved in singing and song learning (Nottebohm, 1981; Mooney, 2009). This system receives auditory input from ascending, primary auditory pathways beginning in the cochlear nuclei (Co), which project to the lateral dorsal mesencephalic nuclei (MLd). MLd in turn projects to the thalamic *nucleus ovoidalis* (Ov), which in turn projects to Field L in the forebrain. Song processing begins in secondary auditory areas in the caudal mesopallium (cM) and caudomedial nidopallium (NCM), which interact with the anterior forebrain pathway for song plasticity and learning. This pathway includes the HVC in the dorsal forebrain, which projects to Area X, whose projections form a loop between the dorsolateral thalamus (DLM) and the lateral magnocellular nucleus of the anterior nidopallium (LMAN). Then, both HVC and LMAN project to the robust nucleus of the archipallium (RA), which forms the song motor output pathway.

This system enables birds to process a complex species-specific identification of both self and con-specifics as well as other dynamics in birds' acoustic environments (e.g., competitors, prey, predators; Mooney, 2009). These acoustic environments as well as their reproductive and survival relevance are not constant. Territories change hands and the available range of mates fluctuates. In order to effectively interpret the acoustic features in song, the auditory system must structure its representation in such a way that allows for dynamic behavioral goals of the organism. At the same time, the structure and behavior of song itself must be tuned to reproductively appropriate situations.

Both the probability of a male bird to sing in response to a given stimulus as well as the size and complexity of the song control nuclei within its brain vary depending upon the time of year (Nottebohm, 1981). Photosensitive birds in the short days of winter possess small HVC, RA, and (depending on the species) other structures in the system. When birds are photostimulated as photoperiod increases, the song control nuclei grow in parallel with the growth of the testes. As they become photorefractory, these structures regress in both size and complexity. Some of the growth in these structures, especially in HVC, is due to de novo neurogenesis from neural stem cells residing in periventricular areas of the lateral ventricle (Alvarez-Buyla et al., 1988). These cells are born predominantly during the fall and migrate into the HVC over the course of the winter, where they differentiate and extend axonal projections to RA and other structures. In addition, increases in neuropil and glia contribute to this growth. Regression of these structures is characterized by programmed cell death as well as retraction of neuropil.

Seasonal fluctuations in androgens and estrogens appear to be critical for changes in song control. Song control nuclei contain both androgen receptors (AR) and both estrogen receptor subtypes (ERα and ERβ), as well as aromatase, which are capable of converting androgens into biologically active estrogens (Ball and Balthazart, 2010). Further, the rate of male song in several songbird species increases when testosterone levels are high; castration decreases this rate, and hormone replacement reestablishes vernal song patterns (Balthazart et al., 2010).

Even so, a few studies have indicated gonad-independent regulation of song control nuclei under different photoperiods.

In both American tree sparrows (Bernard et al., 1997) and house sparrows (Whitfield-Rucker and Cassone, 2000), HVC and RA increase in size in response to a change in photoperiod from a short day to long day (Figure 35.9). Castrated birds in these studies also exhibited photostimulated song control nuclei, although the level of induction was not as great as in the sham-operated birds. Thus, while the song system certainly responds to the seasonal changes in gonadal steroids, regulation of song control nuclei comprises a gonad-independent as well as a gonad-dependent aspect. As stated above, recent studies have implicated neurosteroids in this supplemental signal to the song system (Soma et al., 1999, 2003).

Alternatively, studies employing *in vitro* receptor binding and 2[^{125}I]iodomelatonin (IMEL) in the 1980s and 1990s demonstrated high affinity melatonin receptor binding and the identity of three receptor subtypes, Mel_{1A}, Mel_{1B}, and Mel_{1C} melatonin receptors, in a variety of vertebrates (Reppert et al., 1995, 1996). In birds and reptiles, IMEL binding predominates in retinorecipient and integrative structures within the visual system (Cassone et al., 1995), which has led to the view that visual sensitivity and contrast detection are under circadian control. In male house sparrows (Whitfield-Rucker and Cassone, 1996) and European starlings (Bentley and Ball, 2000), but not female birds, high affinity IMEL binding was present in song control nuclei HVC, RA, LMAN, and, to a lesser extent, Area X. Both HVC and RA express the Mel_{1B} melatonin receptor (Jansen et al., 2005).

These observations point to a role for melatonin in song behavior and in the growth and regression of song control nuclei. Bentley et al. (1999) have shown that continuous administration exogenous melatonin attenuated the long-day-induced volumetric increase in HVC and also decreased the volume of another song-control nucleus, area X, in European starlings. This effect was independent of the birds' reproductive state. House sparrows exposed to constant light (LL), which abolishes circadian patterns of behavior, and subsequent rhythmic administration of summer-like (short duration) or winter-like (long duration) melatonin, which entrains their behavior, also affects the volumes of song control nuclei HVC and RA (Cassone et al., 2008). Birds that received no melatonin or the short duration melatonin cycle (who entrained to the regime) exhibited large HVC and RA, but birds that received the long duration melatonin entrained to the melatonin regime but showed regressed HVC and RA. This showed that melatonin affects song control nuclei independently of gonadal state and whether they entrained to the melatonin cycle (Figure 35.10).

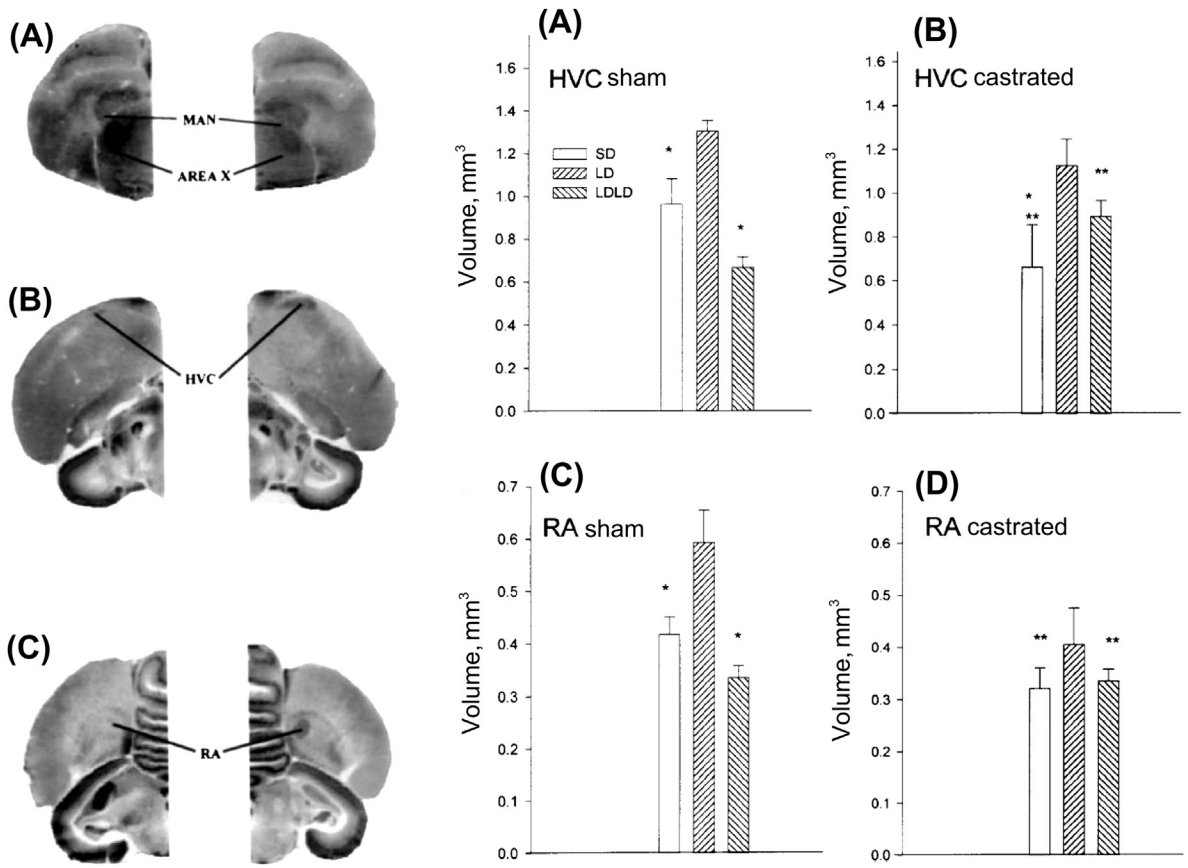

FIGURE 35.10 Bird song structures, such as HVC and the robust nucleus of the archipallium (RA) change in size and complexity depending on the photoperiod. HVC and RA are small in short days (left) and large in long days (right). Castration attenuates but does not abolish these seasonal cycles. *From Whitfield-Rucker and Cassone (2000).*

35.6 MOLECULAR MECHANISMS OF PHOTOPERIODISM

Yoshimura and coworkers envisioned an external coincidence model in which circadian oscillators within the MBH are entrained by photoperiod co-localized in that structure. When the length of the photoperiod coincides with a φ_{pi}, *Dio2* is induced, enabling a metabolic cascade in response to T3 hormone, and gonadal induction occurs. It is not clear, at this stage, what molecular components link the circadian clock to *Dio2* or *Dio3*. The MBH of quail and the PMM of turkeys rhythmically express clock genes (Ikegami et al., 2009; Ikegami and Yoshimura, 2012; Leclerc et al., 2010). The availability of chicken genome sequences has permitted the expansion of studies from single-gene to genome-wide transcriptome analyses in avian species. Microarray analysis of photoperiodism have identified waves of genes that were induced or reduced by long day stimulus. Long day-induced thyrotropin (thyroid-stimulating hormone, TSH) in the pars tuberalis of the pituitary gland induces *DIO2* expression and reduces *DIO3* expression through the TSH receptor (TSHR)-Gαs-cAMP signaling pathway (Nakao et al., 2008b). Because chronic administration of TSH into the hypothalamus causes full testicular development, it is suggested that the thyrotropin secreted from the pars tuberalis is the master factor regulating seasonal reproduction. This result was unexpected because of the well-known function of thyrotropin in stimulation of thyroid gland.

35.7 COMPARISON TO OTHER VERTEBRATE TAXA

In marked contrast to nonmammalian vertebrates, the eyes are the only photoreceptor organs in mammals. Light information received by the eye is transmitted to the pineal gland through the suprachiasmatic nucleus. Melatonin is secreted during the night as in the case of birds, but the mode of melatonin action on seasonal reproduction had been unclear until recently. It has been demonstrated that melatonin receptors are expressed in the pars tuberalis of mammals and that melatonin suppresses TSH expression in the pars tuberalis via the MT1 melatonin receptor (Ono et al., 2008; Hanon et al., 2008; Yasuo et al., 2009) (Figure 35.11).

Most fish living in temperate zones also exhibit a photoperiodic response and the involvement of thyroid hormone in seasonal reproduction has been reported extensively. However, fish do not possess anatomically distinct pars tuberalis. Recent work has demonstrated that the saccus vasculosus (SV) of fish acts as a sensor of seasonal reproduction (Nakane et al., 2013). All the photoperiodic signaling pathways from photoreceptors (opsins) to neuroendocrine output (thyrotropin and DIO2) are localized in the coronet cells of the SV, and isolated SV responds to photoperiodic changes *in vitro*. Thus, the coronet cells of the SV may be the ancestral seasonal sensor in vertebrates (Figure 35.12).

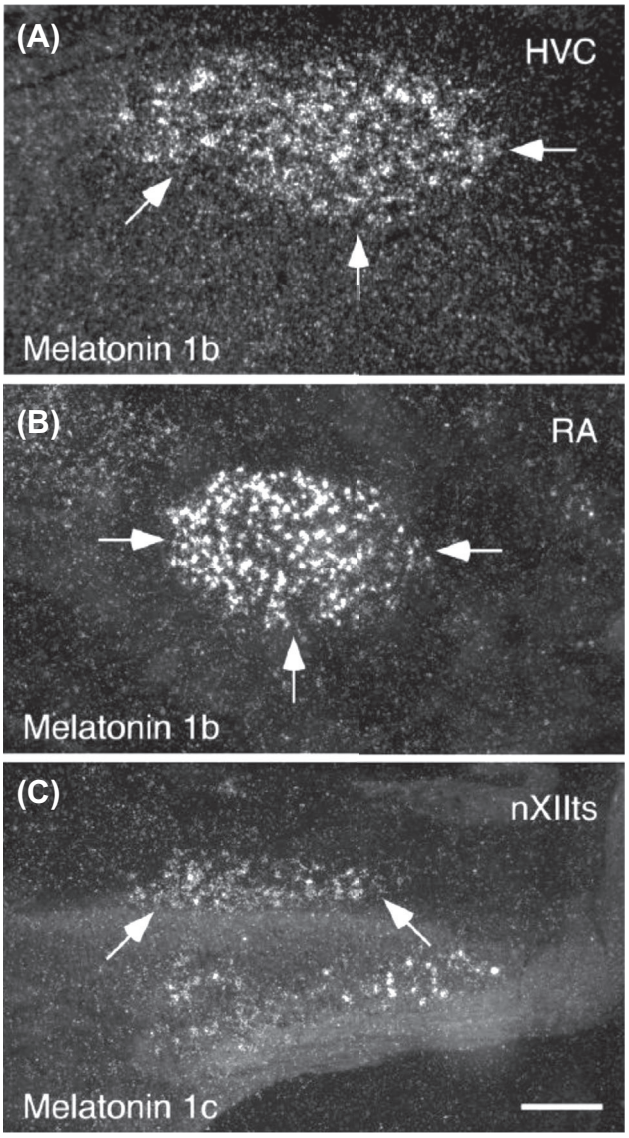

FIGURE 35.11 In situ hybridization of melatonin receptors in (A) HVC, (B) robust nucleus of the archipallium (RA), and (C) the nucleus tractus solitaries (nXIIts) of the zebra finch. *From Jansen et al. (2005).*

35.8 CONCLUSION

The selective pressures to breed and reproduce at the most advantageous times of year, when food is most likely to be present for the provision of young, are particularly strong in the many species of birds that express seasonal rhythms. This is largely due to the relatively large efforts birds expend raising their young. In addition, birds' complex life cycles require a concerted orchestration of seasonal events, ranging from migration to molt to courtship to reproduction and so on. This complex phenology shares a variety of mechanisms,

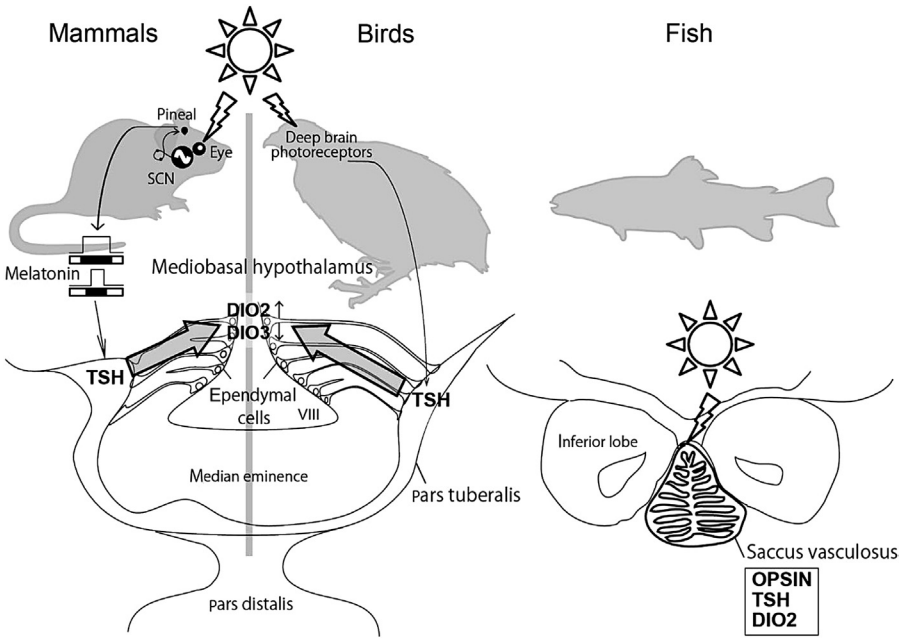

FIGURE 35.12 Vertebrates share common pathways for reproductive seasonality but vary in several aspects. In mammals, light information arrives in the tuberal hypothalamus via transduction of the pineal hormone melatonin within the pars tuberalis, while in birds and fish, tuberal hypothamic structures are directly light sensitive. The signal converge, however, through a common regulation of *DIO2* and *DIO3*.

but these are not completely known. In oscine passeriforms, for example, the mechanisms regulating primary reproductive function (which appear to be oscillators within the tuberal hypothalamus) seem to be functionally separated from those associated with courtship and song, which in part involve pineal melatonin. Future research focused on the coordination of other processes, such as migration, molt, and female reproduction, will go a long way toward fully understanding the complex seasonality of birds.

36.1 INTRODUCTION

Research into the mechanisms underlying the annual cycles of birds began in the 1920s with the pioneering work of Rowan (1925, 1926) exploring effects of changing photoperiod on migratory and reproductive physiology and behavior. Since that time, there has been major progress toward a deep understanding of these mechanisms at the organismal, cellular, and molecular levels. There also has been increasing investigation of the orchestration of transitions among stages of the entire annual schedule—not only the timing of breeding and migration—and exploration of seasonal changes in demanding processes, such as immune function, that must be maintained at all times. Current interest is high in the implications of timing mechanisms for responses to human-induced environmental changes, such as climate change. This chapter focuses on the current state of research on avian annual schedules, highlighting the areas of recent progress and interest. Birds continue to be exciting and productive models for understanding the basic mechanisms by which organisms respond to the environment, from molecular to whole-organism levels, and for revealing the importance of these mechanisms in evolution.

36.2 BACKGROUND: PATTERNS OF ENVIRONMENTAL VARIATION AND AVIAN ANNUAL SCHEDULES

Long-term changes of physiology, behavior, and morphology, orchestrated by the neuroendocrine and endocrine systems, are prominent in most species of birds. In many cases, these represent consistent annual cycles, particularly for species that spend all or part of the year at mid to high latitudes, where relevant changes in environmental conditions (the "ultimate factors" of Baker, 1938) track the seasons, but also in tropical areas with regular seasonal patterns of rainfall. Less regular long-term changes in physiology, behavior, and morphology prevail in species occupying environments where conditions change more erratically, such as certain deserts where rainfall is unpredictable (Perfito et al., 2007), or even in otherwise seasonal environments where variation in the food supply is not regularly seasonal for some reason (Hahn et al., 1997, 2008). In at least some of these species (e.g., crossbills), temporally flexible changes in physiology, behavior, and morphology are superimposed on underlying seasonal cycles (Hahn, 1995, 1998; Hahn et al., 1997, 2008; Cornelius and Hahn, 2012). In others (e.g., Darwin's finches), it remains unclear to what extent changes in reproductive physiology are entirely opportunistic versus based in part on an underlying seasonal program (Hau et al., 2004; Hahn et al., 2008).

Whether regularly seasonal or more flexible or erratic, annual schedules all must at least coordinate reproduction and plumage molt, and often also migrations and a nonbreeding "overwintering" stage (Wingfield, 2008). Timing and coordination of these processes are crucial to fitness, and mechanisms permitting this have responded to selection (Bradshaw and Holzapfel, 2007, 2010). The timing mechanisms that evolve are based on cue response systems that link neuroendocrine and endocrine regulatory mechanisms to "proximate factors" (Baker, 1938)—cues such as day length, temperature, food supply, and social

Sturkie's Avian Physiology.

interactions—that provide predictive information either in the short or long term regarding changing ultimate factors. These cue response systems generally include a long-term component that sets the time windows when particular cycle stages can occur and that dictates general features of physiological preparation for and termination of the stages, based on some combination of response to changing photoperiod and an endogenous program (the so-called initial predictive cues of Wingfield, 1980, 1985; Gwinner, 1986; Wingfield and Farner, 1993; Wingfield and Kenagy, 1991; Dawson, 2002; Bradshaw and Holzapfel, 2007; Wikelski et al., 2008; Helm et al., 2013). This long-term component is then combined with fine-tuning of precise timing by responses to more immediate cues that provide accurate short-term information about local conditions, such as changing temperature, weather, food supply itself, and behavioral cues from other individuals (Wingfield, 1980, 1985).

Annual schedules of different species vary in their complexity and therefore potentially in the mechanisms required to orchestrate them. The different components (e.g., reproduction, migration, plumage molt, overwintering) can theoretically overlap temporally or be separated into very distinct "finite states" of the annual schedule (Jacobs and Wingfield, 2000; Wingfield, 2008). Certain activities simply cannot overlap (e.g., egg laying, incubation, and care of nestlings are incompatible with migration), but many components of "breeding," such as the gonadal maturation process (Wingfield et al., 1992; Bauchinger et al., 2007, 2008, 2009), pair formation (Ganter et al., 2005), and extended parental care of fully mobile youngsters can be compatible with migration, and plumage molt need not be incompatible with any stage of reproduction (Bond et al., 2013) or migration (Yuri and Rohwer, 1997; Voelker and Rohwer, 1998). Coordination of reproduction, migration, and molt can be viewed as an overlap continuum, from near-complete temporal separation at one extreme to near-complete temporal overlap (within constraints noted above) at the other. A critical and fundamental trade-off is associated with this continuum. Specifically, greater overlap of components confers greater temporal flexibility but at the expense of scope for tolerance of variation in environmental conditions. Conversely, greater separation of components into distinct stages ("finite states") confers improved tolerance scope for environmental variation but at a cost to temporal flexibility.

Two relatively extreme examples illustrate this concept (Figure 36.1; Wingfield, 2008). A regular seasonal migrant, the Gambel's white-crowned sparrow (*Zonotrichia leucophrys gambelii*), displays a six-part annual schedule consisting of separate and minimally overlapping stages of overwintering, partial prealternate molt, vernal migration, breeding, complete prebasic molt, and autumnal migration. The phenotypic traits expressed during each of these stages broaden the scope of environmental variation (e.g., temperatures that can be endured, foods that are acceptable) the birds can tolerate across the entire year as compared with tolerances within any one stage. This benefit comes at a cost of temporal flexibility, however; breaking the year into multiple stages, each with unique phenotypic characteristics requiring time and energy to gear-up and terminate, reduces how nimbly the animal can adjust to any environmental changes that deviate from the normal routine it has evolved to track. In contrast, certain desert-dwelling reproductive opportunists, such as zebra finches (*Taeniopygia guttata*) in parts of the arid interior of Australia, display such extensive overlap between stages that no truly separate stages exist. Although the birds do not breed continuously, they can maintain near-readiness to breed for long periods of time, they apparently can move in search of better conditions at any time, and they display a low-intensity but essentially continuous plumage molt that may overlap with both breeding and any migratory movements that do occur (Cornelius et al., 2011). Expression of this single chimaera stage confers high temporal flexibility because any activity is possible at any time, but at the cost of scope for tolerating environmental extremes. This strategy is an example of the jack-of-all-trades being master of none (Huey and Hertz, 1984).

The capacity to express these different patterns depends on coordination mechanisms. Specifically, separation of the annual schedule into distinct stages requires mechanisms synchronizing the cycle with the environment, as well as mechanisms of coordination that limit overlap between stages, maintain the stages in an adaptive sequence, and orchestrate transitions from stage to stage so that processes involved in termination of one do not interfere with processes involved in development and onset of the next (Wingfield, 2008). In contrast, if components are to overlap partially or completely, mechanisms that facilitate this overlap must be present. The next section will address recent advances in understanding the mechanisms by which diverse annual schedules, from relatively fixed and seasonal to extremely flexible or opportunistic, are generated, with particular focus on the rapidly advancing field of avian photoperiodism. We return later to the question of whether these diverse patterns reflect adaptively specialized mechanisms or plastic outputs of common mechanistic underpinnings.

36.3 EFFECTS OF AND MECHANISMS OF RESPONSE TO PHOTOPERIOD AND OTHER ENVIRONMENTAL CUES

36.3.1 Photoperiodic Response

Annual schedules of reproduction, migration, plumage molt, and overwintering that track consistent seasonal changes in the environment have long been known to depend on proximate responses to changing photoperiod (Rowan, 1925, 1926; Dawson et al., 2001; Dawson, 2002; Sharp,

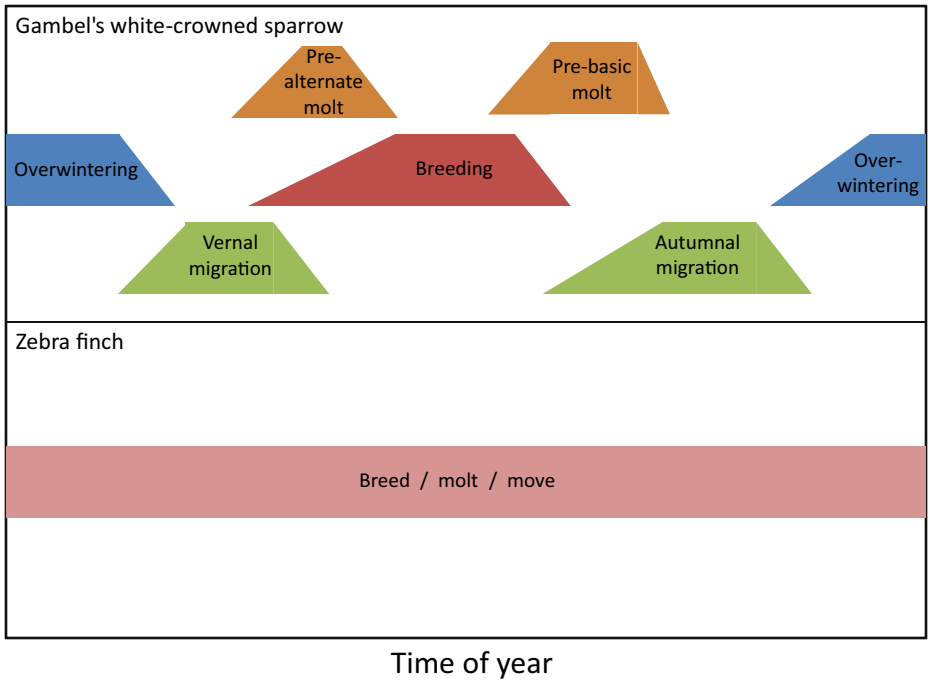

FIGURE 36.1 Diagrammatic representation of the multiple life cycle stages of a long-distance migrant seasonal breeder, the Gambel's white-crowned sparrow (*Zonotrichia leucophrys gambelii*, top panel), and of the single chimaera life stage of a nomadic reproductive opportunist, the zebra finch (*Taeniopygia guttata*, bottom panel). *Adapted from Wingfield (2008).*

2005; Dawson and Sharp, 2007; Bradshaw and Holzapfel, 2007). A system that uses photoperiod as a proximate cue for regulation of annual schedules, either as a driver or as an entrainer of an endogenous program, requires a combination of a mechanism for detecting light (photoreceptors), a mechanism for determining the length of the day (known in birds to depend on a circadian clock), and a mechanism for transducing the photoperiod information into neuroendocrine and endocrine signals that regulate the different components of the schedule, such as the septo-infundibular GnRH-I system that regulates reproduction (see Follett, 1984).

Recent advances in our understanding of how photoperiod may be measured and transduced into regulatory signals have been particularly impressive regarding photoperiodic regulation of reproductive cycles, although much remains to be done to flesh out details and to determine which mechanistic features are universal versus unique to particular species or populations. Most birds are long day breeders, and the annual reproductive cycle of seasonal breeders breaks naturally into three stages: sensitivity, stimulation, and refractoriness (see Goodson et al., 2005; Ball, 1993; Dawson et al., 2001). The transition from being *sensitive* to long days but reproductively inactive to *stimulated* by long days depends on interpretation of increasing day length as an activational cue. Birds possess a circadian cycle of photoinducibility, whereby light occurring during a window of circadian times is interpreted as a long day, and activation of the hypothalamo-pituitary-gonad axis results

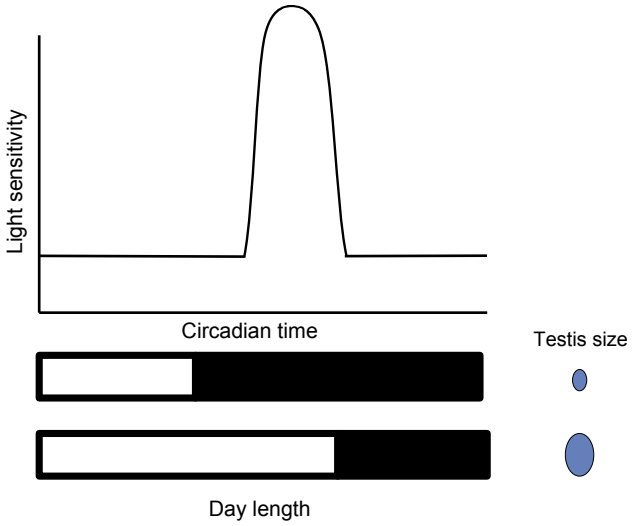

FIGURE 36.2 Illustration of the circadian cycle of photoinducibility displayed by photoperiodic birds. The reproductive system is responsive to the stimulatory effects of light during a particular phase of the circadian cycle, represented by the peak between about circadian hours 12 and 20 in the top panel. On short days, the light period always ends before this inducible phase begins; hypothalamo–pituitary activity remains minimal and gonads remain small (middle panel). On long days, the light period extends beyond the beginning of the inducible phase; hypothalamo–pituitary activity increases, and the gonads grow. Experiments manipulating the circadian time when short (8 h or less) pulses of light occur demonstrate that it is not how long it is light, but what circadian time it is light that determines whether the bird activates the reproductive axis (Hamner, 1963, 1964; Follett et al., 1974).

(Hamner, 1963, 1964; Follett et al., 1974; Figure 36.2). Recent discoveries have revealed new ideas regarding the process of light detection, evaluation of the day length, and transduction into neuroendocrine signals regulating changes in physiology, behavior, and morphology.

Detection of the light cue regulating seasonal cycles of birds has long been known not to be retinal (Benoit, 1935), and has been confirmed not to require either the retina or the pineal; all key components of avian photoperiodism—photostimulation and photorefractoriness in response to long days, and dissiptation of the refractory state in response to short days—are expressed normally in pinealectomized/enucleated American tree sparrows (*Spizella arborea*; Wilson, 1991). Deep brain photoreceptors are responsible for photodetection regulating seasonality in birds and other nonmammalian vertebrates (Silver et al., 1988; see reviews in Foster et al., 1994; Foster and Soni, 1998). These cerebrospinal fluid contacting neurons are thought to reside in the mediobasal hypothalamus (MBH) and/or lateral septum (LS); recent studies increasingly point to the cells in the LS as the key photodetectors in the avian photoneuroendocrine system (see Li et al., 2004). Details of how the long day cue is transduced are beginning to emerge, although virtually all of the work to date is restricted to Japanese quail (Figure 36.3). In quail, these photoreceptors (Opsin 5 positive CSF-contacting neurons) detect light, and when light occurs during the inducible phase of the circadian cycle of photoinducibility (see Figure 36.2), this long day signal is transmitted to thyroid-stimulating hormone (TSH)-producing cells in pars tuberalis (PT). TSH from these cells putatively acts on the nearby ependymal cells (ECs) lining the third ventricle (VIII), inducing transcription of the Dio2 gene that codes for the type 2 deiodinase enzyme responsible for converting T4 (thyroxine) to the physiologically active form T3 (3,5,3′-triiodothyronine). This TSH also induces down-regulation of expression of the Dio3 gene in these cells, thus reducing the deactivation paths from T4 to reverse T3 (rT3), and from T3 to T2 (3,3′-diiodothyronine), both inactive forms. Inside these ependymal cells, short days reduce T3 production by enhancing Dio3 expression, leading to increased conversion of T4 to rT3 and T3 to T2. When T3 is low, glial endfeet appear to ensheath axon terminals of gonadotropin-releasing hormone (GnRH-I) cells, separating them physically from the basal lamina in the median eminence (ME), thereby presumably obstructing GnRH-I secretion into the hypothalamo-hypophysial portal blood. As a result, gonadotropin release from the anterior pituitary remains low under short days. In contrast, under long days, Dio2 expression in the ECs is enhanced so T4 conversion to the biologically active T3 is emphasized. T3 release from the ECs is therefore high under long days, and this may cause retraction of the glial endfeet sheathes so that

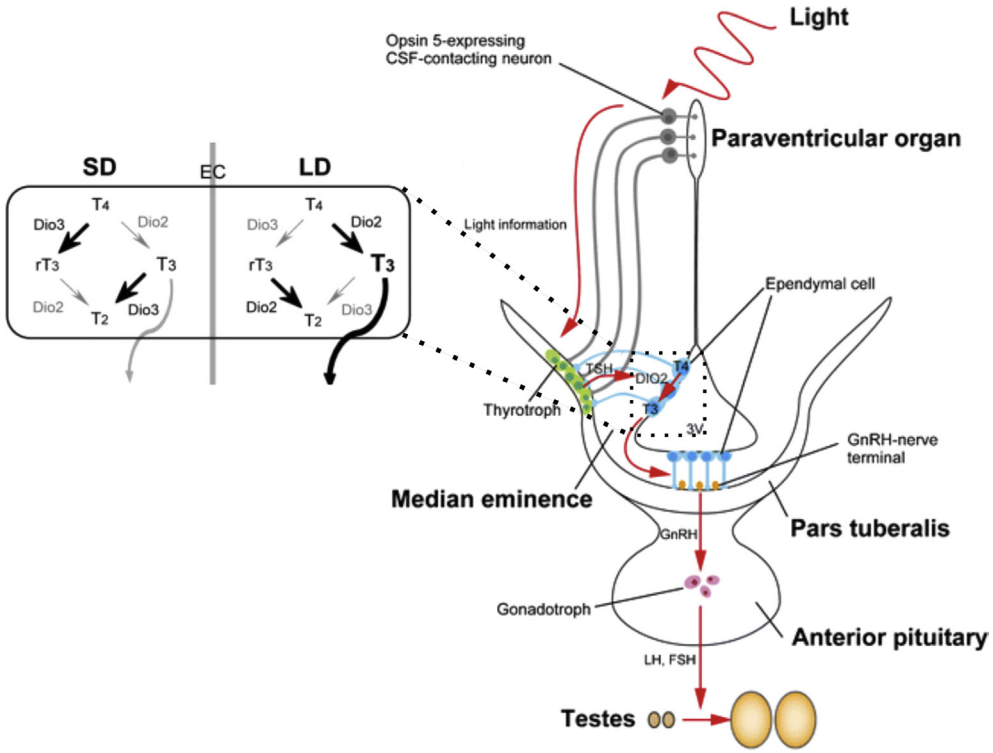

FIGURE 36.3 Illustration of the key components of the photoneuroendocrine system of the Japanese quail (*Coturnix japonica*). Inset at left shows the enzymatic pathways emphasized under short (SD, left) and long (LD, right) days in the ependymal cells (EC) lining the third ventricle. Full explanation in text. *After Ikegami and Yoshimura (2012).*

GnRH-I axon terminals are closely apposed to basal lamina and GnRH-I release is high, leading to high gonadotropin secretion and gonadal growth (see Ikegami and Yoshimura, 2012 for review).

Whether the scenario outlined above applies generally to photoperiodic regulation of avian seasonality or only to Japanese quail exposed to abrupt changes in photoperiod remains unclear at present. Seasonal changes in Dio2 and GnRH-I expression in European starlings (*Sturnus vulgaris*) allowed to breed in outdoor aviaries on naturally changing photoperiods are not consistent with the above quail-based model (Bentley et al., 2013). Specifically, breeding males with maximal testis volume and GnRH-I gene expression did not have significantly higher Dio2 expression in the MBH than did refractory individuals on declining photoperiods. Further, photosensitive individuals with small gonads on still-declining photoperiods in autumn had higher Dio2 expression than did photostimulated individuals in spring. It is not known whether this deviation from the pattern described for Japanese quail relates to phylogenetic differences, to differences in photoperiodic characteristics (starlings becoming absolutely refractory, whereas quail become only relatively refractory), or to differences resulting from the experimental conditions used (naturally changing photocycles for starlings, stepwise changes in photoperiod for quail). Regardless of the explanation, it is clear that more work testing the effects of different photoperiod conditions on a wider range of species is needed to identify robust general features of the neural mechanisms underlying photoperiodic regulation of annual schedules in birds (Bentley et al., 2013).

The mechanistic details of the connection between a circadian cycle of photoinducibility and the decision of the photoneuroendocrine system to increase TSH within the PT remain obscure at present. However, it is noteworthy that cells within the MBH maintain steady expression profiles of key clock genes under different photo-regimes, consistent with the possibility that they are responsible fundamentally for maintaining the temporal phasing of photoinducibility (Yasuo et al., 2003; see also Ikegami and Yoshimura, 2012).

The above details apply to the process of photostimulation, which leads to development of the reproductive axis as well as preparations for spring migration. Mechanisms underlying photorefractoriness, regulation of the timing of molt, autumn migration, and the dissipation of the refractory state are much less well-studied, but the basic structure of the entire annual schedule likely depends on the seasonallychanging responses to photoperiod. The transition out of the reproductive state generally depends on development of photorefractoriness (Nicholls et al., 1988; Hahn et al., 1997; Hahn and MacDougall-Shackleton, 2008). Expression of absolute photorefractoriness is a two-stage process, first involving cessation of release of GnRH-I at the median eminence, followed by a dramatic decline in the presence of the GnRH-I peptide and reduction in transcription of the GnRH-I gene (Ubuka et al., 2009; Stevenson et al., 2009, 2011; see Stevenson et al., 2012 for review). Return of photosensitivity is associated with reappearance of the GnRH-I peptide first in the preoptic area, followed by the median eminence in European starlings (Dawson and Goldsmith, 1997); as refractoriness dissipates, birds become progressively more responsive to long days (Hamner, 1968). Species vary in the extent to which steroid feedback during fall and winter helps to keep gonadotropin secretion of photosensitive individuals in check until days increase sufficiently for photostimulation (Cockrem, 1995).

36.3.2 Processing of Nonphotic Cues

There is much more information on the phenomenology and physiological consequences of the effects of nonphotic cues on annual schedules than there is on the mechanisms by which these cues are processed. This section will discuss effects of a variety of nonphotic cues on annual schedules.

36.3.2.1 Effects of Temperature

Ambient temperature is correlated with local variation in vegetation and food phenology and consequently can be a valuable supplementary proximate cue fine-tuning timing of transitions between life cycle stages. Experimental studies reveal effects of temperature on reproductive development under photostimulation (Wingfield et al., 1997, 2003; Perfito et al., 2005; Silverin et al., 2008; Caro and Visser, 2009; Visser et al., 2009, 2011; Schaper et al., 2012), on the transition from reproduction to photorefractoriness and molt (Wingfield et al., 1996, 1997, 2003; Wada, 1993; Wada et al., 1990; Dawson, 2005; Silverin et al., 2008; Visser et al., 2011), and on preparations for spring and/or fall migration (white-crowned sparrows: Wingfield et al., 1996, 1997, 2003). The effects on reproductive development appear to be locally adapted as functions of breeding latitude (Wingfield et al., 1996, 1997, 2003; Silverin et al., 2008, Figure 36.4), elevation (Perfito et al., 2005), and status as a migrant or resident (Meijer et al., 1999; Dawson, 2005). These findings support theoretical predictions that populations inhabiting more predictable environments will be less responsive to supplementary environmental cues than those inhabiting less predictable environments (Wingfield et al., 1992, 1993). Birds appear to be more responsive to temperature increases across the season than to average daily temperatures or daily temperature fluctuations (Schaper et al., 2012). It is important to note that different results have been obtained when using different artificial fixed photoperiods (Silverin and Viebke, 1994; Silverin et al., 2008) or using naturally changing photoperiods versus artificially long or short days (Dawson, 2005).

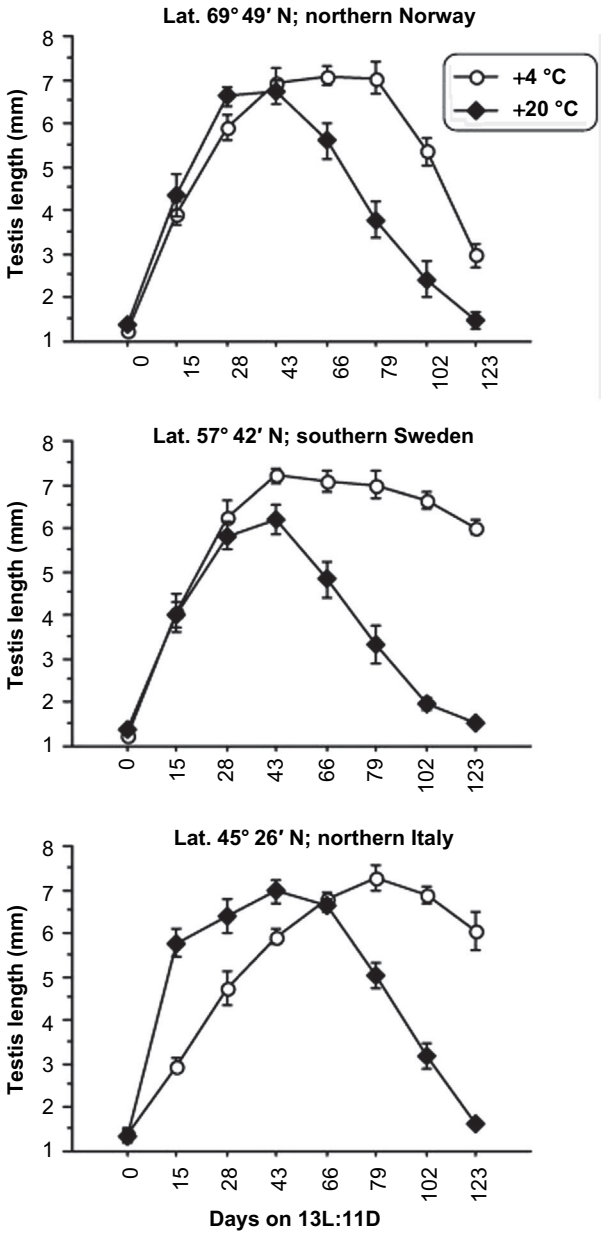

FIGURE 36.4 Effects of different temperature treatments on photoinduced gonadal development in male great tits (*Parus major*) from populations living at three different latitudes. Low temperatures delayed termination of reproductive competence in all three populations but only affected rate of gonadal development in the lowest latitude population. *From Silverin et al. (2008).*

The influence of temperature on the onset of refractoriness and the transition to molt and fall migration has been less well studied. Persistent low temperatures under photostimulation retard the transition to gonadal regression and progression of molt while persistent high temperatures advance these life history stages (Wingfield et al., 1997, 2003). High temperatures under photostimulation also cause earlier gonadal regression in European starlings (Dawson, 2005) and great tits (Silverin et al., 2008; Visser et al., 2011). Some of the most detailed investigations on the role of temperature during the transition from reproduction to photorefractoriness have been conducted in Japanese quail. Some strains of Japanese quail express relative photorefractoriness simply when exposed to a decline in photoperiod after a period of reproductive maturity (Robinson and Follett, 1982). Others do not express refractoriness without a concomitant decline in ambient temperature (Wada, 1993; Wada et al., 1990).

A few studies suggest that the annual schedule of males and females responds differently to temperature cues. High temperatures advanced brood patch and follicular development in female Puget Sound white-crowned sparrows, while testis development in males was unaffected (Wingfield et al., 1997).

Several pathways may be involved in the integration of temperature information with other physiological systems. Early studies found no difference in luteinizing hormone (LH) secretion associated with temperature treatment despite differences in gonadal development (Wingfield et al., 1996, 1997, 2003). However, three populations of great tits did display differences in timing of LH secretion with temperature treatment (Silverin et al., 2008). Thyroid hormones and prolactin are also likely candidates for mediating temperature effects (Caro et al., 2013). In one strain of domesticated Japanese quail, the transition to refractoriness appears to require temperature-dependent conversion of T4 to T3 (Wada, 1993; Wada et al., 1990). It would be particularly interesting to explore the temperature dependence of local production of T3 in the MBH of this strain of quail in light of recent discoveries regarding this process in quail photoperiodism (see above). Additional studies propose that thyroid hormones, as mediators of metabolism, may play a role in reproductive timing through changes in energy balance (see below.)

Results of studies investigating the role of prolactin in transducing temperature signals to gonadal development and regression have been inconclusive (Maney et al., 1999; Perfito et al., 2005; Dawson and Sharp, 2010). Differences in prolactin were associated with temperature treatments and gonadal development in female *Z. l. pugetensis* and male and female *Z. l. oriantha* but not in *Z. l. gambelii*, consistent with observed patterns of temperature sensitivity in these taxa (Maney et al., 1999). However, prolactin levels did not differ in high and low temperature treatments in two populations of song sparrows (Perfito et al., 2005); work in starlings provides no support for changes in prolactin levels leading to the advancement of photorefractoriness under high temperatures (Dawson and Sharp, 2010).

Temperature could influence seasonal timing by acting directly on effectors or indirectly through energy balance (Caro et al., 2013; Meijer et al., 1999). Because temperature affects thermoregulatory costs, the amount of energy available for various processes will be altered by

ambient temperature, and this may affect timing of transitions between stages (Meijer et al., 1999). Although this is an intriguing possibility, this hypothesis has not been rigorously tested and the mechanisms by which physiological decisions about energy allocation are made remain largely unknown. Great tits exposed to high and low temperature treatments did differ in oxygen consumption, but without coincident differences in testis growth rate (Caro and Visser, 2009). This implies no energetic constraint of temperature on gonadal growth in males; however, other trade-offs, such as a decrease in immune function, were not investigated. In house sparrows, basal metabolic rate and thyroid hormone levels were positively associated, and early breeding birds had an earlier peak in thyroid hormone than late breeding birds (Chastel et al., 2003). Perhaps late breeders face a metabolic constraint that prevents them from breeding early, and thyroid hormones play a role in mediating this relationship (Chastel et al., 2003). Further studies, especially investigations including females who face greater energy demands during follicle maturation, are needed.

The mechanisms by which environmental temperatures influence behavioral timing remain a mystery. It is still unclear how the temperature cues that influence seasonal timing are detected or how are those cues are integrated with systems that control changes in morphology, physiology and behavior. Typically, ambient temperature is detected by thermoreceptors in the periphery. It is possible that these receptors may detect seasonal changes in temperature, although this has not been explored (Caro et al., 2013).

36.3.2.2 Effects of Food

Birds living in seasonally fluctuating environments time reproduction to coincide with periods of high food availability as well as availability of specific foods required by the young (Lack, 1968; Perrins, 1970); individuals that match rearing of young with peak food supply generally enjoy relatively high reproductive success (Perrins, 1991; Nager and van Noordwijk, 1995; van Noordwijk et al., 1995). Indeed, the evolution of the entire photoneuroendocrine timing system in birds has presumably evolved as a consequence of selection for tracking seasonal changes in food supply. However, food itself is also a potent supplementary proximate factor (Hahn et al., 2005) that can assist in fine tuning transitions of the annual schedule to local conditions. Studies of the proximate effects of food on annual schedules include correlative field studies, experimental field studies, and experimental studies with captive birds.

It can be challenging to relate food supply to annual scheduling when birds consume a wide variety of foods, but specialist taxa, such as crossbills (*Loxia* spp.), provide unique opportunities in this regard. Field studies of crossbills show close correspondence between breeding and intake rates of conifer seeds in these nomadic opportunistic breeders (Benkman, 1990). Crossbills also make the transition from breeding to molt earlier in years of low cone crops (Cornelius, Schultz, and Hahn, unpublished data), but this could be simply because the birds forego breeding or terminate it earlier in years with low food supply, not because low food "stimulates" molt. However, reducing food is a well-established means of stimulating the transition from egg-laying to molt in domestic poultry (see Yousaf and Chaudhry, 2008 for review), so it remains plausible that this transition responds directly to food supply as a proximate cue in free-living populations as well. There is some evidence that natural changes in food supply affect migration schedule. For instance, free-living American redstarts alter spring departure date interannually as a function of variation in rainfall and arthropod abundance (Studds and Marra, 2011). Likewise, redstarts wintering in higher quality (wetter, better food supply) habitats arrive on the breeding grounds earlier than those from lower quality wintering habitat (Tonra et al., 2011; Marra et al., 1998). Drought in stopover areas has been implicated in dramatic delays in arrival on breeding grounds by trans-Saharan migrants, probably because of reduced refueling rates owing to poor food supplies (Tøttrup et al., 2012). Some experimental evidence also supports the interpretation that food supply can affect timing of migration. Free-living American redstarts that are experimentally "upgraded" from low-quality habitat by creating vacancies for them in nearby high-quality habitat show earlier spring migration departure (Studds and Marra, 2005). Likewise, dark-eyed juncos brought temporarily into captivity and subjected to experimental diets (restricted versus copious) varied in migration departure date (inferred from resighting surveys after release), with individuals displaying higher body condition indices departing earlier (Bridge et al., 2010). Together these data are consistent with the idea that food supply can act as a supplementary cue, influencing details of migration timing under major control by photoperiod and/or an endogenous program. Some irruptive species, such as crossbills, appear to be able to initiate long-distance movements at most times of year, and these movements probably are in direct response to declines in food supply. Experimental studies with captive crossbills indicate that these birds are very sensitive to changes in food supply, modifying activity, fat deposition, and circulating corticosterone levels in ways consistent with the hypothesis that they use food availability as a cue to regulate timing of migratory movements (Cornelius et al., 2010).

Numerous studies have been performed in the field and a few in captivity manipulating aspects of food supply to determine how responsive the reproductive axis is to food as a proximate cue. Food supplementation of free-living birds generally advances timing of egg-laying (Arcese and Smith, 1988; Meijer et al., 1990; Schoech, 1996; Nager et al., 1997). Availability of calories is not all that matters.

For instance, in calcium-poor environments, calcium supplementation can significantly advance egg laying date (Mand et al., 2000). Some of the most elegant field experiments have provided groups of free-living Florida scrub jays with isocaloric food supplementation that differs in protein content. Although food supplementation with either high protein or low protein pellets advanced egg-laying date compared with unsupplemented controls, the high protein supplement advanced lay date significantly more than did the low protein supplement (Schoech et al., 2004). Meta-analyses of the results of field experiments reveal a latitude effect on responsiveness to food supplementation; high latitude populations are less responsive to the advancing effects of food supplementation than are low latitude populations (Schoech and Hahn, 2007). However the representation of low latitude populations in this analysis is very small. Further, the apparent latitude effect is probably more directly the consequence of whether populations are single or multiple brooded (Dhondt, 2010). In any case, these analyses are consistent with the interpretation that populations are locally adapted in terms of responsiveness to supplementary cues fine tuning reproductive timing.

Food manipulations with captive birds generally reveal at most very subtle effects of food alone on reproductive development (in the absence of concomitant photostimulation), even in flexible breeders such as crossbills (Hahn et al., 2005). However effects of food manipulations in photostimulated birds can be quite dramatic. For instance, pine siskins (*Spinus pinus*) on modestly stimulatory photoperiod provided seeds in addition to commercial pellets show dramatically advanced gonadal development compared with those lacking seeds, and this effect occurs irrespective of social environment (Watts and Hahn, 2012, Figure 36.5).

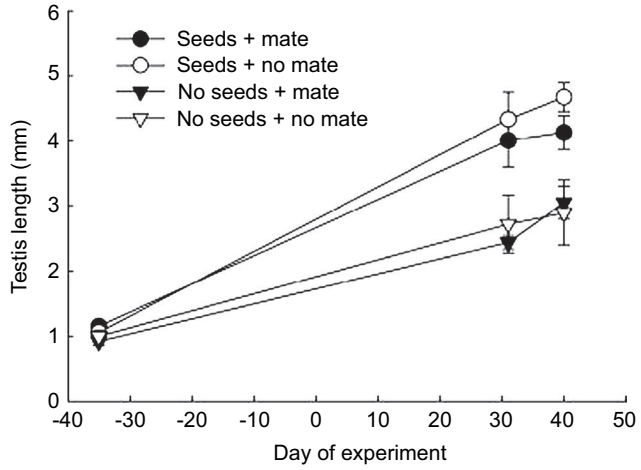

FIGURE 36.5 Effect of provisioning with sunflower seeds in addition to commercial pellet diet as compared with pellet diet alone in pine siskins (*Spinus pinus*). Access to seeds accelerated photoinduced gonadal development comparably whether or not the males were housed with a conspecific female. *From Watts and Hahn (2012).*

In tropical spotted antbirds (*Hylophylax naevioides*), food cues can have dramatic effects on timing of reproductive development (Hau et al., 2000; O'Brien and Hau, 2005), and at least part of this effect appears to be via nonnutritional pathways; exposure to live insect food, even if it cannot be eaten, has a pronounced positive effect on singing behavior (Hau et al., 2000). This is similar to some flexibly breeding temperate zone species, such as pinyon jays, which can show late summer reproductive development if allowed to handle as well as consume seeds from fresh developing pinyon pine cones (Ligon, 1974). It is important to note that effects of long days on reproductive development could potentially be explained in part by increases in food intake under longer days, however experimental restriction of time available to feed or amount of food provided to short-day levels reveal only modest effects of food as compared with photoperiod, even in the very flexible crossbills (see Dawson, 1986; Hahn, 1995; Hahn et al., 2005).

It remains important to consider the extent to which effects of food are direct ("income" effects) or operate through effects on body condition and reserves ("capital" effects; Meijer and Drent, 1999). At least part of the effect of elevated protein on laying date in scrub-jays is likely to be through improved condition and protein reserves in females (i.e., may be a capital effect; see Schoech et al., 2004). Capital effects on reproductive output are well-known in large birds (e.g., snow geese; Ankney and MacInnes, 1978), but some of the effects in food supplementation experiments are consistent with nutrient reserves (capital effects) influencing reproductive timing of small passerines as well (see Arcese and Smith, 1988).

36.3.2.3 *Effects of Behavioral Factors*

Behavioral interactions between conspecifics can provide valuable information for fine-tuning timing of transitions of physiology, behavior, and morphology, and are essential for coordination of pair, family, and group activities (Wingfield and Marler, 1988).

Two excellent examples of the influence of social factors on annual scheduling come from experimental studies of the transition from reproduction to molt in songbirds. Photostimulated captive male European starlings delay gonadal collapse and onset of molt when housed with females (Schwab and Lott, 1969). Co-habiting with photostimulated females is now known to affect GnRH-I gene transcription in the septo-infundibular GnRH-I system of male starlings (Stevenson and Ball, 2009), supporting a centrally-mediated signalized mechanism for the delaying effects of females on males' transition out of the breeding state to refractoriness and molt. Likewise, free-living male song sparrows (*Melospiza melodia melodia*) delay gonadal collapse and molt when paired to females whose reproductive competence is experimentally

prolonged with exogenous estradiol. This effect is unique to males: female song sparrows paired with testosterone-implanted males show no such socially-mediated delay of the breeding-molt transition, despite their mates remaining reproductively active, territorial, and delaying molt themselves.

Although there are potentially multiple sensory modalities through which behavioral interactions might influence individual schedules, acoustic stimuli from conspecifics have received more attention than any others. Male song has potent effects on female reproductive development (see Bentley et al., 2000 for review), and these effects can be very rapid. For instance, female white-throated sparrows (*Zonotrichia albicollis*) exposed to male song show rapid (within 1 h) elevation of circulating LH and enhanced Egr-1 (ZENK) immediate early gene expression in the mediobasal hypothalamus (Maney et al., 2007a,b). These studies reveal at least parts of the picture regarding how the annual schedule may be affected by these types of cues, and again highlight the role of the MBH in processing environmental cues that regulate annual schedules.

36.3.3 Integration of Multiple Cue Types: Parallel or Serial Processing?

One fundamental question about how different kinds of cues are processed and integrated relates to whether there is a hierarchy of cues, one or more of which must be stimulatory or at least permissive before others can have their effects (i.e., cues acting in series), or whether different cues can substitute for one another (i.e., cues acting in parallel). As noted above, at least for many species, the general role of endogenous mechanisms combined with seasonal changes in photoperiod take a primary role in a hierarchy of cue processing; days must first be above a certain threshold in length and/or the bird must be at the correct phase of an annual program before other cues can have an influence. This fits well with the general paradigm envisioned by Wingfield (1980, 1985), in which supplementary cues and synchronizing and integrating cues serve to fine-tune the development of a life cycle stage that has been initiated by initial predictive cues. Few studies permit evaluation of whether this cue hierarchy exists, but female white-crowned sparrows (*Z. l. gambelii*) only show enhanced reproductive development with exposure to male song if they are also photostimulated (Morton et al., 1985). It is possible, however, for cues to operate in parallel. That is, the same outcome of initiation of a life cycle stage might be achieved either through stimulation with one type of cue or with another, but both are not necessary, and neither takes hierarchical priority (i.e., is necessary before the other can have its effect). Red crossbills (*Loxia curvirostra*) provide a possible example of this type of processing. These birds can be in full reproductive condition and breed in the wild on both the shortest and longest days of the year (Berthold and Gwinner, 1978; Hahn, 1998), and in outdoor aviaries they can come into full breeding condition in January, when days have barely begun to increase in length and when temperatures are low, as long as they have unlimited food and a mate (Hahn et al., 1995). They also come into near-full breeding condition under long-day stimulation even if they do not have mates (Hahn, 1995). These findings are consistent with the interpretation that long days and some combination of abundant food and mates can essentially substitute for one another in terms of stimulating the reproductive system in some species.

In some cases, cue hierarchies may deviate from those described above. An experimental study of zebra finches showed that enhanced food alone or in combination with long days could accelerate reproductive development, whereas long days were not stimulatory if food supply was mildly restricted (Perfito et al., 2008). These data are consistent with the interpretation that changes in food may actually act as the initial predictive cues for certain opportunists (see Hahn et al., 1997), and any effects of photoperiod may either be permissive or mediated through time available to eat, unlike in many temperature zone photoperiodic species.

It is unclear whether it is more productive to think of endogenous programs and photoperiod—both considered to be forms of initial predictive cues by Wingfield (1980, 1985)—as interacting in a hierarchical fashion, or simply as complementary components of the annual scheduling process. The phase of the annual cycle (e.g., whether refractory or not) definitely determines the nature of the response to photoperiod, but photoperiodic history also has dramatic effects on whether and when transitions between stages of the annual schedule occur (see Gwinner, 1986). However, the fact that annual schedules of many species persist in the absence of clear timing cues from the environment seems consistent with the idea that it may be most appropriate to consider the endogenous ("innate") component as primary, and the modulatory effects of the environment as secondary, at least for some species.

36.4 ADAPTIVE VARIATION IN CUE PROCESSING MECHANISMS AS IT RELATES TO LIFE IN DIFFERENT ENVIRONMENTS

There is abundant evidence of adaptive variation in life cycle scheduling in different environments, and some evidence of adaptive variation in underlying mechanisms. There has been substantial focus on variation in photoperiodic regulation of reproductive development (Lofts and Murton, 1968; Lambrechts and Perret, 2000; Lambrechts et al., 1996, 1997; Hahn et al., 2009; Helm, 2009; Liedvogel et al., 2009; Caprioli et al., 2012), photorefractoriness (Lofts and Murton, 1968; Nicholls et al., 1988; Hahn and MacDougall-Shackleton, 2008; Hahn et al., 2009), as well

as timing of molt and migratory restlessness (see Gwinner, 1986 for review).

One of the key distinctions that must be established is whether interpopulation variation in annual schedules is the consequence of evolved differences in endogenous timing mechanisms and responsiveness to environmental cues or simply a result of populations experiencing different environmental conditions. This problem can be addressed in several different ways. Examination of the phylogenetic distribution of reproductive photorefractoriness is consistent with the interpretation that failure to demonstrate refractoriness is a derived trait associated specifically with the most flexible or opportunistic annual schedules (Hahn and MacDougall-Shackleton, 2008). Thus, birds such as crossbills, zebra finches, and some tropical taxa with particularly flexible annual schedules fail to develop absolute photorefractoriness when exposed to extended periods of constant long days. Such taxa wait for input from the environment before making the transition from reproduction to molt and reproductive quiescence, in contrast to most temperate zone seasonal breeders, which spontaneously enter molt and collapse the reproductive system after some period of reproductive activity, even if the environment provides no direct information about impending deterioration of environmental conditions (Nicholls et al., 1988). Evolutionary loss of absolute photorefractoriness is, then, an adaptive specialization in these highly flexible taxa (Hahn and MacDougall-Shackleton, 2008).

Another way of investigating whether intertaxon variation in schedules represents adaptation to different environments is to look for evidence of a genetic basis for the observed variation. This has been reviewed copiously in the context of avian circannual rhythms by Gwinner (1986); a number of species of migratory songbirds display good evidence of robust differences in timing of diverse elements of their annual schedules (e.g., molt, migratory restlessness, body mass, reproductive condition) that persist in the absence of changing environmental conditions (see Gwinner, 1986). In addition, many studies demonstrate persistent interpopulation differences in scheduling under common garden constant conditions and intermediate scheduling phenotypes in F1 hybrids between different populations (see Gwinner, 1986 for review). Some more recent studies look specifically at heritability (a prerequisite for adaptive change in response to selection) as well as population-level response to artificially applied selection. For instance, variation in timing of onset of autumn migratory activity of blackcaps (*Sylvia atricapilla*) is heritable, and two generations of directional selection for later migration onset led to a 10-day shift in mean date of onset of autumn migratory restlessness (Pulido et al., 2001). This result supports the interpretation that at least some populations contain heritable variation in scheduling traits that is responsive to selection.

An elegant demonstration of adaptive variation in annual scheduling combined common garden manipulations of photoperiod with studies of hybrids between two subspecies of stonechats (*Saxicola torquata*) that differ in natural annual schedules (Helm et al., 2009, Figure 36.6). European stonechats undergo earlier reproductive development, remain in reproductive condition longer, and show a more protracted postbreeding plumage molt than do Siberian

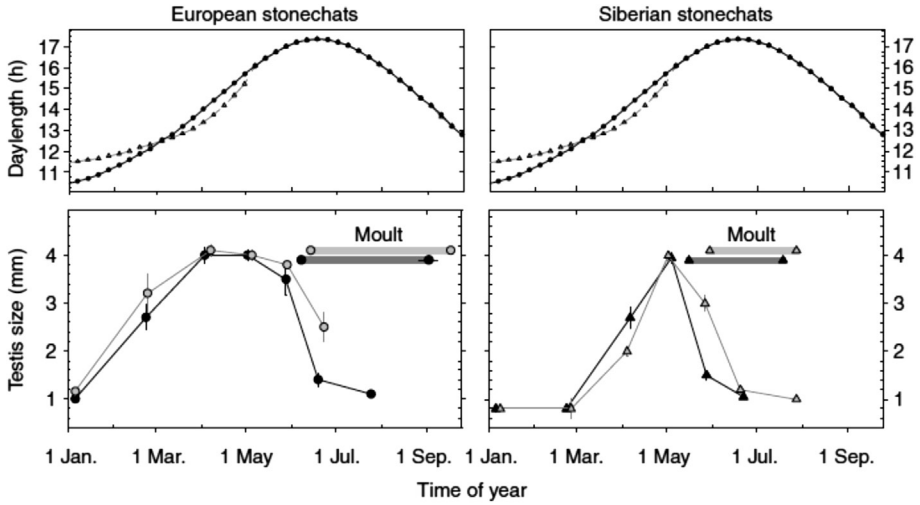

FIGURE 36.6 Comparison of patterns of gonadal development and plumage molt in European and Siberian stonechats (*Saxicola torquata*) exposed either to the photocycle typical for their own population or that typical of the other subspecies. In the bottom left panel, response of European stonechats exposed to photocycle typical of free-living members of their population is illustrated by black line and filled dots, and by darker molt bar; response of those exposed to photocycle typical of the Siberian population is illustrated by finer line and open circles, and by the paler molt bar. In the bottom right panel, response of Siberian stonechats exposed to photocycle typical of free-living members of their population is illustrated by finer line and open triangles, and by paler molt bar; response of those exposed to photocycle typical of the European population is illustrated by the darker line and black triangles, and by the darker molt bar. *From Helm et al. (2009).*

stonechats. These differences could in theory result from environmental condition-dependent plasticity. However, birds from the two different populations show persistence of the key differences in schedules when held under identical constant photoperiod, and F1 hybrids between the two display intermediate scheduling characteristics. Further, exposure to the subtly different photocycles that the different populations would experience on their different migration and wintering areas (summer photoperiods for the two are similar) produce different outcomes in the two populations. European stonechats exposed to seasonal photoregimes typical of the wintering and migration experience of Siberian stonechats shift onset of reproductive development even earlier and retain their prolonged period of reproductive competence and protracted molt. In contrast, Siberian stonechats exposed to the European seasonal photoregime only slightly advance onset of reproductive development, and retain their brief periods of reproduction and molt (Helm et al., 2009). This study thus shows that the specific annual schedules of these two subspecies differ because of an interaction between differences in both endogenous programming and in the phase-dependent response of the system to environmental inputs, not simply because the environments they experience differ.

36.5 INTEGRATED COORDINATION OF STAGES AND CARRYOVER EFFECTS

As noted above, stages of the annual cycle do not exist as separate entities but are intricately linked with the stages preceding and following them. The transition from one stage to the next involves termination of one stage and development of the next (Wingfield, 2008), each of which requires mechanistic control. This may involve one mechanism controlling both termination of one and development of the next or separate mechanisms. The first scenario could ensure that stages follow in the correct sequence throughout the year. For instance, in the transition from breeding to prebasic molt, the inactivation of the hypothalamus-pituitary-gonadal axis (HPG) axis as photorefractoriness develops leads to a precipitous decline in circulating sex steroids. This decline results in regression of secondary sex characteristics (e.g., cloacal protuberance, beak color, brood patch) and declines in song and courtship as well as facilitating the final stages of parental care in males (Nicholls et al., 1988; Hahn et al., 1997; Hahn and MacDougall-Shackleton, 2008). Because sex steroids inhibit molt, the decline in their levels allows molt to proceed (Schleussner et al., 1985; Nolan et al., 1992; Dawson, 1994, 2004).

However, stages occurring in the correct sequence could also result from two separate mechanisms controlling termination and development phases of adjacent stages. This is possible if one mechanism provides a trigger for the next. As with the breeding-molt transition example above, although photorefractoriness and the resulting decline in sex steroids is important for terminating breeding and the onset of molt, other physiological changes are occurring. Changes in prolactin and thyroid hormones have long been thought to be necessary for molt, but whether these are simply correlated events or play causal roles remains unresolved (Dawson, 2006, 2008; Mishra et al., 2004).

How transitions between stages are coordinated (e.g., whether stages overlap or remain distinct) has important consequences. One major source of these consequences is a phenomenon called carry-over effects, which occur when processes or conditions in one stage affect timing or performance in subsequent stages (Norris and Marra, 2007, Harrison et al., 2011). Most studies of carry-over effects examine individuals, but population-level consequences also may occur (Norris and Marra, 2007). At the individual level, carry-over effects often result from the constraint that transitional stage overlap can place on energy or resource allocation. An example of stage overlap and resulting carry-over effects occurs when the development of the breeding stage overlaps with the final phases of the preceding vernal migration stage. Many physiological changes take place during the transition between migration and breeding, including changes in musculature, nutrient and energy reserves, fat deposition, organ size and functioning associated with gonadal development and migration termination, as well as hormone and yolk precursor level changes (Arizmendi-Mejía et al., 2013). For example, female Macaroni penguins (*Eudyptes chrysolophus*) initiate vitellogenesis (yolk production) while they are still at sea migrating to the breeding territory (Crossin et al., 2010). With greater overlap of breeding preparation during migration, Macaroni penguins are able to start laying eggs sooner upon arrival. However, simultaneous expression of these functions constrains the rate of egg formation, as evidenced by lower vitellogenin levels, and therefore lower reproductive readiness, upon arrival in late-arriving females. This effect carries over to influence the size difference between the two eggs in the clutch (Crossin et al., 2010, Figure 36.7).

Similarly, the transition from migration to breeding stages in female black-browed albatrosses (*Thalassarche melanophrys*) involves a carry-over effect on the breeding stage as a result of processes occurring during migration. Postmigratory condition (weight and hematocrit) and reproductive readiness (progesterone (P4), testosterone (T), and vitellogenin levels (VTG)) were lower in females that ended up deferring breeding compared with those who did lay eggs. This suggests a resource- or condition-based allocation trade-off underlying this carry-over effect in which returning females in better condition (those that cope more effectively with the metabolic demands of migration) are more likely to initiate breeding. Furthermore, of the birds that attempted breeding, success was associated with low T and high VTG levels, compared with failed breeders whose

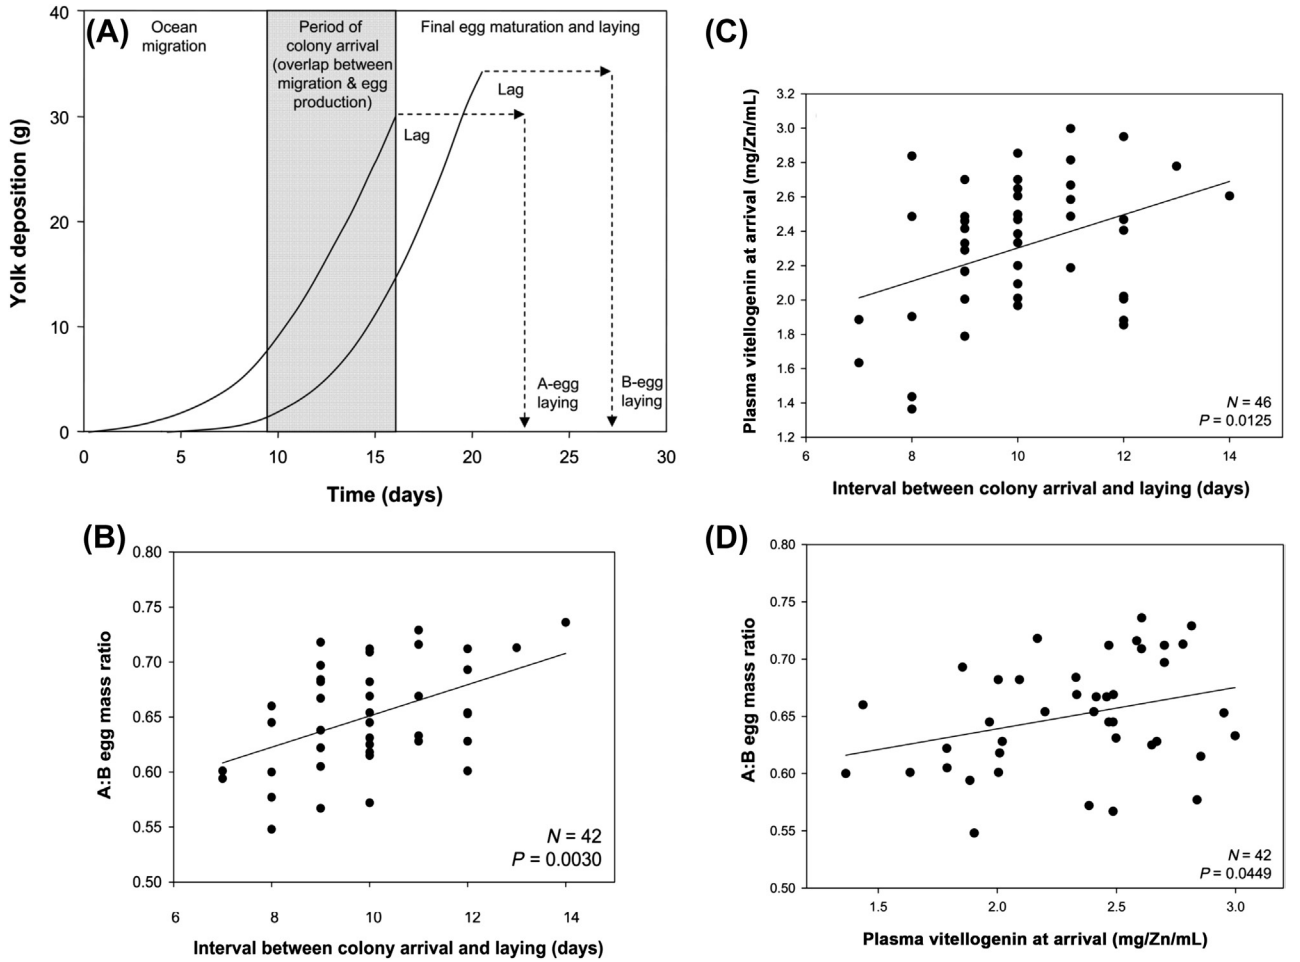

FIGURE 36.7 Egg formation process and timing during migration and colony arrival in female macaroni penguins (graph A). Degree of overlap between migration and yolk deposition influences the interval between colony arrival and laying (lag time). This interval affects egg size dimorphism (graph B) and plasma vitellogenin levels at arrival (graph C). Vitellogenin at arrival also predicts egg size dimorphism (graph D). Lines are best linear fit. *From Crossin et al. (2010).*

eggs did not hatch. This finding suggests another possible mechanism underlying carry-over effects: conflicting physiological processes. The differences in T and VTG levels between successful and failed breeders indicates a potential difference in the levels of aromatization from T to estradiol (E2), a necessary step in the process of vitellogensis (E2 stimulates vitellogenesis in the liver). The inhibition of aromatization, possibly by a stress-related mechanism, may be influencing the migration-breeding transition and its resulting carry-over effects.

Reproductive decisions and outcomes are influenced by processes occurring earlier, during the migration stage; however, processes even earlier, during the wintering stage, can have carry-over effects on migration and breeding (Marra et al., 1998; Studds & Marra, 2005; Norris et al., 2004). For example, American redstarts wintering in low-quality, drier scrub habitats are in poorer body condition and have higher corticosterone levels than those in wetter habitats (Marra et al., 1998). Both males and females wintering in drier areas, as well as those in poorer physical condition in general, tend to depart for migration later (Marra et al., 1998). This effect was shown experimentally, when birds that were upgraded from low- to high-quality winter habitats had higher body mass and departed earlier than controls (Studds and Marra, 2005). High-quality wintering grounds translate into earlier arrival on breeding grounds and higher reproductive success Norris et al., 2004). Males arriving earlier from better wintering grounds sired more offspring, both within-pair and extra-pair, and had greater fledging success (Norris et al., 2004). Early-arriving females started laying and fledging young earlier; high-quality winter habitat predicted production of at least two more young than for females from poor-quality wintering grounds (Norris et al., 2004). Similarly, as already described above, food supplementation during the overwintering stage can lead to advancement of onset of egg laying and improved reproductive success, processes occurring

weeks to months postsupplementation, in song sparrows, kestrels, and scrub jays (Arcese and Smith, 1988; Meijer et al., 1988; Schoech, 1996). Further, female snow geese arriving on breeding grounds with higher nutrient reserves had more ovarian follicles, suggesting a larger potential clutch (Ankney and MacInnes, 1978). All of these examples illustrate potential carryover effects of the ability to obtain food during one stage on transition to, and performance in, following stages.

Carry-over effects such as these often are presumed to result from resource allocation trade-offs. However, studies documenting such tradeoffs often lack direct evidence to support this underlying mechanism (Harrison et al., 2011). In Cassin's auklets (*Ptychoramphus aleuticus*), a resource allocation trade-off based on quality of pre-breeding diet, as measured by stable isotopes in body feathers grown during prealternate molt, directly influenced laying date. Female auklets that consumed more energy-rich copepods during the period prior to breeding began laying earlier and laid larger eggs than those that consumed more energy-poor juvenile rockfish. Although studies like these help to illuminate the potential mechanisms responsible for carry-over effects (and also provide additional examples of responses of annual schedule timing to food cues), much more research is needed (Norris and Marra, 2007; Harrison et al., 2011). Most studies involve observational field work, but experimental manipulations are necessary to learn more about the physiological mechanisms (Harrison et al., 2011).

In addition, more research examining carry-over effects related to other aspects of the annual cycle is needed. Much attention has been paid to carry-over effects between migration and breeding (Norris and Marra, 2007), but fewer studies have looked at carry-over effects involving molt timing. Late breeding can lead to delayed molt or increased overlap of breeding with prebasic molt (Morton & Morton, 1990). Delayed molt can carry-over to result in later migratory departure in Wood thrushes, and can also require a faster molt that produces inferior feathers (Dawson et al., 2000). Future research should also attempt to track longer-term carry-over effects. Most studies examine effects between adjacent stages, but carry-over effects may trickle across the entire annual cycle and may even exert effects interannually.

As evidence accumulates about how carry-over effects lead to changes in the timing of all aspects of the annual cycle, it becomes even more apparent that changes in the environment can have long-term and far-reaching consequences. Indeed, processes during the wintering stage can influence timing of breeding, a stage that often occurs thousands of miles away (Norris et al., 2004). Therefore, understanding how rapid human-induced environmental change can affect seasonal timing is important. This is the topic of the next section.

36.6 VARIATION IN SCHEDULING MECHANISMS AND RESPONSES TO HUMAN-INDUCED RAPID ENVIRONMENTAL CHANGE

Climate change, as well as other human-induced changes to the environment such as urbanization, can have rapid and substantial effects on the timing of seasonal activities (Helm et al., 2013). Photoperiod (usually a primary proximate driver, as noted above) is unchanging with respect to climate change; however, temperatures are changing rapidly and varying stochastically between years and regions where birds spend different parts of their annual cycle (Visser et al., 2004). Although birds can adjust flexibly to changing temperatures (see above), climate change is causing temperatures to deviate from historic ranges and is affecting different parts of the year differently. For these reasons, and because reproductive decisions must be made well in advance of when selection pressures are acting (i.e., the timing of food peaks), climate change poses a significant challenge to birds' ability to time processes appropriately (Visser et al., 2004). Conversely, phenology in species at other trophic levels, particularly of insect prey, directly respond to temperature changes because they have very different response mechanisms than birds (Bradshaw and Holzapfel, 2010). This can contribute further to mistimed breeding in birds (Visser et al., 2004; Bradshaw and Holzapfel, 2010). A temporal mismatch between peak abundance of insects and the peak of need for feeding nestlings has occurred in a population of great tits. Over a span of 23 years in which spring temperatures continued to increase, the tit egg-laying dates did not advance enough to match the much earlier peak in caterpillar abundance (Visser et al., 1998, Figure 36.8). Similar reproductive mistiming has been documented in many species and has been shown to lead to population declines in some (Visser et al., 2004; Both et al., 2006); it is specifically populations that have not advanced breeding times that are in decline. In at least some cases it is through adaptive individual plasticity, rather than evolved changes in cue responsiveness, that some populations have been able to closely track environmental changes (Charmantier et al., 2008).

Species differences like these emphasize the importance of how species variation in seasonal timing mechanisms can lead to important differences in responses to climate change. As described in detail throughout this chapter, the relative reliance on photic versus nonphotic cues varies among species. For example, rigidly seasonal species tend to rely more heavily on photoperiod, whereas opportunistic species show stronger responses to nonphotic cues in addition to their photoperiodic response (Hahn et al., 1997, 2008). Therefore, species differences in responsiveness to nonphotic cues could correlate with ability to cope with climate change.

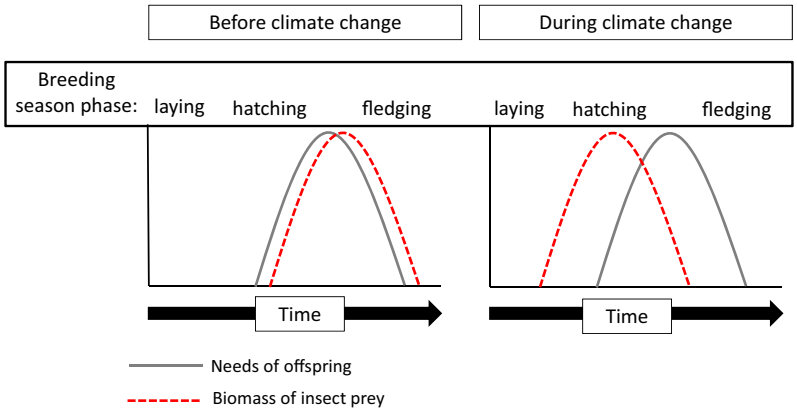

FIGURE 36.8 Schematic showing reproductive mistiming in great tits. The need for food for offspring (gray solid line) is highest between the hatching and fledging stages. Laying dates have remained similar over the years, yet the peak of caterpillar biomass (dotted red line) has shifted much earlier due to climate change, which results in a mismatch between the time nestlings are fed and the peak food abundance. *Adapted from Visser et al. (2004).*

In contrast to the hypothesis that mismatched timing is a maladaptive result of the fact that photoperiodic cues no longer accurately predict the best time to initiate breeding (cues hypothesis), an interesting and counterintuitive alternative is that mismatched breeding may actually be adaptive (Visser et al., 2012). The constraint hypothesis states that reproductive mistiming could be adaptive if the costs resulting from trying to breed early enough to match insect peak abundance outweighs the benefit that would be gained if they did match (Visser et al., 2012).

36.7 EFFECTS OF SEASONALITY ON IMMUNE FUNCTION

Although annual schedules often consist of several distinct life cycle stages, birds also adjust investment in processes that span multiple stages. These processes may be maintained at all times, during every stage, yet the appropriate level of investment may vary as a function of resource availability, environmental conditions, individual age or condition, and so forth. In this section, we will discuss one particularly interesting example of such processes that has been receiving increasing attention in the context of annual scheduling: seasonal adjustments of investment in immune function.

36.8 SEASONAL MODULATION OF IMMUNE FUNCTION

36.8.1 Overview

Across the annual cycle, dynamic environments expose organisms to extensive seasonal variation in weather, resource availability, and disease potential (King, 1974). Natural selection dictates that longer-lived organisms, such as birds, should time costly energetic processes to maximize fitness by balancing seasonal allocation to both reproduction and survival-related processes such as immune function (see Box 36.1 for summary of key immune system components). Immune function contributes to survival by detecting pathogens and limiting infection, but because maintenance of immunity can be costly (Schmid-Hempel and Ebert, 2003; Nelson, 2004; Sheldon and Verhulst, 1996; Klasing, 2004), especially if immune activation is overused (Lochmiller and Deerenberg, 2000) or not sufficient to clear an infection (Nelson et al., 2002), investment in immunity is often variable (Martin et al., 2008). Many environmental and physiological variables can contribute to these changes in investment patterns in immunity (Buehler et al. 2008a, 2008b; Martin et al., 2008; Nelson et al., 2002). Examples of these contributing environmental factors include endogenous and/or photoperiodically regulated annual cycles, changes in disease threat or parasite pressure, food availability and weather and temperature conditions (Nelson and Demas, 1996; Nelson et al., 2002; Martin et al., 2008; Adelman et al., 2013; Hasselquist, 2007). Other factors that contribute to changes in immune function include competing physiological processes such as reproduction (Sheldon and Verhulst, 1996; Lochmiller and Deerenberg, 2000) and other survival-related processes such as plumage molt (Moreno-Rueda, 2010; Buehler et al., 2008b), growth (Prendergast et al., 2004), or migration (Nebel et al., 2011, 2013).

36.8.2 Seasonality of Immune Function

Much of what is known about the seasonality of immune function has focused on mammals, specifically small rodents, with many studies documenting the effects of temperature, photoperiod, and food availability (Demas and Nelson, 1998; Zysling et al., 2009; Bilbo and Nelson, 2003). To summarize, a small mammal's investment in immune function tends to decrease during the summer months, while peaking during the winter months (Nelson and Demas, 1996; Sinclair and Lochmiller, 2000), mainly

Box 36.1 Specific Components of the Immune System and Their Costs

In general, all components of the immune system are not created equal in terms of energetic cost of maintenance and use, in that some components (described below) are substantially more costly to maintain than others. Broadly, the immune system can be categorized along an innate (nonspecific)-acquired (specific) axis and a constitutive (noninduced)-induced axis (Schmid-Hempel and Ebert, 2003). Further, a constitutive response is a baseline response or a response that will deploy without previous exposure, whereas an acquired response requires previous exposure to that pathogen or antigen (Schmid-Hempel and Ebert, 2003). Innate immune function provides an immediate and nonspecific response to a pathogen, whereas acquired immunity is activated by the innate response to produce specific antibodies against the pathogen (reviewed in Martin et al., 2008; Lee, 2006) and is typically slower in response time. Because of the differing costs of the different components of immunity, seasonal variation in immune function is expected to differ for different immune axes.

Constitutive Innate Immunity. Examples of innate defenses include anatomical barriers (e.g., skin, mucus membranes), resident microflora such as nonpathogenic bacteria, humoral factors (complement and acute phase proteins), and cellular components (white blood cells responsible for phagocytosis and an inflammatory response) and other antimicrobial proteins such as lysozyme, defensins (reviewed in Demas et al., 2011; Lee, 2006). The costs of constitutive innate immunity are not well studied, but overall are thought to be low due to the lower cell turnover rate that occurs when an immune response is not required and overall small combined tissue mass of the innate cells and proteins listed above (reviewed in Lee, 2006; Klasing and Leshchinsky, 1999).

Induced Innate Defense. If necessary, cells and proteins of the constitutive innate response will induce local inflammation via inflammatory cytokines, and if the infection is large enough, a systemic inflammatory response will be further induced. This response is also called the acute phase response (APR) and is characterized by increased production of acute phase proteins by the liver, changes in energy and nutrient metabolism, activation of the hypothalamo-pituitary-adrenal axis (HPA), inhibition of the HPG axis, decreased locomotor and social activities, anorexia, and fever (Klasing and Leshchinsky, 1999). This portion of the immune system is effective at quickly eliminating invading pathogens but can be extremely energetically expensive and potentially self-damaging (Klasing, 2004).

Constitutive Acquired (Adaptive) Defense. Natural, nonspecific antibodies such as IgM provide a baseline defense against pathogens and tend to circulate in the blood without requiring previous exposure to a pathogen (unlike most other antibodies) (reviewed in Lee, 2006). Overall, this response is not considered energetically costly to maintain.

Induced Acquired (Adaptive) Defense. This component of the adaptive response includes two types: cell-mediated and humoral. The cell-mediated component is responsible for killing infector host cells, and develops immunological memory for intracellular pathogens such as viruses via T-helper cells (Th-1) and B-cells. This response can often induce systemic inflammation, and the cellular turnover rate required for this response and developmental costs of specific antibodies makes this response substantially energetically demanding when induced (reviewed in Lee, 2006; Janeway et al., 2004). The humoral response is responsible for killing extracellular host cells and develops immunological memory for extra-cellular pathogens and parasites via T-helper cells (Th-2) and B cells. Overall, the energetic cost of this response is much lower than the cell-mediated component (Janeway et al., 2004).

to counteract the environmentally induced immunosuppressive effects (such as stress caused by inclement weather and low food availability) that occur during winter (Demas and Nelson, 1998). Overall, it appears that these mammals use photoperiod as their primary cue to modulate investment in immunity (with some effects of food levels and ambient temperature), so as to be best prepared for the upcoming and potentially inclement season (Nelson et al., 2002).

Far less information is available on overall seasonal patterns of avian immunity, with most published studies focusing on single components of the annual cycle, such as breeding compared to nonbreeding or breeding compared to molting (reviewed in Martin et al., 2008). For example, experimental manipulations of brood size in collared flycatchers (*Ficedula albicollis*) found that brood size and immunity were inversely related (Gustafsson et al., 1994). A meta-analysis of experiments increasing and decreasing clutch size found that immune function and brood size were inversely related (Knowles et al., 2009). Additionally, when incubation, mating effort, flight cost, or thermoregulatory costs were increased, immunity decreased (reviewed in Hasselquist and Nilsson, 2012). Another meta-analysis by Møller and colleagues (2003) found that T-cell cellular-based immunity increased during the summer months in 13 passerine species. Finally, a common garden experiment by Martin and colleagues (2004) demonstrated that house sparrows exhibited lower unspecific T-cell mediated response (to PHA, a nonpathogenic, stimulatory novel protein) during the early breeding season when compared to late breeding or fall.

Mechanistically, these effects have been attributed to changes in seasonal hormone profiles, such as glucocorticoids, androgens, and estrogens (which all can suppress immunity in certain contexts) (reviewed in Martin et al., 2008). Some of the same hormones that affect timing of territory establishment, reproduction, parental care, and molt affect immune function (reviewed in Martin et al., 2008; Koustos and Klasing, 2013). For example, both

glucocorticoids and androgens can depress immunity, but their effect on the immune system is highly dependent on the overall level and duration of increase, as well as what immune component is measured (reviewed in Koustos and Klasing, 2013). In general, acute stress or quick elevations of glucocorticoids increases levels of immunity, while chronic or persisting levels of stress dampen immune responses. For testosterone and other androgens, it is difficult to disentangle the direct effects from the indirect effects of glucocorticoids; that is, elevated levels of testosterone may depress immunity by elevating levels of glucocorticoids (Koustos and Klasing, 2013).

36.8.2.1 Captive Studies

Of the few studies of annual cycles of immunity, most have occurred in captivity. These studies have shown that both cellular and humoral immunity have either been higher during the winter months or show no change when compared to summer months (Martin et al., 2008; Lee, 2006). In a study of red knot immunity sampled over the annual cycle (Buehler et al., 2008b), both higher energetic cost phagocyte-based (cellular) immunity and lower-cost lymphocyte-based (antibody) immunity were higher during periods of mass change (i.e., during fattening and spring migration in wild birds), but there was a clear shift toward lower-cost lymphocyte-based immunity during peak molt. Due to the high costs associated with synthesizing feathers (Haake and Sawyer, 1986), it is preferable for birds to use a lower cost, less phagocytic-based immune strategy, as was demonstrated in the above study. In a subsequent experiment using low, high, and variable temperatures, there was little effect on annual variation in immune function (Buehler et al., 2009), perhaps due to the presence of *adlibitum* food. However, when food levels were restricted alone in a follow-up experiment, no change in constitutive immunity (natural antibody and complement levels) was observed, although food restriction did diminish investment in the acute-phase or induced immune response that is substantially more energetically demanding (Buehler et al., 2009). Conversely, a captive study of white-crowned sparrows did not find robust seasonal changes in immunity (specifically the acute-phase response) (Owen-Ashley and Wingfield, 2007); however, the acute phase response was more pronounced in sparrows during the winter months but was highly correlated to body condition and depended on which population was sampled (Owen-Ashley and Wingfield, 2007).

36.8.2.2 Studies of Free-Living Birds

Because captivity can reduce both inflammatory and phagocytic (cellular)-based immunity (either by reducing the pathogen pressures or due to the increased stress associated with being held in captivity) (Buehler et al., 2008a), it is important to study immunity both in the wild and captivity however, few studies do so (Adelman et al., 2013). In free-living birds, very few studies have looked at multiple immune indices over several components of the entire annual cycle (as opposed to just comparing two stages such as breeding to nonbreeding as the studies mentioned above). One study on nonmigratory great tits (*Parus major*; Pap et al., 2010) found significant seasonal changes in immunity. Specifically, total immunoglobulin and heterophil levels were highest during the summer breeding months and continued to increase until September when the birds began molting and then decreased until the following spring. Lymphocyte levels, however, were higher in the winter than in the summer. Another study, in skylarks (Hegemann et al., 2012), is the only published study to date to look at multiple immune indices over several years. Metrics of constitutive innate immunity (complement, natural antibody, and haptoglobin levels) varied interannually but were consistently lower during fall migration than during the breeding season.

Migration is an important and energetically demanding component of a bird's life history (Wikelski et al., 2003). Thus, energetic tradeoffs with immune function often occur, as has been documented in several studies. For example, a study in thrushes (Owen and Moore, 2008) and Bewick's swans (*Cygnus bewickii*) (Van Gils et al., 2007) found that migratory activity can be immunosuppressive. Two recent studies using a flight chamber found, similar to the aforementioned studies, that simulated migration depresses several aspects of immunity. The first study on European Starlings (*Sturnus vulgaris*) found that three of the four immune measures (haptoglobin, natural antibody and complement levels) decreased after the birds were placed in the wind tunnel for 1–4 h of continuous flight (Nebel et al., 2013). Another related study on long-distance migrant western sandpipers (*Calidris mauri*) found that flight performance (flight duration of 3 h) was not diminished by a previous immune challenge of LPS (lipopolysaccharide, which induces a "sickness response"), but flight while mounting a sickness response negatively affected other aspects of immune function including bacterial killing ability and natural antibody levels (Nebel et al., 2013).

Chapter 37

Regulation of Body Temperature: Strategies and Mechanisms

Shlomo Yahav

Department of Poultry and Aquaculture Sciences, Institute of Animal Sciences, ARO, The Volcani Center, Bet-Dagan, Israel

LIST OF ABBREVIATIONS

AVT arginine vasotocin
BDNF brain-derived neurotrophic factor
BMR basal metabolic rate
CAM chorioallantoic membrane
CNS central nervous system
CVS cardiovascular system
CWL cutaneous water loss
E evaporative heat loss
E embryonic day
EST eggshell temperature
EWL evaporative water loss
HR heart rate
HSP heat shock protein
IR infrared
LCT lower critical temperature
M metabolic energy
NGF nerve growth factor
NST non-shivering thermogenesis
PO/AH preoptic anterior hypothalamus
Q_c convective heat loss
Q_r radiative heat loss
RH relative humidity

DEFINITIONS—ACCORDING TO IUPS THERMAL COMMISSION (2001)

Endothermy The pattern of thermoregulation of animals in which the body temperature depends on a high and controlled rate of heat production.

Ectothermy The pattern of temperature regulation of animals in which body temperature depends mainly on the behaviorally controlled exchange of heat with the environment.

Poikilothermy Wide variability of an organism's body temperature as a function of ambient temperature, without effective autonomic temperature regulation.

Homeothermy The pattern of temperature regulation in a tachymetabolic species in which cyclic variation in core temperature—either diurnally or seasonally—is maintained within arbitrarily defined limits, despite much wider variations in ambient temperature, i.e., the body temperature is held within a narrow range.

Heterothermy A pattern of temperature regulation in a tachymetabolic species, in which the variation in core temperature, either diurnal or seasonal, exceeds that which characterizes homeothermy.

Basal Metabolic rate (BMR) Metabolic energy transformation calculated from measurements of heat production or oxygen consumption in a rested and awake organism that has fasted sufficiently long to be in a postabsorptive state and a thermoneutral zone.

Resting Metabolic Rate (RMR) The metabolic rate of an animal that is resting in the thermoneutral environment but not in the postabsorptive state.

Body temperature (T_b) regulation, which is an exclusive characteristic of endothermic birds and mammals, allows for the adaptation of processes and survival under varied environmental conditions. This chapter focuses on the evolution of endothermy, which enables maintenance of T_b within a relatively small range; the mechanisms of heat production and heat loss; various strategies to maintain T_b; the development of endothermy during embryogenesis; and the cost of endothermy in various ecological niches.

Sturkie's Avian Physiology.

37.1 INTRODUCTION

Anaximander—a Greek philosopher of about 570 B.C.E asserted: "Living things had been produced in the course of natural processes that were under the necessity of either adapting themselves to their environment or perishing".

Body temperature (T_b) control is a unique feature of endothermic organisms. Endothermy was adopted by birds and mammals in the course of their evolution, in order to better adapt to the varying environment.

Endothermy in general is a collective outcome of physiological adjustments coupled with morphological modifications; it profoundly affects the biology of birds, in conferring various physiological, ecological, and behavioral benefits that enable the wide aerial, aquatic, and terrestrial distribution of birds. Endothermic species maintain T_b within a relatively narrow range, such that T_b is the most physiologically guarded parameter of the body. Therefore, the thermoregulatory system in these animals operates at a very high gain, in order to control T_b within a relatively narrow range despite moderate to extreme changes in the environment.

The ability to maintain a relatively stable T_b springs from the mechanisms that control heat production and heat loss—mechanisms that changed in the course of evolution to enable endothermy to replace ectothermy. Both processes, especially heat production, are probably older than endothermy (Silva, 2006; Morrison et al., 2008; Richards and Proszkowiec-Weglarz, 2007). The mechanism of heat production involves increases in lung ventilation rates, cardiovascular system capacity, oxygen consumption (VO_2), and internal heat production that is based on aerobic metabolism. The enhanced aerobic mechanism provides avians with the ability to sustain high levels of activity which, in turn, enable birds to migrate over long distances and to inhabit varied environmental niches (Ruben, 1995). The evolutionary changes from ectothermy to endothermy were achieved because the developmental regulatory mechanisms maintained a balance between heat production and heat loss. It is not clear when birds attained endothermic status; however, the close phylogenetic affinity of birds to the extinct but successful vertebrates—the dinosaurs, which dominated the Mesozoic Era—received considerable attention as the phylogenetic source (Horner et al., 2001). Understanding the processes leading to the changes in metabolic rate and heat loss that result in the transition from ectothermy to endothermy is of great importance for understanding the mechanisms that enable control of T_b.

Birds are divided into altricial and precocial species. Altricial species are hatched at an undeveloped stage and are poikilothermic, being able to develop endothermic thermoregulation when they grow to one-third to one-half of adult size (Cooper and Geiser, 2008). In contrast, precocial birds hatch with a developed endothermic thermoregulatory system that continues its maturation process, mainly the feedback mechanism, up to 10 days posthatch (Arad and Itsaki-Glucklish, 1991).

This chapter will focus on the evolution of endothermy, which enables maintenance of T_b within a relatively narrow range; the mechanisms of heat production and heat loss; different strategies to maintain T_b; the development of endothermy during embryogenesis; and the cost of endothermy in various ecological niches.

37.2 THE EVOLUTION OF ENDOTHERMY

The evolution of endothermy attracts great attention as one of the most significant transitions in vertebrate evolution. Endothermy in birds is a major physiological specialization that profoundly affects their biology. It imparts a variety of physiological, ecological, and behavioral advantages that enable the distribution of birds among a wide variety of environments.

Study of the evolutionary development of endothermy must take into account the fact that endotherms are assumed to be typically homeothermic (i.e., characterized by stable and high T_b). However, some birds are characterized by heterothermy rather than homeothermy (i.e., they exhibit daily and seasonal variations in T_b; McKechnie and Lovegrove, 2002) or torpor, which involves controlled reductions of metabolic rate and T_b (Cooper and Geizer, 2008).

During the course of evolution, the transition from ectothermic to endothermic ancestors is theoretically attributed to either direct selection for high T_b and high resting metabolic rate (RMR) or selection for increased endurance and sustainable activity (the aerobic-capacity model). The first of these theoretical models of endothermic selection was based on various models implied that body warmth enabled higher RMR, which had enhanced selective value. This selective value enabled endothermic birds to support RMRs 5–15 times as great as those of ectotherms of similar body size (Bennett et al., 2000), and field metabolic rates that in general exceeded the reptilian rate by 20- to 30-fold (Nagy, 1987). The second model excluded warmth as a sufficient causative factor for higher RMR, but rather considered the high metabolic rate as a consequence of selection for postural changes that led to increases in physical activity and brain size and allowed enhanced aerobic capacity. In turn, selection for increased aerobic capacity supported higher levels of sustained activity that led to higher RMR and higher heat expenditure, thus enabling the transition from ecto- to endothermy (Grigg, 2004).

The transition from ecto- to endothermy during the course of evolution necessitated changes related to heat production and controlled lowering of heat conductance. Changes in heat production generally resulted from locomotor activity, shivering thermogenesis, high resting metabolic rate, nonshivering thermogenesis. All four were

sufficiently enabled by the ability of birds to maintain gradients across plasma membranes, generated by sodium/potassium ATPase pumps—a process that apparently requires generation of significantly increased levels of metabolic energy (Else et al., 2004). On the other hand, control by means of lowered heat conductance is achieved by insulation based on plumage and feathers, body-fat distribution, and changes in peripheral blood flow (i.e., vasoconstriction and vasodilatation).

These physiological changes could not take place without anatomical changes, among the most important of which, in birds, involve the respiratory system; they enable the higher metabolic rate and T_b than those of mammals. Collectively, the respiratory organs of birds are different from those of mammals; the small, compact lungs communicate with voluminous, thin-walled air sacs. Such a respiratory system has been considered as an adaptation to flight, in light of its volume and the co-current air flow, which is a product of the anatomical modifications. Comparison between the respiratory volume of a 1kg bird with that of a mammal of identical body weight shows total respiratory volumes of 160.8 and 54.4 ml for birds and mammals, respectively (Shmidt-Nielsen, 1975). The anatomical modification in birds permits air to flow through the lung and continuously past the exchange surface, whereas in mammals air must flow in and out. The continuous air flow through the bird lung exchange surface significantly improved the efficacy of O_2/CO_2 exchange in the lungs; it is facilitated by the positions of the air sacs (anterior and posterior) in the body, which enable co-current air flow.

Collectively, the evolutionary processes combined anatomical and physiological modifications/adaptations that enabled exploitation of the ecological opening for development of endothermic birds from developed ectothermic reptiles. The evolutionary changes from ectothermy to endothermy were achieved as a result of the developmental regulatory mechanisms that maintained a balance between heat production and heat loss; the mechanisms of both are permanently activated and regulated by both neuronal and hormonal signals (Silva, 2006; Richards and Proszkowiec-Weglarz, 2007; Morrison et al., 2008).

37.3 DIFFERENT STRATEGIES TO MAINTAIN ENDOTHERMY

Two vital resources are crucial for any organism to exist—energy and water. Therefore, maintaining energy and water balances is the goal of life. For an endothermic organism, the "fire of life" means an energy balance that facilitates functioning of the body systems and enables maintenance of the dynamic steady state of the internal systems. Endothermy facilitates homeothermy and/or heterothermy, as expressed in T_b. Bligh (1966) formulated the two-tier theory of thermoregulation, according to which there are two distinct levels of thermal control: the fine or narrow-band control that acts to hold T_b within its normal variation range (i.e., the condition of normothermia) and the wide-band control, which is activated when T_b deviates markedly from the normal range (i.e., a condition of hyperthermia or hypothermia).

During their life span, birds of each and every species experience extreme environmental conditions that may cause difficulties in holding T_b within the normothermic range; therefore, they must be able to thermally tolerate the environmental changes.

To sustain thermal tolerance and avoid the deleterious consequences of thermal stresses, three direct responses are elicited in birds: the rapid thermal stress response (RTSR) characterized by response times ranging from minutes to hours (Parsell and Lindquist, 1994; Yahav, 2009); acclimation/acclimatization, characterized by response times of days to weeks (Yahav et al., 1997; Horowitz, 2002); and epigenetic adaptation during the perinatal period, which is based on timing (Nichelmann et al., 1999; Tzschentke et al., 2001; Piestun et al., 2008). The RTSR can be defined as an immediate response to temperature stress; it initiates the recruitment of body resources to maintain the organism's dynamic steady state. This response cannot be maintained for a long period; therefore, under continuous severe temperature stress, a cascade of events may lead to temperature stroke. Acclimation is defined as physiological or behavioral changes that occur within the lifetime of an organism and which reduce or enhance tolerance of the strain caused by experimentally induced stressful changes—specifically, climatic factors (IUPS Thermal Commission, 2001). Whereas acclimation refers to experimental procedures, acclimatization refers to natural processes. Epigenetic adaptation has been defined as a lifelong adaptation that occurs during prenatal (embryogenesis) or early posthatching ontogeny; it takes place within critical developmental phases that affect gene expression. Its presumed occurrence is based on the assumption that during critical developmental phases, environmental factors, especially ambient temperature (T_a), have a strong influence on determination of the set point for physiological control systems. Dörner (1974) first described this as the determination rule.

37.4 REGULATORY MECHANISM OF ENDOTHERMY

37.4.1 Neuronal Signals to and from the Preoptic Anterior Hypothalamus

The body temperature of endothermic birds is regulated through a variety of thermoregulatory responses, such as shivering thermogenesis (ST), nonshivering thermogenesis (NST), panting, cutaneous vasomotion, and behavior (Figure 37.1). All these responses are controlled and

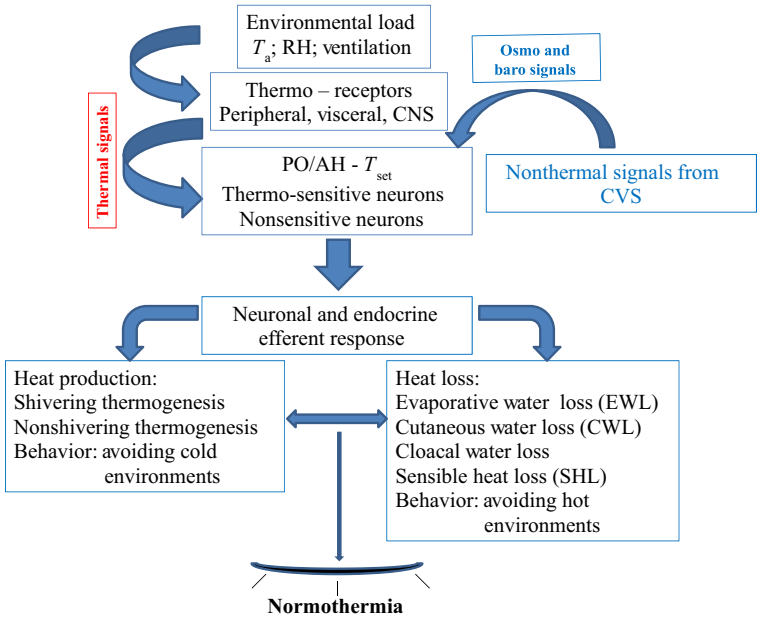

FIGURE 37.1 Schematic flow chart describing how environmental heat load is transformed to thermal information by thermoreceptors, and transferred to the preoptic anterior hypothalamus (PO/AH) to elicit thermoregulatory responses in the animal (heat production and heat loss efferent response) mediated by the neuronal and endocrine systems. Nonthermal signals, mainly from the blood system, can modify the response. ST, shivering thermogenesis; NST, nonshivering thermogenesis; CNS, central nervous system; CVS, cardiovascular system; EWL, evaporative water loss; CWL, cutaneous water loss; SHL, Sensible heat loss; T_{set}, set-point temperature.

orchestrated by the brain to optimize the internal T_b in order to facilitate appropriate molecular activities and reactions (involving enzymes, ion channels, etc.; Nakamura, 2011). The thermoregulatory system that enables maintenance of a relatively constant T_b consists of a sensory afferent part (involving thermo-, osmo-, and baro-receptors), an integrating part (the thermoregulatory center), and the command efferent part (involving neurological and endocrine signals; Figure 37.1).

The *sensory afferent part* comprises thermal information transferred by thermoreceptors from the bird's surface (skin), all internal organs, the spinal cord, and the brain itself. Whereas the thermoreceptors in the internal organs, spinal cord, and brain sense a relatively constant and protected internal environment, those of the skin sense the variable environment outside the body. Changes in the external environment encompass its temperature, relative humidity (RH), and ventilation, all of which affect the animal's surface temperature, and form the data base transferred by the peripheral thermoreceptors to the integrating center. Skin thermoreceptors are also continuously affected by the body core temperature, as heat is transferred from body core to the periphery by blood flow (i.e., the vasomotor response).

One of the nonthermal information items transferred to the integrating center (Figure 37.1) refers to another homeostatic parameter, the osmolality, which includes afferent signals coming from peripheral and central receptors that are sensitive to osmotic pressure, volume, and sodium concentration of the extracellular fluid and that can be closely represented by the blood system (Keil et al., 1994). The homeostasis systems that control thermoregulation and osmolality, respectively, are linked via the evaporative heat-loss mechanism: thermogenesis is balanced by energy loss, which depends mainly on evaporative water loss (EWL) which, in turn, depends on the body water and salt equilibria. It is well established that thermal homeostasis is modified under conditions that shift the osmotic balance (Simon and Notel, 1990; Keil et al., 1994) and vice versa (Landgraf et al., 1994), and this interaction was demonstrated in many endothermic animals. In general, at high T_a, the frequency of thermal polypnea decreased because of the reduction of extracellular fluid volume that resulted from the high evaporation rate; this leads to dehydration, hypovolemia, and hyperosmolarity (Yahav et al., 2005). In such cases, hyperthermia continues to develop.

The *integrating part* is neuroanatomically located in the preoptic area, which is located in the rostral pole of the hypothalamus (i.e., the preoptic anterior hypothalamus, PO/AH; Boulant, 1996; DiMicco and Zaretsky, 2007). The tight correlation between thermoregulation and osmoregulation focuses the maintenance of T_b and water/salt equilibrium in the PO/AH, so that lesions of this site elicit both severe thermoregulatory disturbances and deficiencies in drinking behavior and osmoregulation (Bligh, 1973; Hatton, 1990; Kuznetsov and Kazakov, 2000).

This area plays a dual role: it monitors local temperature changes and integrates temperature information received from the periphery (Hellon and Taylor, 1982; Patapoutain et al., 2003; Wechselberger et al., 2006). In mammals and birds, temperature is monitored by temperature-sensitive neurons, which change their firing rate in accordance with the hypothalamic temperature (Griffin et al., 2001) and can be described as the hypothalamic setting point (Boulant, 2006). These temperature-sensitive neurons form 40% of the PO/AH neurons; the rest are temperature-insensitive neurons. About 75% of the temperature-sensitive neurons are warmth sensitive (their firing rate increases strongly when the hypothalamic temperature increases), whereas about 25% of them are cold sensitive with a firing rate that changes in the opposite sense to the hypothalamus temperature (see Tzschentke et al., 2004 for birds; Boulant, 2006 for mammals). However, in endothermic mammals (in which most of the research was done) the evidence confirms that the PO/AH comprises 70% temperature-insensitive neurons and 20% temperature-sensitive ones (Nakayama et al., 1961).

In various models (Hammel, 1965; Boulant, 2006), the PO/AH serves to define a temperature set point (T_{set}) in order to promote heat production and/or heat loss. When the PO/AH site is cooled below its T_{set}, efferent neuronal signals will promote heat production by means that include ST and NST, peripheral vasoconstriction (in the skin), and behavioral responses that include huddling and seeking a warm environment. When PO/AH is warmed above T_{set}, heat loss mechanisms will promote panting, skin vasodilatation, and behavior that facilitates cooling, such as seeking shade and/or a ventilated environment or exposing nonfeathered skin areas. Each of these responses has its own T_{set}, and the magnitude of the response depends on the hypothalamic T_{set}.

However, additional neurons are encompassed by the concept of hypothalamic T_{set} based on temperature-sensitive neurons. These are the temperature-guardian neurons (Basta et al., 1997), which were detected in the PO/AH of Muscovy ducks. These neurons reacted exclusively to critical brain temperature signals and possibly stimulated a second type of thermoregulatory effector activity. This type of neuron falls within Bligh's (1966) two-tier concept which, in this case, operates when T_b shifts outside the normothermic range, in cases of hyperthermy or hypothermy.

The *efferent neurons* can be characterized according to the Hammel (1965) model, as updated by Boulant (2006). Basically, the warmth- and cold-sensitive and temperature-insensitive neurons, together with the efferent neurons, control the thermoregulatory responses. The efferent neurons are located within the PO/AH or in sites such as the posterior hypothalamus and brain stem; they are either spontaneously firing neurons or silent ones that are synaptically excited by warmth- and cold-sensitive neurons, or are inhibited by temperature-insensitive neurons.

The *endocrine efferent response* is mediated mainly by the hypothalamus–pituitary–thyroid axis. In birds, the metabolic rate is associated with secretion of the hormone thyroxine (T_4), which is secreted by the thyroid gland and is deiodinated to triiodothyronine (T_3) in all peripheral tissues. T_3 is the main metabolism-stimulating hormone (McNabb and King, 1993; Gabarrou et al., 1997) that was found to be associated with T_b regulation (McNabb and King, 1993; Yahav, 2000).

In summary, the mechanisms of both heat production and heat loss are permanently activated and are regulated by both neuronal and hormonal signals.

37.5 PHYSIOLOGICAL PROCESSES THAT ENABLE ENDOTHERMY

37.5.1 The Energy Balance Equation

In endotherms, the initial exposure to the thermal environment starts at the skin surface and extends outward into surroundings that are characterized by varied air temperature and humidity, radiation, and barometric pressure that varies with altitude. The last of these is most important for birds that spend migratory periods at high altitudes, exposed to low barometric pressure, coupled with high radiation and low ambient temperatures. In addition, the environment, including all the aforementioned factors, plays a crucial role in modifying heat transfer from the bird's surface via four principal processes: radiation, convection, conduction, and evaporation.

The thermogenic response of endotherms to changes in the environment can be divided into three zones (Figure 37.2): a zone of body cooling, a zone of evaporative regulation, and a zone of comfort. In the first zone, the regulation of T_b is controlled by heat retention (through vasoconstriction), followed by ST and NST. In the zone of evaporative regulation, T_b is regulated by vasodilation, followed by evaporation and sensible heat loss (SHL). In the comfort zone—the "thermoneutral zone"—T_b is controlled mainly by conduction. In both the cooling and the heating zones, the main concern is how tolerant the bird will be of extreme conditions and how long it will take to acclimate to such environments by changing the response thresholds of the physiological reactions. Thus, the thermogenic response will affect the development of hypothermy (in a cold environment) or hyperthermy (in a hot environment).

Collectively, heat transfer modeling has been used to understand thermoregulation in endotherms in general. The models assume a constant T_b for an animal not performing external work and are represented by the following heat-balance equation, based on the first law of thermodynamics:

$$S = M - E \pm R \pm C \pm K \qquad (37.1)$$

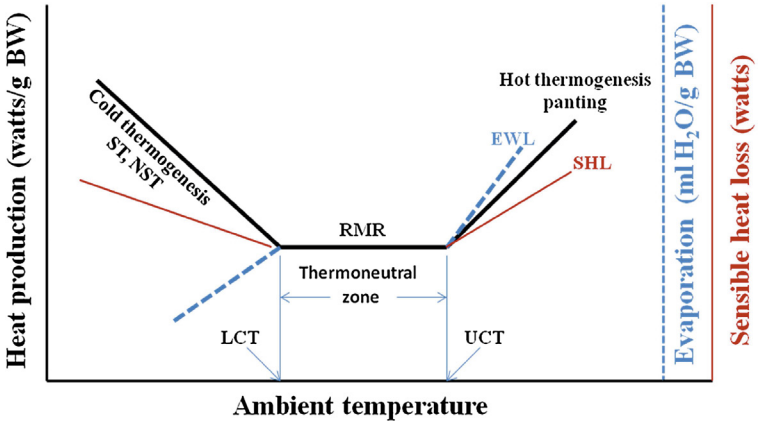

FIGURE 37.2 A general thermogenetic curve of endothermic organisms. The thermoneutral zone ranged between the lower and upper critical temperatures (LCT and UCT, respectively); it represents the organism's resting metabolic rate (RMR). Below the LCT heat generation by shivering thermogenesis (ST) and nonshivering thermogenesis (NST) increases in response to cold exposure. Above the UCT, thermogenesis increases to permit evaporative water loss (EWL), mainly via panting. Sensible heat loss (SHL) increases above the UCT as a result of increased ventilation, whereas below the LCT it increases as a result of the increased differences between the organism surface temperature and the ambient temperature.

in which S is the bodily heat gain or loss that must be balanced by M, metabolic heat production; E, evaporative heat loss; R, radiative heat gain or loss; C, convective heat loss or gain; and K, conductive heat loss or gain. Body temperature will remain unchanged when S is zero—that is, heat gain matches heat loss. If more heat is produced and/or gained than lost, then S will be positive and T_b will rise and vice versa.

Within Eqn (37.1), thermogenesis (heat production, M) can be divided into obligatory and facultative thermogenesis (Silva, 2006). Obligatory thermogenesis refers to the energy required to maintain T_b as long as the ambient temperature (T_a) lies in the thermoneutral zone—the range within which the body is in thermal equilibrium with the environment and produces energy at a level termed the resting metabolic rate (RMR) (Gordon, 1993). Facultative thermogenesis refers to stimulated energy production, which is required when T_a deviates below or, to some extent, above the thermoneutral zone.

37.5.1.1 Metabolic Energy

The metabolic rate represents the free energy produced by the transformation of chemical energy during aerobic and anaerobic metabolic activities within the organism. Energy is obtained through oxidation of feedstuffs; therefore, VO_2 can be used as measure of energy metabolism. However, it must be noted that under hypoxic conditions, when anaerobic mechanisms play a role, VO_2 will not be an adequate measure of energy metabolism.

Metabolic energy as measured per unit of time is termed the metabolic rate; it can be determined from the differences between energy intake (i.e., the energy value of all feed consumed) and that of all excreta (mainly feces and urine, which can be determined with a bomb calorimeter). This method requires measurements over a relatively long period, during which the bird has to have a relatively constant body weight, which is not the case with poultry. A second means of determining the metabolic rate is based on providing accurate information about the substance (feed stuff) that is oxidized and the amounts of energy produced for 1 g of carbohydrate, fat, and protein—4.2, 9.4, and 4.25 kcal, respectively. A third method uses direct measurement of VO_2, either in a calorimetric cage or an open air flow system. The calorimetric cage involves long-term measurements that encompass feed and water intake, feces and urine excretion, evaporation, etc. An open air flow system is based on short-term measurements (Buffenstein and Yahav, 1991), applying to a resting animal that is in a relatively steady-state condition (i.e., constant body weight, relatively empty gastrointestinal tract, and stress-free). A fourth method is based on the double-labeled water technique that uses $D_2{}^{18}O$ and $^3H_2{}^{18}O$, which is considered the gold standard for measuring energy expenditure under free-living conditions (Shaffer, 2011). The reason that oxygen can be used as a practical index of metabolic rate is based on the relatively constant amounts of heat produced for each liter of oxygen used in metabolism—5.0, 4.7, and 4.4 kcal for carbohydrate, fat, and protein, respectively.

37.5.1.2 Metabolic Rates of Passerine and Nonpasserine Birds

The total VO_2 of birds cannot be used to provide an accurate comparison among different species. However, calculation of VO_2 per units of weight and time, as well as conversion of the results to values appropriate to conditions of 0 °C, barometric pressure at sea level (760 mm Hg), and a dry environment, will provide a sufficient basis to compare bird species.

A comparative study (Lasiewski and Dawson, 1967) of metabolic rates of 58 non-passerine birds of body weights ranging from 3 g (hummingbird) up to 100 kg (ostrich) established an equation with a regression line corresponding to the following:

$$\dot{V}o_2 = 4.6 \times M_b^{0.723} \quad (37.2)$$

in which $\dot{V}o_2$ is the entire nonpasserine VO_2, M_b is body mass, and 0.723 is the slope of the regression line.

A comparative study of 36 passerine species of body weights ranging from 6.1 to 866 g yielded the following equation:

$$\dot{V}o_2 = 7.54 \times M_b^{0.724} \quad (37.3)$$

The regression slopes for passerine and nonpasserine birds were similar, but the metabolic rate of a passerine bird can be expected to be higher by about 65% than that of a nonpasserine bird of similar body weight (Lasiewski and Dawson, 1967). It must be noted that birds that deviated from the regression line were adapted to environments such as deserts, high altitudes, or polar regions, which differed from a so-called regular environment.

37.5.1.3 Metabolic Rates of Domesticated Birds

There has been massive genetic selection processes for over 50 years in domestic poultry; for example, broiler chickens and turkeys are selected for high growth of meat (muscle) and laying hens for high egg production. The development in the genetic selection of meat-type fowl—broilers (Havenstein et al., 1994, 2003a) and turkeys (Havenstein et al., 2007)—led to rapid growth, with increased feed efficiency and metabolic rate (Janke et al., 2004), which has led to heavy poultry with relatively short growth periods. Such development logically necessitates parallel increases in the size and efficacy of visceral systems, such as the cardiovascular and the respiratory systems, to support body energy balance. However, inferior development of such major systems (Havenstein et al., 2003b) has led to a relatively low capability to balance the significantly increased energy expenditure and, consequently, to a relatively low capability to control T_b efficiently under extreme environmental conditions (Yahav, 2009). These difficulties, in turn, lead to severe difficulties in maintaining a dynamic steady state—difficulties that can impair productivity. The dynamic changes in energy expenditure of poultry prevented acquisition of information that could lead to formulation of a general equation for comparing $\dot{V}o_2$ of domestic birds of differing body weights, as was accomplished for passerine and nonpasserine birds (Eqns (37.2) and (37.3)).

37.5.1.4 Nonshivering Thermogenesis

Although birds have no distinct brown adipose tissue or related thermogenic tissue, there is strong evidence that the NST mechanism in birds plays an important role during exposure to cold; the NST process has been implicated in the regulation of T_b and metabolic rate. For many decades, birds were known to meet their increased burden of thermogenic requirements in response to cold stress by adopting ST (West, 1965), and only recently was NST recognized in birds too, despite their lack of brown adipose tissue. This recognition sprang from the finding that NST occurred in skeletal muscle tissue too, as previously was recorded in mammals (Vidal-Puig et al., 1997), and also in studies on European finches that, under severe cold conditions, exhibited an independent rate of VO_2, distinct from their integrated pectoral electrographic activity; this suggested the involvement of NST (Saarela et al., 1995). However, it must be noted that the general assumption is that under severe cold exposure, birds will activate both ST and NST simultaneously to ensure sufficient control of T_b.

In both ST and NST, mitochondrial functioning is of prime importance because it combines the production of energy through adenosine triphosphate (ATP) synthesis coupled with a chain of redox reactions and production of reactive oxygen species (ROS). Mitochondrial respiration may be uncoupled from ATP synthesis by a proton leak induced by a thermogenic uncoupling protein (UCP). Uncoupling proteins are transporters present in the mitochondrial inner membrane; some of them (mainly UCP1, UCP2, and UCP3) were described in mammals, whereas in avian species (broilers, duckling) they were designated as avUCP (Collin et al., 2005). The avUCP is predominantly muscular UCP, which was reported to be an ortholog of mammalian UCP3 and that could be involved in glucose metabolism, cold-induced thermogenesis, lipid metabolism, and limitation of ROS production. The expression of avUCP is modulated by genotype; hormones such as thyroid and glucagon, which are the most lipolytic hormones in birds; low ambient temperatures; and nutritional status. Furthermore, several studies in birds had yielded some evidence that a β-adrenergic system controls mRNA expression of avUCP in chicken muscle (Joubert et al., 2010).

In summary, it can be concluded that both ST and NST are the main mechanisms that control T_b below the thermoneutral zone.

37.5.1.5 Evaporative Heat Loss

The evolution and success of endothermy enabled the control of T_b to be independent of the external thermal environment when ambient temperatures were low. However, it required the development of appropriate strategies for

enhancing heat loss in hot environments. Loss of heat in the form of latent heat of evaporation of water is one of the physiological mechanisms available to birds for controlling T_b in the face of variable environments and excess metabolic heat. In birds, EWL occurs across the skin as cutaneous water loss (CWL), through the respiratory tract as respiratory water loss (RWL), and via the cloaca. The rate of heat dissipation and the proportional contribution of each pathway to the total evaporative water loss (TEWL) are strongly influenced by acclimatization and natural selection, and they vary among species (Williams and Tieleman, 2002).

Heat transfer by evaporation is unique in its coupling of heat loss with resource loss (i.e., of body water content). This underlines an important biological conflict: the birds with least access to water, such as desert birds, are the ones with the greatest need to lose water to maintain T_b. This conflict between competing needs—for water retention and for water evaporation—leads to a tradeoff between avoiding overheating and avoiding dehydration.

In many species of birds, evaporative water demand is relatively high because most birds are diurnal and, therefore, are exposed to higher solar radiation, higher T_a and higher ventilation than nocturnal animals (Maclean, 1996). Furthermore, their high metabolic rate which, in turn, results in high oxygen demand, positively influences RWL (Tieleman et al., 1999), which, for many years was regarded as the main mechanism for EWL. All other routes were neglected, on the assumption that their role in EWL was negligible (Hillman et al., 1985). However, it was well established during recent decades that CWL is an efficient and advantageous means to maintain and control T_b, and that its contribution to overall evaporative loss varies with the environmental conditions. Only recently was another route—the cloacal one—recognized as a path for EWL (Hoffman et al., 2007).

Phenotypic flexibility/plasticity is one of the factors involved in adjustment. Adjustment of evaporation necessitates changes in the evaporative conductance and/or the surface area of the exposed epithelia. Dissipation of latent heat of vaporization of water by panting and or cutaneous routes demonstrates phenotypic flexibility, especially when adaptation to diverse environments is considered. All three evaporation routes—respiratory, cutaneous, and cloacal—may be subjected to selective pressures as a result of birds' exposure to high T_a, or scarcity of drinking water and food in the desert or during migration (McKechnie, 2008; Versteegh et al., 2008).

37.5.1.6 Respiratory Evaporation: Panting

The respiratory system plays a determinant role in the regulation of T_b and water balance. Respiratory temperature control is exercised through evaporative and convective cooling. During inspiration cool air passes through the system, where it becomes heated and saturated with water vapor, and during expiration energy taken up by the air is transported out of the respiratory system. Because respiratory gas exchange requires the humidification of inspired air, an increase in respiratory ventilation will also elevate evaporation. However, respiratory ventilation must take into account the exchange of oxygen and carbon dioxide that is needed to preserve the requirements of gas exchange and dynamic steady-state pH level (i.e., homeostasis). The increase in ventilation to drive EWL should be confined to the dead space in which humidification takes place and should not comprise gas exchange. Thus, increasing respiratory frequency while proportionately decreasing tidal volume will achieve the E required to control T_b, and thermal panting occurs in most birds during exposure to high T_a (Marder and Arad, 1989). Heat stress markedly increased respiratory frequency while the tidal volume decreased, and the net effect was found to be a sixfold to sevenfold increase in minute ventilation (Ludders, 2004). An increase in ventilation subsequently decreases arterial P_aCO_2 and increase pH, causing blood respiratory alkalosis (Houpt, 2004). Birds, unlike mammals, have peripheral receptors named intrapulmonary chemoreceptors located in the parabronchi of the lungs; they are sensitive to the partial pressure of CO_2 in the lung, but not to that of oxygen (Burger et al., 1974). These receptors act as an afferent control for PCO_2; they become stimulated, i.e., increase their rate of discharge when the CO_2 partial pressure decreases, and thus the ventilation rate declines. This chemoreceptor site enables control of P_aCO_2 from breath to breath in spite of possible variations in conditions that depend on the ecological niches occupied by different species (e.g., desert compared with mesic).

Total evaporative heat loss (E) can be calculated from the following equation:

$$E = \dot{m}_e \cdot \lambda \tag{37.4}$$

in which ($\dot{m}_e$) is total water loss and λ is the latent heat of water vaporization, which is approximately 40.8 W h/g or 2.4 J/g. Total water loss involves respiratory loss E_{res} and cutaneous loss E_{cuta} as in Eqn (37.5):

$$E = E_{res} + E_{cuta} \tag{37.5}$$

A simple way to measure EWL is based on changes in body mass of a bird over a defined period, with changes in body mass through defecations taken into account. Then Eqn (37.5) becomes:

$$E = \dot{m} \cdot \lambda / A_D \tag{37.6}$$

in which $\dot{m}$ is obtained from continuous measurements of rate of change of body mass (g/min) and A_D is the skin total surface area.

To distinguish respiratory from CWL, the following equation has to be used:

$$E_{res} = V\left(\text{pex} - \phi_a p_{in}\left[10^{-2}\right]\right)\lambda\,(\text{W}) \qquad (37.7)$$

in which V is respiratory volume per minute (l/min), pex is water content (g/l) of expired saturated air at the expiration temperature, ϕ_a is the RH (%) of inspired air, p_{in} is the water content (g/l) of the inspired saturated air at ambient air temperature, and λ is the latent heat of water vaporization in the expired air (J/g).

37.5.1.7 Cutaneous Evaporation

Cutaneous water loss (CWL) is one of the mechanisms that control T_b under varying environmental conditions. Until the early 1980s, no mechanisms for control of CWL were known, and the respiratory avenue was considered as the main evaporation route in birds (Dawson, 1982). This perception was challenged by several studies that revealed cutaneous evaporation to be the predominant avenue of water loss while resting and at high ambient temperatures, and that its regulation involved, to some extent, the outer skin layer, the stratum corneum (SC), which exhibits phenotypic plasticity. Phenotypic plasticity can be expressed within individuals; it can be the reversible phenotypic plasticity of adults or the developmental plasticity of young, and it can be influenced by natural selection (Piersma and Drent, 2003).

The difference between RWL and CWL lies in the disorders associated with respiratory alkalosis caused by RWL, which do not occur when CWL predominates. Indeed in many studies CWL was found to contribute at least half of total water loss in birds (Wolf and Walsberg, 1996), thereby reducing the deleterious effect of respiratory alkalosis.

A putative model of the mechanism involved in CWL can be summarized in the following equation:

$$\text{CWL} = (\rho_s - \rho_a)/r_v \qquad (37.8)$$

in which CWL is expressed in g/cm/s; ϱ_s is absolute humidity (i.e., water content, g/m^3) below the surface of the skin, assumed to be saturated at skin temperature; ϱ_a is absolute humidity (g/m^3) above the skin; and r_v is the total resistance to vapor diffusion.

The total resistance to vapor diffusion comprises the resistances of the skin, the boundary layer, and the feathers. However, the last two of these parameters contribute less than 10%, which focuses attention onto the skin as presenting the primary resistance to water loss, and onto the SC, as the outermost layer of the epidermis in birds (Boouwstra, 1997). One of the main questions regarding CWL is whether water permeation through the skin is a passive diffusion process or whether it involves an active physiological control mechanism; some studies suggested the former, whereas others suggested an active mechanism, driven by changes in ion gradients (Falkenberg and Georgiadis, 2008) or affected by the vascular blood supply to the dermis (Ophir et al., 2004). If the CWL process is under active physiological control, there should be differences between live and dead birds, in light of the facts that ion gradients are maintained by metabolic activity and, therefore, would not persist after death, so that there would be no blood flow to the periphery in dead birds. Ro and Williams (2010) conducted experiments on 12 bird species that inhabit various ecological areas; in dead birds, they found a reduction of about 16% in CWL, suggesting that at least part of CWL was controlled by active physiological mechanisms. However, different adaptations may be adopted under differing, possibly harsh environmental conditions. A study on the heat-acclimated rock pigeon (*Columba livia*) had shown a complex regulatory pathway for CWL; it consisted of α_2 and β_2 adrenergic receptors.

Whether the CWL is passive or active depends mainly on the intracellular lipids in the SC, which forms the physical barrier to water vapor diffusion. The intracellular lipids in the SC of birds had been identified as a mixture of cholesterol, free fatty acids, ceramides, and cerebrosides. The rate of water loss through the skin did not appear to be determined by the total quantity of lipids in the SC, but rather by the specific mixture of lipid classes, such as free fatty acids, ceramides, and cerebrosides, which were found to be tightly associated with differences in CWL (Muñoz-Garcia and Williams, 2005). In general, desert birds have lower rates of CWL, which suggests that natural selection has the potential to modify water loss through the SC.

It can be concluded that CWL represents an important component of water evaporation; it is higher in mesic-zone-inhabiting birds than in arid-zone ones. The most important boundary layer, which to some extent controls evaporation, is the SC. The fact that studies found only limited physiological control of CWL may explain why, when facing shortage of water, desert-inhabiting birds use mainly the respiratory water loss (RWL) pathway—the physiologically controlled one.

37.5.1.8 Cloacal Evaporation

Only one study on birds (Hoffman et al., 2007) addressed cloacal EWL; it described its importance for thermoregulation in adult Inca doves. The idea of cloacal evaporation evolved from a study on a desert reptile, the Gila monster; this study showed for the first time in any animal the importance of cloacal evaporation for thermoregulation (DeNardo et al., 2004).

The study by Hoffman et al. (2007) on the Inca dove—a bird that inhabits desert areas and can tolerate high ambient temperatures—showed that at 42 °C these doves can evaporate as much water from the cloaca as from the respiratory

tract: 21.2 and 25.4%, respectively, of total EWL. These results suggest that Inca doves can employ all three routes to regulate their thermal status; or, in another words, that all three routes contribute to the control of T_b, at least under harsh environmental conditions. Under low T_a, CWL is minimized and cloacal evaporation is eliminated by constricting the cloacal sphincter.

In desert inhabitants, the use of respiratory evaporation is limited by respiratory alkalosis and cutaneous evaporation is maximized to its limit, which is determined by the integument structure. In such cases, the cloacal epithelium is exposed in order to provide further evaporation, which enables these birds to survive the harsh environmental conditions.

37.5.1.9 Sensible Heat Loss

Heat transfer by evaporation is unique in that it couples heat loss with loss of a resource—body water content. This highlights an important biological conflict: that the birds with least access to water, such as desert birds, are the ones with the greatest need to lose water to maintain T_b. This conflict between the competing needs for water retention and water evaporation leads to a tradeoff between avoiding overheating and avoiding dehydration. Furthermore, E, which uses panting as the main mechanism for evaporation, causes respiratory alkalosis, which, in turn, affects the steady state of the bird. The two evaporation-limiting effects can be reduced by efficient sensible-heat loss through radiation, convection, and conduction.

It has been assumed that SHL does not play an important part when T_a is above the upper boundary of the thermoneutral zone (Hillman et al., 1985). This assumption was based on the small difference between the body surface temperature (T_s) and T_a, as well as the fact that in fully feathered birds only limited areas (i.e., legs, head, wattle, and comb) are unfeathered. However, use of infrared (IR) thermal imaging enables noninvasive measurement of birds' surface temperature to identify the various routes of nonevaporative heat loss, according to different models.

Infrared thermal imaging technology has undergone major developments in the early twenty-first century; it has been developed rapidly, through use of automated systems. Infrared thermal imaging cameras measure the amount of near-IR radiation (characterized by the wavelength range of 8–12 μm) that is emitted from a surface, and convert it to a radiative temperature reading, according to the Stefan–Boltzmann Equation:

$$R = \varepsilon\sigma \mathrm{T}^4 \tag{37.9}$$

in which ε is the emissivity of the surface, defined as its ability to emit and absorb radiation, and which, for biological surface tissues, ranges between 0.94 and 1.0 (Monteith and Unsworth, 1990); σ is the Stefan–Boltzmann Constant ($5.67 \times 10^{-8}\,\mathrm{W/m^2/K^4}$); and T is the surface absolute temperature in kelvins (K).

The major advantage of IR is that it provides a noninvasive, contact-free method of measuring surface temperature, at either short or relatively long distances, depending on the goal of the thermal study. For any thermal study, a thermal resolution of 0.1 °C is recommended, and spatial resolution must be sufficient and appropriate for the size of the studied object and its distance from the IR camera. In general, a spatial resolution of (320 × 240) pixels, as determined by the characteristics of the detector array, is used and is found sufficient. Use of a lens with a 24-degree field of view, with the camera placed 60–80 cm from the object, resulted in images in which each pixel corresponded to a rectangular detail of 0.9–1.5 $\mathrm{mm^2}$ (Figure 37.3; Yahav and Giloh, 2012). Infrared thermal imaging provides accurate measurements of the surface temperature of the whole object—measurements that are undoubtedly more precise and accurate than those provided by thermocouples (Mohler and Heath, 1988).

The IR technique plays a major role in biological research applications, including thermal physiology of mammals (Klir and Heath, 1992) and birds (Yahav et al., 2004; Stewart et al., 2005); fever diagnosis in homeothermic birds and mammals, including humans (Teunissen and Daanen, 2011); cancer diagnosis (Kontos et al., 2011); and animal population counts. For birds, the actual temperature measured by IR thermal imaging represents the temperature beneath the outer physical surface of the insulating layer. The matrix nature of plumage (which in general lasts for up to 3 weeks on poultry) and of the subsequent feathers causes radiation to be exchanged at varied depths within the outer layer, with the result that the radiative temperature is usually higher than the temperature at the outermost physical surface (McCafferty et al., 2011). Therefore, the IR technology measures the temperature of the feathers/plumage several millimeters below the surface. However, several regions, such as the face, wattle, comb, legs, and beak, and unfeathered areas below the wings radiate directly; their measured temperatures will be those at the surface (Figure 37.3).

Surface temperature is significantly correlated to the vasomotor responses of the bird. It is well documented that the vasomotor response—vasodilatation or vasoconstriction—is affected by the bird's T_b, whether it is hyperthermic or hypothermic, respectively. Heat is transferred from the body core via various internal tissues, and also through external insulating layers, by conduction, and the amount conducted (q_{cond}) is determined by various factors (McCafferty et al., 2011) (Eqn (37.10)):

$$q_{cond} = Ak/d\,(T_{bpart} - T_g) \tag{37.10}$$

in which: d (m) is the depth; k (W/m/C) is the thermal conductivity; T_{bpart} is the body part temperature (°C); T_g is the

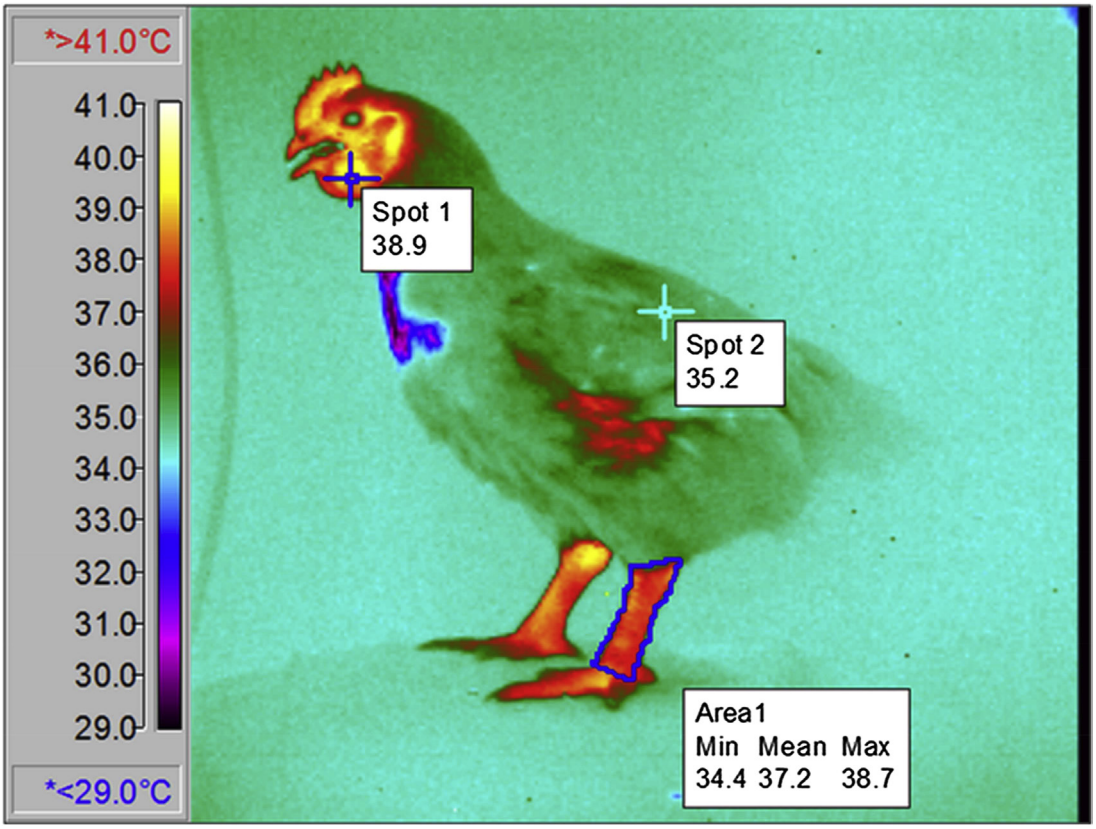

FIGURE 37.3 Thermal image of a broiler chicken exposed to 35 °C. The blue outline on the leg defines a region of interest (ROI, as defined by the camera software) that comprises a section of surface area for which minimum, average and maximum surface temperatures were determined. Spots 1 and 2 exhibit the surface temperature in each spot. Thermal images and their analyses were obtained with the Thermacam P 2.8 SR-1 program. *From Yahav and Giloh (2012).*

ground temperature (°C); and A (m^2) is the contacting surface area.

Most of the models are based on steady-state conditions of the animal, in which heat production is balanced by heat loss. The following calculations for poultry follow that of Yahav et al. (2005). To calculate heat transfer from the fowl, each part of the surface is represented by a corresponding geometrical shape. For each part, radiative and convective heat transfers are estimated by means of available and especially developed heat transfer relationships.

37.5.1.10 Convective Heat Transfer

Heat is transferred by convection when a body at a given temperature is in contact with air at another temperature. The convective heat flux, q_c, depends on the temperature difference ΔT, between the body and the air, the area of contact A, and the heat-transfer coefficient h:

$$q_c = hA\,\Delta T \tag{37.11}$$

The average heat transfer coefficient, h, depends on the geometry of the body, the physical properties of the air, and the flow regime. The major difficulty in calculating q_c stems from the strong dependence of h on the flow regime; it is expressed through the nondimensional group known as the Nusselt number:

$$\mathrm{Nu} = \frac{hD}{k} \tag{37.12}$$

in which D is the body-length scale (i.e., diameter in the case of a sphere or a cylinder) and k is the thermal conductivity of the air. Heat-transfer relationships given in the literature relate the Nusselt number to two other nondimensional groups. The first is the Reynolds number:

$$Re = \frac{UD}{\nu} \tag{37.13}$$

in which U is the air velocity and ν is the kinematic viscosity. The second is the Prandtl number:

$$Pr = \frac{\nu}{\kappa} \tag{37.14}$$

in which κ is the thermal diffusivity of the air. The three groups are related, in general, by:

$$\mathrm{Nu} = f(Pr, Re) \tag{37.15}$$

in which the function f is specific to each geometry and flow regime.

37.5.1.11 Radiative Heat Transfer

Heat transfer by radiation involves electromagnetic radiation from one surface to another because of the temperature difference between them. The rate of radiative heat transfer between two surfaces depends on their temperatures, the view area, and the respective surface emissivities.

Radiative heat transfer between the fowl and its environment and among adjacent organs (e.g., the two legs) of the fowl itself occurs if their temperatures are different. The view area changes frequently because of movement of the bird. In the model that leads to Table 37.1 values, radiation among the parts of the bird's surface was neglected and it was assumed that radiative heat transfer takes place only between the fowl and its environment. The environment was treated as a large surface at uniform temperature that surrounds the relatively small bird.

Radiative heat flux from (or to) the animal is estimated as:

$$q_r = \varepsilon_1 \sigma A_1 \left(T_1^4 - T_2^4\right) \qquad (37.16)$$

in which subscript r stands for radiation; indices 1 and 2 represent, respectively, the body surface and the environment; ε (=0.96) is the emissivity of a biological tissue; σ is the Stefan–Boltzmann constant ($5.669 \times 10^{-8}\,W/m^2/K^4$); A is the surface area; and T is the absolute temperature (K).

The model presented above was used to determine the importance of SHL to thermoregulation above the critical point of the thermoneutral zone, and its association with the water balance of poultry. This was studied in detail (Yahav et al., 2004, 2005) in broiler chickens exposed to 35 °C and a range of ventilation rates from 0.8 to 3.0 m/s. It was obvious that ventilation rate did not affect Q_r over this wide range of air velocities (Table 37.1). However, a significant ($r^2 = 0.998$), linear increase of convective heat loss, Q_c, with increasing ventilation rate was observed. It was well established that exposure of endothermic birds to high ambient temperatures will cause a cascade of thermal events, which include a decline in heat production. Therefore, to establish the contribution of SHL to total heat loss, the overall energy expended for maintenance had to be evaluated. This can be calculated by means of the following equation:

$$M = EI - (EXE + RETE) \qquad (37.17)$$

in which M is the energy required for maintenance; EI is energy intake; EXE is excreted energy; and RETE is retained energy, as evaluated from daily weight gain, on the assumption that 85% of the intake is retained as fat and 15% as protein (Boekholt et al., 1994). Increasing the ventilation rate during exposure to a high T_a (35 °C) had a dramatic effect on the ratio of SHL to maintenance energy. Whereas the ratio was only 29% in broilers exposed to air flows of 0.8 and 1.5 m/s, it exceeded 44% of the energy expended for maintenance in broilers subjected to 3.0 m/s (Table 37.1). This demonstrates that, depending on ventilation rate, SHL (i.e., convection plus radiation) may make a major contribution to heat loss, despite the small temperature differences between the bird surface and the environment.

37.5.1.12 The Association between Energy and Water Balance

Scientifically, it is difficult to devise a process that distinguishes between the energy and water balances maintained by the body in response to exposure to extreme (mainly hot)

TABLE 37.1 The Effect of Ventilation Rate at High Ambient Temperature on Osmoregulation and Sensible Heat Loss by Radiation (Q_r), Convection (Q_c) and (Radiation Plus Convection) (Q_t) as a Percentage of Energy Expended for Maintenance

	Ventilation Rate (m/s)			
Variables	**0.8**	**1.5**	**2.0**	**3.0**
Q_r (watt)	25.2 ± 4.7	25.5 ± 3.6	31.9 ± 4.5	31.6 ± 4.7
Q_c (watt)	55.7 ± 7.0^{d}	78.3 ± 7.4^{c}	104.9 ± 7.1^{b}	132.6 ± 7.0^{a}
Q_t (watt)	80.9 ± 10.2^{b}	104.9 ± 9.4^{b}	136.8 ± 10.4^{a}	164.2 ± 10.1^{a}
Q_t (% of energy expended for maintenance)	24.1 ± 3.7^{b}	29.1 ± 4.4^{b}	36.8 ± 2.2^{ab}	44.7 ± 4.7^{a}
T_b (°C)	43.9 ± 0.08^{a}	42.9 ± 0.08^{c}	42.8 ± 0.09^{c}	43.2 ± 0.10^{b}
Arginine vasotocin (pg/ml)	25.3 ± 1.7^{ab}	22.4 ± 2.4^{bc}	19.2 ± 1.5^{c}	28.0 ± 1.8^{a}
Osmolality (mOsm/l)	324 ± 3.0^{a}	317 ± 2.1^{bc}	314 ± 2.2^{c}	323 ± 1.4^{ab}

environmental conditions. The SHL and RH studies provide the opportunity to understand the dynamic relationship between energy balance and water balance.

In the study of broiler SHL (Yahav et al., 2004, 2005), heat loss by radiation and convection increased linearly with increasing ventilation rate (Table 37.1). Consequently, at the highest ventilation rate (3.0 m/s), T_b of the birds would be expected to be similar to or even less than that monitored at 2.0 m/s. However, increasing the ventilation rate to 3 m/s negatively affected thermoregulation by eliciting negative effects on T_b, body weight, feed intake, and feed efficiency. It was suggested that the effect on body water balance was the main reason for the deterioration in the ability to maintain energy balance and performance. Examination of two osmoregulatory parameters—plasma osmolality and plasma arginine vasotocin (AVT) concentration—supports this hypothesis. Changes in plasma osmolality activate osmo-receptors in the blood system, thereby sending signals to the PO/AH (Figure 37.1) which initiate the "debate" between balancing energy and balancing water. Furthermore, AVT is an important hormone in regulating water balance; it was well documented that water deprivation resulted in increased plasma osmolality and plasma AVT concentration, and the two parameters were positively correlated (Arad et al., 1985; Saito and Grossmann, 1998). The results of the study of broilers (Yahav et al., 2004, 2005) (Table 37.1) reveal a significant ($R^2=0.84$) and positive correlation between plasma osmolality and plasma AVT concentration. The significant increases of these two parameters in broilers exposed to high ventilation rates indicate difficulties in balancing body water as a consequence of increased RWL and CWL and/or inability of broilers to drink sufficient water under extreme environmental conditions. Thus, a high degree of water loss from the respiratory tract and the cutaneous surface, together with insufficient drinking capacity lead to some degree of dehydration, associated with increases in plasma osmolality and AVT concentration, leading to increase in T_b and to the debate between energy balance and water balance.

The RH study (Yahav et al., 1995) was based on exposing broilers to high T_a, coupled with several different RHs; in this study, the association between T_b and panting rate was evaluated. Yahav et al. (1995) demonstrated a decline in broiler panting rate despite increases in T_b; it was speculated that mild dehydration depressed panting rate and reduced water loss at low RH of 40%, leading to increased T_b. In both studies, it was speculated that hyperthermia developed as a result of body water deficit. However, whereas the deficit at high ventilation rate resulted, most likely from CWL, the deficit observed at low RH most likely resulted from a high panting rate.

The effort to control T_b within the normothermic range is energetically far more expensive in domesticated birds than in wild ones as a result of their high productivity. The broiler study shed new light on the difficulties of maintaining energy and water balances at high ambient temperatures. The efforts to control T_b and total body water directed a large amount of energy toward maintenance in broilers exposed to an optimal ventilation rate and thereby prevented the hyperthermia that can develop at high temperatures. In such cases, it would have been expected that unbalanced domesticated birds would expend an enhanced amount of energy for maintenance, especially when energy consumption was reduced. However, the results obtained in the broiler study (Yahav et al., 2005) suggested an opposite response, namely a decline in energy invested for maintenance, which was manifested in a development of severe hyperthermia (T_b of 43.9 °C; Table 37.1). It can only be speculated that the genetic selection for growth is so dominant in these fowls that even hyperthermia and dehydration do not significantly alter the amount of energy invested in maintenance.

37.5.2 Body Temperature

Balance or imbalance of the parameters presented in Eqn (37.1) will cause the development of hyper- or hypothermy in birds. Body temperature is the main parameter that represents the thermal status of an organism; therefore, endotherms aim to maintain a relatively constant temperature that will permit efficient functioning of the cells, tissues, and organs. However, differences are maintained among the temperatures of different organs as a result of their locations (i.e., visceral or peripheral), activities, and diverse biological functions (e.g., smooth or striated muscle). With no exception, endotherms will maintain a temperature gradient between the core (visceral) and the surface (peripheral) in order to control heat exchange with the environment.

For many years, endothermic birds and mammals were characterized as homeothermic. However, use of modern techniques for measuring T_b established endothermic organisms as heterothermic. Heterothermy involves changes in T_b in response to changes in the environment, such as alterations in T_a or in food and water availability (Table 37.2). Changing T_b from normothermic values in response to environmental alterations saves energy and is a key component of thermoregulation in birds of different sizes exposed to different environments: tropical, subtropical, arid, and mesic (McKechnie and Mzilikazi, 2011).

It is known, from studies that were conducted during many decades and were summarized by Prinzinger et al. (1991), that in birds T_b cycles diurnally and differs among resting, active, and high-activity phases. In resting birds, T_b may range from 35.0 to 40.8 °C; in active ones, between 35.6 and 44.6 °C; and high activity increases the range to 40.4–47.7 °C. Despite the fact that endotherms are considered to be homeothermic, this is not the case, and their T_b fluctuates diurnally by 2.48–2.84 °C, depending on

the bird's prevailing metabolic phase. The highest T_b ever recorded in a wild bird was 47.7 °C in the white crowned sparrow *Zonotrichia leucophrys* (Southwick, 1973). Such extreme development of hyperthermia is in most cases irreversible.

Body temperature varies among species also as a result of body mass, ecological niche (e.g., aquatic), and varied availability of diet during the year (Table 37.2). In genetically selected poultry, T_b in the resting and active phases is significantly higher than those recorded for undomesticated birds; it is related to their higher metabolic rates. The values presented in Table 37.3 show various environmental factors that have considerable effects on domesticated birds' T_b.

In general, both invasive and noninvasive techniques are used to measure T_b in birds. The commonly used ways to record T_b in domesticated birds involve invasive techniques, which are time-consuming and may be traumatic as a result of handling, and may affect T_b within a few minutes by the induction of fever that increases T_b by up to 0.5 °C (Cabanac and Aizawa, 2000). In both wild and domesticated birds, a telemetry technique is applied, which involves implantation of temperature-sensitive transmitters, usually into

the abdominal cavity. This enables long-term recording of undisturbed birds (Bligh and Heal, 1974).

Whereas the telemetry technique involves handling and implantation, the IR thermography technique is an entirely noninvasive and contact-free method of measuring surface temperature, at either short or relatively long distances (Figure 37.3; Giloh et al., 2012). Thermographic imaging for T_b determination can be relevant only if a satisfactory correlation exists between the body and surface temperatures; in the case of birds, the surface must be unfeathered. Use of the temperature of an unfeathered surface is based on its significant correlation with the vasomotor responses of the bird; it is well documented that the vasomotor response—vasodilatation or vasoconstriction—is affected by the bird's T_b. Studies conducted on broiler chickens demonstrated that such a correlation could indeed be found; they also demonstrated a high correlation between facial surface temperature (T_{fs}) and T_b. In laboratory studies, where the climatic conditions were relatively similar for all the chickens, individual body temperatures correlated well with individual facial surface temperatures for chickens that were exposed to acute environmental heat conditions, both with and without ventilation, and to persistent heat without ventilation (Figure 37.4; Yahav and Giloh, 2012).

It can be concluded that, regarding T_b, birds are mainly endothermic, heterothermic organisms.

37.6 THE DEVELOPMENT OF ENDOTHERMY DURING EMBRYOGENESIS

The bird model used to investigate the metabolic transition from ectothermy to endothermy during embryogenesis is based on the increase of aerobic capacity which occurs at two functional levels that are regulated independently of one another: upregulation of gene expression and a significant increase in the catalytic activity of the main oxidative control enzymes. This switch occurs because of the development of the physiological regulatory mechanisms that govern metabolism. These regulatory pathways involve changes in gene and protein expression, coupled with changes in cellular physiology. It is of great interest to understand the process leading to the high metabolic rate that enables endothermy, and to know whether these changes are fixed in time or can be modified by environmental changes.

The development of thermoregulatory competence in birds has been studied in both altricial and precocial species during the perinatal period. Although the development of

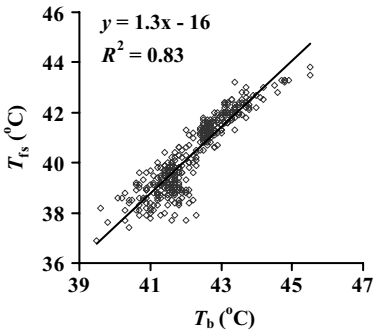

FIGURE 37.4 Correlation of individual facial temperature (T_{fs}) with body temperature (T_b). Chickens were reared under controlled conditions. On each of days 8, 15, 22, 29, and 36, a group was randomly chosen for exposure to three different heat treatments: acute heat only, acute heat together with ventilation, and persistent heat. Each treatment included nine chickens for monitoring the responses of body and facial temperatures. The data presented in the graph represent all measurements of individual chickens of all ages in all treatments. *From Yahav and Giloh (2012).*

thermoregulation in altricial birds is an event that mostly takes place after hatch, precocial species exhibit incipient thermogenesis during the later stages of incubation and during the first 10 days posthatch (Tazawa et al., 1989; Arad and Itsaki-Glucklish, 1991). Therefore, precocial birds were used as a model for elucidating the cellular and molecular physiological mechanisms involved in the transition towards endothermy in embryos.

For precocial birds, the transition has been suggested to comprise four stages during embryogenesis (Tazawa et al., 2001): the Arrhenius-limited stage, in which the metabolic rate is directly related to environmental temperature; the O_2-conductance-limited stage, in which VO_2 is limited by oxygen diffusion through the shell and the chorioallantoic membrane (CAM) in response to the embryo's oxygen demands; the power-limited stage, in which the embryo has limited capacity to generate heat in response to cold exposure; and the full-blown stage, in which the organism is homeothermic. These four stages are typical of precocial birds, whereas the altricial birds seem to be confined to the Arrhenius-limited stage until after hatching.

37.6.1 The Transition from Ectothermic to Endothermic Embryo: Cellular and Molecular Aspects

The BMR of endothermic birds is 5–10 times greater than that of ectothermic vertebrates (Bennett et al., 2000), despite the fact that metabolic pathways are highly conserved among vertebrates (Smith and Morowitz, 2004). The transition from ecto- to endothermy is based on modifications to the systems and mechanisms that regulate metabolic enzyme activities. Such a transition necessitates increased capacity of the respiratory system, changes in the cardiovascular system (CVS) such as possession of four heart chambers, increased efficiency of the gastrointestinal tract, and modifications to the neural and endocrine systems (Chiba et al., 2004). Mechanisms that may regulate metabolic enzyme activities include changes in protein structures, modifications to membranes, and up- or down-regulation of genes (Hulbert and Else, 2005).

The egg temperature is maintained (in nature by the incubating parents or in domesticated birds by industrial incubators) at a level conducive to the development of the embryonic tissues. During early stages of embryogenesis, the survival of embryos confronted by alterations of the incubation temperature is entirely dependent on their tolerance, and not on thermoregulatory mechanisms. At this stage, the embryos' thermotolerance protects them, to some extent, against incubation temperature fluctuations. However, there is no doubt that, close to hatch, thermoregulatory mechanisms become necessary. The questions of interest concern when the ability to effectively maintain T_b appears, and what is the molecular and physiological evidence that confirms that the embryo reached the endothermic stage. The time-point at which to expect incipient thermoregulation is close to hatch, when tissues, organs, and the control axis achieve the maximal degree of development (Whittow and Tazawa, 1991).

During the development of precocial birds, VO_2 increases until shortly before hatching, at which point (i.e., the oxygen plateau) it stabilizes as embryos reach their hatching mass (Prinzinger et al., 1995). The increase in oxidative metabolic rate during embryogenesis is facilitated by mitochondrial density enhancement, mitochondrial uncoupling, proton leakage across the inner mitochondrial membrane, and the increase in enzyme activity that coincides with development of oxidative pathways. Reaching this stage of metabolic capacity requires the activity of enzymes of the oxidative phosphorylation and citric acid cycles (Walter and Seebacher, 2009). Metabolic regulation of enzymes enables cells to use the existing pool of mitochondria to match energy production to energy demands. Cells can regulate energy by altering the structure of mitochondria, but they can do so without changes in structure or enzymology (Harper and Himms-Hagen, 2001), by alteration of the magnitude of the proton leakage across the inner mitochondrial membrane, which determines the proportion of energy that is released as heat (Porter et al., 1996). Another important characteristic of endothermy is the permeability of the plasma membrane to Na^+ and K^+ ions, which leads to enhanced activity of Na^+/K^+-ATPase, in order to maintain the ion gradient across the membrane. The increased enzyme activity increases energy demand, which requires increased proton flux to increase ATP synthesis in the mitochondria. The capacity to maintain endothermy is controlled by several nuclear hormone receptors, such the thyroid receptor, retinoic acid receptor, peroxisome proliferator-activated receptors (PPARα, γ and δ) and, most importantly, their coactivators PGC-1α and

β (Puigserver and Spiegelman, 2003). Thyroid hormones, mainly triiodothyronine (T_3), can modulate aerobic metabolic capacity by regulating mitochondrial biogenesis and PGC-1α gene expression, which control transcription of genes that encode enzymes involved in metabolic pathways (Lin et al., 2005).

Endothermy, therefore, can be defined as interactions among uncoupling and proton leakage in mitochondria, cellular energy demand, and oxidative capacity. It is usually accepted that activities of these mechanisms are completed close to hatch, but at no specific time-point.

37.6.2 The Transition from Ectothermy to Endothermy: Physiological Parameters

Three physiological parameters of the embryo—T_b, heart rate (HR), and VO_2—evidently can shed light on this transition. Research into the physiological transition is based mainly on precocial models, in which the incubation temperature is the most important vital parameter during embryogenesis; and for several decades the practice in breeding poultry was, and still is to keep this parameter stable. Optimizing the incubation temperature is essential for achieving the best hatchability (Swann and Brake, 1990; French, 1997) and chick quality (Wilson, 1991; Decuypere and Michels, 1992), while avoiding possible deleterious effects on the development of the chicken embryo (Krausova and Peterka, 2007). The temperature of the embryo does, indeed, depend on its incubation temperature, but also on other environmental parameters such as RH, air speed, and air flow, which are basically the parameters of the physical microenvironment around the egg (Meir and Ar, 1987; Swann and Brake, 1990). These factors, coupled with the heat exchange between the egg and its microenvironment, and the capacity of the embryo to produce heat, will determine the embryo's T_b (Van Brecht et al., 2005).

37.6.2.1 Embryonic Body Temperature

The thermoregulatory capability of the embryo may not be effective in the sense that of enabling the embryo to maintain T_b during environmental cooling or warming but, in fact, the embryo responds to changes in incubation temperature with an appropriate change in T_b. The ability to respond is pronounced in the poultry that has a precocial mode of development, which results in a mature state at hatch, whereas the altricial mode of development results in a very immature hatchling. Therefore, the precocial mode can provide a better model for observing the development of endothermy.

The confirmation of complete metabolic responses to altered environmental incubation temperatures that would provide proof of the development of endothermy prior to hatch will depend on the measurement of T_b. Previous studies measured embryonic temperature within the egg adjacent to the embryo (Tazawa and Rahn, 1987; Holland et al., 1998). One of the techniques used involved measurement of the allantoic fluid temperature (T_{af}), and recently (French, 1997; Joseph et al., 2006; Piestun et al., 2008; Zimerman et al., 2013) eggshell temperature (EST) was also found to be a reliable proxy for T_b. However, measurement of T_{af} or EST rather than embryonic T_b is a compromise based on the following facts. The allantoic fluid and the egg shell both lie within the temperature gradient (i.e., the path of heat conduction between the embryo and the environment), and the advantage of EST is that it is a noninvasive IR temperature measurement. The disadvantage of EST stems from the effect of convection on the measurement. However, in all the studies that used EST measurement to determine the embryonic T_b the convective effects were minimized.

Although there is no doubt that both T_{af} and EST are lower than the embryonic T_b, they significantly reflect embryonic T_b and its pattern of response to changes in incubation temperature, as was demonstrated by Piestun et al. (2008) and Shinder et al. (2009). Figure 37.5 shows that EST remained relatively constant during the periods of organ development (E9 to E11 in broilers and E13 to E15 in turkeys). Subsequently, energy was directed mainly towards embryo growth—a process that coincided with elevation of heat production by the embryo, which led to increases in EST through E16 and E22 in broiler and turkey embryos, respectively. This was followed by 3 days of relatively constant EST, which parallels the VO_2 plateau and results from the limited ability of the CAM to deliver an adequate amount of oxygen and which, in turn, initiates the preparation for internal and external piping, during which EST increases dramatically.

Tazawa et al. (1988) reported evidence of a weak metabolic response to lowered T_a in chicken embryos at E18 of incubation. Nichelmann et al. (1998) decreased the incubation temperature of Muscovy ducks to about 31 °C for 4 h during the last third of incubation; the study found that although they responded with declines in T_{af} and heat production, T_{af} remained always higher than the incubation temperature and there was only a moderate drop in heat production. This demonstrated a thermoregulatory response, although it was weak.

Yahav and Piestun (unpublished data) exposed embryos of broilers and laying hens from embryonic day (E) E10 through E19 to 39.5 and 34.5 °C, for 10 h/d (Figure 37.6) and turkey embryos to the same temperatures from E16 through E25 (Figure 37.6), and measured EST to determine the birds' responses to the alterations in incubation temperature. The results are presented as the difference (Δ°C) between EST prior to the exposure and its average values during the exposure. In all three species—broilers, laying hens, and turkeys—exposure to 39.5 °C induced a decline

in Δ°C of EST with days of exposure. However, whereas the slope for broilers and turkeys was −0.061 and −0.04, respectively, in laying hens it was −0.11.

The ability of laying hens to maintain a lower decline in Δ°C of EST with time than broilers and turkeys reflects, most probably, their embryonic heat production. It was well documented that genetic selection of these species during recent decades significantly increased their heat production during embryogenesis, and that broilers and turkeys exhibited the most dramatic alterations of heat production (Hulet, 2007). Thus, maintaining EST during exposure to an increased incubation temperature turns out to be a difficult task for broiler and turkey embryos. However, the decline in Δ°C EST with time may shed light on the development of thermoregulatory capacity.

Exposing the embryos to 34.5 °C induced progressive increase in EST with accumulating days of embryogenesis. However, in this case, turkey embryos were able to maintain much better EST with increasing age, despite the lower T_a; their EST slope increased by 0.10, compared with 0.049 and 0.06 for broilers and laying hens, respectively. It is not clear what caused these differences. One of the reasons why turkey eggs maintained much better EST could be the size of the eggs; turkey eggs weighed 80–100 g, whereas those of broilers and laying hens weighed between 60 and 70 g; therefore the ratio of surface area to volume favored turkey eggs. In all three species, although coping with changes in incubation temperature was observed to improve with age, Δ°C EST at E19 indicated weak thermoregulatory capacity. For all three species maintenance of an optimal incubation temperature resulted in Δ°C EST close to zero, emphasizing that the industry's incubation temperature is within the comfort zone for embryogenesis.

In a study (Shinder et al., 2009) in which broiler embryos were exposed to 15 °C for 30 or 60 min on E18 and E19, the capacity to withstand such extreme environmental conditions was observed. On E18, during the first cold exposure, EST dropped from 38.3 °C to 26.9 and 21.1 °C after 30 and 60 min of exposure, respectively. On E19, EST dropped to 27.5 and 22.0 °C after 30 and 60 min of exposure, respectively. The ability to maintain an EST significantly higher than the incubation temperature despite the extreme drop in

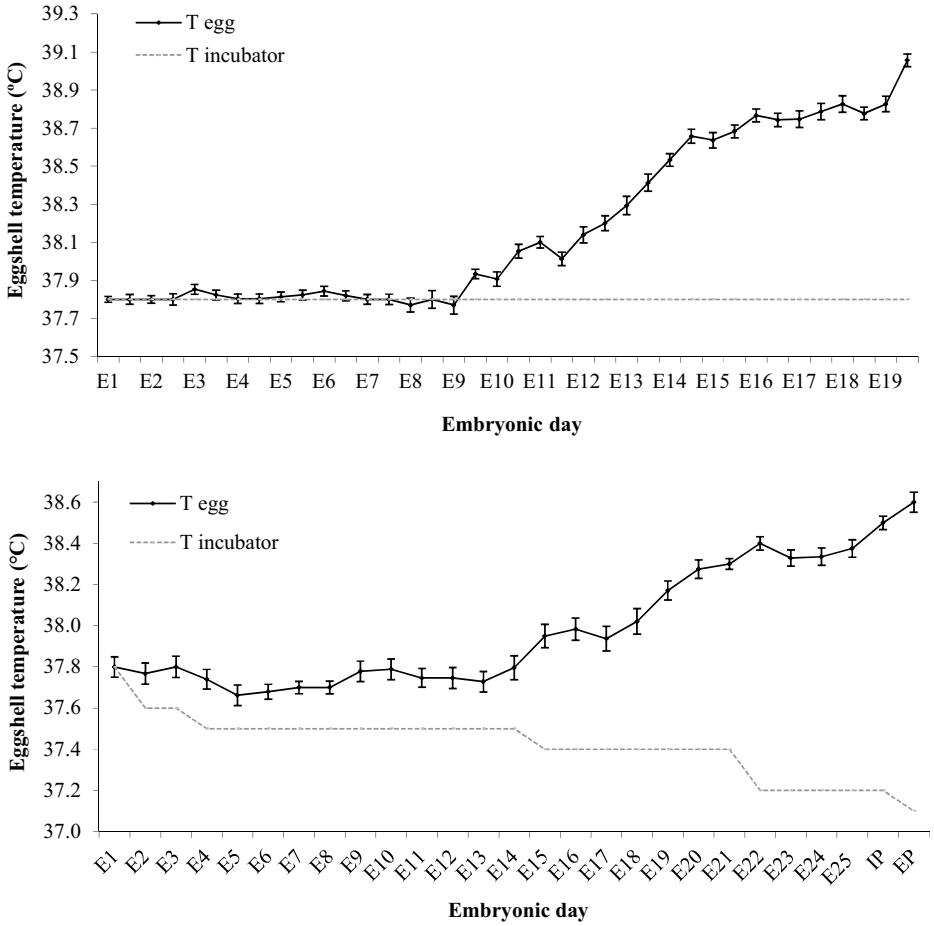

FIGURE 37.5 Eggshell temperature (°C) measured by infrared thermometer during 21 days of incubation of broilers (upper graph) and 28 days of incubation of turkeys (lower graph). The gray line indicates the incubation temperature.

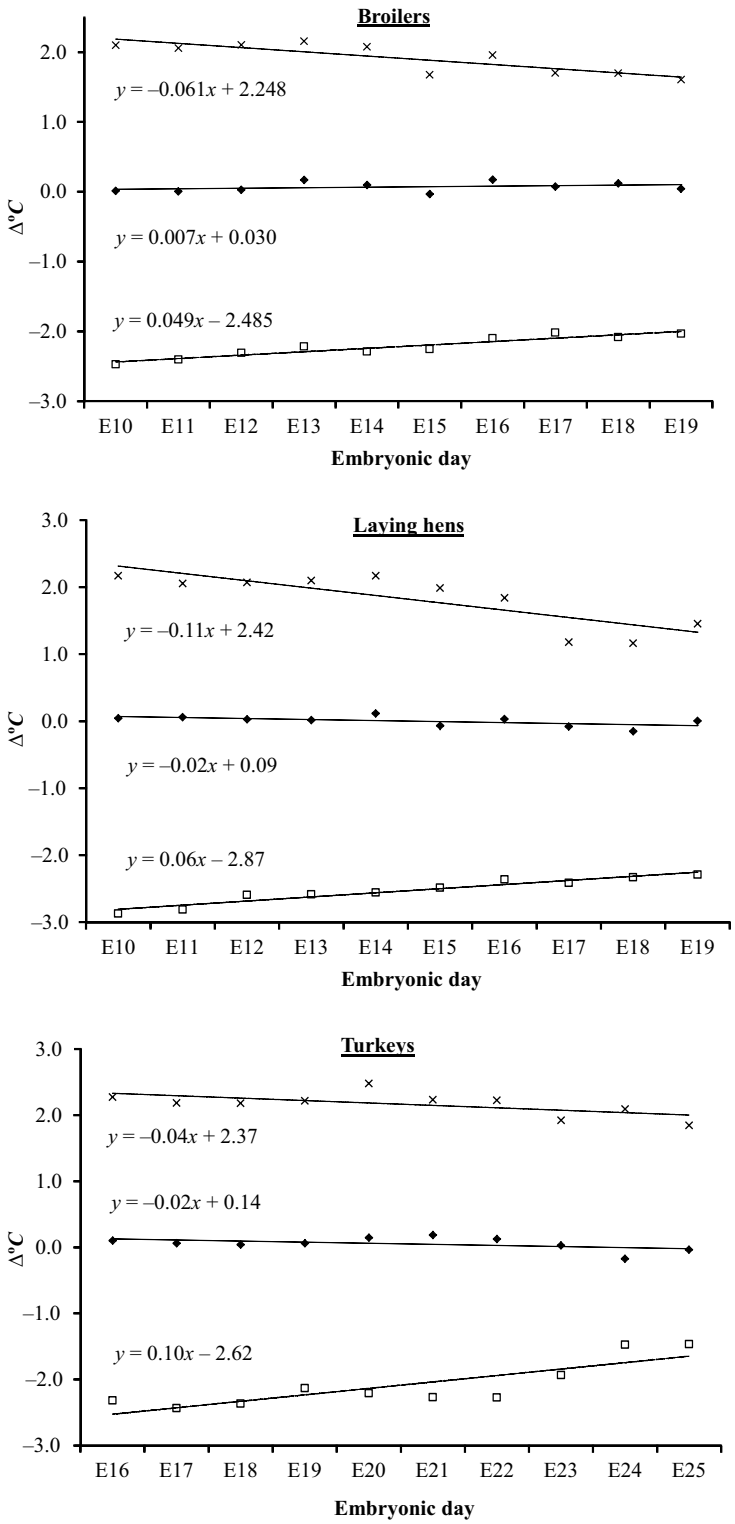

FIGURE 37.6 The effects of increasing incubation temperature from 37.5 °C (♦-line) to 39.5 °C (×-line) or decreasing it to 34.5 °C (□-line) for 10 h/d from embryonic day (E) E10 through E19 (broiler and laying hen embryos) and from E16 through E25 (turkey embryos) on the difference (Δ°C) between eggshell temperature prior to the exposure and its average values during the exposure, in embryos of broilers (upper graph), laying hens (middle graph) and turkey (lower graph).

the latter on E18 and E19 can be attributed to the thermoregulatory ability of broilers close to hatch. This evidently was the case with Muscovy ducks at E34 (Nichelmann et al., 2001).

37.6.2.2 Embryonic Heart Rate

An appropriate HR is essential to produce blood flow in order to transport respiratory gases, nutrients, hormones, and metabolic wastes. In the early stages of birds' embryogenesis, after the heart is formed and has started to beat, a high HR is not required for transportation of gases from the environment to the embryo tissues. In these stages, HR and blood flow are relatively insensitive to changes in environmental oxygen partial pressure, but they play a role in the angiogenesis processes of the embryo (Burggren, 2004).

However, as the embryo develops (from embryonic day ~E11 during 21 days of embryogenesis in chickens and laying hens, and from ~E15 during 28 days of incubation in turkeys and ducks), the tissues' demand for oxygen increases dramatically and the heart provides the mechanical thrust to supply oxygen to the embryo's body. Although HR alone provides little insight into the developmental mechanisms because it is relatively stable during embryogenesis, with the exception of the internal and external period (Figure 37.7), it can be used to provide information about thermoregulatory development (Andrewartha et al., 2011).

By exposing embryos to lower and higher incubation temperature of 34.5 and 39.5 °C, respectively, Yahav and Piestun demonstrated a dramatic effect on HR. Broiler and laying hen embryos exhibited a more pronounced HR response than turkey embryos (Figure 37.8) during exposure to 39.5 °C. They both reduced HR with increasing embryonic age; by E19, their HR was close to that monitored prior to heat exposure. However, this did not occur in turkeys, which on E19 still maintained an HR higher than the control level. Opposite responses were observed when the three species were exposed to 34.5 °C: there were relatively slow increases in HR as embryonic development of broilers and laying hens progressed, whereas the turkey embryos exhibited the pronounced response. It can be concluded from the HR responses that embryos cope better with exposure to high incubation temperatures than to low ones. This may be related to the 1 °C difference between the temperature elevation (2 °C) and the reduction (3 °C). Nevertheless, it still could be related to a better physiological capacity to cope with higher incubation temperature, because of the wide range of abnormalities that high incubation temperature might cause.

In all three species, a significant correlation was found between EST and HR at the high and low incubation temperatures, whereas a very low correlation between these parameters was exhibited at the regular incubation temperature (37.5 °C), which highlights the designation of this temperature as the physiological comfort temperature.

37.6.2.3 Embryonic Oxygen Consumption

The general perception of the developing embryo is that precocial birds pass through four stages during embryogenesis (Tazawa et al., 2001), whereas altricial ones seem to remain in the Arrhenius-limited stage until post hatch. Thus, differences between the qualitative patterns of O_2 consumption of altricial and precocial embryos were suggested by different authors.

In precocial birds O_2 consumption is described as exhibiting a plateau phase of metabolic rate in late incubation, whereas in precocial ones the metabolic rate continued to increase exponentially till hatch. Several recent studies demonstrated that in both altricial and precocial birds the developmental mode exhibited a plateau phase (Prinzinger and Dietz, 1995; Prinzinger et al., 1995). From these studies, it appears that the plateau was present, irrespective of egg mass and length of incubation period; it basically represents the shift of respiration from the CAM to the lungs. However, the two modes of hatching differ in the level and duration of their plateau phase. In the study by Prinzinger and Dietz (1995), the altricial birds exhibited an VO_2 plateau that was lower by 35% than that of precocial ones, whereas the durations of the plateau, as percentages of the total incubation duration, were 8.9 and 17.6%, respectively. The two modes differed also in total energy consumption during incubation, being lower by 15% in the altricial than in the precocial birds.

In general, heat production of endothermic birds at temperatures below and above the thermoneutral zone is a result of two processes—thermoregulatory heat production and energy metabolism, of which the latter follows the van't Hoff rule. In avian embryos, a drop or increase in T_b as a result of changing incubation temperature will cause a decrease or increase, respectively, in net heat production, but these changes maybe moderate compared with that expected from the van't Hoff rule. The available information on heat production during embryonic development is contradictory. Most of the studies were based on cooling the environment during incubation. Romijn and Lockhorst (1955) did not find any changes in heat production in poultry embryos following exposure to cooling until internal piping occurred, whereas Freeman (1964) found a transient metabolic response. Piestun et al. (2009) demonstrated a significant decline in VO_2 from E17 in broiler embryos that had been continuously exposed to an elevated

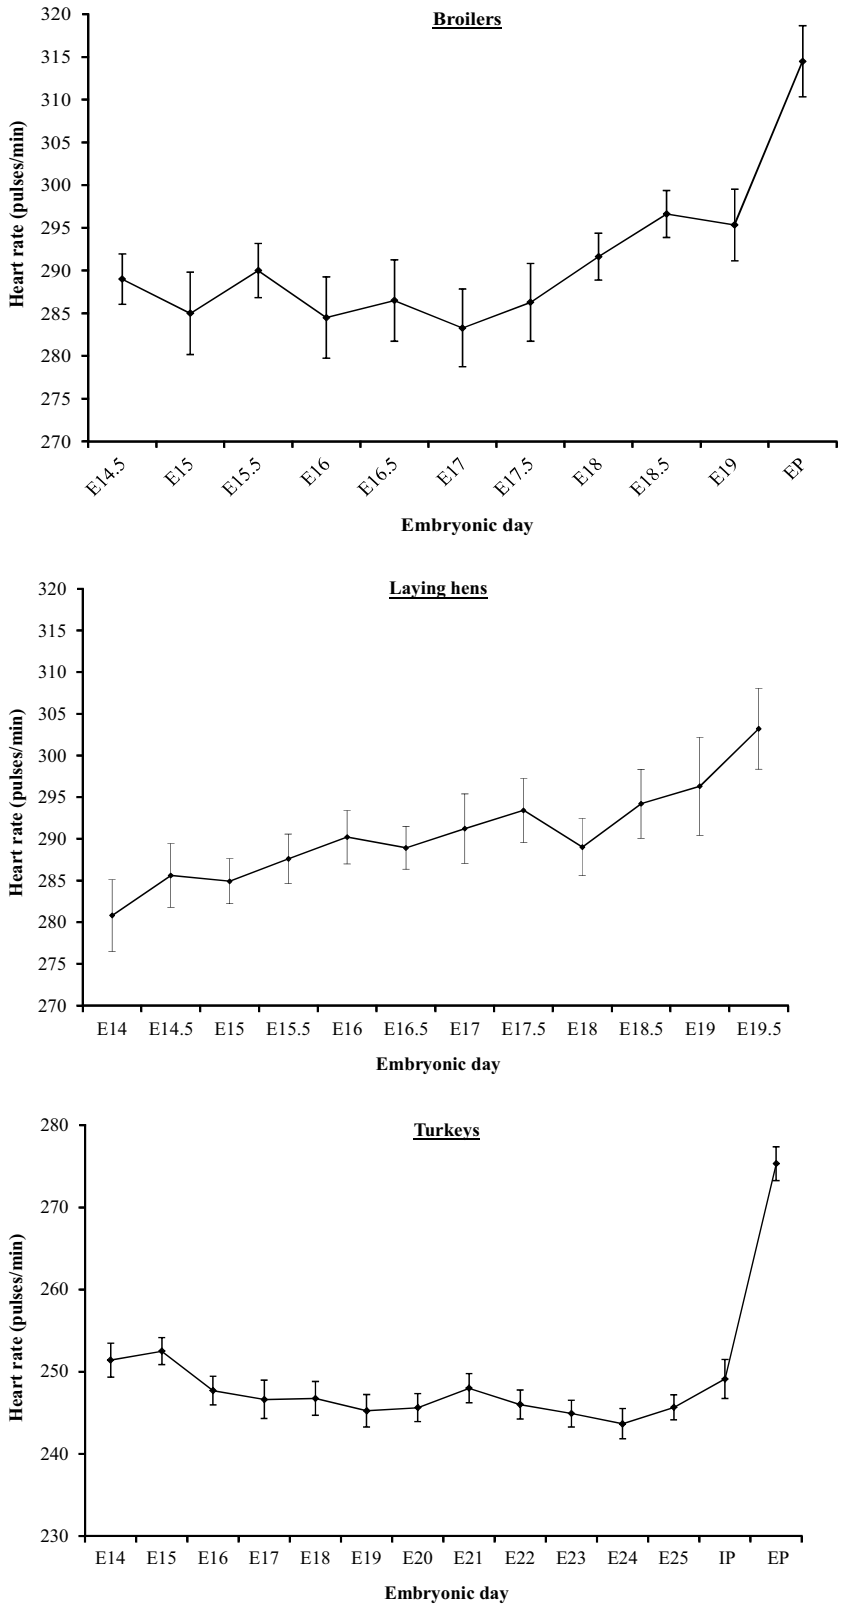

FIGURE 37.7 **Embryonic heart rate (HR, pulses/min), as measured by Buddy digital embryo HR monitor during incubation of broilers (upper graph), laying hens (middle graph), and turkeys (lower graph).**

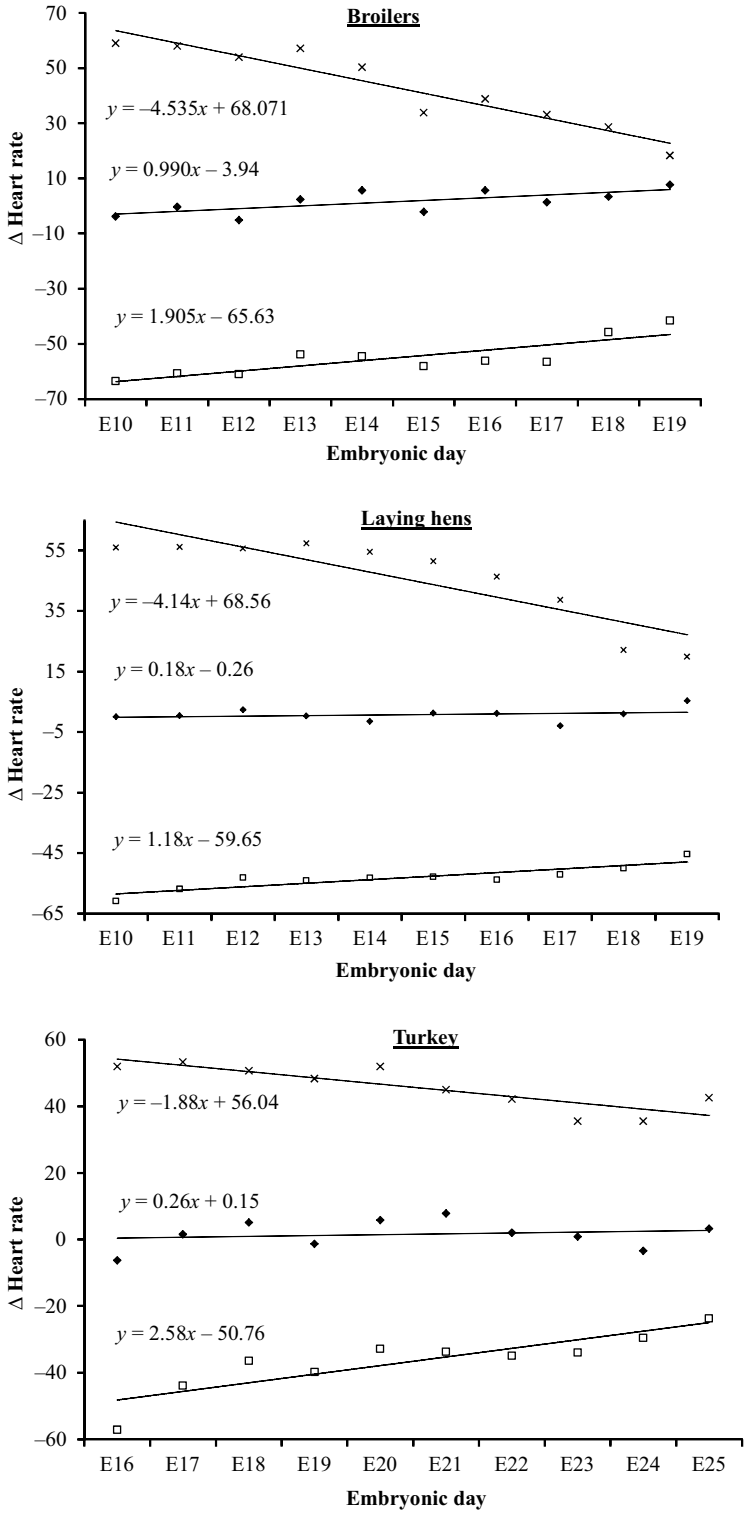

FIGURE 37.8 The effect of increasing incubation temperature from 37.5 °C (♦-line) to 39.5 °C (×-line) or decreasing it to 34.5 °C (□-line) for 10 h/d from embryonic day (E) E10 through E19 (broiler and laying hen embryos) and from E16 through E25 (turkey embryos) on the difference between heart rate (Δ HR) prior to the exposure and its average values during the exposure, in embryos of broilers (upper graph), laying hens (middle graph), and turkeys (lower graph).

incubation temperature of 39.5 °C from E7 through E16 (Figure 37.9). The ability to maintain lower VO_2 than that of the control from E17 onwards, despite being exposed to a similar incubation temperature, may indicate thermoregulatory capacity.

In Eqn (37.18), Q_{10}, whose value indicates endo- or ectothermy, is based on O_2 consumption; it is defined as the increase in VO_2 that results from an increase of 10 °C in T_a:

$$Q_{10} = [VO_2\,(2)\,/VO_2\,(1)]^{10/T_2 - T_1} \qquad (37.18)$$

in which $VO_2(2)$ and $VO_2(1)$ represent the VO_2 when T_a is T_2 and T_1, respectively.

A Q_{10} value higher or lower than 2 indicates ectothermy or endothermy, respectively (Whittow and Tazawa, 1991); these authors had shown that in chicken embryos at a very early stage of development in which no endothermic reactions occurred, Q_{10} was between 2.0 and 2.4. A study by Nichelmann et al. (1998) found a value of Q_{10} lower than 2.0 in chicken embryos from day E14 onward, suggesting endothermic capability from this E onward.

In summary, it can be concluded that the transition from ectothermy to endothermy occurs in precocial birds during embryogenesis, as early as the oxygen plateau phase, which is associated with the development mode of becoming independent immediately post hatch. In contrast, altricial birds seem to undergo a transition towards endothermy via a poikilothermic stage that lasts until the end of the nestling stage.

37.6.3 Reducing Body Temperature by Using the Epigenetic Temperature Adaptation Approach during Embryogenesis

37.6.3.1 The Epigenetic Approach

Epigenetic temperature adaptation is based on the assumption that, during critical developmental phases, environmental factors, especially T_a, play a strong role in determination of the set point for physiological control systems. Dörner (1974) first referred to this as the determination rule. Epigenetic adaptation, which has been defined as a lifelong adaptation that occurs during prenatal (embryogenesis) or early post-hatching ontogeny, takes place within critical developmental phases that affect gene expression (Tzschentke et al., 2004), and seems to offer a suitable opportunity to reach the goal of improved acquisition of thermotolerance in poultry. During early development, most functional systems evolve, according to the transformation rule (Dörner, 1974), from an open-loop type without feedback to a closed-loop control type with feedback. Application of thermal manipulation (TM) during the critical phases of this development process may induce alterations in the thermoregulatory control system.

37.6.3.2 The Epigenetic Temperature Adaptation Approach: The Embryogenesis Model

In nature, incubation conditions are not uniform (Webb, 1987) because of searching for food, escaping from

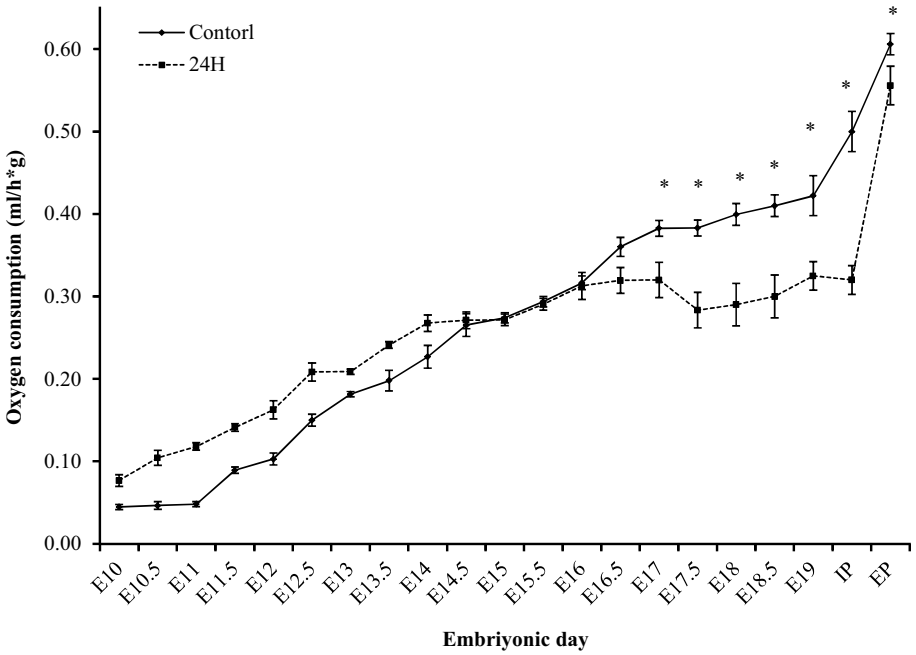

FIGURE 37.9 Oxygen consumption of broiler embryos incubated under control (37.8 °C, 56% RH) or thermally manipulated continuously (TM—24H treatment; 39.5 °C, 65% RH) from E7 through E16 (180 through 408 h of incubation). For each day of incubation, an asterisk indicates significant differences ($p \leq 0.05$) between treatments.

predators, and nonuniform nest insulation. This may be one of the reasons why birds in the wild are quite able to cope with extreme environmental temperatures, while maintaining T_b as close as possible to the normothermic range through efficient use of thermoregulatory mechanisms. In contrast to the nonuniform conditions in nature, commercial incubation conditions are strictly uniform. The uniform incubation conditions, coupled with the consequences of genetic selection for high production, confront the mature poultry with a great challenge to cope with extreme environmental conditions, especially with regard to T_a. The uniformity of incubation conditions makes possible the use of precocial domesticated embryos as a model for epigenetic temperature adaption by using altered incubation temperature—the TM model.

Three critical parameters have to be considered in using the TM approach during chick embryogenesis: the timing of the critical phase, the temperature level to which the embryo is exposed, and the duration of exposure. Determination of the critical phase of embryogenesis that would enable successful application of TM to improve acquisition of thermotolerance is based on the hypothesis that the set point or response threshold of controlling systems related to metabolic rate could be altered most efficiently during the development/maturation of the hypothalamus-hypophyseal-thyroid axis, which is associated with thermoregulation, and the hypothalamus-hypophyseal-adrenal axis, which is associated with stress but which plays a major role in activation of the thyroid axis during incubation.

Until mid-incubation, the thyroid gland exhibits only limited ability to synthesize hormones. This period is characterized by the synthesis of monoiodotyrosine on E8, of diiodotyrosine on E9, and of T_4 and thyroid-stimulating hormone (TSH) by the hypophysis on E10. The linkage of the hypothalamic-pituitary-thyroid axis is formed between E10.5 and E11.5. Levels of T_3 start to increase on E12, and increase significantly prior to hatching, in preparation for their roles in the final maturation of many tissues and in the physiological integration of hatching. Therefore, application of TM during the sensitive period of development of this axis may affect the set point of the heat-production threshold. Although the major function of the adrenal axis relates to stress, during incubation corticotrophin-releasing hormone stimulates the secretion of TSH and corticosterone prevents T_3 from being deiodinated to T_2. In this situation, both axes are involved in determining the embryo metabolic rate, and determination of the sensitive period for application of TM must consider both. Furthermore, it was suggested that the embryo is susceptible to stress. Therefore, increasing the incubation T_a during the development and maturation of the hypothalamic-hypophyseal-adrenal axis may also affect the stress response of the posthatch chick and, in turn, its metabolic rate.

The other two factors that play significant roles with respect to planning TM use are the temperature level and the exposure duration. Neither must affect the performance of the genetically selected organism, but they should significantly improve its thermotolerance.

Studies that addressed all three parameters were conducted by Piestun et al. (2008, 2009). In these studies, TM of 39.5 °C and 65% RH was applied between E7 and E16 for 12 h per day (12H treatment). The TM alterations with respect to the regular incubation conditions were 1.7 °C and 9% RH. Application of TM caused a significant decline in EST, HR, and VO_2 from E18 onward (Figure 37.10), and significantly affected the metabolic rate of the hatched chicks. This was manifested in a significantly reduced T_b, accompanied by significantly reduced plasma T_4 and T_3 concentrations posthatch. Although T_3 is the potent hormone with regard to the chick's metabolic rate, the fact that plasma T_4 concentration was also significantly reduced in the hatched TM chicks suggests that there was reduction in the activity of the thyroid gland upon hatch, which emphasizes the significant effect of TM in reducing the metabolic rate. However, the plasma corticosterone concentration was significantly greater in the TM chicks than in the control ones, which may have been due to the hatching difficulties exhibited by the treated chicks. Despite the changes in the hatched chicks' metabolic rate, there was no significant effect on their hatchability or body weight at hatch.

A similar approach was applied to turkey embryos, except that the sensitive period was changed to match the development and maturation of thyroid and adrenal axis in turkeys (i.e., E10 through E22; Zimerman et al., 2013). This application caused a reduction in the embryos' metabolic rate, as indicated by changes in EST, HR, and VO_2 (Figure 37.11) from E23 onwards (i.e., after the TM treatment was terminated).

To study whether TM has a long-lasting effect, posthatch thermal challenges must be applied. It was previously reported that exposing embryos to high or low temperatures during incubation improved their capacity to adapt to hot or cold environments, respectively, in the posthatch phase (for review, see Yahav, 2009). However, most studies challenged the broilers only at a young age or tested their potential with a mild heat stress. A study that evaluated the potential of broilers to cope with severe heat stress at marketing age (Collin et al., 2007), following TM at E8 through E10, E16, through E18 or a combination of the two treatments during embryogenesis, could not demonstrate that TM conferred any advantage in coping with deleterious environmental temperatures, mainly because TM was not applied during the most sensitive period. To be able to evaluate thermotolerance acquisition of chickens that were exposed to TM from E7 through E16 (Piestun et al., 2008), hatched chicks were raised up to marketing age (35–42 days of age) under environmental comfort conditions and were exposed to heat challenge (high T_a and low RH) for

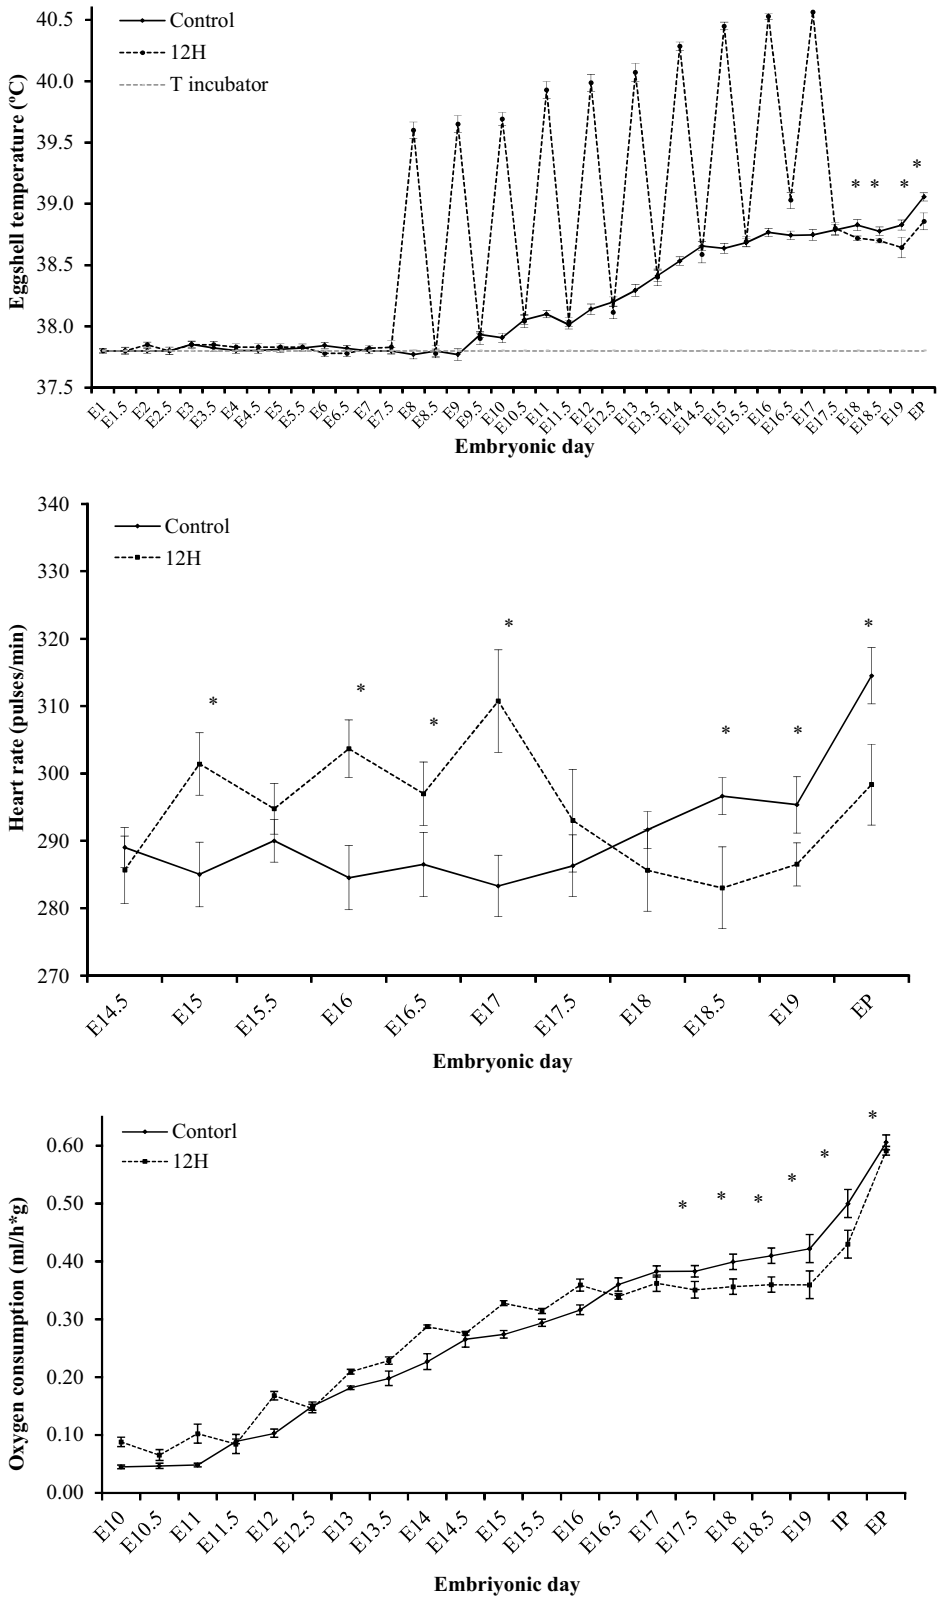

FIGURE 37.10 Eggshell temperature, heart rate, and oxygen consumption of broiler embryos incubated under control (37.8 °C, 56% RH) or intermittently thermally manipulated (TM—12H treatment; 39.5 °C, 65% RH) from E7 through E16 (180 through 408 h of incubation). For each day of incubation, an asterisk indicates significant differences ($p \leq 0.05$) between treatments.

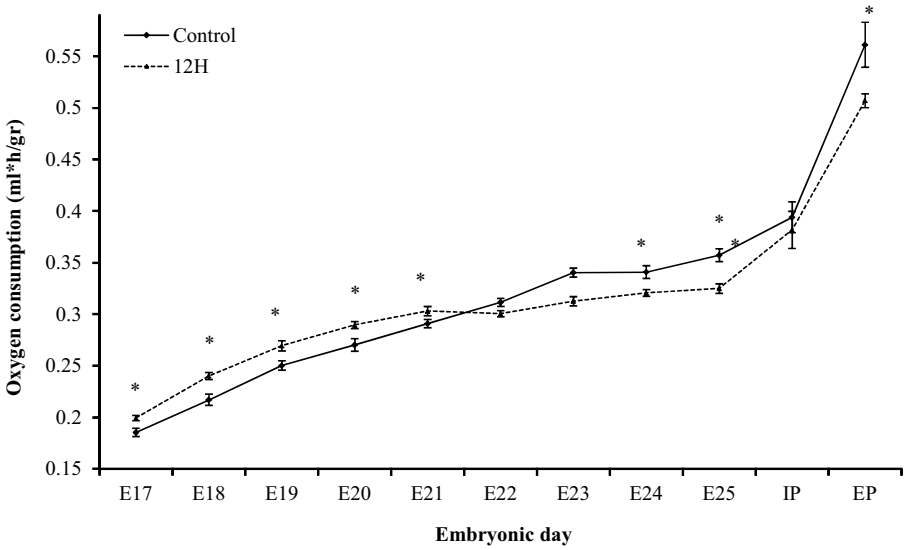

FIGURE 37.11 Oxygen consumption of turkey embryos incubated under control (37.5 °C, 56% RH) or intermittently thermally manipulated (TM—12H treatment; 39.2 °C, 65% RH) from E10 through E22 (240 through 528 h of incubation). For each day of incubation, an asterisk indicates significant differences ($p \leq 0.05$) between treatments.

several hours. Thermotolerance acquisition can be defined by reference to several parameters, such as T_b, thyroid and corticosterone hormones, and vasomotor responses. Thermal challenge induced a severe hyperthermia in all birds but, when the distributions of T_b were examined, the advantage of 12H TM was pronounced (Piestun et al., 2008): the number of birds that developed T_b in the range between 43 and 44 °C was much higher among the TM-treated ones, whereas the number of those that developed T_b of 44–45 °C was much higher among the nontreated ones, and the ability to recover from a hyperthermic condition with T_b of 44–45 °C was very low (Yahav, 2000). The ability of the TM-challenged chickens to maintain lower T_b springs from a sufficient reduction in the activity of the thyroid gland; a reduction in the peripheral deiodination of T_4 to T_3, coupled, most probably, with enhanced activity of 5-monodeiodinase (which would transform T_4 to the nonactive form of T_3; that is, the rT_3); and an adequate vasomotor response, as measured by radiative and convective heat loss. Figure 37.12 demonstrates heat loss by radiation and convection of broilers exposed to 23 °C (the regular T_a) and then to the challenge temperature of 35 °C. At 23 °C, heat loss was significantly lower in the 12H treatment than in the controls, whereas exposure to 35 °C caused a complete change in the response: exposing birds with the lower metabolic rate (12H treatment) to a lower T_a (23 °C) elicited vasoconstriction to retain heat, which was expressed in lower SHL, whereas exposure to a high T_a (35 °C) elicited vasodilatation, which was expressed in high SHL. Inducing different thermoregulatory pathways in order to reduce the development of hyperthermia caused only a mild increase in plasma corticosterone concentration, which indicated mild stress of the TM-treated chickens.

In sum, the accumulating evidence precludes a regular physiological adaptation, in light of the time elapsed between the TM treatment and the posthatch challenge. However, the evidence shows that the epigenetic adaptation approach and its association with changes in the incubation environment—with emphasis on fine-tuning the level and duration of stress to coincide with the critical phase—can elicit efficient epigenetic temperature adaptation in broiler chickens.

37.6.3.3 The Epigenetic Temperature Adaptation Using the Posthatch Model

Broiler chicks complete development of their brain and T_b regulation at the age of 10 days posthatch (Arad and Itsaki-Glucklish, 1991). Until this time point, body and brain temperatures are maintained at lower levels than in adult chickens. Subsequently, as age increases, the difference between body and brain temperatures increases linearly and significantly. The epigenetic response has been successfully modulated by early-age TM of posthatching chicks, by exploiting the incomplete maturation of the thermoregulatory system: TM involving exposure of a 3 day old broiler to 37–38 °C at 60–80% RH for 24 h was found to improve acquisition of thermotolerance. The improvement achieved was manifested in the ability of the TM chicks to reduce heat production efficiently during exposure to acute thermal challenge at marketing age. This was accompanied by the following (Yahav, 2009): an alteration in SHL through convection and radiation; a significant reduction in the stress level of the TM chickens, as indicated by their plasma corticosterone concentration; and pronounced decrease in the

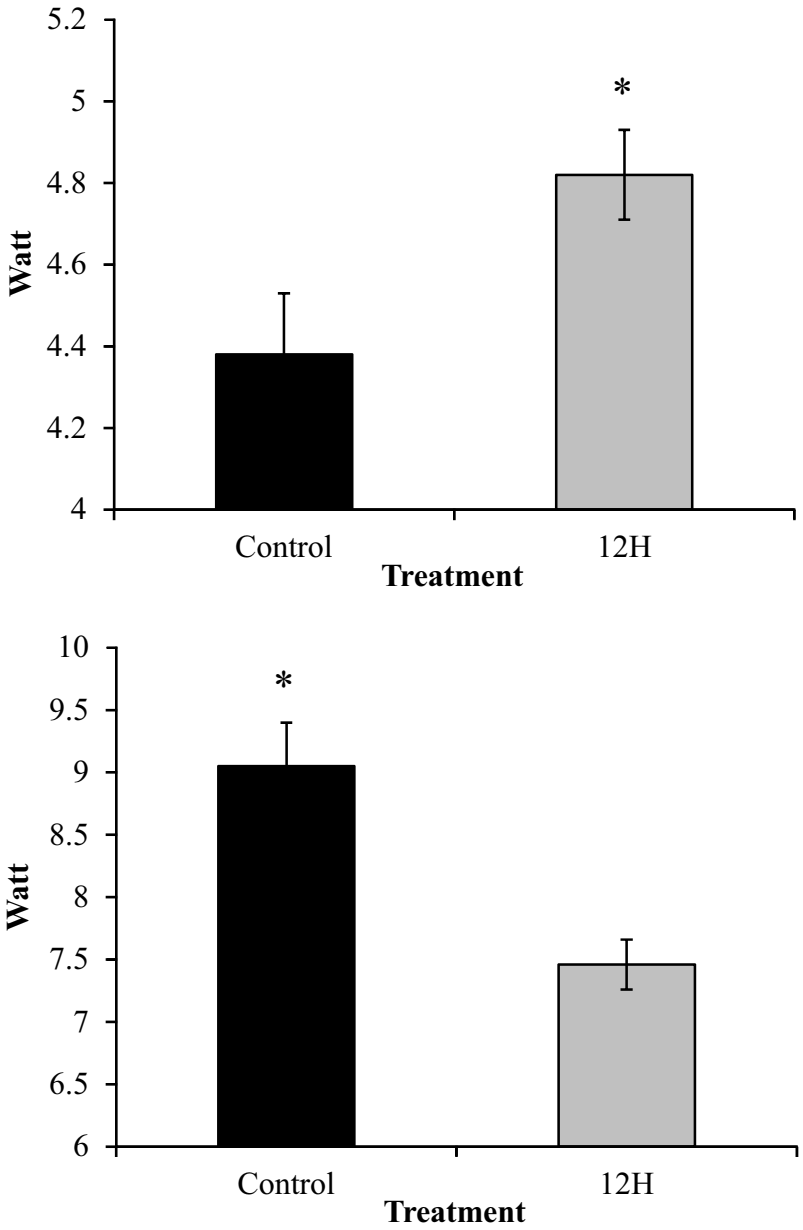

FIGURE 37.12 Sensible heat loss (via convection and radiation) from 35 day old broilers exposed to control conditions (23 °C, lower graph) or to thermal challenge of 35 °C for 5 h (upper graph). The broilers were incubated under control (37.8 °C, 56% RH) or thermally manipulated (TM; 39.5 °C, 65% RH) intermittently for 12 h (12H treatment) from E7 through E16 (180 through 408 h of incubation). Asterisk indicates significant difference between treatments ($p \leq 0.05$).

27, 70, and 90 kDa heat-shock proteins (HSPs) in the heart muscle and lung tissue of TM chickens during thermal challenge. As a result of this study, it has been suggested that the induction of HSPs is correlated with T_b, and that the HSP response is not part of the long-term mechanism elicited by the early-age TM. The reduction in heat production, coupled with increased SHL, enabled relatively slow development of hyperthermia and thus dramatically reduced mortality. The TM application at 3 days of age also induced compensatory growth, leading to improvement of performance and muscle growth, because of proliferation of skeletal muscle satellite cells during TM (Halevy et al., 2001). It was further found to positively affect the post-TM development of the gastrointestinal tract (Uni et al., 2001).

37.6.3.4 The Plasticity of the PO/AH and Its Association with Posthatch TM

Although the effect of TM on long-term storage of information was not studied in embryos, there was great interest in

elucidating the mechanisms by which sensory information affects neural circuits during other critical developmental periods. Like other sensory mechanisms, the thermal response set point is probably elicited by TM causing alterations in cellular properties in the hypothalamus (Boulant, 2006).

Posthatch TM, which induces long-term changes in the ability of chicks to withstand heat stress later in life, recently stimulated research that aims to understand the alteration in the PO/AH thermoregulatory control site. Recently, the signal-transduction pathways underlying postnatal hypothalamic-neuronal-network reorganization were characterized, revealing that in chicks there are three known neurotrophic factors: nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and neurotrophin-3 (NT-3). Of these three factors, BDNF plays a pivotal role in developmental plasticity. Katz and Meiri (2006) found that during TM of 3-day-old chicks, expression of BDNF mRNA, but not that of NGF or NT3, was induced in the PO/AH; a threefold increase in mRNA expression occurred 6 h after the initiation of TM. In order to test the hypothesis that BDNF activation was critical for the association of PO/AH plasticity with TM, BDNF was "knocked down" by using antisense, thereby providing the opportunity to induce transient changes in gene expression (downregulation) during significant time windows (Kramer and Cohen, 2004). Indeed, use of BDNF antisense inhibited BDNF expression in the PO/AH by 80% during the TM experiment (Katz and Meiri, 2006) and thereby impaired the TM chick's thermal tolerance. This confirmed the critical involvement of BDNF in thermotolerance acquisition as a result of TM, in that BDNF acted not only as an effector during TM but also as a mediator whose expression was correlated with long-term thermal set-point determination. Furthermore, it was found that the acquisition of thermotolerance was mediated in the PO/AH by R-Ras3, which is known to participate in growth-related signal transduction in the brain (Labunskay and Meiri, 2005), and 14-3-3ε, which is known as a chaperon of phosphorylation and of determination of cellular localization in establishing thermal control. In its role as a chaperon, 14-3-3ε activates transcription via Jun (Meiri, 2007). The process has been shown to be regulated at the translational level by induction of eIF2B expression.

In sum, induction of growth signaling during TM probably can account for the changes in cellular properties in the PO/AH that may, in turn, lead to changes in the thermal set point that induce thermotolerance acquisition.

37.7 THE COST OF MAINTAINING BODY TEMPERATURE IN POULTRY COMPARED WITH THAT IN OTHER BIRD SPECIES

The costs of maintaining T_b in various species with differing backgrounds (i.e., domesticated versus undomesticated) and diverse environmental situations (e.g., exposure to extreme environmental conditions, migration) necessitate a variety of physiological responses in order to adjust to the new challenges. These responses may differ according to any specific challenge. Irrespective of the differences among the challenges, the adjustment will always aim to maintain T_b within the limits of the two-tier theory of thermoregulation.

37.7.1 Domesticated Fowl and Thermotolerance: Acute Heat Exposure

Recent decades have seen significant developments in the genetic selection of meat-type fowl—that is, broilers (Havenstein et al., 1994, 2003a) and turkeys (Havenstein et al., 2007). These developments led to rapid growth, accompanied by increased feed efficiency and metabolic rate (Janke et al., 2004) but relatively poor enhancements in functional efficiency of several visceral systems, such as the cardiovascular and respiratory systems. Thus, acute exposure of chickens to extreme conditions, such as hot spells, confronts broilers, and, to a lesser extent, turkeys with difficulties in maintaining T_b. This is an outcome of the conflict between high production and thermotolerance, which leads to the relatively diminished ability of domesticated fowl to maintain a sufficiently dynamic steady state in face of severe changes in the environment (Yahav, 2009).

The level of hyperthermia from which a sufficient recovery can occur was found to be between 44.0 and 44.5 °C for broilers and turkeys (Yahav et al., unpublished data). It can be speculated that above this level, heat stroke is developed; it is characterized by detrimental changes at the cellular and molecular levels—changes that lead to the fatal cascade of events comprising decreased blood pressure, brain hypoxia, neuronal dysfunction, cell fatigue, etc. (Hales et al., 1996). Thus, heat stroke may be the reason for insufficient recovery that is characterized by neuronal disorders, or for complete inability to recover. However, to avoid reaching this stage of hyperthermia, the body will strongly activate two main mechanisms—EHL and vasodilatation—although one important mechanism, facultative heat production, will decline.

The vasodilatation response increases blood flow to the skin, especially to the nonfeathered areas of the fowl, as well as to the upper respiratory passageways, in order to transport heat from the viscera to the periphery. Vasodilatation will follow the development of hyperthermia. Development of hyperthermia, followed by increase in surface temperature, was monitored in broiler chickens by Giloh et al. (2012), who found that, irrespective of the broiler's age, hyperthermia developed in a short time. T_b reached values of 42.9–44.9, 42.6–43.7, 42.6–43.3, and 43.1–44.6 °C at the ages of 9, 16, 22, and 36 days, respectively; the increased facial surface temperatures (e.g., vasodilatation) that developed in parallel reached 40.9–43.0, 40.9–42.3, 41.2–41.7, and 42.5–44.0 °C, respectively. The increase in surface temperature enhances heat loss by radiation convection

and conductance (i.e., SHL). However, whereas before the acute exposure to heat stress a difference of approximately 2.0 °C between T_b and facial surface temperature was measured, this difference was significantly reduced during the development of hyperthermia, suggesting a limited capacity for vasodilatation despite the progressive development of hyperthermia.

In parallel to vasodilatation, also EWL is activated. However, evaporative cooling through panting may lead to dehydration, which may dramatically affect the functioning of the blood system, leading to heat stroke. During the first stages of acute heat stress, before the development of dehydration, although the blood supply to the skin and the upper respiratory passageways is enhanced, there is no impact on the blood supply to other important tissues. This is mainly because of the increase in cardiac output that results from the increases in HR and, to a much lesser extent, in stroke volume, and from the redistribution of blood flow among tissues, by which blood flow is diverted from nonvital tissues to vital ones. The resulting increases in HR and venous return support an overall increase in cardiac output that refills the arterial pressure reservoir more rapidly and prevents further reduction in arterial pressure (Whittow et al., 1964; Sturkie, 1967; Zhou, 2000). However, as dehydration develops, depletion of the blood volume will cause a reduction in venous pressure which, in turn, will diminish blood flow to the skin and the upper respiratory tract, thereby impairing the efficacy of the *E* routes. This will lead to lethal levels of hyperthermia, with T_b that could reach 46–47 °C.

A further combined mechanism involves modulation of heat production, which declines with increasing duration and level of heat stress, to prevent excessive accumulation of heat in the body. Under acute heat stress, the main and immediate mechanism to reduce T_3 and, thereby, heat production acts by reducing the deiodination of peripheral T_4 to T_3 and increasing the transformation of T_3 to rT_3.

It can be concluded that activation of the physiological mechanisms that lead to enhancement of heat loss via every route, coupled with reduction of heat production will minimize the deleterious effect of heat stress. However, long-term (hours) incidence of extreme heat stress may eventually lead to the cascade of heat stroke events that eventually will end in death.

37.7.2 Physiological Adjustments of Birds to Arid, Cold, and Aquatic Environments

Living in a desert environment exposes endothermic birds to shortage of energy and water while exposing them to high T_a and solar radiation during the day. Such environmental conditions force birds to exhibit physiological and behavioral adaptations to enable them to cope with such deleterious environmental conditions. Most desert species of birds are diurnal, and they may be exposed to shade temperatures (T_a) around 50 °C. Exposure to high T_a not only necessitates efficient thermotolerance, but it also puts an additional strain on water and energy balance in an environment that lacks these elements. On the other hand, low T_a increases the energetic costs required for maintenance of homeothermy. For some small birds or those living in extreme environments, the level of heat production that would be required to maintain T_b will reach levels that necessitate the adoption of thermoregulatory adjustments, such as cyclic torpor or hypothermia, which enable energy reserves to last through the stressful period (Körtner et al., 2000; McKechnie and Lovegrove, 2002).

37.7.2.1 Desert Environment

In desert mammals, BMR and total evaporative water loss are significantly lower than in nondesert species. Across-species comparison between desert and nondesert birds demonstrated that, on average, arid zone birds exhibited lower RMR (Tieleman and Williams, 2000) and lower total evaporative water loss (Williams, 1996) than those of other zones. Other strategies are shifting the thermoneutral zone towards higher environmental temperatures and minimizing the dry heat gain from the environment. *Dry heat gain* is calculated as:

$$\text{Dry Heat Gain} = h\,(T_b - T_a) \qquad (37.19)$$

in which h is the dry heat transfer coefficient, which is influenced by skin vasodilatation, feather insulation, the bird's volume-to-surface ratio, and subcutaneous fat tissue; and $(T_b - T_a)$ is the difference between T_b and the environmental temperature. When T_a exceeds T_b, heat will flow into the body, and the physiological adaptation requires h to decrease to a minimal level.

However, it must be pointed out that a comparison between desert and nondesert species may be misleading. Species differ not only in habitats, but also in their phylogenetic backgrounds, behavior, and diets.

A study by Tieleman et al. (2002), which tried to avoid differences in these parameters addressed various species of larks (*Alaudidae*), compared birds from the arid zone (e.g., Hoope larks and Dunn's larks with those from the mesic zone (e.g., skylarks and woodlarks)). The study found that in desert larks BMR and total water turnover were lower by 43 and 27%, respectively than those observed in the mesic species, and the T_b monitored in the desert species was lower by 1.1 °C. However, the value of h in the desert species was not lower when T_b was equal to T_a, and a similar pattern of h at high environmental temperatures was found in other small-bird species. Minimizing the heat transfer coefficient should minimize heat gain from the environment, in order to reduce the loss of water through evaporation, which is the only mechanism that can cool the body when T_b is equal to or below T_a.

An important determinant for BMR is the size of internal organs, such as the heart, kidney, liver and intestine (Chappell et al., 1999). The selection for low energy requirement that the environment imposes on desert birds may lead to minimal BMR and ratio of metabolic organ size to body mass. On the other hand, reduction in total evaporative water loss may be associated with the structure of the SC of the skin that influences CWL (Peltonen et al., 1998).

37.7.2.2 Cold and Aquatic Environments

As mentioned above, the main concern raised by exposure to cold environments involves the cost of the energy required for maintaining T_b. This cost is even higher for aquatic species because the thermal conductance of water is 25 times as high as that of air, and because of the drastic reduction of the insulation provided by plumage or feathers in water. Thus, several physiological adjustments are required in order to reduce or maintain the activity of the organism.

Birds, and especially, small species, are able to employ torpor (i.e., controlled reductions of metabolic rate and T_b) to substantially reduce energy expenditure during certain parts of the day or year, and thereby to minimize the impact of energy challenges. This response is most pronounced during long and severe winters, when low T_a is combined with reduced availability of feed. However, temporary variations in food resources also may trigger heterothermy/torpor; a study of torpor in Malachite Sunbirds (*Nectarinia famosa*) found that T_b fell to 26.8 °C when they were exposed to T_a of 5 °C (Downs and Brown, 2002). Although torpor was associated mainly with small birds, McKechnie and Lovegrove (2002) found $T_b < 15$ °C in avian species with body mass larger than 70 g, indicating the importance of food availability. Although measurements of T_b in free-ranging birds are quite common, birds may be torpid and save energy and water by utilizing metabolic depression, which would not be manifested in their T_b (McKechnie and Mzilikazi, 2011).

Whereas low T_a coupled with food scarcity will cause torpor, in diving birds searching for food low T_a necessitates different physiological adjustments. In such cases prevention of body cooling should be the strategy employed by diving birds such as penguins. To achieve this, a dramatic decrease in the peripheral T_b is used, to reduce peripheral heat loss. Such reduction is an outcome of compression of the air in the feathers at depth and speed, combined with peripheral vasoconstriction. The peripheral vasoconstriction causes the warm blood to bypass the cold-exposed tissues and enhances their cooling, while the internal tissues are isolated and the core temperature is maintained (Schmidt et al., 2006).

37.7.3 Physiological Adjustments of Birds to Migration

Each year in autumn, billions of birds fly from their breeding grounds to wintering grounds, from which they return in spring. This is a highly energetic process that enables the birds to escape adverse local conditions during winter and to return in spring to search for breeding sites. Thus, the process is influenced by the thermoregulatory difficulties caused by the energy cost of transport. Modern tracking of migration records revealed round trips of more than 64,000 km/year by some marine birds, and another physical achievement was demonstrated in a single nonstop flight of 11,000 km from Alaska to New Zealand by the bar-tailed godwit (*Limosa lapponica* L.) (Weber, 2009). Such extreme physical accomplishments must involve the evolution of specific adaptations that make these records possible.

37.7.3.1 Variations in BMR

Mobility of any organism has been identified as a major determinant of selection that affects maintenance energy demands. Therefore, it would be expected that migrating birds would exhibit variations in BMR, because migration is associated with wide changes in a bird's body weight in the course of long-distance movements, sometimes with no breaks. Migration may affect BMR in three different ways: long-distance migration may necessitate high rates of energy acquisition in preparation for migration, thus leading to higher BMR than that of nonmigrating birds (Kvist and Lindstrom, 2001); seasonal presence in the breeding region may remove some of the selection pressure on BMR that affects nonmigrating birds, such as the need to survive through the cold winter; and alternating occupation of differing environments may cause differences in BMR when migrating and nonmigrating birds are compared. Among migrants, BMR may vary strongly both within and between individuals during preparations for migration, whereas in nonmigrants little variation in BMR was observed previously (McKechnie, 2008).

37.7.3.2 Minimizing the Cost of Migration

Migrating birds evolved various strategies to minimize migration costs. For instance, the use of locomotory muscles can generate force with very high efficiency (Kvist et al., 2001). They minimize body mass by atrophying the digestive and reproductive organs before taking off, in parallel with escaping the winter shortage of food, and decrease the maintenance costs of other tissues that are not essential for migration (McWilliams and Karasov, 2004). They use selection of lipids to store energy for muscle activity, because lipids provide the highest ATP yield per gram of fuel, and generate more metabolic water upon oxidation than proteins or carbohydrates; the premigration lipid reserve can reach 50% of body mass.

The amount of energy produced during migration must cause an elevation of T_b, but there is almost no information in the literature on migrants' T_b. The most up-to-date report focuses on T_b fluctuations in migrating birds during stopovers. Stopovers to refuel may be efficient if the bird is able to reduce energy costs by becoming hypothermic or even entering torpor while at rest; facultative reduction of a bird's T_b is known to be a common procedure. A study on the Blackcaps passerine (*Sylvia atricapilla* L.) by Wojciechowski and Pinshow (2009) shed some light on the thermal physiology of this species during stopover. This species breeds in Europe, migrates to northern Africa in autumn, and returns in spring. During stopover, the birds reduced their T_b by up to 10 °C below normothermic, which ranges between 39 and 44 °C (Prinzinger et al., 1991). The decline in T_b reduces the difference between T_b and T_a and thereby significantly reduces the energy expenditure needed to maintain T_b, which, in turn, accelerates the rate of fuel accumulation during stopover. Small migrating birds may also reduce energy expenditure and maintain mild hypothermy by huddling (Gilbert et al., 2010).

The hypothermic response, whether during stopover or at the end of the migration, facilitates efficient recovery from the harmful consequences of migration.

37.8 SUMMARY AND CONCLUSIONS

Body temperature control exclusively characterizes endothermic birds and mammals. It results from physiological adjustments coupled with morphological modifications. In birds, its profoundly varied physiological, ecological, and behavioral benefits enable wide aerial, aquatic and terrestrial distributions. Controlling T_b necessitates a very-high-gain thermoregulatory system that prevents deleterious environmental effects; it operates via control of heat production, such as by shivering and NST, and heat loss, such as via evaporation and SHL. In the course of evolution, to enable endothermy to replace ectothermy, these control mechanisms changed through modifications to the neuronal and endocrine regulatory systems that maintain a balance between heat production and heat loss. Understanding the processes that lead to changes in metabolic rate and heat loss, and the transition from ectothermy to endothermy, is essential for understanding the mechanisms that enable control of T_b.

It can be concluded that body temperature control is a unique characteristic of endothermic birds and mammals. Endothermy was selected during evolution in order to better adapt to a varying environment. T_b is the most physiologically guarded parameter of the body; its maintenance operates at a very high gain, achieved by the developmental regulatory mechanisms that maintain a balance between heat production and heat loss, and that are activated and regulated by both neuronal and hormonal signals. T_b of endothermic birds is regulated through a variety of thermoregulatory responses, controlled and orchestrated by the brain, that optimize the internal T_b in order to enable appropriate molecular activities and reactions.

Furthermore, to sustain thermal tolerance and avoid the deleterious consequences of thermal stresses, three direct responses are elicited by birds: the RTSR, characterized by response times ranging from minutes to hours; acclimation/acclimatization, characterized by response times ranging from days to weeks; and epigenetic adaptation during the perinatal period, which is based on timing. Endothermy heterothermy involves changing T_b in response to changes in the environment, such as alterations in T_a, and food and water availability. Furthermore, changing T_b from normothermic values in response to environmental alterations saves energy and is a key component of thermoregulation in birds of diverse sizes exposed to differing environments: tropical, subtropical, arid, and mesic. The transition from ectothermy to endothermy necessitates increased capacity of the respiratory system, changes in the CVS, increased efficiency of the gastrointestinal tract, and modifications to the neural and endocrine systems that regulate metabolic enzyme activities. These modifications include changes in protein structure, modifications to membranes and up- or down-regulation of genes. This transition occurs in precocial birds during embryogenesis, in which it takes place as early as the plateau phase, whereas in altricial birds the transition takes place during poikilothermic stage, which lasts until the end of nestling.

Accumulating evidence on TM precludes a regular physiological adaptation but emphasizes the occurrence of an efficient epigenetic temperature adaptation process. TM induces growth signaling, which probably can account for the changes in cellular properties in the PO/AH that may lead to the changes in the thermal set point that induce thermotolerance acquisition. Finally, living in extremely low T_a environments necessitates the adoption of thermoregulatory adjustments, such as cyclic torpor or hypothermia, whereas extreme high-T_a environments necessitate adjustments to RMR and changes in the CVS to permit efficient SHL.

Chapter 38

Avian Molting

Alistair Dawson
NERC Centre for Ecology & Hydrology, Midlothian, Edinburgh, UK

38.1 INTRODUCTION

Good-quality plumage is essential for the survival of birds. However, feathers wear out and need to be replaced normally on an annual basis. This process of molt is one of the key life-history stages of birds' annual cycles. Despite the critical importance of molt and research over many decades, we know remarkably little about its physiological control. Voitkevich wrote a 335-page treatise on the subject (translated from Russian and published in 1966). Payne wrote later in a review (1972): "The physiological bases of the control of the time and rate of molting and the integration of molt into the annual cycle are of considerable interest, and their discovery remains a challenge to the comparative physiologist"—a challenge that remains (Bridge, 2011; Kuenzel, 2003).

38.2 ANATOMICAL AND ECOLOGICAL CONSIDERATIONS

38.2.1 Feathers

Feathers are the characteristic feature of birds, with birds being defined as feathered vertebrate animals. Birds evolved from reptiles, and there is evidence that dinosaurs had feathers (Zelenitsky et al., 2012) and that the ontogeny of their feathers resembled that of modern birds (Xu et al., 2010).

The plumage of birds—the collective name for the covering of feathers—serves a number of functions. It provides insulation and waterproofing, in an analogous way to pelage in the other group of homeotherms, the mammals. Uniquely and crucially, it also enables most birds to fly by providing surfaces that give aerodynamic lift on the wings and tail. The contoured body shape reduces air resistance during flight; in waterbirds, plumage provides buoyancy. The color of plumage can provide camouflage or patterns that are used for sexual or aggressive displays.

To provide these functions, the plumage is made up of a variety of specialized feather types: flight, contour, semiplume, down, bristle, and filoplume (Ginn and Melville, 1983). All feathers are constructed largely of keratin and are essentially two-dimensional with a tapering central shaft, the base of which is embedded in the feather socket or follicle (Voitkevich, 1966). In the contour feathers, which include the flight feathers, the base of the shaft is hollow, cylindrical, and devoid of side branches. The rest of the shaft (rachis) is solid and bears rows of parallel side branches (barbs). Each barb has two rows of smaller side branches (barbules). There are two forms of barbule: those that point towards the tip of the feather are laterally flattened with hooked projections, and the others which lack the hooked projections. The hooks on one barbule link onto the adjacent barbule. This linkage system forms a two-dimensional lattice, the feather vane, which is light but strong. Other forms of feather differ in that they do not have the hooked projections on the barbules so that the barbules remain unlocked and downy. The color of feathers can be provided in two ways: (1) the feathers can contain pigments, of which there are three types, melanins, carotenoids and porphyrins; and (2) the structure of the feather can provide either iridescent or noniridescent color.

The feathers are distributed into seven or eight distinct tracts (pterylae) with areas between them (apteria) that are devoid of feathers or have only sparse coverage. In some species, such as penguins, the apteria are few and small so that feather coverage is almost even over the whole body. Even in species with significant apteria, these are not obvious externally because feathers in adjacent pterylae completely overly them. The total number of feathers on a bird varies widely, with large birds tending to have more. However, feather density also varies, which may be related to insulation requirements; penguins have particularly high densities, and, within species, feather density can be higher during winter.

Sturkie's Avian Physiology.

Each feather is formed from a cone-shaped structure deep in the feather follicle. Development of the complex feather structure may be the result of changing topology of stem cells within the follicle (Yue et al., 2005). The first generation of feathers forms at different rates in different species. In many species, particularly precocial species such as domestic poultry, the first feathers develop before hatching, and there are subsequent molts before birds are fully grown. In most altricial species, birds hatch naked and their juvenile plumage develops during the nestling period (Samson, 1976). There may, or may not, be a postfledging molt into adult plumage.

The importance of good quality plumage means that birds spend a significant portion of each day in feather care. The bill is used to preen—to clean the feathers, restore their structure, and apply preen oil from the uropygial gland. Nevertheless, feathers are dead structures; they degrade with time and cannot be repaired. They become bleached through the effects of UV radiation, abraded through contact with adjacent feathers and possibly vegetation in the bird's habitat; they may break and they will probably degrade as a result of infestation with ectoparasites. Because good-quality plumage is essential for survival, feathers need to be replaced on a regular basis. This renewal process is molt. During molt, there is also regeneration of other epidermal structures, particularly the bill and claws.

The molting process is the shedding of old feathers and the development of new ones in their place. It is thought that development of a new feather pushes out the old feather. However, if an old feather is pulled out, it is often replaced by a new one, suggesting the reverse—that it is the shedding of the old feather that stimulates development of a new feather.

38.2.2 Molt

All birds molt at least once during the year. The plumage that birds have during the nonbreeding and overwintering period is called the basic plumage. The molt that results in this plumage is therefore termed the prebasic molt; this often, but not always, occurs after breeding and hence is sometimes called the postnuptial molt (Ginn and Melville, 1983; Jenni and Winkler, 1994). The prebasic molt is the subject of this chapter. Some species of birds additionally undergo a prenuptial (or prealternate) molt into the breeding, or alternate, plumage. This molt involves some of the head and/or body plumage and occurs during spring in advance of breeding and brightens the appearance of the bird or emphasizes a "badge".

During the prebasic molt, all feathers are eventually replaced (except in some large birds), but this happens in a strict bilaterally symmetrical sequence so that the various functions of plumage are not normally compromised. Molt often starts with the shedding and replacement of the proximal primary feather, followed by the next primary and so on to the end of the wing. Normally, only a few primaries are in the process of molt at any one time so that flight performance is not compromised. If birds are under time constraint to finish molt rapidly, this is achieved by molting more feathers at once, rather than increasing the growth rate of each feather. The two wings are usually at exactly the same stage of molt. After primary feather molt has started, molt of the other feather tracts proceeds, again symmetrically. Molt of the other tracts is normally completed before the end of the primary molt. As a general rule, larger birds tend to take longer to molt than smaller birds. Rohwer et al. (2009) showed that, due to allometric constraints, large birds may not have time to molt all of their flight feathers sequentially each year and so must adopt one of two strategies. Some large waterbirds, such as ducks, swans, grebes, pelicans, and auks, molt all of their flight feathers simultaneously. During this period, they cannot fly and complete the process on lakes, estuaries, or at sea in order to minimize their vulnerability to predators. Other large birds—those that depend on flight to feed—molt only some of their flight feathers each year, and require 2 or even 3 years to complete molt. Some species have an additional full molt each year (Prys-Jones, 1991; Underhill et al., 1992) and some have partial repeated molts (Bridge et al., 2007).

In the U.S. poultry industry, induced molting is used to increase or rejuvenate egg production (Bell, 2003; Berry, 2003; Webster, 2003). Induced molting and ovarian regression are achieved by feeding a nutritionally deficient diet and reducing photoperiod. The minimum photoperiod is 8 h of day light and water is available *ad libitum*. Subsequent gonadal recrudescence is achieved by restoring a nutritionally replete diet and stimulatory photoperiod. This practice is not permitted in the European Union.

In many species, the plumage is sexually dimorphic, often with the male having the brighter showy plumage. In species that molt only once per year, the prebasic molt, the sexual dimorphism is under genetic control (Owens and Short, 1995). Castration of males or ovariectomy of females has no effect on the plumage. Similarly, treatment with exogenous testosterone or estrogen is without effect. In those species in which the males undergo a prenuptial molt in spring from a dull winter plumage into bright breeding plumage, it is frequently assumed that this is testosterone-dependent. This is not the case. Unlike mammals, in birds it is the males that are homogametic, so the showy plumage is the default state. Estrogens block the subsequent production of the bright male plumage. Castration of males has no effect on this plumage, but ovariectomy of females causes them to develop the bright male plumage. Thus, showy male plumage is not the result of masculinization by testosterone (Owens and Short, 1995).

38.2.3 Molt as a Life History Stage

Birds, as other animals, live in conditions that change on an annual cycle; to maximize fitness, they need to retain phenotypic flexibility. They switch from one life history stage to the next in a one-way sequence. Molt is important for birds' survival; birds that have been experimentally prevented from molting by treatment with testosterone (Nolan et al., 1992) or that have had to molt rapidly so that they had poor quality plumage (Nilsson and Svensson, 1996) survive less well over winter. Therefore, all birds have annual cycles in which molt features as a life history stage. In nonmigratory birds, there may be just three basic life history stages: winter/nonbreeding, breeding, and molt (Wingfield, 2008). In migratory species, there are two additional stages: a vernal migration (which has to precede breeding) and an autumn migration (which follows breeding).

Breeding and molt are both energetically demanding and take time (Murphy and King, 1992), and molt impairs flight performance (Swaddle and Witter, 1997; Tucker, 1991). Therefore, the prebasic molt is usually, but not always, delayed until breeding has finished (Hemborg, 1999; Hemborg and Merila, 1999; Morton, 1992). Even in equatorial or neotropical species, prebasic molt may closely follow breeding (Dittami and Gwinner, 1985; Moore et al., 2005; Wikelski et al., 2003). Consequently, in these situations, breeding birds start to molt later than nonbreeders; females often start to molt later than males, and birds with extended or late breeding molt later than those that curtailed breeding activity earlier (Morton and Morton, 1990; Newton, 1966; Newton and Rothery, 2000). Some temperate and high-latitude species are opportunistic breeders—they can breed at widely differing times in different years depending on the availability of food. Nevertheless, molt occurs at a comparatively fixed time of year and breeding does not occur during this period (Hahn, 1998). Some species, however, do overlap breeding and molt. This is more common in larger species because the time required for rearing young, as well as the time required to replace flight feathers, increases with body size. For example, in some raptors, the female starts to molt while she is incubating and being fed by her mate, so she does not need to fly (Young et al., 2009). It is also common in species with long breeding seasons and in low-latitude opportunistic breeders. In such cases, the rate of molt is slow during breeding and few flight feathers are replaced at a time, presumably to minimize the energetic and flight performance costs of molting on reproduction (Echeverry-Galvis and Hau, 2012; Hahn et al., 1992).

Migration is also energy demanding and, of course, molt impairs flight efficiency. Therefore, molt and migration tend also to be temporally separated, but there are a variety of strategies to achieve this (Barta et al., 2008). Some species molt immediately after breeding on the breeding grounds, whereas others migrate to their wintering grounds before molt is initiated (Kjellén, 1994). Some species molt after breeding before migration and again after migration on the wintering grounds, and others interrupt migration in order to molt. The scheduling of molt is the result of a tradeoff between having a high feather quality during breeding versus during the nonbreeding period (Holmgren and Hedenstrom, 1995) and the comparative availability of food on the breeding or wintering grounds (Barta et al., 2008).

Because life history stages tend to be temporally separate, excess time taken over one will incur constraints on the time available for subsequent stages. In particular, birds which breed late or for longer have less time available for the prebasic molt. Data on the duration of molt in free-living birds are rare, probably because of the difficulty of retrapping the same individuals over the period of molt. Nevertheless, several studies have shown that birds that start to molt late will molt more rapidly (Bojarinova et al., 1999; Morton and Morton, 1990; Newton, 1966). During a normal molt, new feather mass is accumulated at a fairly constant rate (Dawson, 2003; Seel, 1976; Underhill and Joubert, 1995). When birds molt more rapidly, they achieve this by growing more feathers simultaneously (Dawson, 2004). As a result, feather quality is compromised (Dawson et al., 2000), which leads to a subsequent decrease in survival. The timing of the end of breeding and the start of molt is a tradeoff between reproduction and individual survival.

38.3 ENVIRONMENTAL AND PHYSIOLOGICAL CONTROL

Physiology has to control how an old feather is shed, how a new feather starts to grow, and the appropriate development of that feather. It has to control the sequence of molt, when molt of each feather tract starts and how it progresses along that tract, and control the bilateral symmetry of the progress of molt. It has to integrate environmental cues, photoperiodic and nonphotoperiodic, so that molt starts at the appropriate time and progresses at the optimum rate. We have very little understanding of the process(es) involved.

38.3.1 Photoperiodic and Nonphotoperiodic Control

In free-living birds within the tropics, the timing of prebasic molt may be dependent on the timing of breeding. For example, in equatorial stonechats (*Saxicola torquata axillaris*), molt follows breeding, but the cues that control the time of breeding are unclear (Dittami and Gwinner, 1985). Two equatorial populations of rufous-collared sparrows (*Zonotrichia capensis*), at the same latitude and separated by just 25 km, breed seasonally but out of phase with each other and also molt out of phase (Moore et al., 2005). However, for birds outside the tropics, the timing of prebasic molt within the annual cycle, like other life history stages,

is largely controlled by the annual cycle in photoperiod. The timing of the start of molt, the subsequent rate of molt, and hence the duration of molt, are largely under photoperiodic control. Experimental manipulation of photoperiod for captive birds gives insight into how this may operate.

38.3.1.1 Start of Molt

The start of molt is usually closely associated with the end of breeding and regression of the reproductive system, which in turn is dependent on the development of absolute or relative (Nicholls et al., 1988). In general, birds do not molt under short photoperiods—birds need to experience long photoperiods. In some species, those that become absolutely photorefractory, molt starts at some time after exposure to long photoperiods, and in such cases the time until the start of molt decreases as photoperiod increases. For example, white-crowned sparrows (*Zonotrichia leucophrys gambelii*) moved from a short mid-winter photoperiod to 20 h of light per day (20L:4D) started to molt sooner than birds transferred to 16L:8D (Chilgren, 1978). Starlings (*Sturnus vulgaris*) moved from 8L:16D to 18L:6D started to molt sooner than birds moved to 13L:11D (Dawson, 1994). However, there are differences in the length of photoperiod needed to induce molt. White-crowned sparrows moved to 12L:12D do not molt (Chilgren, 1978; Donham et al., 1983; Farner et al., 1980). Starlings moved to 11L:13D never molt, but birds moved to 11.5L:12.5D (Dawson, 2007) or 12L:12D do molt and then may undergo repeated circannual cycles of gonadal maturation, regression, and molt. Such repeated cycles have been shown in a number of species held on constant neutral photoperiods (Dolnik and Gavrilov, 1980; Guyomarc'h and Guyomarc'h, 1995; Gwinner, 2003). Starlings moved to 13L:11D molt once but not thereafter (Gwinner et al., 1989). However, if starlings are moved after completion of molt from 13L:11D to 18L:6D, another molt is induced (Dawson, 1994).

In species that become relatively photorefractory, such as Japanese and European quail (*Coturnix coturnix*), birds need to experience a decrease in photoperiod after a period of exposure to long photoperiods to induce molt to start (Boswell et al., 1993; Robinson and Follett, 1982). There are also intermediate situations, such as house sparrow *Passer domesticus* (Dawson, 1991, 1998; Hahn and Ball, 1995) song sparrows *Melospiza melodia* (Wingfield, 1993), and Cardueline finches (Pereyra et al., 2005), where birds will start to molt spontaneously at some time after transfer to a constant long photoperiod, but in which a decrease in photoperiod will advance the onset of molt.

38.3.1.2 Rate of Molt

Under different constant long photoperiods, although molt starts sooner under longer photoperiods, the subsequent rate of molt is similar (Dawson, 1994). However, changes in the photoperiod after the start of molt affect the rate of molt. An increase in photoperiod slows the rate of molt, a decrease to a shorter photoperiod increases the rate (Dawson, 1994, 1998; Kobayashi, 1953a), but a decrease to a short photoperiod can stop further progress of molt. Most species of birds in temperate latitudes molt after the summer solstice; individuals molting later in the year will be subject to shorter days and a more rapid decrease in photoperiod during their molt. Presumably this accounts for the shorter molt durations seen in late breeding birds (see Section 38.2.3).

38.3.1.3 Natural Photoperiods

All of the above experimental data were obtained from birds transferred from one fixed photoperiod to another. This situation would never be experienced by free-living birds. In such birds, molt normally occurs after the breeding season. In birds with short breeding seasons early in the year, molt starts before the summer solstice when photoperiod is still increasing. In birds with longer breeding seasons, molt starts during decreasing photoperiods. How is the timing of molt controlled by natural changes in photoperiod? One way to examine this is to look at the timing of molt within populations of the same species at different latitudes. Miller (1960) showed that the end of the period of active spermatogenesis, which is associated with the start of molt, within species and subspecies of the genus *Zonotrichia* ended at the same time at all latitudes. Two independent studies investigated the timing of molt in California quail (*Lophortyx californicus*). Genelly (1955) studied free-living quail on San Pablo Ridge, California (38°N) and Anthony (1970) studied them along the Snake River, southeastern Washington (47°N). In both studies, molt started at the same time: mid-June for males and mid-July for females. In the white-crowned sparrows of the Pacific seaboard (*Zonotrichia leucophrys nuttalli* and *Zonotrichia leucophrys pugetensis*), males begin molting earlier than females by as much as 2 weeks; for both sexes, the date on which molt begins is independent of latitude. However, molt duration decreases northward by an average of 2.6 days per degree of latitude between the southernmost (35.2°N, molt duration 83 days) and northernmost (48.9°N, 47 days) limits of the breeding range (Mewaldt and King, 1978). In common starlings, molt starts in early June in birds at 37°N and at 52°N (Dawson, 2013 Rothery et al., 2001) and blackbirds *Turdus merula* in the north of England start and finish molt at the same time as birds in southern England (Dawson, 2013). In all of these studies, birds at different latitudes will have experienced different changes in photoperiod; both absolute photoperiod and the rate of change in photoperiod will have differed, and so neither can directly control the timing of molt.

The conclusion that molt starts at the same time at different latitudes is confirmed by studies in which captive birds are kept under photoperiods simulating annual

changes at different latitudes. In starlings on photoperiods simulating 9°N or 52°N, molt occurred at the same time (Dawson, 2007). In siskins (*Carduelis spinus*) exposed to natural photoperiods simulating 40°N, 55°N, and 70°N, which encompass the natural breeding range of this species, molt occurred at the same time in all three groups (Newton and Dawson, 2011). Similarly, greenfinches (*Carduelis chloris*) held on photoperiods simulating natural cycles at 20°N and 60°N showed testicular regression and molt at the same time (Figure 38.1). These data suggest that birds are not using absolute photoperiod, or rate of change in photoperiod, to time gonadal regression and molt. They suggest that birds are using photoperiod in some more subtle way. They also suggest that the earlier start to molt in birds transferred to longer constant photoperiods is an artifact of the experimental design.

38.3.1.4 Nonphotoperiodic Environmental Control

Although the annual cycle in photoperiod is the major environmental cue used to time the start of molt, other supplementary information can be important (Dawson, 2008). Because the start of molt is closely associated with the end of breeding and gonadal regression, any factors affecting this will also affect molt. Unfavorable conditions that delay breeding, or favorable conditions that allow birds to raise an extra brood, will consequently delay the start of molt. Lower temperature delays the timing of regression and the end of breeding, resulting in a later start to molt, with the consequence that the subsequent molt occurs more rapidly (Dawson, 2005; Visser et al., 2011; Figure 38.1).

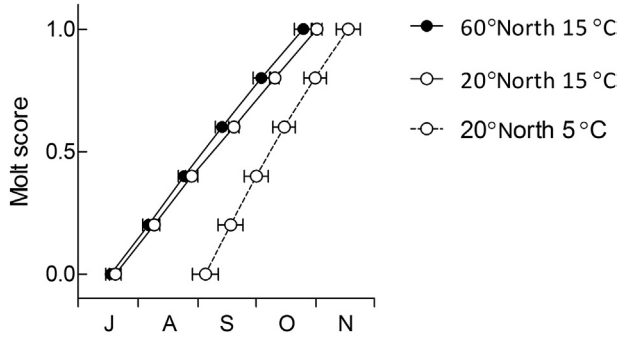

FIGURE 38.1 Molt in greenfinches (*Carduelis chloris*). Three groups of captive greenfinches were kept under photoperiodic regimes simulating latitudes of 60°N or 20°N. Two groups, one at each latitude, were held at a constant temperature of 15 °C and the other, at 5 °C. Molt is expressed as a proportion of total new primary feather mass (Dawson and Newton, 2004). The groups simulating 60°N and 20°N, at the same temperature, both started to molt at the same time (during July) and had the same duration of molt. The group at the lower temperature, 5 °C, started molt considerably later than the group at 15 °C and 20°N, and then molt proceeded more rapidly.

38.3.2 Physiological Control

There must be physiological processes that translate photoperiodic information into control of the whole process of molt: shedding of a feather, growth of the replacement feather, the sequence of this process along each feather tract, lateral symmetry in the progress of molt, timing of the start of molt, and subsequent rate of molt. The first studies on the endocrine control of molting were done nine decades ago, yet to date we still have little understanding of these processes. There is often a close temporal correlation between the end of breeding and the start of molt. This may mean that both share a common physiological trigger or, possibly, that molt is a comparatively passive event that is otherwise inhibited by an active reproductive state. Evidence for the latter view is that a complete molt can be triggered in a chronically reproductively inactive bird in the absence of a reproductive period. At least three hormone systems have been shown to play some role—thyroid hormones, steroid hormones, and prolactin—and there may be interactive effects between these.

38.3.2.1 Evidence for the Involvement of Thyroid Hormones

There is clear and long-standing evidence that thyroid hormones are in some way involved in molt (Torrey and Horning, 1922). Removal of the thyroid glands before transfer to a long photoperiod, which would normally induce a molt, prevents molt. Acute treatment with exogenous thyroid hormones can induce molt at times when a molt would not naturally occur (Himeno and Tanabe, 1957). However, molt is closely associated with gonadal regression and photorefractoriness, and thyroid hormones have long been known to be involved in these processes (Benoit, 1936; Boulakoud and Goldsmith, 1991; Chaturvedi and Meier, 1989; Dawson, 1989; Follett and Nicholls, 1985; Goldsmith and Nicholls, 1984; Lien and Siopes, 1993; Reinert and Wilson, 1996; Wilson and Reinert, 1993; Woitkewitsch, 1940). Consequently, a specific role for thyroid hormones in molt, rather than molt being a consequence of reproductive changes, cannot be substantiated. Exogenous thyroid hormones can to some extent act to mimic the effects of a longer photoperiod. For example, starlings held on a short photoperiod (8L:16D) and treated with exogenous thyroxine show enhanced gonadal maturation but do not molt. Starlings held on a photoperiod of 11L:13D and treated with thyroxine become photorefractory and molt as if photoperiod was greater than 12L:12D. Thyroidectomizing birds just before transferring them to long photoperiods does not apparently affect gonadal maturation but does prevent the subsequent onset of photorefractoriness and molt, suggesting a specific role for thyroid hormones in one or both of these processes. However, the full effects of thyroidectomy take some time. In chronically thyroidectomized starlings, all photoperiodic

responses become suppressed: photoperiodically-induced gonadal maturation, the onset of photorefractoriness, and molt. In other words, thyroidectomized birds become photoperiodically blind (Dawson, 1993).

Several studies have measured changes in concentrations of thyroxine and triiodothyronine following change in photoperiod and during the annual cycle. In general, thyroxine concentrations tend to be higher under long photoperiods but with no consistent result in relation to molt. Scanes et al. (1979) and Lien and Siopes (1993) found that thyroxine was maximal during molt in turkeys (*Meleagris gallopavo*). Bentley et al. (1997) investigated whether the long-photoperiod-induced increase in plasma thyroxine is necessary for the induction of photorefractoriness and molt. Photosensitive starlings were thyroidectomized, given thyroxine in their drinking water at concentrations that resulted in plasma thyroxine at short-photoperiod physiological concentrations or lower, and then transferred to long photoperiods. The group with short-photoperiod concentrations of plasma thyroxine became photorefractory and molted at the same time as intact controls transferred to long photoperiods. It would appear, therefore, that thyroid hormones need to be present and have a passive role in all photoperiodically-controlled events rather than a direct causal role in molt.

Not only do thyroid hormones need to be present for molt to start, they are also needed for normal feather formation. Thyroid hormones are involved in somatic growth and development. Birds thyroidectomized soon after hatching fail to grow successfully, their plumage is slow to develop, and feathers grow abnormally (Dawson et al., 1987, 1994; Voitkevich, 1966). The barbs on normal contour feathers have highly asymmetric barbules (see Section 38.2.1). The barbs of feathers from thyroidectomized birds have long smooth symmetrical barbules, so adjacent barbs do not link together and the feathers appear more like down. This feather structure is characteristic of adult ratites, such as ostriches and emus. The neotenous condition of ratites (de Beer, 1956) may be related to hypothyroidism (Dawson et al., 1996). Because renewal of feathers during molt is essentially the same as growth of first feathers, this too can be considered a developmental process. Interestingly, if thyroidectomized birds are transferred to a long photoperiod, they do not molt. If they are treated with an acute dose of thyroxine, this does trigger a molt to start. Although the exogenous thyroxine will rapidly be cleared from the circulation, molt progresses to completion. However, in the absence of thyroxine, the feathers grown develop the downy structure described above (Dawson et al., 1994).

38.3.2.2 Evidence for the Involvement of Gonadal Steroids

Because birds aim to start molt as soon as breeding has finished, but at the same time avoid breeding/molt overlap as much as possible, it is intuitive to think that a reproductive hormone could act to inhibit the start of molt. And, indeed, that is true. As with thyroid hormones, the first indication that gonadal steroid hormones may influence molt dates back many decades (Greenwood and Burns, 1940; Kobayashi, 1954). Treatment with implants of exogenous testosterone prevents or delays the onset of molt (Dawson, 1994, 2004; Nolan et al., 1992; Schleussner et al., 1985). If the implants are then removed during the period that molt would have naturally progressed, molt starts and then proceeds more rapidly, in a way analogous to birds in which the start of molt is delayed by late breeding (Morton and Morton, 1990; Newton, 1966). If the implant is removed after the normal duration of molt, when photoperiod has decreased, then molt does not start. If testosterone is implanted after molt has started, this stops the progress of molt; if the implant is removed, molt either resumes from where it was stopped or a new molt starts. Thus, testosterone inhibits molt during the period of normal photoperiodically timed molt; a decrease in testosterone is not the stimulus that triggers molt. Castrated birds also molt at the normal time of year, strongly suggesting that changes in circulating gonadal steroid concentrations are not implicit in the control of the timing of molt (Dawson and Goldsmith, 1984; Dawson and Sharp, 2010; Greenwood and Burns, 1940).

38.3.2.3 Evidence for the Involvement of Prolactin

As with thyroid hormones and gonadal steroid hormones, the first suggestion that prolactin may play a role in molt goes back several decades (Juhn and Harris, 1958; Kobayashi, 1953b). There is considerable circumstantial evidence suggesting that prolactin has a role. Several studies have investigated seasonal cycles in prolactin secretion in free-living birds: rooks (*Corvus frugilegus*; Lincoln et al., 1980), starlings (Dawson and Goldsmith, 1982), white-crowned sparrows (Hiatt et al., 1987), song sparrows (Wingfield and Goldsmith, 1990), great tits (*Parus major*; Silverin et al., 1997), white-winged crossbills (*Loxia leucoptera*; Deviche and Sharp, 2001). Other studies have investigated captive birds under natural changes in photoperiod: starlings (Dawson and Goldsmith, 1984), grey partridge (*Perdix perdix*; Sharp et al., 1986), European quail (Boswell et al., 1996), and turkeys (Lien and Siopes, 1993). In each of these, peak prolactin concentrations were found at or just before the start of molt, or when molt is known to occur if it was not recorded in the study. In starlings held on a simulated natural cycle in photoperiod at different temperatures, birds at the higher temperature started to molt before those at the lower temperature, but in each case, peak prolactin coincided with the start of molt (Dawson, 2005).

Prolactin secretion is photoperiodically controlled. In starlings under experimental photoperiodic manipulations,

prolactin only increases to a peak under photoperiods that are also long enough to induce a molt (i.e., equal to or greater than 12L:12D), and then peak prolactin concentrations coincide fairly closely with the start of molt (Dawson and Goldsmith, 1983). Under constant photoperiods of 12L:12D, starlings undergo repeated circannual cycles of gonadal maturation and molt; in this condition, prolactin also cycles with peak values coinciding with the onset of molt (Dawson, 1997). Importantly, when starlings were actively immunized against vasoactive intestinal peptide (the prolactin-releasing hormone in birds) and transferred to a long photoperiod, the increase in normal prolactin was prevented and these birds did not molt (Dawson and Sharp, 1998).

In these studies on free-living and captive experimental birds, high prolactin concentrations and the start of molt both followed breeding (or gonadal maturation and regression) and so it is impossible to differentiate a direct role for prolactin from a temporal coincidence. However, Dawson (2006) exposed starlings to photo-schedules that challenged the normally close relationship between gonadal regression and molt. Photorefractory birds on moderately long photoperiods that had completed molt were moved to longer photoperiods or briefly to short photoperiods and then back to the longer photoperiod. This induced renewed prolactin secretion and another molt, without renewed gonadal maturation. Therefore, there was no consistent relationship with gonadal regression and the start of molt (molt could be triggered in the absence of a gonadal cycle), nor was there a consistent relationship between photoperiod (or the increase in photoperiod) and the timing of the start of molt. However, there was always an association between the start of molt and prolactin. In all cases where molt was induced, there had been an earlier increase in prolactin, strongly suggesting a causal role for prolactin. However, the timing of molt was related to the time of peak prolactin, not the magnitude of that peak.

The temporal coincidence between the time of peak prolactin and the start of molt, and the absence of molt in the absence of prolactin, suggests that high prolactin concentrations could be instrumental in initiating molt. However, there are problems with this conclusion. Although prolactin secretion is photoperiodically controlled, secretion increases much more in incubating birds and highest values occur during incubation (Dawson and Goldsmith, 1985; Goldsmith, 1982; Hiatt et al., 1987; Wingfield and Goldsmith, 1990). Yet, incubating birds do not start to molt during or soon after incubating their clutch, and multibrooded birds certainly do not start to molt soon after incubating their first clutch. In fact, the reverse is often true—breeding activity can delay the onset of molt (see Section 38.2.3).

However, the fact that peak prolactin coincides with the start of molt also means that molt starts at or about the time that prolactin starts to decrease, and molt progresses during the period of decreasing prolactin. So, it may not be the case that high concentrations of prolactin stimulate molt; the reverse may be true. High concentrations of prolactin may inhibit molt, so that molt only starts when prolactin begins to decrease. This would still result in a close correlation between peak prolactin and the start of molt and may be a mechanism that minimizes breeding/molt overlap, but at the same time ensures that molt starts as soon as breeding activity has finished. The pattern of molt in mute swans (*Cygnus olor*) offers a model to test this. As in many species, molt is delayed in breeding birds compared to nonbreeders. In addition, in successfully breeding swans, males initiate molt 4–6 weeks after their mate (Czapulak, 2002; Heinroth, 1911; Scott, 1972), whereas in nonbreeding flocks males and females molt at about the same time (Coleman et al., 2002). In breeding pairs that lose their young, both sexes molt at the same time (McCleery et al., 2007). It is possible that males with dependent young delay their molt until the female has well-grown feathers so that at least one of the parents has fully feathered wings to protect the young. The changes in prolactin correspond to these different molt patterns. The seasonal decrease in prolactin in nonbreeding birds of both sexes starts at the end of May and is associated with the initiation of molt 4 weeks later. The decrease in plasma prolactin in breeding females is more pronounced, as a consequence of increased prolactin secretion associated with incubation behavior (only females incubate), but also starts at the end of May, and is associated with the onset of molt 6 weeks later. In breeding males, plasma prolactin increases at the end of May when they start to care for their newly hatched cygnets. Correspondingly, prolactin began to decrease 3–5 weeks later in males than in females. These males start to molt in mid-August, at least 4 weeks later than females (Dawson et al., 2009).

This supports the view that molt is related to decreasing plasma prolactin. Prolactin secretion is tightly controlled by photoperiod, and is further stimulated by incubation behavior. This would explain why molt only occurs under long photoperiods and only starts after an increase in photoperiod. It would also explain why once molt has started, a decrease in photoperiod accelerates the rate of molt. In breeding birds it would explain why the start of molt tends to be delayed until the end of breeding, and why in late breeding birds molt then progresses more rapidly (because photoperiod would be shortened and decreasing more rapidly later in the year). However, the evidence to support this is still only correlational. There is no direct evidence showing that exogenous prolactin controls molt, except for contradictory early papers that show that prolactin inhibits molt (Kobayashi, 1953b) or stimulates molt (Juhn and Harris, 1958). It is difficult to understand how a decrease in a hormone concentration can have an effect, but this does seem to be the case since a complete absence of photoperiodically-induced prolactin secretion prevents molt (Dawson and Sharp, 1998).

38.3.2.4 Interrelationships between Thyroid, Gonadal Steroids, and Prolactin

The evidence for the involvement of prolactin is strong. Nevertheless, both thyroid hormones and gonadal steroids also have effects. Are there interrelationships that can rationalize this? Thyroid hormones are involved in some way in the perception of photoperiod. Thyroidectomized birds are photoperiodically blind and exogenous thyroid hormones can act as a long-photoperiod mimic. So thyroidectomized birds show no photoperiodically-induced increase in prolactin secretion and exogenous thyroxine stimulates prolactin secretion. Therefore, the involvement of thyroid hormones in molt can be explained through effects on prolactin. Evidence suggests that exogenous gonadal steroids can enhance prolactin secretion, so the effects of gonadal steroids may also be mediated by prolactin.

38.3.2.5 GnRH Agonist

The GnRH system of birds shows a remarkable degree of seasonal plasticity (Stevenson et al., 2009). The onset of molt coincides with gonadal regression and downregulation of GnRH gene expression and/or a decrease in GnRH secretion. Treatment of domestic hens with leuprolide, a GnRH agonist, induces gonadal regression and molt (Attia et al., 1994; Burke and Attia, 1994; Dickerman and Bahr, 1989). GnRH agonists cause ovarian regression by downregulating pituitary GnRH receptors followed by reduced gonadotropin secretion. The mechanism by which this treatment induces molt is unknown. A decrease in circulating gonadal steroid hormones (at least in progesterone) occurs, but any effect on prolactin is unknown.

38.4 CONCLUSIONS

Molt is critically important to birds. There is a lot of information on the timing of molt in different species and its relationship with other aspects of the annual cycle. There is a lot of information on the sequence of feather loss and renewal along the various feather tracts. There is quite a lot of information on how photoperiod controls the timing of the start of molt and the subsequent rate of molt. However, we know very little about the physiological control. There is correlational data implicating three types of hormone: thyroid hormones, gonadal steroid hormones, and prolactin. Of these, prolactin seems to be the best candidate for a role. Prolactin is a multifunctional hormone throughout vertebrates, but many of these roles can be related to the epidermis, including its eponymous role in milk production, in both mammals and birds (specifically pigeons; Riddle et al., 1932). Prolactin is involved in broody and parental behavior and so could clearly play a linking role between the end of breeding and the start of molt. Prolactin has also been linked to the control of molt in mammals. However, it is difficult to comprehend how a circulating hormone could control the sequence of feather loss and renewal—molt starting with the shedding of the proximal primary feather on each wing, and then progressing along the feathers of each tract in turn. Could receptors in adjacent follicles have different threshold triggers? It may be more plausible that a paracrine system is important rather than an endocrine system. Feather follicles are innervated, so perhaps the autonomic nervous system is involved (Kuenzel, 2003). Clearly many questions remain to be answered on the physiological control of molt.

39.1 INTRODUCTION

Birds are probably best known for the evolution of their intricate feathers and the subsequent development of wings along the forelimbs, eventually leading to flapping flight. Some of their Theropod dinosaur ancestors even experimented with feathered hindlimbs, which may have assisted their early attempts at gliding, or provided additional lift generation, but the vast majority of extinct and extant birds have two independent locomotor systems, the legs and the wings. Powered flight has evolved in four unrelated groups: the insects, the pterosaurs, the birds, and the bats (Bomphrey, 2012), and in most cases the wings are entirely specialized for aerial (or rarely, aquatic) flapping locomotion. All these animals have had to overcome the initial problem that weight support in air while traveling slowly requires specialized adaptations and is energetically expensive (Pennycuick, 1968).

As a result of these difficulties, many of the descendants of feathered dinosaurs probably never gained the ability to fly, while the reverse evolution of flying birds back to flightlessness may not have been uncommon among ancestral birds (e.g., *Hesperornis*), and is not only a feature of the modern day ratites (e.g., ostriches and emus) and penguins but has evolved on a number of occasions in rails, geese, ducks, grebes, ibises (McNab, 1994), and Galápagos cormorant *Phalacrocorax harrisi*. As these authors point out, flightlessness in terrestrial birds is always associated with a reduction in the mass of the pectoral muscles with a consequent reduction in basal energy consumption, which may be related to overall energy conservation. Conversely, a complete reliance on flight as the only means of locomotion is seen in just a few families, such as the swifts, swallows, hummingbirds, and sunbirds. Hummingbirds exhibit an exceptional form of flight in that they are the only birds known routinely to use prolonged periods of "stationary" or hovering flight and are even capable of flying backwards, due to their unique wing kinematics (Warrick et al., 2009). However, most birds have the best of both worlds, the ability to walk, run, or swim using the legs and the ability to fly in air (or rarely, even water) using the wings and tail.

Various ideas have been put forward to indicate how even a primitive wing design might have assisted early proto-birds to survive (Dial, 2003; Hutchinson and Allen, 2009), but, even once airborne, forward flapping flight is, for birds of similar mass, energetically more costly per unit of time than running or swimming at the surface (Butler, 1991). However, during flight over long distances, birds are able to maintain relatively high velocities, which means that the energy required for a given mass to travel a given distance (i.e., the cost of transport) is considerably less than the energy cost of transport during walking, running, or surface swimming (Tucker, 1970; Schmidt-Nielsen, 1972). Thus, a number of species of birds are able to migrate over long distances in a relatively short time period (Gill et al., 2009; Klaassen et al., 2011). Flight also enables birds to travel relatively long distances on a daily basis, to and from their nests or roosting areas (Jouventin and Weimerskirch, 1990).

The high rate of energy consumption required for flapping flight to be sustained over a prolonged period of time can only be maintained by "oxidative" or "aerobic" metabolism of fuel substrates, and places large demands on the respiratory, cardiovascular, and muscular systems of birds. Around 18% of the world's bird species undergo long-distance migration (Sekercioglu, 2007), and in temperate latitudes this is closer to 50%, despite the added problem of the birds initially carrying a relatively large amount of fuel (Alerstam and Lindström, 1990; Hedenström and Alerstam, 1992; Witter and Cuthill, 1993). At the same time they have to control body temperature and evaporative water loss in the face of the large

amount of heat that is generated by the intense muscular activity. The energy cost of spring migration may be so high as to influence the subsequent energy dynamics of reproduction (Bromley and Jarvis, 1993). The postbreeding autumn migration follows a period of relatively sedentary behaviors such as incubation, brooding, and molt for the adults, during which there is evidence, for some species at least, that the main flight muscles atrophy (Mainguy and Thomas, 1985; Piersma, 1988; Bishop et al., 1996; Portugal et al., 2009). In addition, the energy and time taken for birds to molt and replace their flight feathers may be a major consideration in regulating the length of the breeding season and even the maximum size of flying birds. Thus, for postbreeding and postmolting adults, as well as for the season's fledglings, the flight muscles and supporting systems have to achieve an adequate level of aerobic fitness and functionality in preparation for the forthcoming migratory flights. Those species of birds that fly at high altitudes during their migration also have the combined problems of engaging in this energetically costly activity in a severely hypoxic and cold environment and at a reduced air density (Butler, 2010; Scott, 2011).

At the other extreme from sustained flight is the explosive "burst" flapping flight of many species of Galliformes and Tinamiformes birds, which they utilize to escape terrestrial predators or to roost in trees. These birds rely on "anaerobic" metabolism and are unable to sustain such activity for more than a few minutes and may be rendered incapable of flying at all after repeated bursts of activity (Marden, 1994). During takeoff, or when sprinting to maneuver or avoid predators, even the most aerobic of avian species, the Trochiliformes or hummingbird, can briefly support "burst" flight performance by high levels of creatine kinase in their muscles, supporting rapid phosphocreatine regeneration of adenosine triphosphate (ATP) (Chai et al., 1997). In between these two extremes of aerial locomotion are birds such as vultures, storks, and albatrosses which are able to remain airborne by soaring and gliding and expend a fraction of the energy required for forward flapping flight during foraging trips and migration. In addition, small species of birds appear to use different "gaits" or flight modes, such as flap-bounding and flap-gliding (Tobalske and Dial, 1994; Tobalske et al., 2009), in order to maintain the wingbeat frequency at the most energy-efficient rate (Rayner, 1985a).

This chapter will focus primarily on the energetics of bird flight, including long-distance migration; the function, physiology, and biochemistry of the flight muscles, including physical fitness in preparation for migration; deposition of fuel stores in preparation for migration and their use during migration; respiratory and cardiovascular adjustments associated with flight, including temperature control and water loss; and flight at high altitudes. However, it is not easy to obtain experimental data from a flying animal, and it should be remembered that it is doubtful if any one experimental method can adequately give all of the necessary information required for a full analysis of the physiological responses to flight. Thus, a number of techniques used to study the flight of birds will be discussed. To begin with, however, there is a short introduction to the significance of animal size and scale.

39.2 SCALING

It is important to be able to assess the significance of a particular characteristic or adaptation and compare it with those of other individuals and/or species, even though these other animals may vary greatly in size or mass. The study of the consequences of changes in shape or mass of different animals is called scaling (Schmidt Nielsen, 1984), and it is frequently used in comparative biology, due to the many orders of magnitude differences that occur in body mass both within and between animal groups. If two bodies are the same shape or "geometrically similar" but of different volume (V) and mass (M) (i.e., their various characteristics, such as length and surface area, are directly proportional to their difference in mass), then these bodies are said to scale isometrically with regard to each other. If we consider two cubes of different size, then each side will have a length (L), and the area will be proportional to the length squared ($A \propto L^2$), while the volume or mass (assuming a constant density) will be proportional to the length cubed ($V \propto L^3$). Thus, area will be proportional to volume or mass to the two-thirds power ($A \propto V^{2/3}$), and any length will be proportional to volume or mass to the one-third power ($L \propto V^{1/3}$). Because body mass (M_b) is a relatively easy variable to measure in most animals and one that represents the large size range seen in animals, it is most frequently used as the independent variable in scaling. Thus:

$$L \propto M_b^{1/3} \text{ or } M_b^{0.33} \text{and} A \propto M_b^{2/3} \text{ or } M_b^{0.67}$$

Pennycuick (1982) studied the flight and morphometric parameters of 11 species of Procellariiformes (e.g., petrels and albatrosses), ranging from 0.03 to 9 kg, and found that wing span (b) scaled in proportion to $M_b^{0.37}$ (Figure 39.1(A)) and wing area (S) in proportion to $M_b^{0.627}$ (Figure 39.1(B)). These results indicate that there is a slight tendency for larger birds to have relatively longer wings and smaller wing areas, but that overall they are geometrically very similar. However, Figure 39.1(D) shows that, if the outlines of each species are traced and then displayed so that they all have the same wing span, as the birds become smaller the shape of their wings changes in a systematic way (Pennycuick, 1992). This can be assessed by calculating the dimensionless variable called aspect ratio (Λ), which is the wing span divided by the mean wing width (or chord) and is equivalent to b^2/S. Figure 39.1(C) shows that Λ scales in proportion to $M_b^{0.116}$ and is highly significantly different from the expected isometric value of $M_b^{0.0}$. Thus, this feature of birds

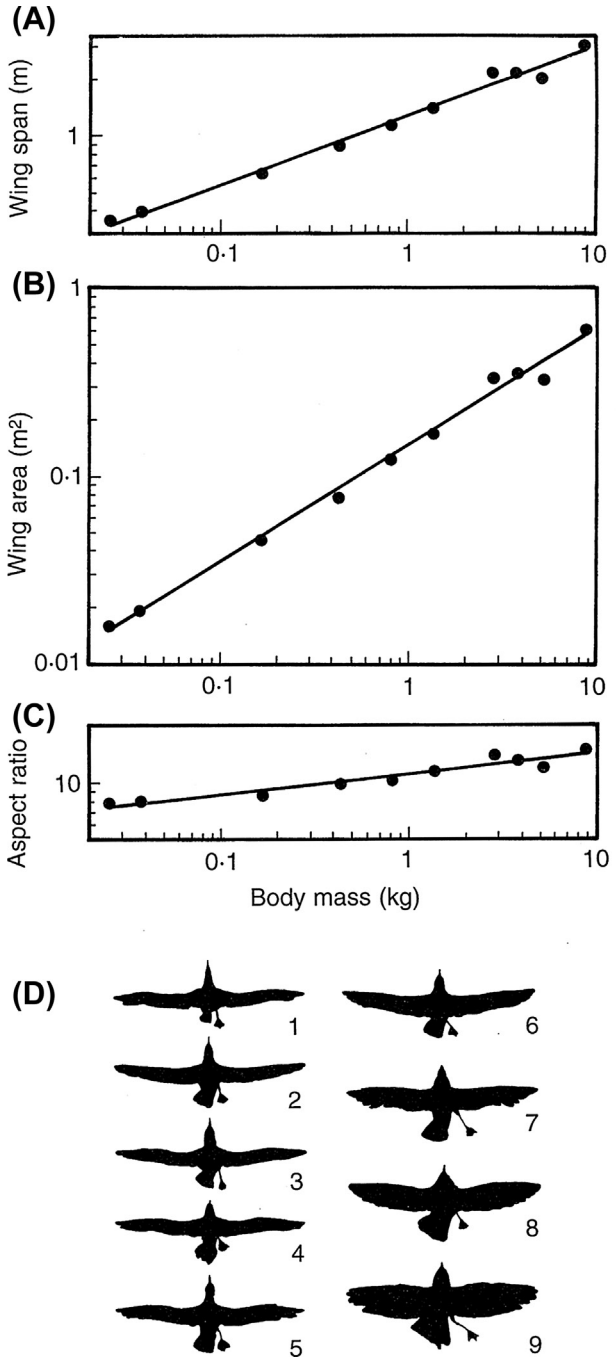

FIGURE 39.1 (A) Wing span, *b;* (B) wing area, *S;* (C) aspect ratio, Λ, of 11 species of Procellariiform birds, plotted against body mass, M_b (*From Pennycuick (1992), by permission of Oxford University Press.*). (D) Wing tracings from nine of these species, with the smaller species enlarged such that all have the same wing span. 1, wandering albatross, *Diomedia exulans*; 2, black-browed albatross, *D. melanophrys*; 3, grey-headed albatross, *D. chysostoma*; 4, light-mantled sooty albatross, *Phoebetria palpebrata*; 5, giant petrel, *Macronectes* sp.; 6, white-chinned petrel, *Procellaria aequinoctialis*; 7, cape pigeon, *Daption capensis*; 8, dove prion, *Pachyptila desolata*; 9,Wilson's storm petrel, *Oceanites oceanicus*. The wing span of the largest species, *D. exulans*, is 3.03 m and that of the smallest, *O. oceanicus*, is 0.393 m. *From Pennycuick (1982); Figure 39.4, The Royal Society.*

scales non-isometrically or allometrically and the study of such relationships is often called "allometry".

Such analyses can also be used to test predictions regarding the scaling of animal energetics. For example, as "geometrically similar" animals increase in mass, their surface area should decline proportional to $M_b^{0.67}$ and so should the rate at which heat will consequently be lost to the environment. Thus, it might be expected that basal metabolic rate (BMR) should also decline in proportion to $M_b^{0.67}$. Until recently, most studies of vertebrates had shown that BMR actually scales allometrically, at around $M_b^{0.72-0.75}$, i.e., slightly greater than predicted from the surface area law. However, at least with respect to the analysis of BMR in birds and mammals, it has become quite a controversial subject, with some authors suggesting that there is no rigid scaling exponent and that it varies with relative exercise intensity (Bishop, 1999) or body temperature. Other studies have suggested that it may also vary between taxonomic groupings or with ecological adaptations. Despite these difficulties, allometric analysis has been used to address a wide variety of issues in biology (Schmidt-Nielsen, 1984), and the scaling of metabolic and biomechanical parameters associated with bird flight will be considered throughout this chapter.

39.3 ENERGETICS OF BIRD FLIGHT

One of the most useful physiological variables is the rate at which a bird expends chemical energy (i.e., power input (P_i)) during flight. The P_i of both resting and exercising animals are important considerations in many ecological and physiological studies of animal behavior and evolution, particularly as it ultimately determines how much food must be foraged from the environment. However, the chemical energy available from the anaerobic or aerobic catabolism of the various fuel molecules must be transformed by the myofibrillar proteins of the flight muscles into the mechanical power output (P_o) required to fly, while the remainder is released as heat. The exact quantity of P_o produced from a given P_i will, thus, depend on the efficiency with which the relevant locomotor muscles can convert the chemical energy into mechanical power. The heat produced can be used to regulate body temperature, but it is almost invariably "lost" to the environment, while the biomechanical P_o results in various forms of locomotory behaviors. Some of the various techniques used to study the biology of flight will be discussed, primarily with respect to the estimation of P_i and P_o during flight.

The SI unit of power is the watt (W) which is equivalent to 1 J per second (J/sec). An estimate of P_i can be obtained by converting the rate of oxygen consumption $(\dot{V}o_2,\ \text{mL/sec})$ to W. The conversion of $\dot{V}o_2$ to P_i depends on the metabolic substrate; for metabolism of

pure carbohydrate, with a respiratory quotient (RQ) of 1, 1 mL O_2/sec = 21.1 W; whereas for pure fat metabolism (with an RQ of 0.71), 1 mL O_2/sec = 19.6 W (Lusk, 1919; Brobeck and DuBois, 1980). Pure protein metabolism in birds would yield an RQ of 0.74 and 1 mL O_2/sec = 18.4 W (Schmidt-Nielsen, 1997). During short-duration exercise, it is likely that carbohydrate oxidation will dominate; for example, short hovering flights during foraging in hummingbirds (Suarez et al., 1990) and soon after takeoff in pigeons (Butler et al., 1977), but during longer bouts of exercise it is likely that fat oxidation will become dominant (Rothe et al., 1987). However, this may be influenced by the feeding regime and by the season: well-fed and summer birds start at a higher RQ and take longer to reach an RQ of approximately 0.7 (Nachtigall, 1995). Thus, if RQ is unknown, a compromise for an RQ of 0.8, of 1 mL O_2/sec = 20.1 W, is often used for calculations of P_i during aerobic activity (Schmidt-Nielsen, 1997).

39.3.1 Techniques Used to Study the Mechanical Power Output Required for Flight

39.3.1.1 Aerodynamic and Biomechanical Models

The use of aerodynamic and biomechanical models provides a theoretical framework for understanding the physiological adaptations and energetics of birds and the likely constraints acting on different species. It is theoretically possible to estimate the P_i of a particular bird, using estimates for P_o based on aerodynamic models (Rayner, 1979; Pennycuick, 1989), provided the efficiency by which the flight muscles are able to transduce chemical energy into mechanical energy is known or can be estimated. However, while Pennycuick (2008) has assumed that flight muscle efficiency is around 23% for all bird species, other authors have pointed out that the overall efficiency appears to scale positively with increasing body mass for many types of invertebrate and vertebrate locomotion, including flight (Alexander, 2005; Bishop, 2005; Askew et al., 2010). The P_o required for different modes of flight is primarily determined by the overall mass, wing kinematics, and detailed morphology of the bird under investigation (Pennycuick, 1968), but it is also modified by the prevailing environmental conditions such as air density, strength of gravity, local air thermals, and deflected currents from nearby surfaces (Pennycuick, 1989, 2008).

During forward flapping flight, a bird has to generate sufficient mechanical power to overcome the downward acceleration due to gravity acting on its own mass (induced power) and the frictional drag of the airflow over its body (parasite power) and wings (profile power), as well as inertial power to accelerate and decelerate the wings during each beat. Inertial power requirements are usually ignored for medium to fast flight speeds, but may be important during hovering and slow flight (Norberg, 1990). A number of aerodynamic models (Pennycuick, 1969; Tucker, 1973; Greenewalt, 1975; Rayner, 1979) have indicated that these components of the overall P_o of the flight muscles should vary with flight speed (U). Calculations indicate that at least parasite power should increase with speed, whereas induced power is high at low speeds and declines at higher speeds.

Thus, overall, P_o should vary with speed in a U-shaped fashion (Figure 39.2). This means that there is a speed at which P_o and, presumably also P_i, are at a minimum (U_{min}) and at which the bird should fly in order to maximize its flying time. However, this is not the speed at which the bird should fly in order to maximize the distance flown for a given amount of fuel consumption (i.e., the speed at which the energy cost of transport is lowest). This is the maximum range speed (U_{mr}, Figure 39.2) and is, theoretically,

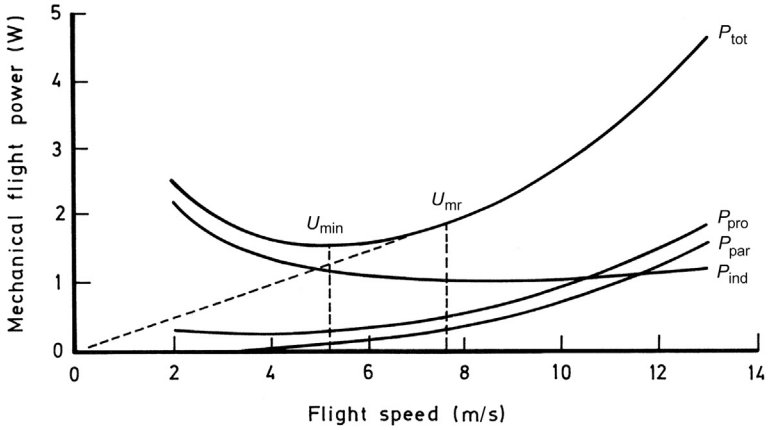

FIGURE 39.2 Calculated mechanical power output (P_{tot}) and its separate components (induced power, P_{ind}; parasite power, P_{par}; profile power, P_{pro}) for the European kestrel, *Falco tinnunculus* (mass 0.21 kg) flying at different speeds. the speed at which a long-distance migrant should fly (Pennycuick, 1969), particularly if the supply of energy is limited for any reason (Alerstam and Lindström, 1990). Hedenström and Alerstam (1995) contend that birds should adapt their flight speed differently when migrating or transporting food compared with when they are foraging and this may depend on whether the bird is time or energy limited (Hedenström, 2008).

Measurement of drag components and the overall body drag coefficient of living birds is relatively difficult (Pennycuick et al., 1988) and the appropriate default values to be used in aerodynamic calculations for different groups of birds is uncertain (Pennycuick, 2008). Data from a teal (*Anas crecca*) and a thrush nightingale (*Luscinia luscinia*) flying in a wind tunnel indicate that the drag coefficients for these species may be only 20% of what was previously assumed (Pennycuick et al., 1996b). Subsequently, body drag estimates based on the speed of dives in wild birds supported the original, rather higher values. More recently, Hedenström and Rosén (2003) have indicated that at least for small passerine species of bird, a confounding variable may be the underestimation of the frontal area of the body. Thus, small birds may have a higher body drag coefficient than larger birds (Pennycuick, 2008). A phenomenon that could reduce induced drag is "ground effect", which is the result of a bird flying close above a plane surface, be it water (e.g., petrels) or land (e.g., certain raptors). It may also be important during takeoff for heavy birds such as swans and vultures. Rayner (1991) has developed a theory for ground effect under fixed wing conditions. While acknowledging the limitations of the model, particularly with respect to its neglect of flapping wings, Rayner (1991) concludes that there are improvements in performance for flight in ground effect, provided the flight speed is not too low. Conversely, attaching tracking devices and data loggers to the backs of birds will disturb the normal airflow over the body and base of the wings and increase overall drag (Obrecht et al., 1988; Bowlin et al., 2010). This may have negative effects on their behavior, energetics, and survival (Gessaman and Nagy, 1988; Barron et al., 2010).

The interspecies scaling of the biomechanical power required to hold the wings out and to support the mass of the body during gliding flight is discussed by Pennycuick (1989). Given the limited amount of data available, he tentatively concludes that the power required should scale with respect to body mass between $M_b^{0.67}$ and $M_b^{0.83}$, i.e., that the power required is approximately a fixed multiple of the aerobic basal metabolic rate in birds of different mass. This is consistent with the limited amount of data on the cost of gliding in birds (see below).

Pennycuick (1968, 1969, 1989) has also discussed the factors that may limit the flapping flight performance of different species of birds. He hypothesizes that, for geometrically similar birds, the P_o required for flight should scale proportional to $M_b^{1.17}$ and predicts that the P_o available from the flight muscles should scale proportional to $M_b^{0.67}$. It might be expected, therefore, that in order to maintain an equivalent flight performance, larger birds should develop relatively larger flight muscles than smaller birds. In fact, the mass of the flight muscles appears to scale in direct proportion to body mass (Greenewalt, 1962; Marden, 1987; Rayner, 1988; Bishop and Butler, 1995), which means that larger birds should have reduced flight performance in terms of rate of climb, speed of takeoff, ability to hover, and so on. In addition, Bishop and Butler (1995) point out that, as the maximum heart rate of vertebrates scales negatively with body mass, maximum sustained flight performance will actually be limited by the negative scaling of maximum cardiac output (Bishop, 1997; Bishop and Spivey, 2013). To some extent, this will be ameliorated by the observation that the aerobic scope of birds and mammals (the ratio between their maximum metabolic rate and their BMR) scales positively with body mass (Bishop, 1999). Nevertheless, because the mass exponents for the P_o required and the P_i available appear to be so different, there should be a clear upper limit to the size of birds that can perform flapping flight (Figure 39.3), and this would appear to be at approximately 12–20 kg (Pennycuick, 1968). Pennycuick (1968, 1969, 1989) suggests that the range of flight performance of any particular bird will depend on the relation between the P_o/U curve and the maximum P_o available from the flight muscles. He distinguishes two categories of maximum power: (1) absolute maximum power (P_{max}), which includes the aerobic (sustained) and anaerobic (burst) capacity of the flight muscles; and (2) maximum sustainable power (P_{ms}), which only includes the aerobic capacity of the muscles and is limited by the rate of delivery of oxygen and metabolite

flux through the cardiorespiratory system. In hummingbirds, both P_{ms} and P_{max} lie above the power required for hovering (Figure 39.4), as these birds can hover aerobically (Chai and Dudley, 1995). In contrast, for the white-backed vulture (*Pseudogyps africanus*), both P_{ms} and P_{max} lie between the minimum power required for flight and that required for hovering, as they cannot hover, whereas they can fly horizontally. Birds such as pigeons are intermediate between these two, possessing a P_{max} sufficient to hover for brief periods using anaerobic metabolism.

39.3.1.2 Airflow Visualization and Direct Force Measurements

Although the mathematical models for estimating aerodynamic P_o have been available for many years, it is only very recently that developments in technology have enabled measurements to be made that could attempt to test the accuracy of the models by obtaining measurements of the aerodynamic forces produced by the wings. Some ingenious early experiments performed by Spedding et al. (1984) and Spedding (1986) enabled the wake of pigeons (*Columba livia*) and jackdaws (*Corvus monedula*) flying in a 4-m long cage to be visualized as they flew slowly through a cloud of neutrally buoyant helium bubbles. Although the data obtained supported the hypothesis (Rayner, 1979) that the wake is composed of a chain of small vortex rings (Figure 39.5(A)), indicating that the upstroke is inactive, the energy (induced power) calculated from the rings was only 60% and 35% (for the pigeon and jackdaw, respectively) of those predicted from the model. The most likely explanation of this "deficit" was that the flights were of too short a duration and that, therefore, the birds were not flying at a constant speed as they flew through the cloud of bubbles. In a further study, Spedding (1987) flew a kestrel (*Falco tinnunculus*) through helium bubbles along a 36 m long corridor at a "medium" speed of approximately 7 m/s. In this case, the wake consisted of a pair of continuous, undulating trailing vortices (Figure 39.5(B)), indicating that the upstroke of the wing was aerodynamically active. As a result, a more simple wake model can be used to calculate induced power, which is very close to that calculated from the model of Pennycuick (1975), based on classical aerodynamic theory. Using wing-beat kinematics to infer lift production, Tobalske and Dial (1996) concluded that black-billed magpies (*Pica pica*) use a vortex-ring gait at all speeds, whereas pigeons use a vortex-ring gait at 6–8 m/s, a transitional gait at 10 m/s, and a continuous-vortex gait at higher speeds.

Recent work, utilizing sophisticated particle image velocimetry (PIV) equipment to monitor the wake of birds flying in wind tunnels, has found the apparently "missing" induced velocity component and demonstrated full weight support is present in the wake vortices (e.g., for thrush nightingales *L. luscinia*; Spedding et al., 2003). There is also a partial confirmation of the original vortex-ring and continuous-vortex gait idea but only at the extremes of the velocity range. In reality, the results for most flight speeds indicate a more complex and somewhat intermediate set of wakes, with strong and continuous wingtip vortices and, at least in the case of swifts (*Apus apus*), additional vortices shed at the root (or base) of the wing (Hedenstrom et al., 2011). Once again, hummingbirds demonstrate their unusual aerodynamic approach, with a bound circulation that is not shed as a vortex at the end of the wingbeat

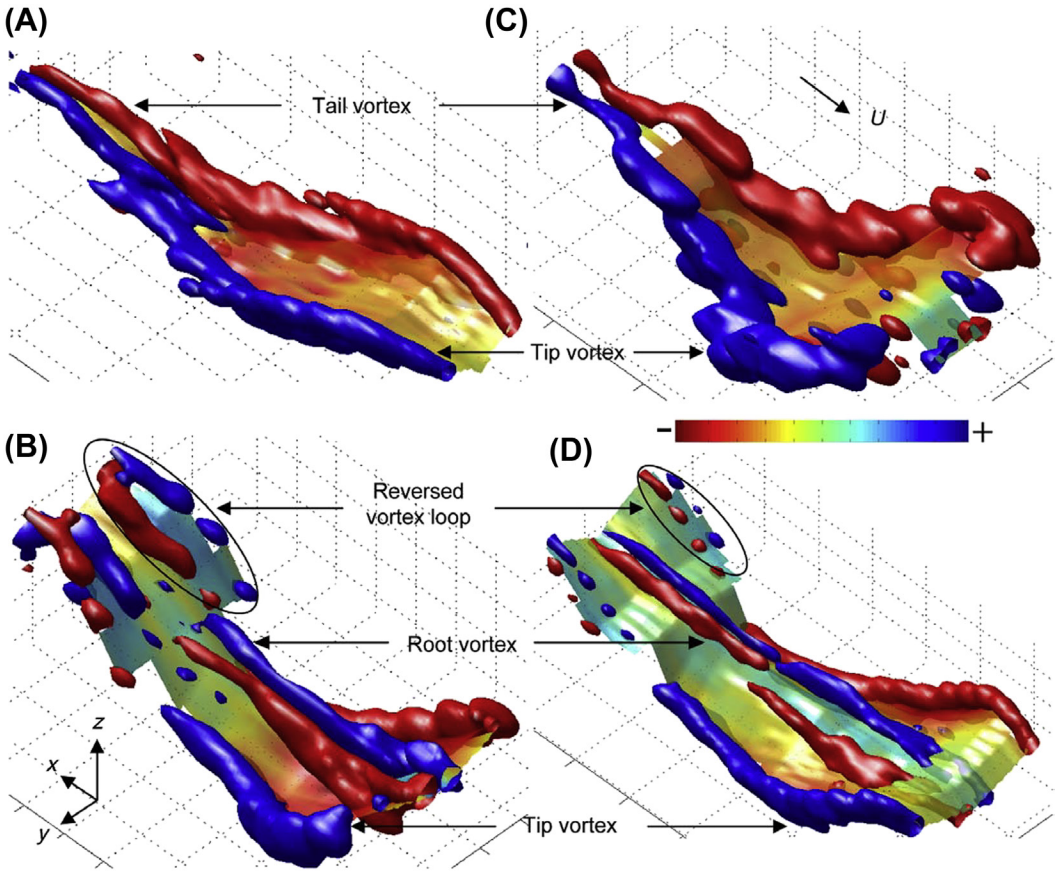

FIGURE 39.6 Reconstruction of the wake topology of a single flap cycle of two species of bird (A & C) and two species of bat (B & D) flying at 7 m/s. (A) Pied flycatcher, *Ficedula hypoleuca*. (B) Pallas' long-tongued bat, *Glossophaga soricina*. (C) blackcap, *Sylvia atricapilla*. (D) Lesser long-nosed bat, *Leptonycteris yerbabuenae*. The color-coded surface shows downwash (see color bar) as the animals fly from right to left. Bats produce root vortix at the base of the wing during the downstroke but have a slightly active upstroke that produces a reversed vortex loop due to generating thrust but negative lift. Birds have a largely inactive upstroke by retracting the wings towards the body and leaving a visible tail vortex. *From Muijres et al. (2012b).*

but persists, so that there is a near-continuous production of lift throughout the wing cycle (Warrick et al., 2009). As a result, some 25% of the weight support is generated by the aerodynamically "active" upstroke of the wing during hovering. While some other birds may hover for very limited periods, they retract the wing on the upstroke so that it almost folds up while sweeping close to the body and is, therefore, aerodynamically "inactive". To compensate for this, the pied flycatcher (*Ficedula hypoleuca*) can produce 23% of its weight support from a combination of it body and tail surfaces (Muijres et al., 2012a). Comparisons of the wake structures of birds and bats (Figure 39.6) show that birds have a higher aerodynamic efficiency (including a high lift to drag ratio) than bats, and this might contribute to the observation that birds tend to migrate more frequently and over longer distances than bats (Muijres et al., 2012b).

The first empirical attempt to measure directly the biomechanical force produced by the muscles of a bird during flight used a calibrated strain gauge, recording from the humerus of a starling (*Sturnus vulgaris*) and a pigeon (*C. livia*) and yielded estimates for the biomechanical P_o generated by the pectoralis muscle (Biewener et al., 1992; Dial and Biewener, 1993). A more complete series of measurements was achieved with black-billed magpies (*Pica hudsonia*), with flight speeds ranging from 0 to 14 m/s (Dial et al., 1997), followed by further studies on cockatiels (*Nymphicus hollandicus*) and turtle doves (*Streptopelia risoria*) over the next few years (Tobalske et al., 2003). For the magpie, only hovering resulted in a significantly higher value of P_o, compared with speeds of 2–14 m/s, yielding a so-called L-shaped curve, and a similarly rather flat profile or even J-shaped curve has been reported for many species when measuring P_i (see Section 39.3.3.2). However, for the cockatiel and the dove, changes in biomechanical P_o during flight showed the occurrence of significant U-shaped power curves with a change in velocity (as predicted by aerodynamic theory), with pectoralis mass-specific P_o ranging from 74 to 231 W/kg for the cockatiel (Figure 39.7). These authors point out that considerable flexibility in the precise shape and positioning of the power curve probably exist between avian species, which may have different flight styles and can functionally morph their wings and tail

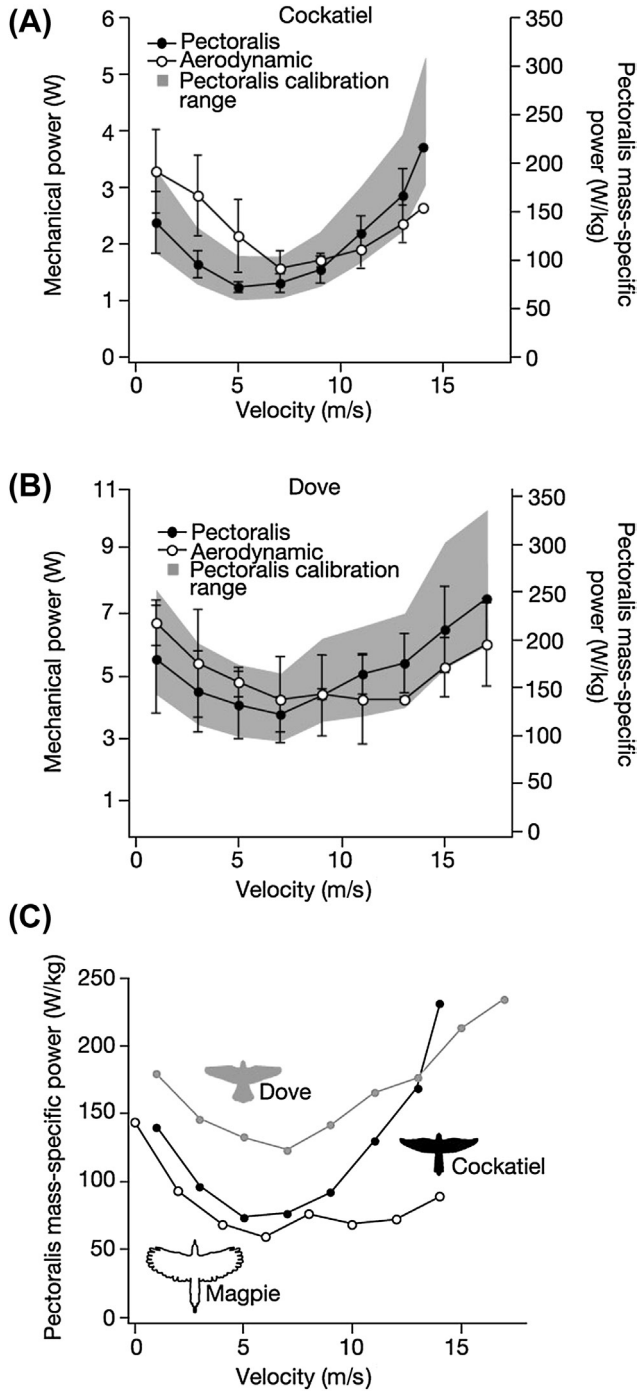

FIGURE 39.7 Mean pectoralis muscle and aerodynamic power output as a function of flight velocity in five cockatiels, *Nymphicus hollandicus* (A) and three ringed turtle-doves, *Streptopelia risoria* (B). The shaded region indicates the range of pectoralis power obtained when "low-power" versus "high-power" aerodynamic coefficients are input to the aerodynamic model. (C) Comparative mass-specific pectoralis power as a function of flight velocity in cockatiels, doves, and magpies, *Pica hudsonia*. *From Tobalske et al. (2003), Nature Publishing Group.*

profiles during flight and, thus, affect their relative P_o (Dial et al., 1997; Tobalske et al., 2003). Of course, this is a complex technique and the authors acknowledge that there may have been some limitations in the calibration of the strain gauges, which would have led to an underestimation of the maximal force and P_o.

Usherwood placed differential pressure sensors along and across the wings of Canada geese, *Branta canadensis*, and pigeons (Usherwood et al., 2005), in order to measure the net aerodynamic forces acting on the wings of birds during takeoff and slow forward flight. This technique was used to determine the lift and drag values for the wings and revealed a muscle mass-specific P_o of 273 W/kg for the pigeon. This value is much higher than that determined by Tobalske et al. (2003) for cockatiels and doves flying at a similar speed (80 and 150 W/kg muscle) but similar to those recorded during maximum fast flights in the wind tunnel and from the similarly sized American crow (*Corvus brachyrhynchos*) during vertical flight (Jackson and Dial, 2011). Askew and Marsh (2001) developed an *in vitro* method for measuring muscle force production in the blue-breasted quail (*Coturnix chinensis*), using typical *in vivo* length and activity patterns, to record average power outputs of 350 W/kg. Of course, these higher values for *in vitro* P_o may not accurately represent sustainable aerobic performance *in vivo*. A similar approach was taken by Askew and Ellerby (2007) to show that *in vitro* P_o from budgerigars (*Melopsittacus undulatus*) and zebra finches (*Taenopygia guttata*) does follow a classical U-shape.

39.3.2 Techniques Used to Measure the Power Input Required for Flight

39.3.2.1 Mass Loss

Some of the earliest measurements of P_i were estimated from the mass loss recorded during a long, nonstop flight, with the assumption that fat constituted by far the major part of this loss and that the net loss of water was negligible (Nisbet et al., 1963). Berger and Hart (1974) criticized this method, as they believe that total water loss may exceed the production of metabolic water, particularly at high environmental temperatures (cf. Nachtigall, 1995), leading to significant dehydration. Even so, Jehl (1994) has used this method to estimate the energy expenditure of black necked grebes (*Podiceps nigricollis*) forced to land during migration as a result of bad weather. The data were inconclusive, mainly because of uncertainty over the time the birds were flying. Another problem with this method is that there is evidence to indicate that migrating birds also catabolize protein (e.g., muscle and intestine) during flight (Piersma and Jukema, 1990; Jenni-Eiermann and Jenni, 1991; Battley et al., 2000), and, whereas fat has an energy density of 39.3 kJ/g, the value for muscle (which is composed of approximately 70% water) is only 5.4 kJ/g (cf. Schmidt-Nielsen, 1997).

Masman and Klaassen (1987) developed a more complex method of using changes in body mass to estimate flight costs. They studied the energy budgets of trained

kestrels (*F. tinnunculus*) performing directional flights in the laboratory. Energy expenditure during flight was calculated by monitoring daily metabolizable energy intake, oxygen consumption, and carbon dioxide production during rest, and time spent flying per day. A similar approach was applied to the study of a single thrush nightingale (*L. luscinia*) flying for very long periods (seven different 12 h flight sessions) in a wind tunnel (Kvist et al., 1998). However, in general, estimates of energy consumption based on changes in body mass may be subject to considerable error as they are very sensitive to the values of protein and/or carbohydrate utilized in the calculation.

39.3.2.2 Doubly Labeled Water

The most commonly used method to determine the field metabolic rate (FMR) of air-breathing vertebrates is the doubly labeled water (DLW) method, and it has been used extensively with free-ranging birds (Hails, 1979; Ellis, 1984; Tatner and Bryant, 1989). This method was first proposed as a means of determining CO_2 production by Lifson and co-workers over 40 years ago (Lifson et al., 1949, 1955). It involves the injection of a mixture of ^2H_2O (or ^3H_2O) and $H_2{}^{18}O$ into the animal, allowing these isotopes to equilibrate with the body water pool(s), taking a body fluid sample after injection, and releasing the animal into the field. After a number of days, the animal is recaptured and another body fluid sample is taken. The difference between the rate of loss of the different isotopes between the two samples is assumed to be equivalent to the rate of CO_2 production $\left(\dot{V}co_2\right)$, from which the metabolic rate and P_i of the animal can be estimated. The maximum time between these sampling points (the maximum duration of the experiment) varies according to the initial enrichment (the greater this is, the longer the time), the mass of the animal (for the same relative enrichment, the greater the mass, the longer the time), and, of course, the level of activity of the animal. The many assumptions that are made when using this technique have been thoroughly discussed by Nagy (1980), Speakman (1990). The relative pros and cons of the DLW technique in comparison with those of using measures of heart rate (see Section 39.3.2.3.1) have been reviewed by Butler et al. (2004).

Although DLW is a relatively simple method to use in the field, it has three major limitations. Perhaps most importantly for field work is the fact that the duration of an experiment is limited by the turnover rate of the ^{18}O, and thus it is necessary to recapture the animal after a sufficient delay following injection of the isotopes to enable a reasonable decline in the enrichment of ^{18}O, but before the enrichment is too low (Nagy, 1983). The second problem is that the technique only gives an average value for energy expenditure between the two sampling points and this is usually over a 24 h daily cycle of activity (Speakman and Racey, 1988). When DLW is used to determine the metabolic cost of a specific activity (e.g., flying), then, as with the body mass method, it is necessary to have accurate information on the duration of the flying period(s) between the initial and final sampling times. Ideally, the respiratory quotient (RQ) also needs to be known to convert the calculated $\dot{V}co_2$ to an estimate of $\dot{V}o_2$ and/or P_i (see above), but this will often introduce further errors. Finally, the method only provides estimates of $\dot{V}co_2$ and yet the results are invariably treated as being absolute. In other words, there is a degree of uncertainty around the individual values obtained, but this is usually ignored. If statistical analyses are performed on means of the individual results, this can lead to type I errors (i.e., a false positive).

Recent validation studies with captive birds exercising at different levels of activity (but not flying) over a period of 72 h have indicated that, provided mean data are used from a number of birds, the DLW method can give estimates of metabolic rate that are within a few percent of those measured by respirometry (Nolet et al., 1992; Bevan et al., 1994, 1995a), although they do have a greater variance around the mean. The only validation study on a flying bird was that of Ward et al. (2004), in which they used three independent techniques—DLW, mask respirometry, and heat transfer modeling—to measure the P_i of the European starling (*S. vulgaris*) flying in a wind tunnel between 6 and 14 m/s. Heat transfer modeling and mask respirometry yielded comparable results and a linear increase in P_i with increasing velocity, but the DLW results had a greatly increased scatter and variance between individual flight measurements.

39.3.2.3 Telemetry and Data Logging

Much progress has been made in the use of biotelemetry and data logging devices for studying the physiology of free-ranging animals. Some of the earlier studies involved attaching relatively large radio transmitters to the back of birds and recording data during flights of only a few seconds duration (Hart and Roy, 1966; Berger et al., 1970a,b). Of course, any externally mounted object is likely to influence the flight performance of a bird, not only as a result of the added mass but also by increasing the aerodynamic drag of the body (Bowlin et al., 2010). These effects may be minimal for a relatively small transmitter that the bird can preen under its contour feathers (Obrecht et al., 1988). However, in some circumstances, the effects can be quite substantial, particularly for high-performance birds like homing pigeons (Gessaman and Nagy, 1988). Butler and Woakes (1980) overcame the problem of increasing body drag by implanting relatively small (<10 g) radiotransmitters into the abdominal cavity of barnacle geese (*Branta leucopsis*) and were able to record heart rate (mean, 512 beats/min) and respiratory frequency (mean, 99 breaths/min) from two birds (mean mass, 1.6 kg) flying behind an

open-topped vehicle. It is now possible to implant data loggers (weighing less than 30 g) that will store basic physiological information (heart rate, body temperature, etc.) over periods of many days. The data can then be downloaded after the animal is recaptured (Woakes et al., 1995; Bevan et al., 1995b).

39.3.2.3.1 Heart Rate

Heartbeat frequency (f_H) can be accurately measured and used as a proxy for metabolic energy consumption. Thus, if properly calibrated and validated, and if mean data are used from a number of animals, f_H may be used as an indicator of the rate of oxygen uptake in free-living birds (Butler et al., 2004). By storing f_H in implantable data loggers, Bevan et al. (1995b) estimated the cost of gliding flight, while having minimal effect on the behavior of the birds. However, the relationships between f_H and $\dot{V}o_2$ that are obtained during walking and running, or during swimming, may not be identical to those obtained when the birds are flying (Gessaman, 1980; Nolet et al., 1992; Ward et al., 2002). Ideally, it is recommended that f_H during flight should be calibrated during flight in a wind tunnel, and values recorded in the field should not exceed the range of f_H measured during calibration. The study by Ward et al. (2002) remains the only report of a direct calibration of heart rate against mask respirometry of a bird flying in a wind tunnel (Figure 39.8), in which there is a reasonable variation in both the measures of heart rate and the rate of oxygen consumption. The calibration relationship for both barnacle and bar-headed geese is different between running and flying but it is not known how typical this may be of other species. It is likely that it is the running relationship that is unusual in these species, given that geese are not thought to be particularly reliant on running in the wild.

39.3.2.3.2 Accelerometry

In recent years, accelerometers have been mounted on the body of animals to provide high-resolution measures of acceleration (or changes in velocity). During steady state locomotion, the average acceleration, taken over a sufficient number of limb cycles (or flapping in the case of flight), is equivalent to the "static" component of acceleration due to gravity. The average of the individual raw acceleration data points minus the static acceleration for a given time period, gives a time-averaged "dynamic body acceleration" or DBA (Qasem et al., 2011). In multidimensional acceleration studies, summing the data taken from the different axes before taking the final average is called overall dynamic body acceleration (ODBA), and taking the vectoral length before averaging is termed VeDBA (Qasem et al., 2011). Both these measures have been shown to be well correlated with rates of oxygen consumption in human subjects and a number of other mammal and bird species while running on treadmills (Qasem et al., 2011).

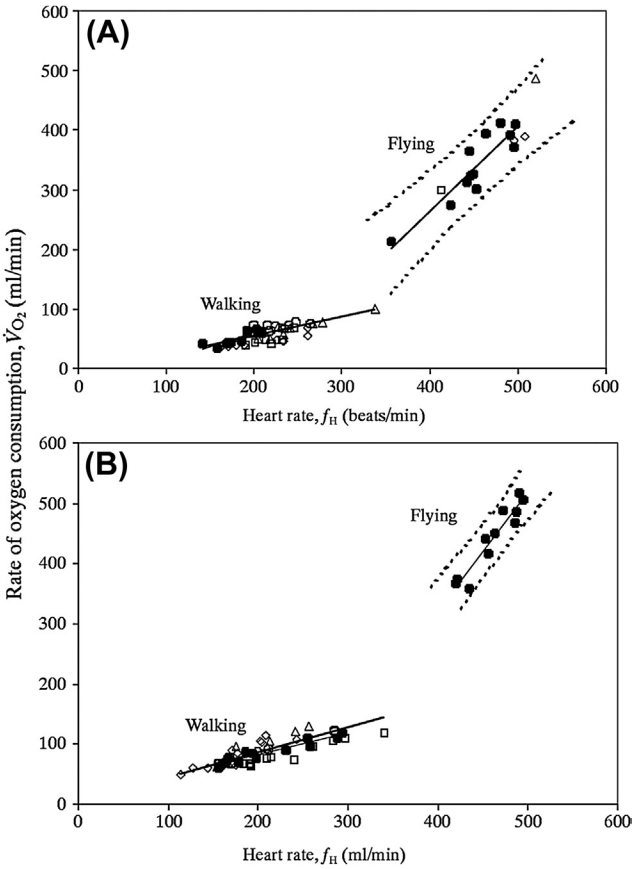

FIGURE 39.8 Linear relationships between mean rate of oxygen consumption $(\dot{V}o_2)$ and mean heart rate (f_H) of (A) barnacle geese, *Branta leucopsis*, and (B) bar-headed geese, *Anser indicus*, walking on a treadmill and flying in a wind tunnel. The filled circles show data from a single bird of each species from which most data on the relationships between f_H and $\dot{V}o_2$ were obtained during flight ($N=12$ flights by barnacle goose B-B and 11 flights by bar-headed goose BH-O). The open symbols show data from other birds. The solid lines show the relationships between f_H and $\dot{V}o_2$ during walking and flight by barnacle goose B–B (walking, $\dot{V}o_2 = 0.47\, f_H - 35.9$, $r^2=0.78$; flight, $\dot{V}o_2 = 1.42\, f_H - 304$, $r^2=0.82$) and bar-headed goose BH-O (walking, $\dot{V}o_2 = 0.35\, f_H + 12$, $r^2=0.88$; flight, $\dot{V}o_2 = 1.97\, f_H - 467.5$, $r^2=0.90$). The broken lines show the 95% prediction intervals. *From Ward et al. (2002). Company of Biologists, Ltd.*

Although no detailed and direct correlation of DBA and energy output has been conducted on birds during flight, ODBA was shown to increase during ascending and decrease during descending flights by a captive Griffon vulture *Gyps fulvus*. Recently, it has been shown that VeDBA is quite well correlated with the average daily energy expenditure of breeding thick-billed murres (*Uria lomvia*), as determined by measurements of DLW. However, as already mentioned, DLW only gives an estimate of $\dot{V}o_2$. In addition, Spivey and Bishop (2013) describe a mathematical model to help to interpret data collected by accelerometers mounted on the body of birds during

flight. By assuming that the body motion of the bird during steady forward flight approximates to a sinusoidal waveform, they showed that the root mean square of acceleration (*a*RMS), another form of time-averaged DBA (which is closely related to VeDBA), can be naturally derived from the mathematics. The biomechanical power visible to the body-mounted accelerometer (P_{body}) can be interpreted in the SI units for mass-specific power (watts = $m^2 \times s^{-3}$) by a number of possible terms:

$$P_{body} \text{ is proportional to } (g \times a\text{RMS}) / f_w$$
$$P_{body} \text{ is proportional to } (a\text{RMS})^2 / f_w$$

Where g is the acceleration due to gravity (m/s^2) and f_w is wingbeat frequency (1/s). Uncertainties regarding the use of accelerometry center around the alignment of the sensor with the axis of movement of the body, the fact that the cost of limb movements may be partially "hidden" from a body-mounted sensor, as may changes in body mass itself, and that rotations of the body not directly linked to movement costs may exaggerate the apparent energy required. However, with more studies, it is likely to become an important technique in assessing animal movement and energetics.

Measurements of acceleration can also be used to determine relative body orientation and kinematics, in particular that of wingbeat frequency. Sato et al. (2008) looked at the foraging loads of chick rearing European shags (*Phalacrocorax aristotelis*) and the results suggested that changes in body mass of an individual could be reliably determined by measuring the wing flap frequency. Sato et al. (2009) studied the flapping frequency of five species of procellariiformes, during takeoff and during forward flight. They showed that during takeoff the wingbeat frequency was higher and scaled with $M_b^{-0.3}$, while during forward flight it scaled as $M_b^{-0.18}$. By extrapolating these two relationships until they intercepted, it was suggested that the maximum limits to practical soaring flight might be around 41 kg for a bird or pterosaur with a wing span of around 5.1 m (Figure 39.9).

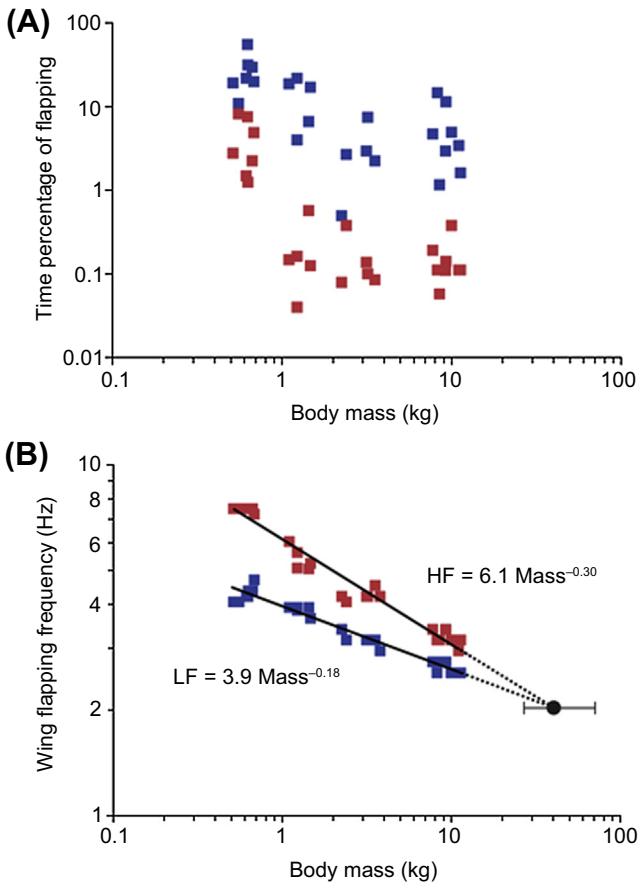

FIGURE 39.9 (A) The relationship between body mass and the percentage of time spent flapping relatively slowly (blue squares) and relatively quickly (red squares) during the foraging flights of five species of albatrosses and petrels. (B) The relationship between body mass and wingbeat frequency for the same species. Regression lines were calculated for high (red squares) and low (blue squares) frequencies and extrapolated for larger animals (dashed lines). The two lines intersect at a body mass of 41 kg (5.1 m wing span), with a 95% CI (26–75 kg). *From Sato et al. (2009).*

39.3.2.4 Wind Tunnel

P_i is most easily estimated indirectly, and under laboratory conditions, by directly measuring the $\dot{V}o_2$ of birds flying in a wind tunnel and then converting that to P_i (see above). The increased use of wind tunnels during the past 30 years has greatly added to our knowledge and understanding of the physiology of birds during flight (Butler and Woakes, 1990; Norberg, 1990). Perhaps the main advantage of being able to use a wind tunnel is that it is possible to make physiological measurements that would be virtually impossible by other means (e.g., repeated blood samples, blood pressure and flow measurements, direct measurements of force production). However, it must also be borne in mind that, as with almost any other method for studying a living animal, the wind tunnel itself can influence the behavior of the animal flying in it and hence affect the data obtained when compared with those from free-flying birds (Butler et al., 1977; Rayner, 1994). In order to obtain physiological data from a bird flying in a wind tunnel, it is often necessary to attach recording equipment to the bird, which will have some effect on the measurements. For example, gas exchange ($\dot{V}o_2$ and $\dot{V}co_2$) is usually determined by means of a lightweight mask that covers the beak and nose and through which air is drawn via an attached tube (Tucker, 1968b, 1972; Bernstein et al., 1973; Butler et al., 1977; Gessaman, 1980; Hudson and Bernstein, 1983; Rothe et al., 1987; Ward et al., 2001, 2002; Peters et al., 2005). The mask and tubing will influence the recorded data because of their mass, but more so because of the extra drag that they impose. $\dot{V}o_2$ can also be measured in a similar way for hummingbirds while feeding at artificial flower-heads (Wells, 1993a, 1993b; Clark and Dudley, 2010). The only studies in which gas exchange has been determined in a wind tunnel without the use of a mask are those by Tucker (1966) and

Torre-Bueno and Larochelle (1978). These authors used airtight, closed-circuit wind tunnels and measured the changing concentration of gases in the tunnel during the flight periods.

An aerodynamic analysis by Rayner (1994) suggests that the P_o required by a bird to fly is reduced when it flies in a wind tunnel with a closed section (unless the tunnel is at least 2.5 times the wing span of the bird and it flies at or near the center of the tunnel) and increased when it flies in a tunnel with an open section (again, the effect is related to the relative size of the tunnel), compared with the situation during free flight. However, at the moment there are few reliable experimental data to support these conclusions. In this context, it is interesting to note that the value for $\dot{V}o_2$ obtained by Butler et al. (1977) for pigeons (mean mass 0.442 kg) flying in a relatively large wind tunnel at 10 m/sec (182 mL O_2/min kg, adjusted for 10% effect of drag of mask and tubing; Tucker, 1972) is similar to that obtained by LeFebvre (1964) using the DLW method for free-flying pigeons (199 mL O_2/min kg, mean mass 0.384 kg). However, it is somewhat less than the mean minimum value obtained by Rothe et al. (1987) for pigeons (mean mass 0.330 kg) flying in a relatively small wind tunnel (248.5 mL O_2/min kg, also adjusted for drag of mask and tubing, but for a 22% effect; Rothe et al., 1987). According to Rayner's analysis, aerodynamic factors alone would lead to $\dot{V}o_2$ being lower for the pigeons flown by Rothe et al. (1987). Rayner (1994) also concludes that, in closed wind tunnels, the P_o-versus-speed curve (see above) will be flatter than that for free-flying birds.

Contrary to the above, other studies have suggested that data on the energy cost of flight obtained from birds flying in wind tunnels are 30% to 50% higher than those obtained from some of the other methods discussed above, such as mass loss and DLW (Masman and Klaassen, 1987; Rayner, 1990). However, the former authors included in their wind tunnel data measurements from hovering hummingbirds and from other experiments that most definitely did not involve the use of a wind tunnel (Teal, 1969; Berger et al., 1970a). Rayner (1990) used the same dataset of 71 birds as Masman and Klaassen (1987), but supplemented it with 40 more values from more recent publications. Unfortunately, he did not give the source of these additional data, so it is not possible to check and if necessary reanalyze them. However, taking the nine values by the DLW technique and used by Masman and Klaassen (1987) and reanalyzing them using the method of reduced major axis (RMA; Sokal and Rohlf, 1981; Rayner, 1985b), P_i (W) during forward flapping flight is calculated as $P_i = 69.5\ M_b^{0.87}$, $r^2 = 0.83$, $n = 9$ (M_b = body mass in kg). Taking the seven values for birds that did actually fly in wind tunnels from the list of Masman and Klaassen (1987) (i.e., numbers 44, 54, 57, 63, 64, 67, 68; note, P_i for bird 44 should be 4.08 W and not 40.8 W) gives $P_i = 58.8\ M_b^{0.76}$, $r^2 = 0.98$. Neither the slopes nor the elevations of these regressions are significantly different from one another. If the minimum values are taken from the seven studies of birds flying in wind tunnels, and if the drag of the mask and tubing is taken into account, then the equation is $P_i = 52.6\ M_b^{0.74}$, $r^2 = 0.95$. Thus, there is no justification for the conclusions made by Masman and Klaassen (1987) and Rayner (1990). It should be noted that Norberg (1996) made similar erroneous inclusions in her "wind tunnel" data (see Table 7.3) to those of Masman and Klaassen (1987).

39.3.2.5 Modeling of Cardiovascular Function

Some of the shortcomings of using the aerodynamic models to estimate P_o and then, subsequently, converting them to estimates of P_i (by assuming a value for efficiency) could possibly be reduced by devising a model to estimate total P_i directly. This was highlighted by the studies of Ward et al. (2001, 2004), who pointed out that starlings may not have a constant value of muscle efficiency throughout their speed range and that conversion of P_o to P_i was sensitive to the value of efficiency. Bishop and Butler (1995) attempted a modeling approach to estimating P_i by assuming that the mass of an animal's heart could be used as a basis for estimating cardiac stroke volume and calculating the animal's aerobic capacity. The role of the various components of the cardiovascular system in presenting O_2 to (and removing CO_2 from) the exercising muscles can best be described by a form of Fick's formula for convection:

$$\dot{V}o_2 = f_H \times V_S \times (C_aO_2 - C_{\bar{v}}O_2)$$

where f_H is heartbeat frequency (beats/min); V_S is cardiac stroke volume (mL); and $(C_aO_2 - C_{\bar{v}}O_2)$ is the difference between the oxygen content in arterial and mixed venous blood (mL of O_2 per mL of blood). In theory, each of these variables can scale independently with respect to body mass such that:

$$\left(\dot{V}o_2\right) M_b^z = (f_H)\, M_b^w \times (V_s)\, M_b^x \times (C_aO_2 - C_{\bar{v}}O_2)\, M_b^y.$$

There have only been two studies in which all four variables of the Fick equation have been measured in a bird during forward flapping flight (Butler et al., 1977; Peters et al., 2005). Bishop and Butler (1995) substituted each of the values from the Butler et al. (1977) study into the above equation, based on a series of general allometric equations ($y = a \cdot x^b$) for the scaling of f_H, V_s, and $(C_aO_2 - C_{\bar{v}}O_2)$, respectively. For birds flying close to their minimum power speeds, the individual components of the Fick equation were estimated to scale as follows: $f_H = 574\ M_b^{-0.19}$, $V_s = 3.48\ M_b^{0.96}$, $(C_aO_2 - C_{\bar{v}}O_2) = 0.083\ M_b^{0.00}$. The estimated scaling of V_s during flight was based on the assumption that V_s should be almost directly proportional to the mass of the heart (M_h), or $V_s = 0.3\ M_h^{1.05}$, while f_H during flight and M_h may be readily determined experimentally.

Bishop and Butler (1995) concluded that, for birds with a high aerobic capacity (such as pigeons), $\dot{V}o_2\,(mL/min) = 166\,M_b^{0.77}$, for birds flying close to their minimum power speeds. This compares favorably with the relationship $\left(\dot{V}o_2 = 160\,M_b^{0.74}\right)$ calculated by Butler (1991) and reanalyzed using RMA for seven species of birds during forward flapping flight in a wind tunnel. Bishop (1997) used a similar approach to estimate the maximum $\dot{V}o_2$ of birds during flight, again using M_h as the basis of the calculation. Although there is a need to obtain more data on the cardiovascular changes that occur in birds of different body mass and during different modes of flight, it would appear that the use of M_h to estimate the aerobic capacity of different species of birds may have more general applicability than the use of the allometric relationship obtained from a few species of birds flying in a wind tunnel. Bishop and Spivey (2013) did a meta-analysis of data from 24 species of birds and mammals that were said to be performing their "primary" modes of locomotion (running, swimming, or flying, respectively) and concluded that there was an overall allometric trend across all species for $\dot{V}o_2$ to be approximately proportional to heart rate squared $\left(f_H^2\right)$. Individuals and different species may vary in how closely they followed this quadratic heart rate exponent, but knowledge of both heart mass and body mass gave the best predictive relationship for rate of oxygen consumption (Figure 39.10).

39.3.3 Empirical Data Concerning the Power Input during Flight

An individual flight by a free-ranging bird will include at least one takeoff and a period of climbing, probably several maneuvers (turns, short periods of "burst" flying, changes of gait) as well as various periods of gliding, soaring, bounding, and flapping flight. The power requirements associated with all of these various types of flight will be different and may be provided by either anaerobic or aerobic metabolic pathways or by a combination of the two.

Species belonging to the Galliformes (e.g., pheasants, grouse, and quail) routinely engage in a powerful "burst" type of flight during takeoff and short-duration flights. Their muscles use intracellular stores of muscle glycogen utilizing predominantly anaerobic metabolism, which leads to the accumulation of lactic acid and to a metabolic acidosis. Fatigue soon develops and, subsequently, the lactate is either oxidized as fuel by tissues such as the heart or reconverted to glycogen by the liver. Thus, a large proportion of the total cost of these explosive flights is "repaid" while the bird is resting on the ground following the flight (Bishop and Butler, 1995) and an assessment of the true cost of such explosive flights, if based on $\dot{V}o_2$, would have to include the post-flight period of recovery. In other words, measurements of $\dot{V}o_2$ can only be used for accurate estimates of P_i if the activity is sustainable for relatively long periods of time (i.e., if the bird is metabolizing aerobically).

39.3.3.1 Gliding and Soaring Flight

Previous study by Pennycuick has hypothesized that the cost of holding the wings outstretched when gliding and soaring should scale at around 1.5 times the BMR. In general, as BMR decreases as body size increases, while at the same time the speed of flight increases, then it would be expected that larger birds should benefit more than smaller species

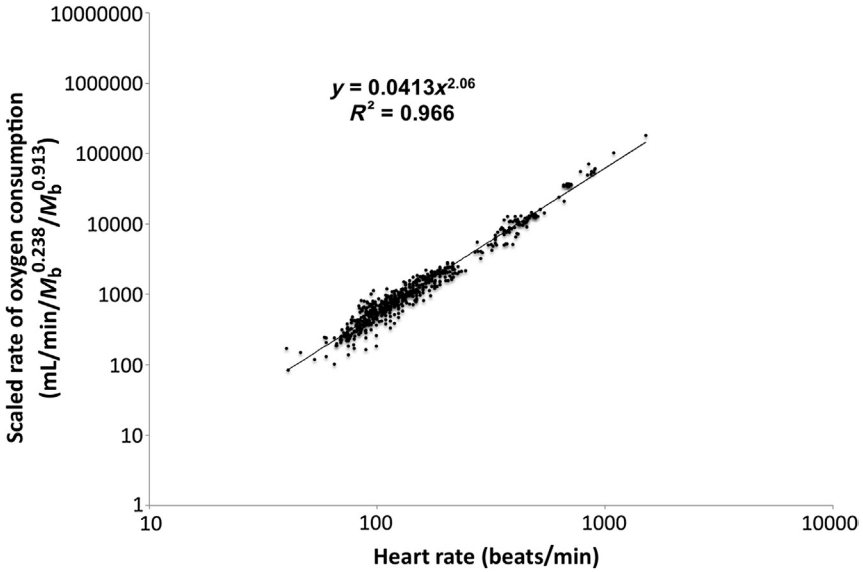

FIGURE 39.10 The relationship between heart rate (beats/min) and the rate of "rescaled" oxygen consumption $\left(mL/min/M_b^{0.328}/M_b^{0.913}\right)$ for 12 species of birds and 12 species of mammals, after taking into account differences in body mass (M_b) and heart mass (M_h) between species. Each species was flying, running or swimming, depending on what was considered their "primary mode" of locomotion, i.e., the form of locomotion that would yield the highest rate of oxygen consumption. *From Bishop and Spivey (2013). Elsevier publishing company.*

from the strategic use of gliding. In reality, most empirical studies have recorded slightly higher costs for gliding. In windy conditions, albatrosses exclusively use soaring and gliding flight and even in near calm conditions, they only beat their wings occasionally (Alerstam et al., 1993). However, it should be remembered that gliding birds can actively adjust the shape and span of their wings, including the sweep angle that they make to the body, in order to adjust air speed and the aerodynamic efficiency of the wing (Rosén and Hedenström, 2001). Using the DLW method, Adams et al. (1986), studying the wandering albatross (*Diomedia exulans*), and Costa and Prince (1987), studying the gray-headed albatross (*Diomedea chrysostoma*), estimated that the metabolic cost of flight is 3.0 and 3.2 times the predicted basal metabolic rate (BMR), respectively (49.7 W for birds of 8.4 kg mean mass, 36.3 W for birds of 3.7 kg mean mass). These estimates were based on the assumption that, when on water, the metabolic rates of the birds were close to those when they were at rest on land and their mean activity budgets were similar to those obtained from other studies on the same species. However, for herring gulls (*Larus argentatus*) gliding in a wind tunnel, P_i (calculated from measured $\dot{V}o_2$) was at 13.9 W for birds of 0.91 kg mean mass, only 2.1 times the resting value (Baudinette and Schmidt-Nielsen, 1974).

In a study on black-browed albatrosses (*Diomedea melanophrys*), Bevan et al. (1995b) used the f_H method to determine the field metabolic rate (FMR) and saltwater switches to determine when the birds were on the water. It was, therefore, possible for these authors to estimate the metabolic rate of their birds when on water and this was 2.6 times that recorded from the birds during incubation and only 1.9 times the predicted BMR; that is, somewhat lower than was assumed by Adams et al. (1986) and Costa and Prince (1987). Interestingly, the average metabolic cost of flying was 21.7 W for birds of 3.5 kg mean mass, 60% of that estimated for the similar sized gray-headed albatross by Costa and Prince (1987) and not significantly different from the value obtained when the birds were on the water. Other studies on sea birds, in which the DLW method has been used to estimate FMR, have used saltwater switches in order to determine when the bird was airborne, but the species studied (Sulidae) use a combination of gliding and flapping flight, so it was not possible to determine the energetic cost of either mode (Birt-Friesen et al., 1989; Ballance, 1995). Similar limitations apply to other studies in which the assumption is that, when not on the nest, the birds are continuously flying (Flint and Nagy, 1984; Obst et al., 1987).

The study by Bevan et al. (1995b) illustrates the importance of accurately determining the behavior of the animals under study and the advantages of using a method for determining FMR that allows the metabolic cost of the separate behaviors to be estimated. By using satellite transmitters and the logging of f_H data, Bevan et al. (1995b) were able to determine the metabolic costs of different sections of a foraging trip of an individual black-browed albatross (Figure 39.11). During section 2 of the trip, it covered a distance of 80.1 km

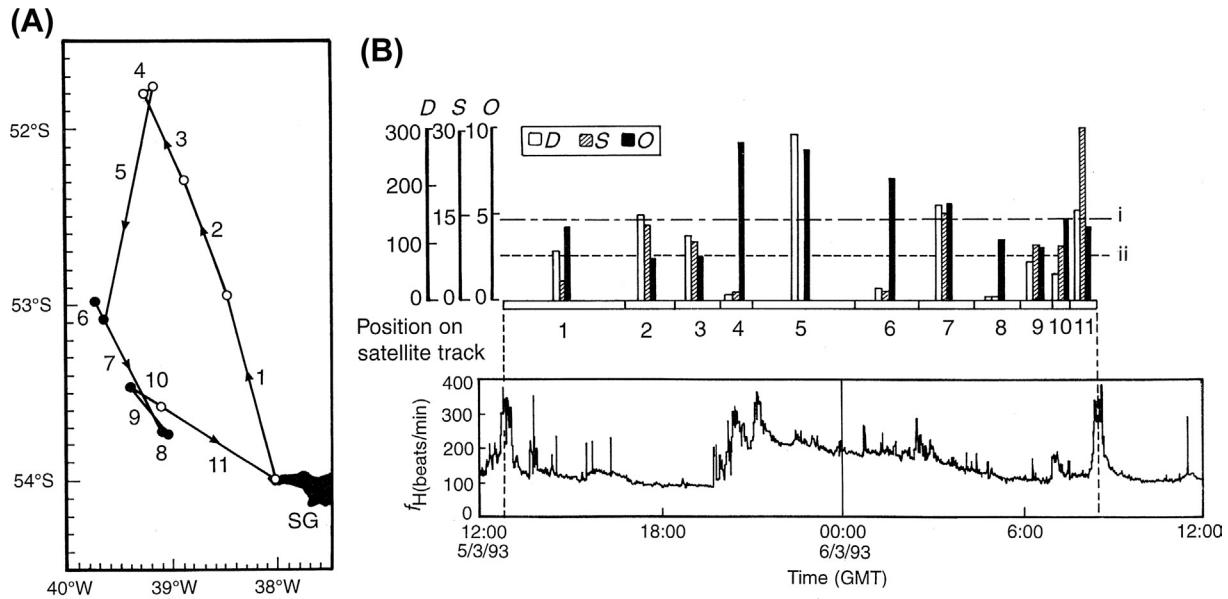

FIGURE 39.11 (A) Flight track of a single foraging trip from South Georgia (SG) by a black-browed albatross, *Diomedea melanophrys*, equipped with a satellite transmitter and a heart rate data logger. Circles represent the position of each satellite uplink, with the solid circles showing positions during the hours of darkness. The arrows show the direction traveled between each successive position, each section being numbered consecutively. (B) Top graph: distance traveled (*D*, km), ground speed (*S*, m/s), and estimated energy expenditure (*O*, W/kg) for each section of the trip depicted in a. The horizontal bars represent the time between each satellite uplink. Mean ground speed (horizontal broken line, i) is from Alerstam et al. (1993) and the incubating metabolic rate (horizontal broken line, ii) is that measured while birds were on the nest incubating (W/kg). Bottom graph: heart rate (f_H) trace over the same period. The vertical dashed lines joining the two graphs show when the bird left and returned to the colony. *Modified from Bevan et al. (1995b). The Royal Society.*

in 1.7 h, a mean ground speed of 13.1 m/s. This is very similar to the mean speed of 12.9 m/s that Alerstam et al. (1993) report for a visually tracked black-browed albatross. This suggests that the bird was flying continually during section 2. Metabolic rate was low during this period (2.4 W/kg) and barely greater than that during incubation (2.2 W/kg). The bird was probably searching for patches of prey and being carried by the wind (Alerstam et al., 1993). On the other hand, during section 4 of the trip, the straight-line distance traveled was only 6.3 km at a mean ground speed of 1.6 m/s. This suggests that the bird was relatively stationary on the water and/or was flying within a restricted area. It exhibited its highest metabolic rate (8.8 W/kg) during this period, indicating that the bird had engaged in some form of relatively strenuous activity, such as more active flight and/or feeding.

As gliding is thought to be more common in larger species of birds, it has seldom been quantified in smaller species, although some small species of birds, such as the Hirundines (martins and swallows) and the Apodidae (swifts) regularly glide. However, Sapir et al. (2010) showed that, like in the study of black-browed albatrosses (Bevan et al., 1995b), the heart rate of resting European bee-eaters was similar to that recorded while gliding and soaring, either on migration or at stopover sites (Figure 39.12). They suggest that not only was gliding metabolic rate only 1.9 times BMR but that the air speed of soaring was sufficiently fast (10.6 m/s) as to make gliding very economic. Assuming an f_H^2 relationship with oxygen consumption, Bishop and Spivey (2013) suggest that gliding flight may be at least five times less costly than typical flapping flight for the bee-eaters. Swifts (*A. apus*) have been predicted to glide most efficiently at velocities of 8–10 m/s (Lentink et al., 2007), which fits nicely with their behavior of climbing high above the ground and gliding slowly at around 10 m/s while sleeping on the wing. Similarly, magnificent frigate birds (*Fregata magnificens*) spend almost all of their time in slow soaring flight, constantly ascending and descending on thermals during the day and night, while looking for infrequent opportunities to feed (Weimerskirch et al., 2003).

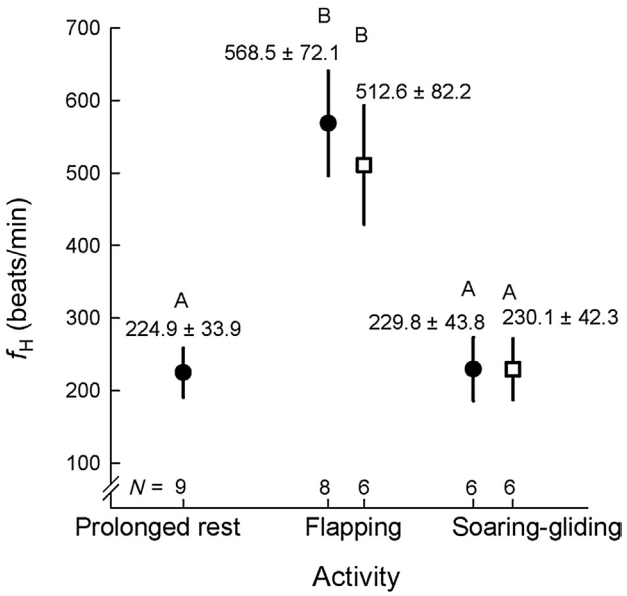

FIGURE 39.12 Heartbeat frequency (f_H) of European bee-eaters, *Merops apiaster*, measured in the field in relation to their behavior. The data is presented as the mean ± standard deviation of f_H for bee-eaters resting for prolonged duration or in different flight modes recorded, during stopovers (filled circles) and migratory cross-country flights (open squares). Different letters above the bars indicate groups that differed statistically. *N* = number of birds whose f_H was recorded during each activity. *From Sapir et al. (2010).*

During gliding flight it is important to minimize body (or parasite) drag and to maintain a high lift to drag ratio. Even turning the head from side to side can significantly increase the effective body drag. Indeed, because birds usually have laterally placed eyes with relatively low stereoscopic fields of view, they often prefer to see things either in one eye or the other. In the case of a fast-diving peregrine falcon (*Falco peregrinus*), it approaches its prey by flying along a spiral path so that it can keep its head facing forward on its body. Moving the head to one side or the other can increase parasite drag by around 50%.

39.3.3.2 Forward Flapping Flight

Some of the most comprehensive data we have on the overall energy consumed by the body (P_i) and the biomechanical power output by the muscles (P_o) during forward flapping flight are those obtained from birds flying in wind tunnels. In particular, the use of wind tunnels has made it possible to estimate both P_o and P_i at different flight speeds, although the details of these relationships appear to vary between species. The majority of studies of P_i were determined by measuring the rate of oxygen consumption while the birds wore a plastic respirometry mask (Figure 39.13). Results from the laughing gulls, fish crows, and white-necked ravens have shown a J-shaped curve (Tucker, 1972; Bernstein et al., 1973; Hudson and Bernstein, 1983), while the starling, barnacle, and bar-headed goose have a relatively flat "curve" (Ward et al., 2001, 2002). Only the budgerigar (*M. undulatus*), cockatiel, pigeon, and hummingbird have shown some kind of U-shaped curve for P_i (Tucker, 1966; Rothe et al., 1987; Bundle et al., 2007; Clark and Dudley, 2010), similar to that predicted by aerodynamic theory for mechanical power output (Pennycuick, 1969; Tucker, 1973; Greenewalt, 1975; Rayner, 1979). Arguably, the J-shaped P_i curves may not be so different from a U-shaped curve, as very low air speeds were not obtained with these species. Some early work on the P_i of hummingbirds, by Berger (1985), indicated that they might also exhibit a J-shaped curve, but a recent study of Anna's and Allen's hummingbirds (*Calypte anna* and *Selasphorus sasin*, respectively),

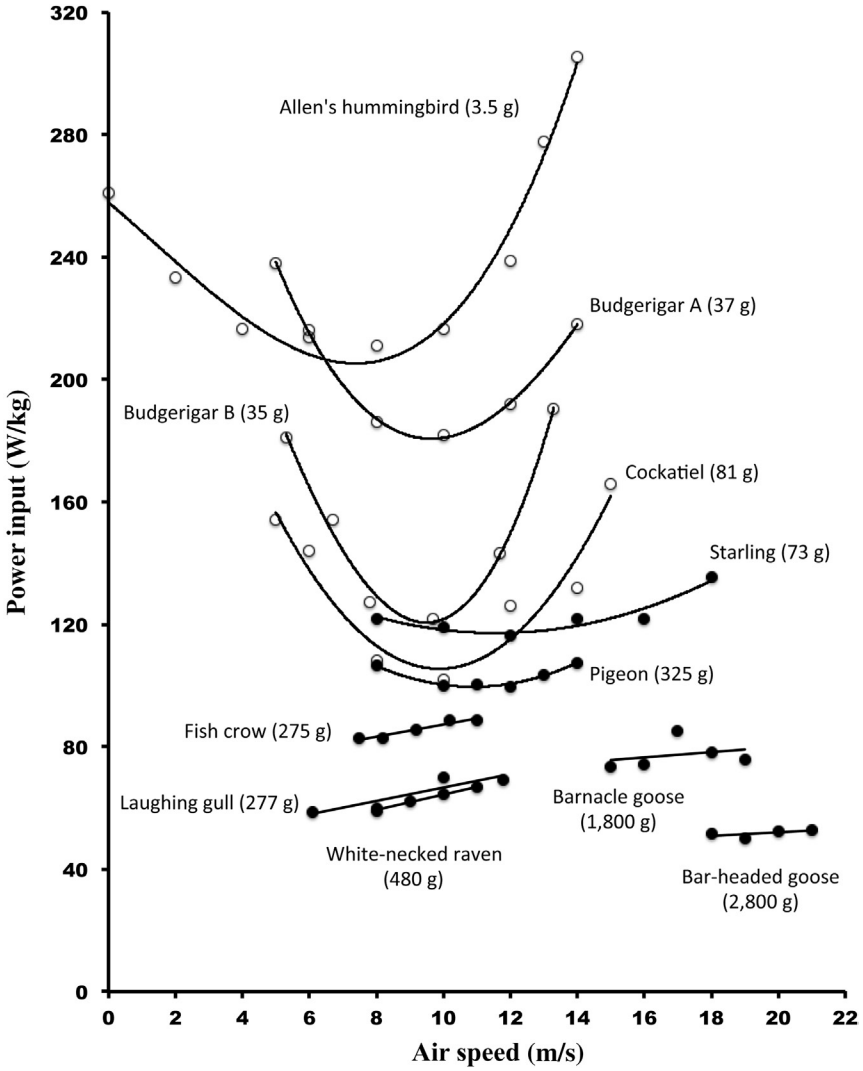

FIGURE 39.13 Power input (W/kg), converted from measurements of rates of oxygen consumption, measured at different air speeds for 10 species of birds during horizontal flapping flight in a wind tunnel. Data taken from Allen's hummingbird, *Selasphorus sasin* (Clark and Dudley, 2010); cockatiel, *Nymphicus hollandicus*, and budgerigar, *Melopsittacus undulatus* A (Bundle et al., 2007); budgerigar B; European starling, *Sturnus vulgaris* (Ward et al., 2001); pigeon, *Columba livia* (Rothe et al., 1987); fish crow, *Corvus ossifragus* (Berstein, Thomas and Schmidt-Nielsen, 1973); laughing gull, *Leucophaeus atricilla* (Tucker, 1972); white-necked raven, *Corvus albicollis* (Hudson and Bernstein, 1983); barnacle goose, *Branta leucopsis*, and bar-headed goose, *Anser indicus* (Ward et al., 2002).

flying between 0 and 14 m/s, indicates that there is a distinct P_i minima at intermediate speeds. Energetic costs during hovering and faster speeds were increased by around 30–40% (Clark and Dudley, 2010), while even relatively slow but backward flights showed a reduction of around 20% over that of hovering (Sapir and Dudley, 2012). The depth of the curve appeared to be slightly increased in birds with higher wing loadings, which was also more typical of males.

Figure 39.14 illustrates an allometric plot of the available data for the minimum P_i of seven species of birds during forward flapping flight in wind tunnels (Tucker, 1968b, 1972; Bernstein et al., 1973; Butler et al., 1977; Torre-ueno and Larochelle, 1978; Gessaman, 1980; Hudson and Bernstein, 1983), and it demonstrates two interesting features. First, on average, the minimum P_i (after adjusting for the drag of the mask and tubing, where necessary) of the seven species (mass range, 35–480 g) is 9.2 times the BMR calculated for nonpasserine birds (Prinzinger and Hänssler, 1980), and second, it is 2.2 times the P_i of mammals of similar mass (up to 900 g) running at their maximum sustainable speed (Pasquis et al., 1970). It can be seen from Figure 39.10 that the minimum metabolic rate during flight of the hummingbird, *Colibri coruscans* (Berger, 1985), is close (within 20%) to that predicted from the extrapolated regression line for the other seven species of birds. If the value from the hummingbird data is included in the regression analysis, the equation becomes $48.5\ M_b^{0.69}$, $r^2 = 0.98$,

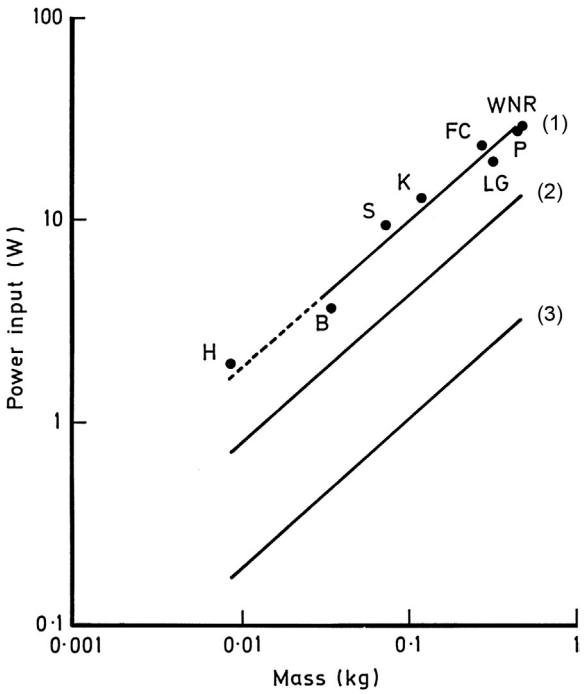

FIGURE 39.14 The relationships between power input (P_i) and body mass, M_b, using least-squares regression analysis for (1) seven species of birds during forward flapping flight in a wind tunnel; B, budgerigar, *Melopsittacus undulatus*; S, starling, *Sturnus vulgaris*, K, American kestrel, *Falco sparverius*; LG, laughing gull, *Larus atricilla*; FC, fish crow, *Corvus ossifragus*; P, pigeon, *Columba livia*; WNR, and white-necked raven, *Corvus cryptoleucus*. Minimum values of power input (P_{im}) were used to construct this curve and $P_{im} = 50.7\ M_b^{0.72}$. (2) Small mammals during maximum sustainable exercise where $P_i = 22.6\ M_b^{0.73}$ (*data from Pasquis et al. (1970)*). (3) Resting nonpasserine birds where $P_i = 5.5\ M_b^{0.73}$ (*data from Prinzinger and Hanssler (1980)*). (*From Butler and Woakes (1985).*) Also included in (1), the minimum P_i of the hummingbird *Colibri coruscans* during forward flapping flight in a wind tunnel (H). *From Berger (1985).*

using least-squares regression analysis. The mean P_i of a 1.8 kg barnacle goose (*B. leucopsis*) flying in a wind tunnel was 102 W, while that of a 2.8 kg bar-headed goose (*Anser indicus*) was 135 W (Ward et al., 2002). These results are reasonably similar to the values of 81 and 113 W obtained for the predicted minimum P_i, determined from an extrapolation of the allometric equation derived from the seven species of birds flying in a wind tunnel (Butler, 1991), recalculated using RMA regression (see above). In addition, using the cardiovascular modeling approach of Bishop and Butler (1995), Butler et al. (submitted-a) estimated the minimum $\dot{V}o_2$ of premigratory barnacle geese (average $M_b = 2.3$ kg) to be around 99 W. The relatively small errors between experimental measurements and these various predictions for flight costs, whether extrapolated towards smaller or larger species using allometric equations, or applying cardiovascular modeling approaches (Bishop and Butler, 1995; Bishop, 1997), suggests that the measurement of P_i is reasonably reliable across different studies.

39.3.3.3 Hovering Flight

As discussed above, hovering flight should be relatively costly, at least compared to intermediate air speeds. While a number of studies show that this is the case for muscle P_o, very few species of birds can sustain hovering for long enough so that P_i can be determined (usually by measuring the rate of oxygen consumption). Both budgerigars (Tucker, 1966; Bundle et al., 2007) and cockatiels (Bundle et al., 2007; Morris et al., 2010) show distinct U-shaped P_i curves, but the slowest speeds that they were willing to fly at while wearing a face-mask were 5 m/s. However, it does seem likely that slower velocities, including hovering, would have increased their flight costs even further. Only hummingbirds have been studied in which $\dot{V}o_2$ for both hovering and forward flapping flight have been determined for the same bird (Berger, 1985; Clark and Dudley, 2010; Sapir and Dudley, 2012). The more recent studies indicate that there is a small, but significant, difference in P_i between the two forms of flight (Figure 39.13). This is consistent with the fact that the values for $\dot{V}o_2$ from six species of hovering hummingbirds lie close to the extrapolated line obtained from larger birds during forward flapping flight, even though the allometric relationships for the two groups are substantially different ($\dot{V}o_2 = 160\ M_b^{0.74}$ for birds during forward flapping flight and $463\ M_b^{0.91}$ for hovering hummingbirds; Butler (1991), and reanalyzed using RMA). If data from three more species of hummingbirds are added to those used by Butler (1991) in his analysis (those from Wolf and Hainsworth (1971) and Wells (1993a)), the relationship for the nine species of hummingbirds, using RMA analysis, becomes: $\dot{V}o_2 = 449\ M_b^{0.90}$, $r^2 = 0.94$. It is interesting to note that the analysis by Bishop and Butler (1995) indicates that minimum $\dot{V}o_2$ during forward flapping flight of hummingbirds should scale $314\ M_b^{0.90}$.

39.3.3.4 Scaling of Flight Muscle Efficiency and Elastic Energy Storage

The efficiency with which the flight muscles can produce mechanical power from chemical energy is of great physiological significance as it determines the overall energy required by the animal during exercise. Excess heat must be lost to the environment in order to prevent hyperthermia. However, in order to estimate efficiency it is necessary to measure both the P_i and the P_o of the flight muscle. As pointed out by Alexander (2005), determination of P_o generally involves calculations that add a good deal of uncertainty. Thus, it seems sensible when reporting on the mechanochemical conversion efficiency of flight muscles to refer to their "apparent" efficiency calculated when specifically combining particular values for aerobic P_i and P_o (Bishop, 2005). Pennycuick (1975) recommended that the value of the mechanochemical conversion efficiency of avian flight muscles should be around 0.23 and treated as

a constant. This was based on the determination of partial efficiency (i.e., the change in P_o/change in P_i) during the flight of budgerigars, laughing gulls, and fish crow (Tucker, 1972; Bernstein et al., 1973), in which partial efficiency ranged from 0.19 to 0.30. However, this runs counter to the more general observation that locomotory muscles for various vertebrate (Alexander, 2005) and invertebrate (Askew et al., 2010) groups exhibit "apparent" muscle conversion efficiencies that scale positively with M_b and negatively with respect to contraction frequency. Theoretically, it should not be possible for muscle fibers to operate with an overall efficiency greater than 28% (Rall, 1985), and in practice, muscle fibers of larger mammals appear to operate with maximal efficiencies of between 20% and 25% (Taylor, 1994).

By using detailed kinematic and morphological analyses, Wells (1993a) calculated an estimate for P_o (100 W/kg) during hovering of the broad-tailed hummingbird (*Selasphorus platycercus*) based on the aerodynamic model of Ellington (1984). $\dot{V}o_2$ was measured as 50 mL/g h, which gave an estimated efficiency of 9–11% (assuming perfect elastic storage of energy). By adding weights to the birds, Wells (1993b) determined that maximum P_o of the pectoral muscles for this species during hovering was around 117 W/kg (assuming perfect elastic storage of energy) and that the efficiency remained approximately 10%. Using the novel and elegant method of flying ruby-throated hummingbirds (*Archilochus colcubris*) in an increasing atmosphere of He/O_2, Chai and Dudley (1995) were able to reduce the density of the medium from the normal air value of 1.23 kg/m^3 to the point (on average, 0.54 kg/m^3) at which the birds were no longer able to hover for more than a few seconds. At this density, the P_o of the highly oxidative pectoralis muscles was calculated to be around 133 W/kg (assuming perfect elastic storage of energy), $\dot{V}o_2$ was measured as 62 mL/g h, and the efficiency was estimated to be around 10% regardless of the intensity of the flight "effort". The above calculations include an allowance of 10% for the cost of cardiorespiratory function (Tucker, 1973; Pennycuick, 1989), but there is no allowance for BMR. However, taking this into account (Krüger et al., 1982) only increases efficiency by approximately 1% in both studies.

Biewener et al. (1992) and Dial and Biewener (1993) used calibrated strain recordings from the humerus of flying birds to measure the force and estimate the power generated by the pectoralis muscles. In the first of these studies, mean P_o for three starlings (*S. vulgaris*) between 70 and 73 g mass and flying in a wind tunnel (for unstated duration) at an estimated speed of 13.7 m/s was 1.12 W. Torre-Bueno and Larochelle (1978) reported mean P_i to be 8.9 W for three starlings of mean mass 73 g and flying in a wind tunnel for 30 min over a range of speeds from 8 to 18 m/s. Thus, after subtracting BMR (Prinzinger and Hänssler, 1980) and allowing 10% for the cost of cardiorespiratory function, the estimated efficiency of the flight muscles for this species is 15.4%. In the second study, mean P_o for four pigeons between 301 and 314 g and flying at approximately 8 m/s along a 47 m long corridor, was 10.5 W/kg. Dial and Biewener (1993) used a P_i value of 106 W/kg (cf. Rothe et al., 1987). Thus, estimated flight muscle efficiency is approximately 11.2%. However, Rothe et al. (1987) estimated that their measurements of P_i were elevated by between 15% and 30% by the presence of the mask and tubing. If a mean overestimate of 22% is assumed, the actual value of P_i would be 87 W/kg, which would give an efficiency of 13.8%. If the value of P_i, after adjustment for the drag on the mask and tube, is taken from Butler et al. (1977) for pigeons of mean mass 442 g and flying at 10 m/s (61 W/kg), a flight muscle efficiency power of 19.9% is obtained. The more recent study of Ward et al. (2001) estimated that flight muscle efficiency in two starlings flying in a wind tunnel varied between 0.13 and 0.23 depending on the bird, the flight speed, and the aerodynamic model used to calculate P_o.

Bishop (2005) estimated the maximum $\dot{V}o_2$ for 15 species of birds studied during migratory climbing flights by Hedenström and Alerstam (1992). The estimated P_i was based on the cardiovascular modeling approach (Bishop and Butler, 1995; Bishop, 1997) and was then compared to the estimated aerodynamic P_o based on the model of Pennycuick (1989). This analysis suggested that the "apparent" mechanochemical efficiency of the avian flight muscles scaled allometrically with body mass, as 0.3 $M_b^{0.14}$ (Figure 39.15). Thus, taken together, these various studies appear to indicate that there may be an increase in overall flight efficiency with an increase in body mass (cf. Rayner, 1990). However, this is a slightly controversial subject due to the potential errors

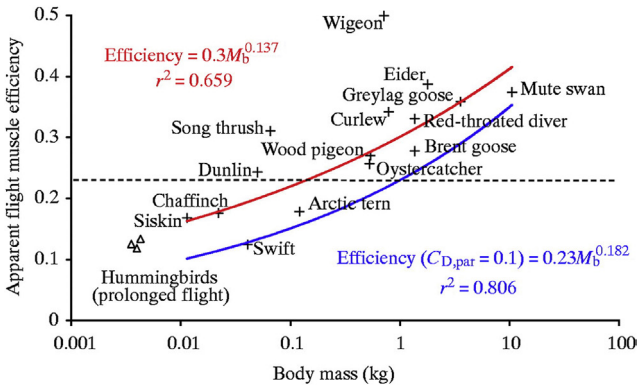

FIGURE 39.15 Estimated "apparent" flight muscle mechanochemical efficiency plotted against body mass (kg) for 15 bird species during migratory climbing flights over Sweden (see Hedenström and Alerstam, 1992). The wigeon, *Anas penelope*, is left out of the analysis as an outlier. The red regression line is based on the estimated sustainable biomechanical power output, calculated using default values for the parasite body drag coefficient ($C_{D,par}$) ranging from 0.25 to 0.4 (Pennycuick, 1989). The blue regression line is based on a value for $C_{D,par}$ of 0.1. Estimates of efficiency for three species of hummingbirds (Δ) are also plotted. *From Bishop (2005), Company of Biologists, Ltd.*

in calculating both P_i and P_o and the fact that the larger species of birds appeared to have efficiencies of over 0.3. As mentioned previously, the calculation of profile and parasite drag values in some aerodynamic models is uncertain, both with regard to differences in body mass between species and with regard to changes in air speed. Typically, there is also a tendency to ignore the inertial costs of accelerating and decelerating the wings of birds by assuming that the energy can be recovered by doing either useful aerodynamic work at the end of the wing stroke or by using elastic storage of wing kinetic energy to reaccelerate the wing in the following beat.

Wells (1993a) and Chai and Dudley (1995) concluded that hummingbirds are able to store the "inertial energy" required to accelerate the wing through each beat in an elastic component of their muscles. This assumption greatly reduces the value for the calculation of the power required to fly, especially for small species of birds that have high wingbeat frequencies. Bird flight muscles lack any associated specialized elastic components, such as long tendons, so any elastic component is likely to be within the cross-bridges of the muscle (Alexander and Bennett-Clark, 1977). Dial et al. (1987) measured the electrical activity of the pectoralis muscles of the pigeon during flight and demonstrated that the pectoralis muscles are active before the end of the upstroke of the wings. They conclude that the cross-bridges of the flight muscles are active during the final phase of the wing stroke and that the muscle could act like a spring (Goslow and Dial, 1990).

As pointed out by Spedding (1994), if zero elastic storage is assumed (cf. Weis-Fogh, 1972), the calculation of efficiency during hummingbird flight is around 25% and that this is still within the theoretical possibilities for vertebrate muscle (Weis-Fogh and Alexander, 1995; Pennycuick, 1992). The aerodynamic models of Pennycuick (1975, 1989) and Rayner (1979) also do not include the costs of accelerating and decelerating the wing during each cycle, as it is argued that the inertial costs are recovered aerodynamically and may, in any case, be relatively small during forward flight at medium to fast speeds. However, Van den Berg and Rayner (1995) suggest that it may be necessary to consider this cost. Van den Berg and Rayner (1995) estimated that the inertial power requirement should scale as approximately 5.8 $M_b^{0.80}$ (allowing for a 25% reduction due to wing flexion on the upstroke). Thus, in the light of the reduced estimates of flight costs of Pennycuick et al. (1996b), the relative importance of the inertial power requirements may have to be increased. Whatever the merits of each side of the debate, it seems possible that perfect elastic storage may prove to be unrealistic. Thus, any increment of the inertial costs that must be met by the flight muscles will increase the estimate of the "apparent" efficiency of the flight muscles. If "near" zero elastic storage is correct, then the inertial costs would dominate the total cost of hovering flight in hummingbirds (Spedding, 1994).

39.4 THE FLIGHT MUSCLES OF BIRDS

39.4.1 Flight Muscle Morphology and Fiber Types

The flight muscles of birds are structurally similar to the striated muscles of other vertebrates and consist of large numbers of long fibers, or cells, aligned essentially in parallel (Figure 39.16(A)). Each fiber can have a distinct biochemical character. At its simplest, each fiber can be specialize either for aerobic or anaerobic energy consumption, they can vary in diameter and cross-sectional area, and are supplied with various metabolites and oxygen via a network of capillaries (Figure 39.16(B)). Different species of birds have different amounts of flight muscle with respect to body mass, termed the flight muscle: mass ratio by Marden (1987), and these muscles are composed of four main cell or fiber types (cf. Rosser and George, 1986a): so-called slow oxidative fibers (SO), fast oxidative glycolytic fibers (FOG), fast glycolytic fibers (FG), and fibers that are intermediate (I) in their oxidative ability between the FOG and FG fibers.

Table 39.1 lists the major characteristics of these different fiber types. Essentially, the SO fibers have relatively slow rates of shortening, but are relatively efficient in producing force during isometric contractions, utilize oxidative metabolic pathways in the biosynthesis of energy-rich ATP, and are resistant to fatigue. FOG fibers are also capable of oxidative metabolism and resistance to fatigue, but can also use carbohydrates as a fuel during anaerobic metabolism, have relatively faster rates of shortening, and are relatively efficient in producing force while shortening in length. FG fibers are susceptible to fatigue and are restricted to anaerobic metabolism of carbohydrates, but produce more power per unit mass of muscle than SO and FOG fibers. One reason for the latter is that they contain a lower volume fraction of mitochondria and associated structures and therefore have room for more myofibrilar proteins.

The function of SO fibers is considered primarily to be of advantage in postural muscles (e.g., in the back and neck muscles) and also in the legs during rest, due to their economic production of force during isometric contractions. So far, SO fibers have only been found in the deep layers of the pectoralis muscles of a limited number of species of birds that are especially adapted for gliding and soaring modes of flight, that is, species belonging to the avian orders of the Procellariformes, Pelecaniformes, Ciconiiformes, and Gruiformes (Rosser and George, 1986a; Rosser et al., 1994). Thus, Rosser et al. (1994) found that the deep "belly" of the pectoralis muscle of the American white pelican (*Pelecanus erythrorhynchos*) is composed exclusively of SO fibers, and other authors have reported SO fibers in the deep layers of the pectoralis muscles of the turkey vulture *Cathartes aura* (Rosser and George, 1986b), red-tailed hawk *Buteo jamaicensis* (Rosser and George, 1986a), double-crested

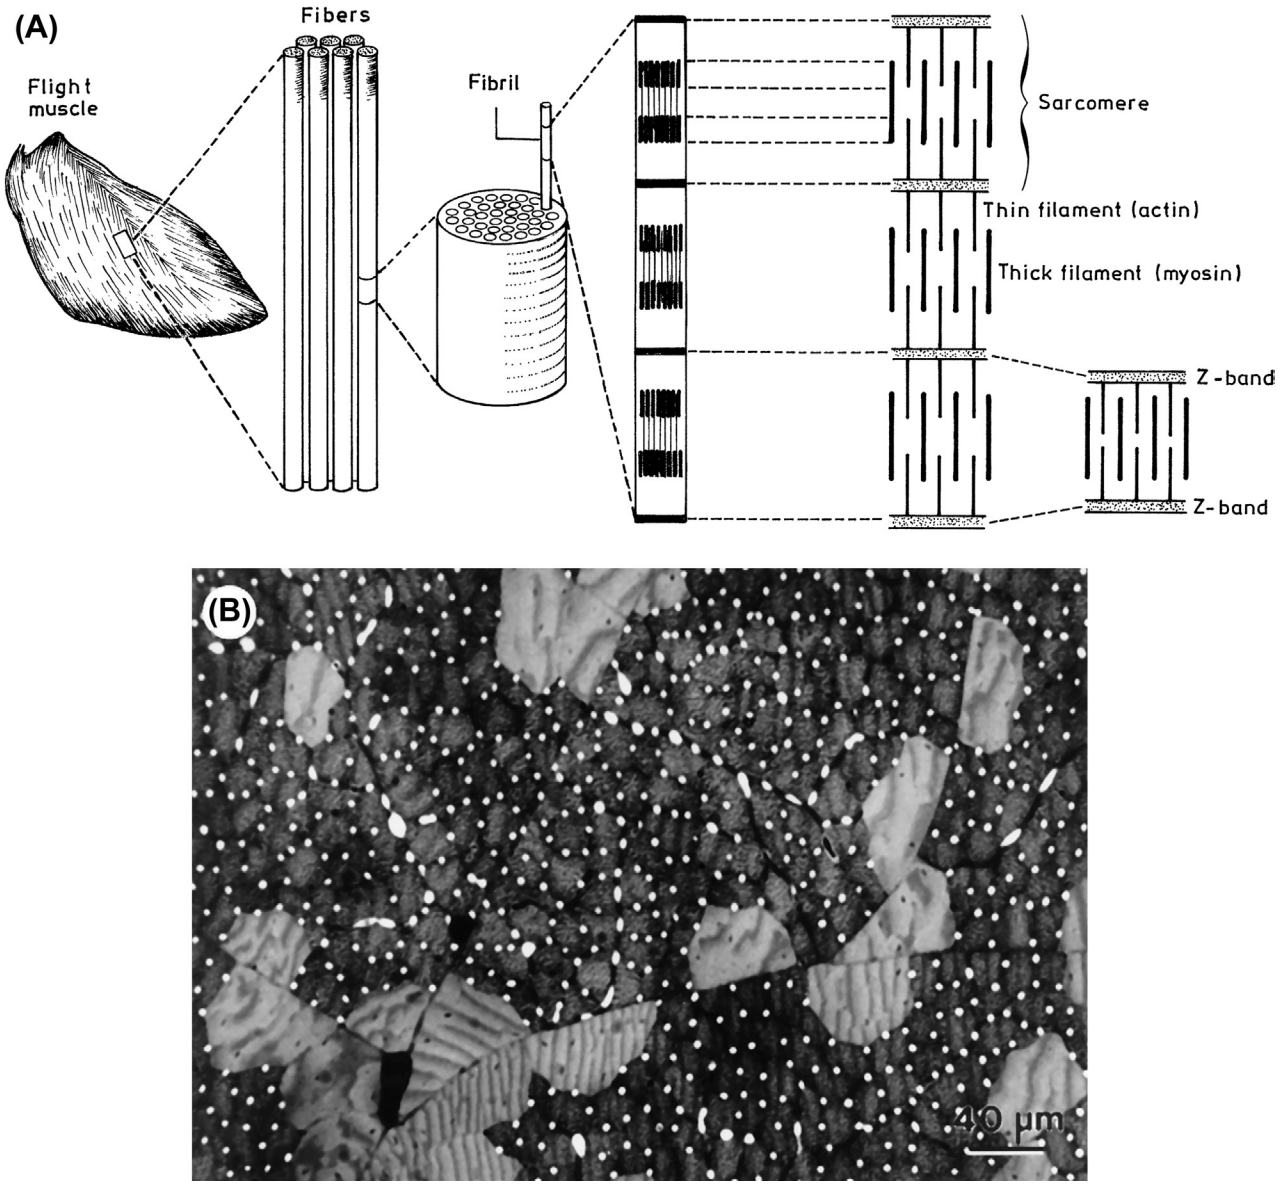

FIGURE 39.16 (A) Schematic illustration of the structure of a bird's pectoral muscle. The whole muscle is composed of many different fibers or cells, each of which consists of many fibrils and each fibril contains many thin actin filaments interspersed between thick myosin filaments. These filaments are organized into sarcomeres, which shorten during contraction as the actin and myosin filaments slide past each other. (*Modified from Schmidt-Nielsen (1997).*) (B) Light micrograph of a 1 µm thick transverse section of pectoralis muscle of the pigeon *Columba livia.* Fast oxidative glycolytic fibers (dark and small) and fast glycolytic fibers (pale and large) can be clearly identified. Capillaries are empty following vascular perfusion fixation. Bar = 40 µm. *From Mathieu-Costello (1991), Copyright © 1991 Wiley-Liss Inc., a division of John Wiley & Sons, Inc.*

cormorant *Phalacrocorax auritus* (Rosser and George, 1986a), and the domestic chicken *Gallus gallus* (Matsuda et al., 1983; Rosser and George, 1986a). However, in general, the occurrence of SO fibers is rare in birds, and they make up only a small percentage of the pectoralis muscle when they do occur.

Thus, while SO fibers may have some role in the thermal soaring flight of the pelican and the red-tailed hawk, or perhaps in the "outstretched" wing posture of the cormorant while drying its feathers, it would appear that most species of birds can manage without this specialized fiber type in their flight muscles (cf. Talesara and Goldspink, 1978; Rosser and George, 1986a).

The most abundant type of fiber to be found in the flight muscles of birds capable of prolonged flapping flight is the FOG (George and Berger, 1966; Rosser and George, 1986a). In general, the flight muscles of small birds are entirely composed of FOG fibers while larger birds have a mixture of different fiber types. However, there is a large degree of interspecies variation. George and Berger (1966)

TABLE 39.1 Simplified Characteristics of Muscle Fiber Types

Property	Slow Oxidative SO (Type I)	Fast Oxidative Glycolytic FOG (Type IIA)	Fast Glycolytic FG (Type IIB)
Speed of contraction	Slow	Medium–fast	Medium–very fast
Aerobic capacity	High	High	Low
Anaerobic capacity	Low	Moderate	High
Capillary supply	Good	Good	Poor
Triglyceride stores	High	Medium–high	Low
Glycogen stores	Medium	Medium–high	Medium–high
Fatigue resistance	High	High	Low
Cross-sectional area	Small	Small–medium	Medium–large

classified the pectoralis muscle of birds into six groups, with each fiber type listed in order of relative numerical abundance: (1) fowl type (FG, I, FOG); (2) duck type (FOG, FG, I); (3) pigeon type (FOG, FG); (4) kite type (mainly I); (5) starling type (FOG, I); and (6) sparrow type (FOG). While most species can be broadly assigned to one of these groups, there are many exceptions. Clearly, each individual species is adapted to cope with its own unique requirements based on its behavioral ecology, its detailed morphology, and the environmental conditions in which it lives.

Even more importantly, the histochemical classification of muscle fiber types can be misleading from a functional perspective. In reality, the fast-twitch fiber types are arbitrary classifications within a continuum of oxidative to glycolytic potentials. In addition, the term "fast" is also arbitrary, as there is likely to be a continuum for the rates at which the flight muscles are optimized to contract, due to the scaling of wingbeat frequency with body mass (Pennycuick, 1990, 1996). A small hummingbird may beat its wings at up to 50 Hz, while a large swan may only have a wingbeat of around 2.4 Hz. Therefore, there are likely to be many associated differences in the molecular characteristics of the contractile proteins from different species of birds. As a consequence, the FOG fibers of a hummingbird are not biochemically identical to the FOG fibers of a swan. It is probable that, even within the muscle of an individual bird, the FOG fibers of the deep layers may have slightly different characteristics to the FOG fibers from the more peripheral layers. Rosser and George (1986a) suggest that, given sufficient detailed knowledge about the protein isoforms of muscle, it is conceivable that almost all muscle fibers could be described as a unique subtype.

Despite the difficulties outlined above, it is still possible to draw some interesting conclusions about the functioning of avian flight muscles by quantifying their fiber type compositions. The Galliformes, such as the domestic chicken and the ruffed grouse (*Bonasa umbellus*), have a majority of FG fibers in their pectoralis muscles (Rosser and George, 1986a). This is matched by their relatively small heart masses and a low capacity to supply the muscles with oxygen (Bishop and Butler, 1995; Bishop, 1997). These birds are restricted to anaerobic flights of short duration. Typically, galliform birds live close to the edges of forests, have relatively short wings and relatively large flight muscles, and escape predation by being adapted for rapid takeoff followed by short flights into dense vegetation or into the branches of trees. The South American ecological equivalent of the Old World Galliformes, the tinamous, also have very small hearts and large flight muscles (Hartman, 1961) and live on the forest floor.

The Galliformes contrast with their closest relatives (Sibley and Alquist, 1990), the Anseriformes (the ducks, geese, and swans). Although of similar body size, the Anseriformes have relatively longer wings and live in open, uncluttered habitats. Their pectoralis muscles contain a high proportion of FOG fibers interspersed among the FG fibers, and their relative heart mass is also much larger (Magnan, 1922; Hartman, 1961). Thus, their wing morphology determines that they have a slightly more efficient form of flight (Rayner, 1988; Pennycuick, 1989), and their muscle physiology and cardiovascular adaptations determine that they are able to prolong these flights over relatively long distances. Similar adaptations are seen in the flight muscles of the doves and pigeons (Columbiformes).

The aerobic nature of the flight muscles of some relatively large species of birds, such as the bustards and swans, has an important consequence for the interpretation of the size limitations to flight performance in birds. It is necessary to distinguish between "burst" flight performance and "prolonged" or aerobic flight performance (Marden, 1994) and to compare flight muscles that are adapted for similar types of flight. The data of Marden (1987) and Pennycuick

et al. (1989) on the maximum lifting ability of flying animals during takeoff refer only to "burst" flight performance, and bird species that have predominantly anaerobic FG flight muscle fibers will be at an advantage during takeoff compared to species that have predominantly aerobic FOG muscle fibers.

Caldow and Furness (1993) studied the histochemical adaptations of two ecologically similar seabirds, the great skua (*Catharacta skua*) and the herring gull (*L. argentatus*). They found that both species had FOG fibers exclusively in their pectoralis and supracoracoideus flight muscles, but that the mass-specific activity of both the oxidative and glycolytic enzymes (see below) were higher in the muscles of the great skua and concluded that this adaptation enabled the skua (Stercorariidae) to be a more effective aerial kleptoparasite than the herring gull (Lariidae). The mass of the pectoralis muscles is relatively small in the herring gull (12% of body mass), but it has a moderately large heart mass (0.9% of body mass), which is consistent with the fact that its flight muscles consist entirely of FOG fibers.

39.4.2 Biochemistry of the Flight Muscles

As discussed by Marsh (1981), the sustained, long-distance flights performed by many migrating birds require two interacting adaptions: the ability to store sufficient fuel reserves for the flight and the ability to maintain supplies of oxygen and fuel to the working tissues. Due to the very high energy density of lipids (39.3 kJ/g), compared to pure carbohydrates (17.6 kJ/g) and proteins (17.8 kJ/g), the energy for migratory flights is predominantly stored as fat in adipocytes. Thus, adaptations for the efficient oxidation of fatty acids and the potential for a high aerobic capacity are some of the most important features of most avian flight muscles. The relatively high mass-specific energy output required from the flight muscles necessitates high capillary and mitochondrial densities and high levels of mass-specific activities for the associated mitochondrial enzymes.

Hummingbirds are able to sustain the highest mass-specific metabolic rates of any vertebrate (Lasiewski, 1963), and Table 39.2 shows data from Suarez et al. (1986) for the maximum activities of various catabolic enzymes in hummingbird flight muscle. The following enzymes are of particular interest: citrate synthase (CS), as an indicator of general aerobic capacity; 3-hydroxyacyl-CoA dehydrogenase (HAD) and carnitine palmitoyl transferase (CPT), as indicators of fatty acid utilization; phosphofructokinase (PFK), as an indicator of general glycolytic flux; pyruvate kinase (PK), as an indicator of anaerobic glycolysis; and hexokinase (HEX) and glycogen phosphorylase (GPHOS), as indicators of plasma glucose and intracellular glycogen utilization, respectively. As expected, the flight muscles of hummingbirds have some of the highest catabolic enzyme activities ever measured. In particular, mass-specific CS and the HEX activities are high and even higher (at 448.4 and 18.4 μmol/min g, respectively) in a subsequent study with a modified extraction procedure (Suarez et al., 1990).

TABLE 39.2 Maximum Enzyme Activities in the Flight Muscle and Heart of the Rufous Hummingbird Selophorus Rufus[1]

Enzyme	Flight Muscle	*n*	Heart	*n*
Glycogen phosphorylase	31.22 ± 2.5	6	Not measured	
Hexokinase	9.18 ± 0.31	4	10.08 ± 1.9	4
Phosphofructokinase	109.8 ± 13	6	Unstable	
Pyruvate kinase	672.4 ± 27	6	507.3 ± 25	6
Lactate dehydrogenase	230.3 ± 23	6	357.4 30	6
Carnitine palmitoyl transferase	4.42 ± 0.46	6	2.83 ± 0.72	4
3-Hydroxyacyl CoA	97.10 ± 13	6	68.51 ± 10	4
Glutamate-oxaloacetate transaminase	1388 ± 70	5	576.4 ± 29	5
Glutamate-pyruvate transaminase	75.97 ± 6.0	5	16.31 ± 2.2	5
Citrate synthase	343.3 ± 8.8	6	190.3 ± 4.8	4
Creatine kinase	2848 ± 337	5	348.9 ± 59	5
Malate dehydrogenase	3525 ± 331	6	2024 ± 191	6
α-Glycerophosphate dehydrogenase	9.37 ± 2.1	6	8.10 ± 2.2	6

[1]*Values are expressed in μmol/min g wet wt and presented as means SE; n, number of birds (from Suarez et al., 1986).*

These two studies (Suarez et al., 1986, 1990) indicate that while it is possible for hummingbirds to meet almost all their flight requirements by oxidizing lipid fuel, it is also possible for them to meet the requirements of hovering flight utilizing carbohydrate fuels. The latter possibility makes sense given that hummingbirds feed mainly on sucrose-rich nectar, and so during the day they would have a good supply of pure carbohydrate direct from the environment. However, for long-term storage, carbohydrates are stored as glycogen, which consists of at least 75% water, thus giving it a relatively poor energy density (4.4 kJ/g). It would not be possible, therefore, to store enough carbohydrates to fuel long-distance flight. In fact, it is unlikely that stored carbohydrate could support hovering flight for around 5 min (Suarez et al., 1990). However in the short-term, it is more efficient to oxidize plasma glucose directly to support flight, due to the 16% lower net yield for ATP

resulting from the cost of synthesizing fatty acids from glucose for long-term storage. This led these authors to suggest that premigratory hummingbirds should behave as "carbohydrate maximizers" by keeping their foraging flights well under 5 min duration. This would provide efficient foraging while allowing excess glucose to be stored as fat. However, while the availability of plasma glucose may not be limiting for hummingbirds, the majority of bird species may place a higher emphasis on carbohydrate sparing. Bishop et al. (1995) found that HEX activity was relatively low in the pectoralis muscles of adult premigratory barnacle geese, and similar results have been reported for the pigeon and domestic chicken (Crabtree and Newsholme, 1972) and for the migratory semipalmated sandpiper, *Calidris pusilla* (Driedzic et al., 1993).

Many studies have shown that prior to long-distance flights, such as those performed during seasonal migrations, birds increase in body mass due primarily to the laying down of fat stores (Blem, 1976). This is usually correlated with hypertrophy of the pectoralis muscle in order to increase the power available for takeoff and forward flapping flight and species-specific changes in catabolic enzyme activities. While Marsh (1981) found no change in the premigratory activity of CS in the pectoralis muscle of the catbird (*Dumatella carolinensis*), he reported a significant increase in the level of HAD (indicating an increase in the potential for fatty acid oxidation). A similar increase in the ability to oxidize fatty acids was found in the semipalmated sandpiper, but the level of CS actually decreased (Driedzic et al. 1993). However, some species of small migratory passerine birds do appear to show an increase in the premigratory activity of both CS and HAD (Lundofgren and Kiessling, 1985, 1986), while CS activity in the premigratory barnacle goose was around 30% greater than that of postmolting birds approximately 4 weeks earlier in the season (Bishop et al., 1995).

Avian muscle capillarity and diffusion distances have been studied in a variety of different tissues, but no significant allometric trends with respect to different body masses were found for any of the variables measured (Snyder, 1990). However, Snyder (1990) did find a small but significant difference in the capillary to fiber ratio (C/F) between the aerobic fiber types (1.8 caps/fiber) and the glycolytic fibers (1.4 caps/fiber). Capillary density and diffusion distances are primarily determined by the cross-sectional area of the individual fibers, and the author argues that there may be little selective advantage in having a C/F greater than 2.0. Studies on avian pectoralis muscles have generally resulted in similar conclusions. Mathieu-Costello et al. (1992) found that the C/F of the rufous hummingbird (*Selaphorus rufus*) is only 1.55 caps/fiber compared to that of the pigeon, which is 2.0 caps/fiber (Mathieu-Costello, 1991). However, fiber diameter and the cross-sectional area are much smaller in the hummingbirds than in pigeons, and therefore the capillary density per unit area is much higher in hummingbirds. Mathieu-Costello et al. (1992) consider that one of the most important determinants of the rate of oxygen flux in aerobic fibers is the size of the capillary-to-fiber interface (i.e., the capillary surface per fiber surface area). However, in order to measure this feature accurately, it is necessary to standardize with respect to both the sarcomere length and the degree of tortuosity of the capillaries.

39.4.3 Neurophysiology and Muscle Function

Birds are capable of synchronizing the extension of the elbow and wrist joints of the wing during flapping flight, using automated coordinating mechanisms involving skeletal and muscular adaptations (Vazquez, 1994). However, the power and thrust generated during the wingbeat cycle, and the complex kinematics of the wing during the flapping flight of different species, require an active neuromuscular control mechanism and specialized adaptations of the flight muscles.

The detailed movements of the wing during flight actually involve a large number of different muscles (Dial et al., 1991; Dial, 1992a) and their differential (Dial, 1992a; Tobalske and Dial, 1994; Tobalske, 1995; Tobalske et al., 1997) or regional (Boggs and Dial, 1993) activation. For most studies, however, it is sufficient to focus on the functioning of the largest flight muscles, pectoralis and supracoracoideus. Dial (1992b) showed that birds were unable to take off or perform controlled landings without the use of the muscles of the forearm, but that they could sustain level flapping flight following an assisted takeoff.

The largest flight muscle, the pectoralis major, can be divided into two anatomical parts (Figure 39.17), the sternobrachialis (SB: which is superficial and lies along the sternum) and the thoracobrachialis (TB: which forms a deep layer lying along the sternum), and these are separated by the membrana intermuscularis (Dial et al., 1987). The SB is primarily innervated by the rostral nerve branch and the TB by the caudal nerve branch of the brachial ventral cord. In the pigeon, the fibers within the SB and TB have different orientations (Dial et al., 1987), while the SB has a lower percentage of FOG fibers and relatively more FG fibers, and the TB is primarily made up of FOG fibers (Kaplan and Goslow, 1989). Thus, the histochemical analysis and the neuroanatomy support the view that the pectoralis major is made up of at least two functional subunits, each with a potential for independent action on the wing during flight (Dial et al., 1987, 1988; Kaplan and Goslow, 1989; Goslow and Dial, 1990). Dial et al. (1987) showed that both the SB and TB muscles of the pigeon were maximally activated during takeoff or during large-amplitude wingbeats. However, during slow flight, the SB was relatively more important, and during low-amplitude wingbeats the activity of the TB could be almost zero. Interestingly, Dial et al. (1987) also indicate that there is a gradual reduction of large-amplitude

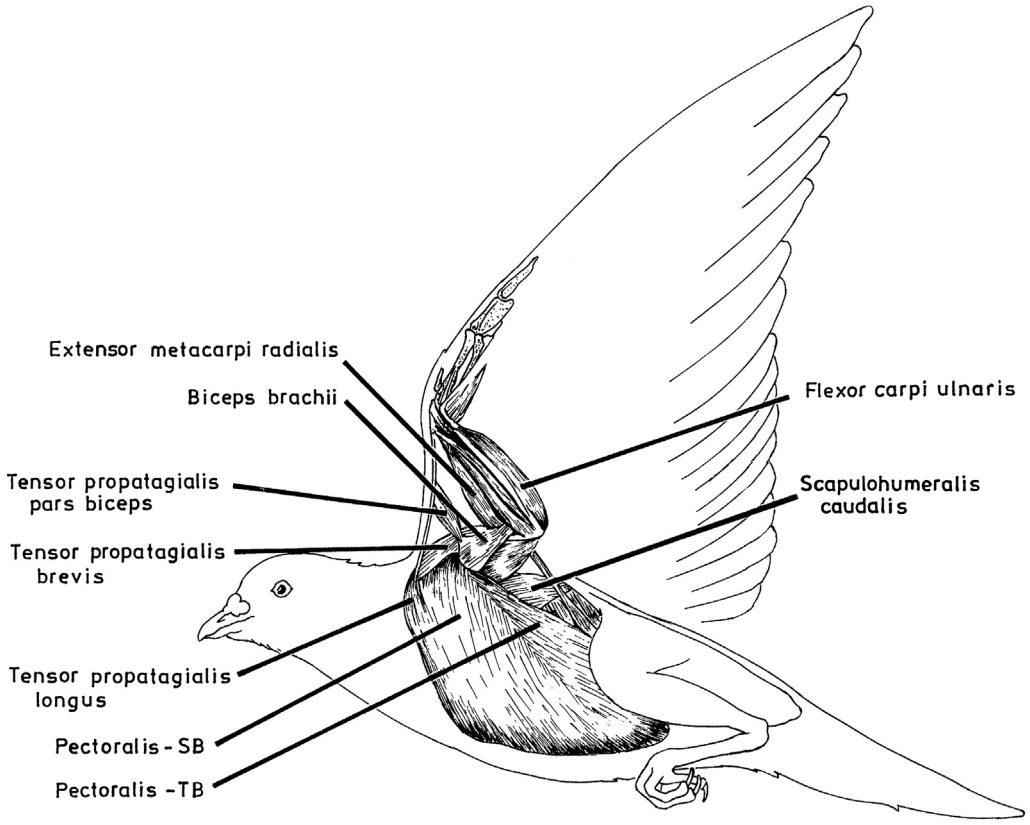

FIGURE 39.17 Illustration of the superficial flight muscles of the wings of a pigeon, *Columba livia.* The supracoracoideus muscles (not shown) are primarily used to power the upstroke and lie directly under the larger pectoralis muscles, which primarily power the downstroke. *Modified from Dial (1992a) Copyright © 1992 John Wiley & Sons, Inc. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.*

electromyogram (EMG) spikes during the transition from takeoff to level flight and that they reappear during landing. This supports the hypothesis that FG fibers are derecruited during level flight.

Tobalske et al. (1997) studied the neuromuscular control and wing kinematics of the black-billed magpie, both in the wild and while flying in a wind tunnel, and showed that this species has a particularly complex flight style, consisting of alternating high- and low-amplitude wingbeats and occasional brief glides. This wide study found that the pectoralis consisted of FOG and I fiber types, as in the woodpecker (see below), and that the I fiber types were probably only recruited during the high-amplitude wingbeats. EMG recordings were made from six different wing muscles, and all showed that the relative intensity of the EMG signal exhibited a U-shaped output with respect to flight speed. Minimum intensity was recorded around 4.4 m/sec and the highest were recorded during hovering and the top speed of 13.4 m/sec. The pectoralis and the biceps brachii muscles showed strong activity during the end of the upstroke and the beginning of the downstroke, while the supracoracoideus, the humerotriceps, the scapulotriceps, and the scapulohumeralis caudalis were important during the end of the downstroke and the beginning of the upstroke.

A more detailed study of the EMG activity of 17 different muscles in the shoulder and forelimb of the pigeon during five different modes of flight was conducted by Dial (1992a). He concluded that the temporal pattern of activity did not vary much between different modes of flight, but that the intensity of the EMG signal was very important in determining the role of the different muscles during different modes of flight (Figure 39.18).

Tobalske (1996) studied the muscle composition and wing morphology of six different species of woodpecker, ranging in mass from 27 to 263 g, and related morphology to the scaling of intermittent flight behavior. Intermittent flight consists of regular alternation between periods of flapping and nonflapping. During the nonflapping phases, the bird's wings are either held folded at its side (flap-bounding flight) or held fully extended (flap-gliding flight). Biomechanical and physiological analyses suggest that intermittent flight is energetically efficient relative to continuous flapping (Rayner, 1985a), particularly for small species that have high wingbeat frequencies that are relatively "fixed" (Rayner, 1985a). Only FOG and I fiber types were found in these six species of woodpecker, with small species having almost exclusively FOG fibers in their pectoralis muscles, while species >100 g tended to have significant amounts of I fibers. All six species were capable of

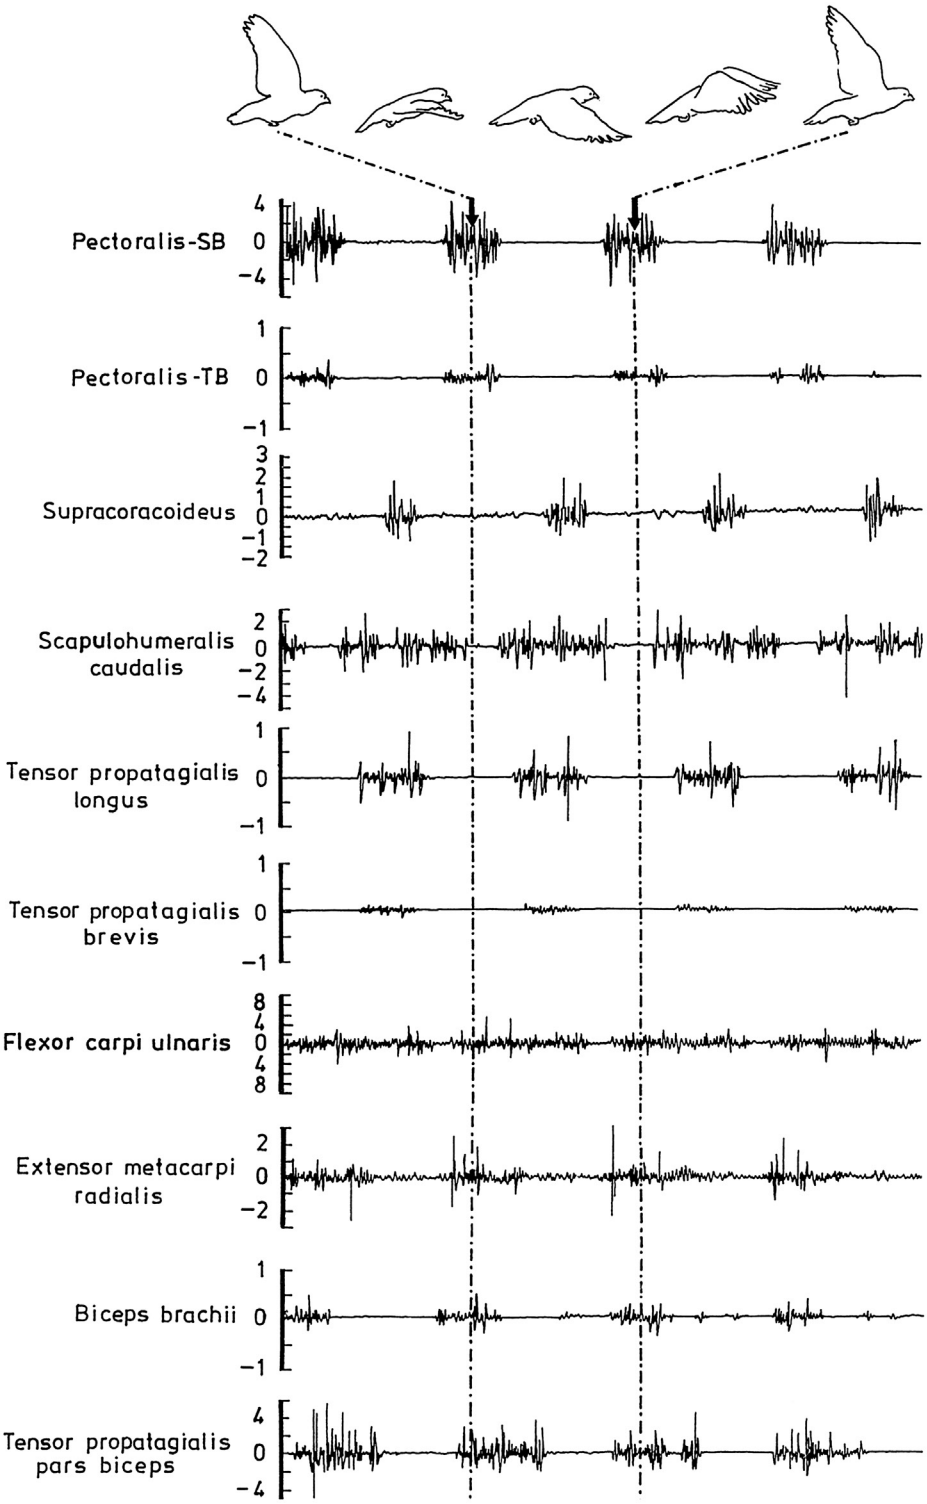

FIGURE 39.18 Electromyogram (EMG) signals recorded during level flapping flight from the various muscles of a pigeon, *Columba livia,* illustrated in Figure 39.13. EMG activity is presented with reference to the phase of the wingbeat cycle, with each downstroke indicated by the vertical dashed line. *Modified from Dial (1992a), Copyright © 1992 John Wiley & Sons, Inc. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.*

exhibiting flap-bounding behavior, although the percentage of time spent flapping increased with increasing body mass. The empirical observations of Tobalske (1996) greatly exceed the theoretical considerations (Rayner, 1985a) that the upper limit for flap-bounding flight should be around 100 g of body mass.

However, the heterogeneous scaling of the fiber type composition of the pectoralis is likely to be one reason why

the theoretical figures underestimate bird flight performance (Tobalske, 1996). FG and I fibers have the potential to produce more force per unit area than FOG fibers and therefore can produce more power for a given degree of fiber shortening and frequency. Thus, Tobalske (1996) argued that the positive scaling of the percentage and cross-sectional diameter of I fibers in the pectoralis of woodpeckers may be a direct result of the positive scaling of the power required for flight compared to the power available from the flight muscles (cf. Pennycuick, 1989; Marden, 1987; Ellington, 1991). Interestingly, among woodpeckers, the scaling of relative heart muscle mass is negative relative to increasing body mass (Hartman, 1961), which matches the decline in FOG content of the flight muscles. Thus, while large woodpecker species may be able to meet the power required to perform flap-bounding flight, it is likely that they will not be able to prolong these types of flight as easily as the smaller species, or perhaps that they might utilize a higher fraction of gliding flight.

Lewis' woodpecker (*Melanerpes lewis*) was found to be able to perform both flap-bounding and flap-gliding flight, contrary to theoretical predictions that it should not perform the former (Tobalske, 1996), and this behavior was not well correlated with the morphology of the wing. In addition, Tobalske and Dial (1994) found that the 35 g budgerigar was also capable of performing flap-gliding behavior when flying slowly, but switched to flap-bounding behavior during fast flight, despite the observation that they only have a single fiber type (FOG) in their pectoralis muscles (Rosser and George, 1986a). Thus, the hypothesis that the FOG fibers of small birds should not be used for gliding as it is inefficient appears to be undermined by the budgerigars, with the pectoralis being active during the gliding phases, but inactive during the bound. Tobalske and Dial (1994) predicted that all other species that show intermittent flight should also be facultative flap-gliders and flap-bounders and that the choice of flight mode is simply dependent on flight speed.

39.5 DEVELOPMENT OF LOCOMOTOR MUSCLES AND PREPARATION FOR FLIGHT

The development of the locomotor and cardiac muscles, together with other morphological features, have been studied in a Svalbard population of migratory barnacle geese, from hatch until it migrates to its wintering grounds in southern Scotland at the age of approximately 12 weeks (Bishop et al., 1996). Up until the age of 7 weeks, the goslings are unable to fly and spend their time walking and foraging. At the age of 5 weeks, the relative mass of the leg muscles is approximately 13% of body mass, while that of the pectoral muscles is only 3.5% of body mass. During the first 5 weeks of their life, there is a strong relationship between mass of the ventricles and mass of the leg muscles (Figure 39.19(B)). During the following 2 weeks, the flight muscles

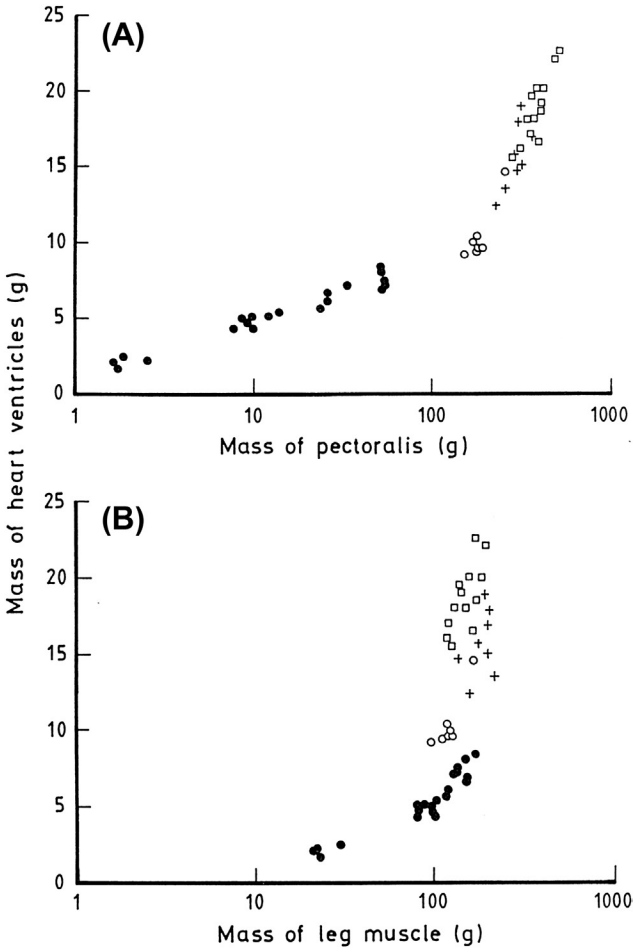

FIGURE 39.19 Scatter diagram of the masses (g) of the heart ventricles plotted against (A) the mass of the pectoral muscles and (B) the mass of the total leg muscles of wild barnacle geese, *Branta leucopsis*. Goslings of 1–5 weeks of age (●), fledgling goslings of 7 weeks of age (○),adult geese captured 7 weeks after the population hatch date (+), and premigratory adult geese (□). *Modified from Bishop et al. (1996), with permission.*

continue to grow in an exponential manner and by the time the goslings are 7 weeks old, these muscles are an impressive 14% of body mass, whereas the relative mass of the leg muscles has declined to approximately 9% of body mass (Figure 39.15). From the age of 7 weeks, the mass of the ventricles is proportional to the mass of the pectoral muscles (Figure 39.19(A)). At 5 weeks of age, ventricular mass is 5.2% of total mass of the leg muscles and at 7 weeks of age, it is 5.5% of mass of the pectoral muscles. Thus, as might be expected, the output capacity of the heart is closely matched to the oxygen requirements of the dominant set of locomotory muscles.

Choi et al. (1993) studied the skeletal muscle growth and development of thermogenesis in European starlings (*S. vulgaris*), the northern bobwhite (*Colinus virginianus*), and Japanese quails (*Coturnix japonica*). The body mass of the altricial starling developed more rapidly than that of the precocial quail species, although the percentage of the

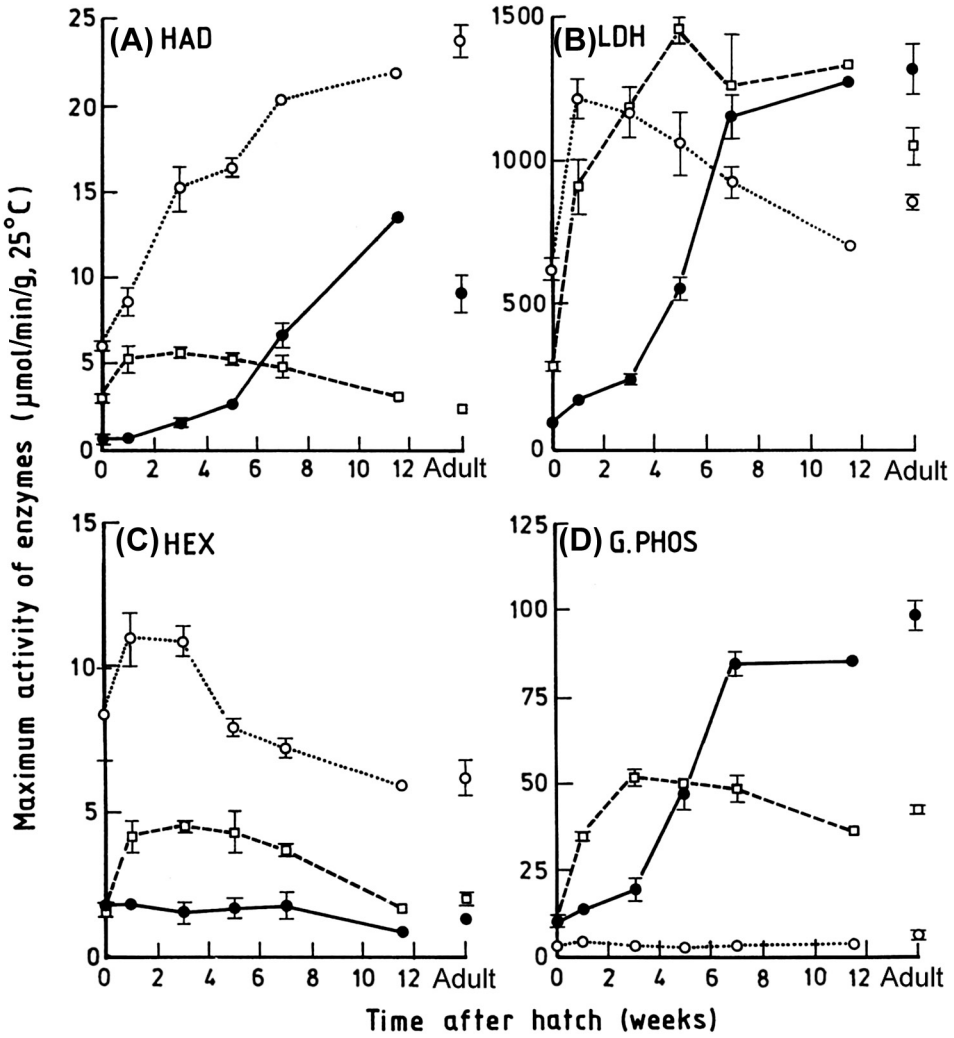

FIGURE 39.20 Mean ± SE of maximum activities of catabolic enzymes (mol/min g wet wt at 25 °C) in pectoral muscle (●——●), heart muscle (○·····○), and semimembranosus muscle (□------□) plotted against age of wild barnacle geese, *Branta leucopsis*. (A) 3-hydroxyacyl-CoA dehydrogenase (HAD), (B) lactate dehydrogenase (LDH), (C) hexokinase (HEX), and (D) glycogen phosphorylase (G.PHOS). $N = 2–8$, except for a single individual at 11.5 weeks of age. Adult geese and 11.5 week old gosling are premigratory (see text). *Modified from Bishop et al. (1995) with permission.*

body mass that was accounted for by muscle mass was quite similar. The main difference between these groups was in the expression of muscle mass-specific enzyme activities. In particular, the activity of CS did not exceed 50 and activity 30 μmol/min g in the pectoralis muscles of *Coturnix* and *Colinus* quail, respectively, throughout development. In the starling pectoralis muscle, CS activity increased rapidly, and linearly, during development and reached 142 μmol/min g around fledging at 16 of age and approximately 230 μmol/min g in adult starlings. In bank swallows (*Riparia riparia*), CS activity increased from around 20 μmol/min g at 2 days of age and reached around 150 μmol/min g after 10 days (Marsh and Wickler, 1982).

A similar study of the barnacle goose found an even more exaggerated developmental pattern (Bishop et al., 1995), with CS expression showing almost no change in activity from hatch (12 μmol/min g) through to 5 weeks of age (20 μmol/min g). Subsequently, the activity increased rapidly to 75 μmol/min g at 30 μmol/min g in the pectoralis muscles of *Coturnix* 7 weeks of age and reached around 100 μmol/min g in the premigratory goslings and adults (see Figure 39.33). The mass-specific activity of four different mitochondrial enzymes showed broadly similar patterns of activity to each other during development (Bishop et al., 1995) and are typified by the results obtained for HAD activity in pectoralis, cardiac, and semimembranosus leg muscle (Figure 39.20(A)). Throughout most of development the cardiac muscle had the highest relative capacity for aerobic metabolic flux and fatty acid oxidation. HAD activity in the semimembranosus leg muscle was intermediate in value prior to fledging at 7 weeks (when the birds first begin to fly), but subsequently declined, while CS activity in the pectoralis flight muscle was initially very low, but reached a peak in the premigratory birds (see Figure 39.33).

The developmental profiles of various glycolytic enzymes, lactate dehydrogenase (LDH, Figure 39.20(B)), hexokinase (HEX, Figure 39.20(C)), and glycogen phosphorylase (GPHOS, Figure 39.20(D)), were more tissue-specific compared to those of the mitochondrial enzymes. Development of LDH and GPHOS activities in the pectoralis muscle show a similar exponential increase as that for CS, but values for HEX remain very low at all ages.

Overall, the results suggest that the relative use of circulating plasma glucose by the pectoralis muscle during flight is low, while intramuscular stores of glycogen are of primary importance during short-burst activity and of intermediate importance during longer-term activity, and that fatty acid oxidation is the main fuel during long-distance flight (Bishop et al., 1995). In general, moderate activity levels were detected in the semimembranosus muscle for all the enzymes that were measured, suggesting that the leg muscles are capable of utilizing all fuel types in almost equal amounts. However, the cardiac muscle had extremely low levels of GPHOS, indicating that it can only utilize aerobic pathways and that metabolic fuel must be primarily supplied by blood. LDH values were relatively high in the heart, while pyruvate kinase levels were very low (data not shown), indicating that the heart is capable of oxidizing circulating lactate as a fuel.

39.6 METABOLIC SUBSTRATE TRANSPORT

The use of fatty acids as the primary fuel during long-distance flights is an important adaptation, as the energy density of fat is much greater than that of other stored fuels. As pointed out earlier, the energy density of pure carbohydrate is 17.6 kJ/g; however, the storage of glycogen in cells involves between 3 and 5 g of water for each gram of glycogen, giving an effective energy density of approximately 4.4 kJ/g compared with that for lipids of 39.3 kJ/g (Schmidt-Nielsen, 1997). Protein may also be used to provide energy, but tissues such as muscle also consist of 70–80% water, so that the energy density of stored protein *in vivo* is around 5.4 kJ/g. Thus, during a long flight, it is likely that the majority of energy is provided by fatty acids. However, fatty acid transport in the plasma (from the adipocytes to the working muscles or the liver) may be a rate-limiting starvation the major source of glucose is via protein step during intense exercise (Newsholme and Leech, 1983; Butler, 1991) as it is insoluble in water and is transported by a carrier protein, albumin. In fact, mammals do not increase the rate of fatty acid metabolism as the intensity of exercise increases. This is achieved predominantly by an increase in carbohydrate metabolism (see Figure 39.21), mainly by the utilization of glycogen stored in the muscles. The rate of fatty acid metabolism may actually decrease with increased intensity of exercise. However, as migrating birds use predominantly FFA as their energy source, and as their rate of

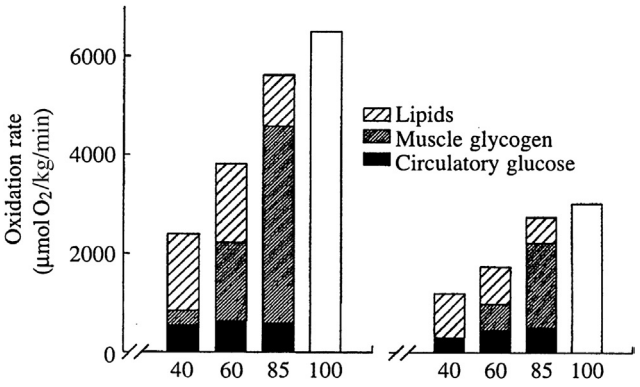

FIGURE 39.21 Substrate oxidation rates at different intensities of exercise in two species of mammals with different aerobic capacities. The large difference in the maximum rates of oxygen consumption of these two species is mainly the result of the larger rate at which glycogen is supplied from stores within the locomotor muscles themselves. *From Weber et al. (1996), Company of Biologists, Ltd.*

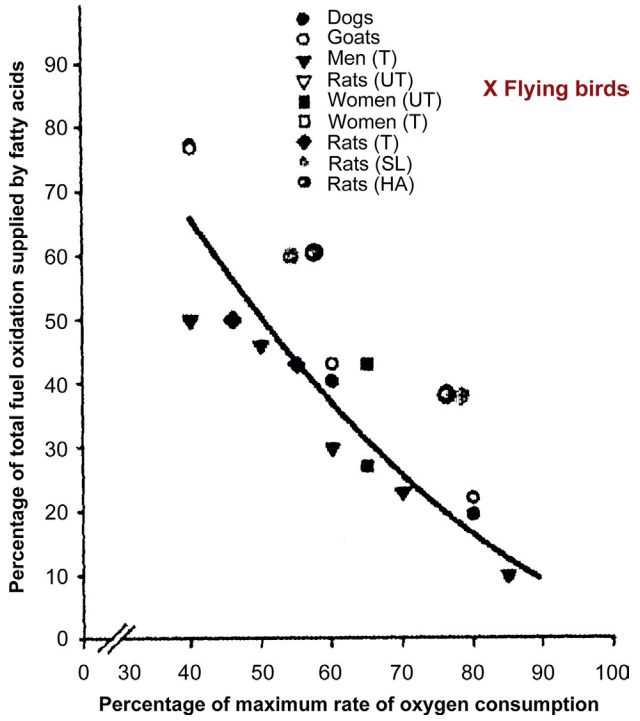

FIGURE 39.22 Percentage supply of fatty acid substrate to the muscles of mammals during increasing exercise intensity. X indicates an estimated value for flying birds. *From McCLelland (2004).*

aerobic metabolic rate is at least twice that of running mammals of similar size, the rate at which migrating birds need to transport FFA may be up to 20 times greater than that of running mammals (Figure 39.22).

A mechanism has been proposed for how small birds could deliver the high rates of fatty acid required by the flight muscles without increasing the concentration of albumin in the blood. Jenni-Eiermann and Jenni (1992) measured various metabolite concentrations in the plasma of three species

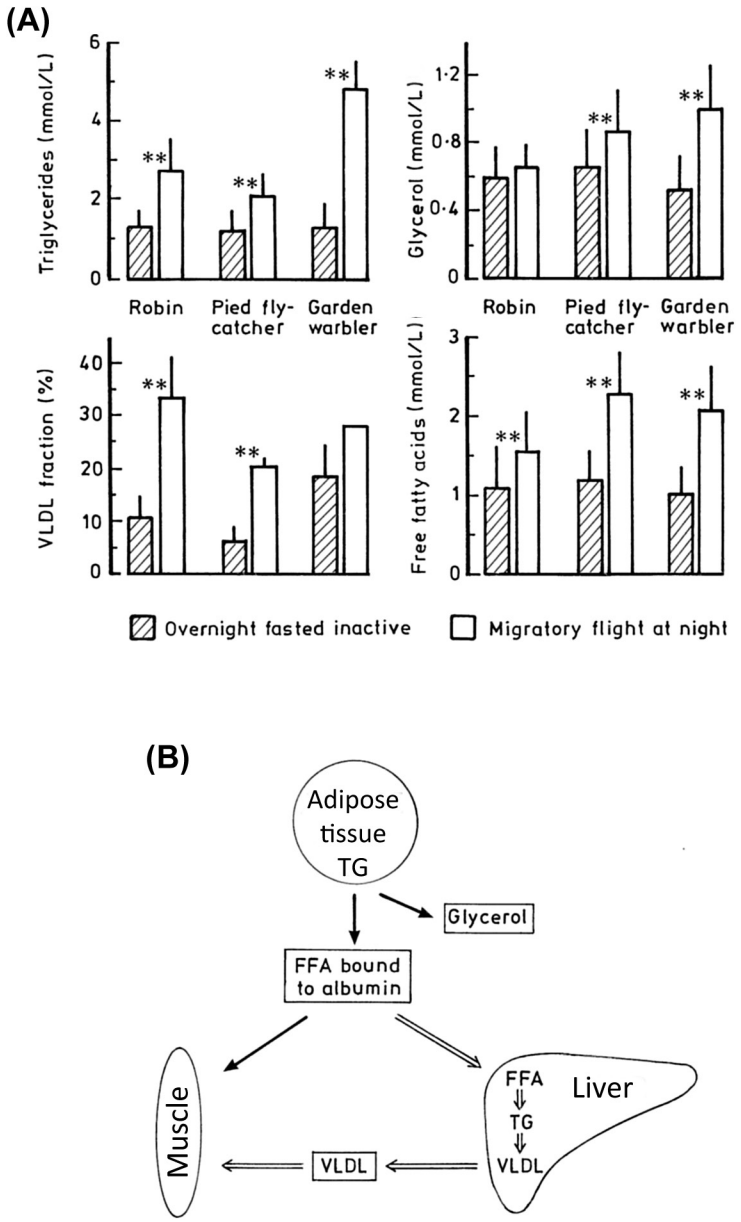

FIGURE 39.23 (A) Means ± SD of various fat metabolite concentrations and very low density lipoproteins (VLDL) in the plasma of three species of birds during overnight fasting (cross-hatched) or during nighttime migratory flights (clear). $^{**}p < 0.01$, Mann–Whitney *U*-test. (B) Diagram illustrating the proposed pathway for fatty acid transport to the flight muscles of small birds. Free fatty acids (FFAs) are released from the triglyceride (TG) stores of the adipose tissue and either taken up directly by the muscles or converted to TG by the liver and transported to the muscles as VLDL. The activity of the latter pathway (double arrows) is suggested to increase in small birds during flight. *Modified from Jenni-Eiermann and Jenni (1992), with permission from The University of Chicago Press. © University of Chicago Press.*

of small night-migrating passerines (Figure 39.23(A)): the robin (*Erithacus rubecula*), garden warbler (*Sylvia borin*), and pied flycatcher (*F. hypoleuca*). Their results indicated that during long-distance flights, plasma levels of triglyceride, glycerol, free-fatty acids (FFAs), and very low density lipoproteins (VLDL) all increased significantly above values at rest.

The rise in triglycerides and VLDL was unexpected, but could provide a mechanism for increasing the FFA supply to the flight muscles. FFAs are re-esterified to triglyceride in the liver and subsequently delivered to the blood as VLDL. Thus, the removal of FFAs from the bloodstream by the liver as well as by the flight muscles will increase the rate at which albumin is able to transport FFAs from the adipocytes. Secondly, the VLDL can be hydrolyzed by lipoprotein lipase in the endothelium of the flight muscle capillaries, thus allowing the uptake of the released FFAs (Figure 39.23(B)). Apart from increasing the availability of FFAs to the flight

muscles, this mechanism has the additional advantage that the overall protein (albumin) concentration of the blood is kept relatively low and prevents unacceptable increase in colloid osmotic pressure. Also, since the proportion of triglycerides in VLDL is 60–70% (compared to only 3% in albumin), there is a dramatic increase in the rate of fatty acid transport by the circulatory system of these birds.

In addition, the rate of uptake of the triglycerides via the VLDL can be controlled by the rate of lipoprotein lipase activity at the site of demand. During the migratory period, these birds accumulate fat in both their flight muscles and the adipocytes. Therefore, overnight-fasted birds were able to preferentially metabolize intramuscular stores of triglycerides, allowing a lower rate of utilization of adipocyte fatty acids and efficient sparing of protein and carbohydrate stores (Jenni-Eiermann and Jenni, 1996). It appears that this process is not as important in other, larger species (for example, Schwilch et al., 1996) and, in the barnacle goose, the maximum concentration of fatty acid-binding protein (considered to act as an intracellular carrier for fatty acids) in the pectoral muscle occurs at the same time as the maximum activity of HAD, just before the autumn migration (Pelsers et al., in press). So, it is still not clear how all species of migratory birds are able to transport FFAs in their blood at a sufficiently high rate to meet their high aerobic metabolic demands. Figure 39.21 shows that dogs have a greater aerobic capacity than pigmy goats, and McClelland et al. (1994) found that their albumin can bind 50% more FFAs than goat albumin. This adaptation of dogs does not, however, increase the proportion of their rate of oxidative metabolism fueled by FFAs. Transport in the blood is not the only problem, FFAs also have to cross the plasma membrane of the muscle cells and the outer and inner membranes of the mitochondria.

Up until the early 1980s it was thought that the uptake of long-chain fatty acids into cells was by passive diffusion. However, evidence now suggests that there are specific fatty acid transport proteins both in the cell membrane and in the cytosol of cells. It is possible, therefore, that there is both passive and protein-mediated transport of fatty acids into cells and into their organelles, such as the mitochondria. Figure 39.24 shows how the fatty acids are thought to cross the plasma membrane in mammals. Once dissociated from the albumin in the plasma, the fatty acids may cross the plasma membrane by passive diffusion and/or membrane-bound fatty acid binding proteins ($FABP_{pm}$) and fatty acid translocase (FAT, or CD36) may be involved in moving the fatty acids into the cytosol. Whichever is the case, once in the cytosol, the fatty acids are converted to fatty acyl-CoA esters either by binding to cytosolic or heart-type fatty acid binding proteins ($FABP_c$, or H-FABP), or directly by acyl-CoA synthetase (ACS). They are then bound to acyl-CoA binding protein (ACBP) and translocated to sites of usage within the cell. Alternatively, fatty acid transport

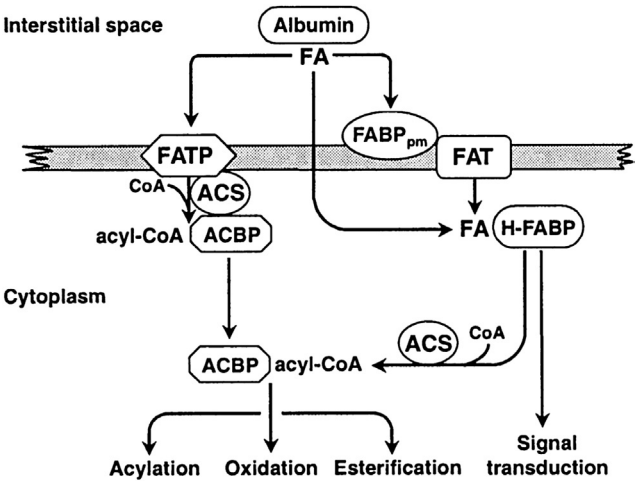

FIGURE 39.24 Long chain fatty acids (FA) are transported in the plasma of mammals bound to albumin. Following their dissociation from the albumin, their movement across a cell membrane into the cytoplasm is either: (1) by passive diffusion, or by membrane-bound fatty acid binding proteins ($FABP_{pm}$) and fatty acid translocase (FAT/CD36), or by a combination of the two; (2) by fatty acid transport protein (FATP), which is also located in the plasma membrane. Once inside the cytoplasm, the fatty acids are converted to fatty acyl-CoA esters by acyl-CoA synthetase (ACS), either via binding to a binding protein called heart-type fatty acid binding protein (H-FABP), or directly. Finally they bind to acyl-CoA binding protein (ACBP). *From Glatz et al. (2003).*

protein (FATP), which is also located in the plasma membrane, may transport the fatty acids into the cytosol, but as FATP is linked to acyl-CoA synthetase, the fatty acids are immediately converted to fatty acyl-CoA esters and bound to acyl-CoA binding protein. Recent evidence suggests that the membrane-bound transport proteins play the major role in fatty acid transport across the plasma membrane (Bonen et al., 2007; Schwenk et al., 2010) Cytosolic fatty acid binding protein acts as a "sink" for fatty acids, thereby increasing their solubility in the cytosol, their rate of removal from the inner surface of the plasma membrane, and their rate of intracellular diffusion.

Figure 39.25 shows how the FFAs enter the mitochondria. Firstly they are converted to their acyl carnitine esters by the enzyme carnitine acyl transferase-1 (CAT 1), which is present on the outer mitochondrial membrane. The acyl carnitine then crosses the inner mitochondrial membrane by the acyl carnitine/carnitine translocase system. Once inside the mitochondria, carnitine acyl transferase-2 (CAT 2), which is located on the inner membrane, regenerates acyl-CoA and free carnitine. This transport process could be the main rate-limiting step in the use of fatty acids by active muscles, with either carnitine or carnitine acyl transferase-1 being the important factors.

Studies on the flight muscles of birds indicate that they have greater concentrations of these fatty acid transporters than mammalian muscles. For example, the flight muscles of migratory western sandpipers (*Calidris mauri*) have

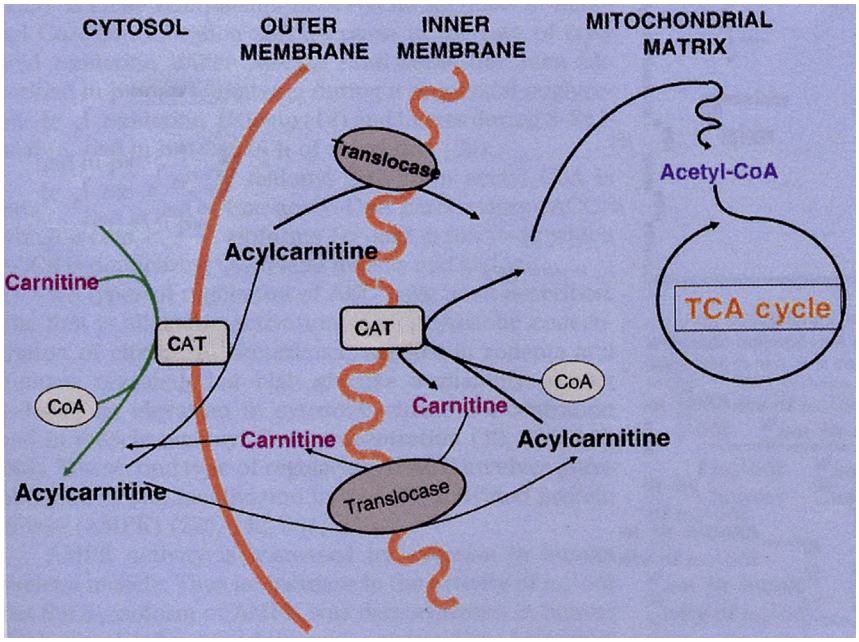

FIGURE 39.25 Transport of long-chain fatty acids (FA) into mitochondria of mammals. Acyl-CoA esters are unable to cross the inner membrane of the mitochondria so they are firstly converted to their acyl carnitine esters by carnitine acyl transferase 1 (CAT 1) which is present on the outer membrane. Acyl carnitine crosses the inner membrane via the translocase system and, once inside the mitochondrion, acyl-CoA and free carnitine are re-formed by CAT 2, which is located on the inner membrane. *From Kiens (2006).*

approximately 10 times greater concentrations of H-FABP than a typical mammalian muscle and approximately 14% of total cytosolic protein is H-FABP in sandpipers. This is the highest value reported for any vertebrate skeletal muscle (Guglielmo et al., 1998). Also, the concentration of H-FABP is 70% greater during the migratory period than during winter (Guglielmo et al., 2002). The presence of FAT/CD36 and $FABP_{pm}$ has been demonstrated in the flight muscle of white-throated sparrows (*Zonotrichia albicollis*), and the genes for these are strongly upregulated during the migratory season (McFarlan et al., 2009). These data indicate that at least three of the muscle fatty acid transport proteins are important in the transport of fatty acids during migration.

There has been much attention recently on the possible significance of a number of polyunsaturated fatty acids (PUFAs) in the diet of premigratory birds, although the evidence for some of these PUFAs having any influence on flight performance is somewhat inconclusive (Guglielmo, 2010). What we do know is that in white-throated sparrows (*Z. albicollis*) there is an increase in the PUFA 18:2n6 in triglyceride stores of muscles and adipose tissue during migration (Klaiman et al., 2009). Also, in European starlings (*S. vulgaris*) there is a 13% reduction in rate of energy expenditure during 6 h flights when they are fed a diet high in 18:2n-6 fatty acids compared with when they are fed a diet high in monounstaturated fatty acids (MUFAs; McWilliams and Pierce, 2006 as quoted by Guglielmo, 2010). The exact details of the mechanisms responsible for this significant saving in rate of energy expenditure are not clear. Two possibilities discussed by Price (2010) are the fuel hypothesis and the phospholipid hypothesis. The fuel hypothesis is based on the facts that unsaturated fatty acids are more soluble and have greater diffusion rates in water than saturated fatty acids. It is postulated, therefore, they should be transported more rapidly from the fat stores to the mitochondria, along the pathways outlined above. The phospholipid hypothesis proposes that, as fatty acids in the diet are incorporated in the phospholipids in membranes of cells and mitochondria, any alteration in composition of mitochondrial membranes affects the various metabolic processes in which they are involved and, therefore, overall performance of the whole organism. For example, in one of the research work done in 2012, the phospholipid hypothesis was developed by highlighting the evidence that fatty acid composition of mitochondrial membranes can alter the leakage of protons in intact mitochondrial preparations and that this proton leak can account for as much as 20% of basal metabolic rate in rats. In that research, it was also pointed out that a by-product of oxidative metabolism is the production of reactive oxygen species (ROS) and that the proton leak may modulate the production of ROS. In a series of experiments on European starlings, Gerson (2012) demonstrated that birds fed on a PUFA-rich diet and flown for approximately 3 h had lower rates of ROS production than those fed on a MUFA-rich diet. The disruption of mitochondrial function by ROS could result in less efficient production of ATP, which could account for the higher flight costs previously shown in European starlings fed a MUFA diet and flown in

a wind tunnel. Gerson (2012) proposed, therefore, that there was reduced oxidative damage and impact on mitochondrial functions during long-duration flight in the PUFA-fed birds. Although protein stores are less energy dense than fatty acid adipocyte stores (see above), in reality it may not be possible entirely to exclude their use during periods of starvation and/or during prolonged periods of exercise. The brain and other nervous tissues are extremely dependent on glucose metabolism for the provision of energy (Newsholme and Leech, 1983). As carbohydrate stores are very limited in most animals, during starvation the major source of glucose is via protein (amino acid) degradation to various metabolic intermediates (called oxoacids), most of which can then enter the gluconeogenesis pathway in the liver. In addition, glycerol that is produced following the hydrolysis of triglycerides can also be converted to glucose. A small number of amino acids (leucine and lysine) are degraded directly to acetyl-CoA and so can contribute to ATP synthesis via the citric acid cycle (CAC) or be converted to fat, as acetyl-CoA cannot enter the gluconeogenesis pathway. Alternatively, excess amino acid production can provide intermediates (e.g., 2-oxalogluterate, succinyl-CoA, fumarate, and oxaloacetate) for the CAC if these should be in short supply or be converted to pyruvate and then to acetyl-CoA either to contribute to ATP synthesis or to be converted to fat. Certainly, there are a number of studies that show that protein, in the form of muscle and the intestinal tract, is catabolized during long periods of flight (Jehl, 1997) or during "simulated" flights by starvation (Biebach, in press).

Protein catabolism during migratory flight may not always be for the reasons discussed above. When catabolized, proteins produce more water per unit of energy released (0.155 g H_2O/kJ) than fats (0.029 g H_2O/kJ). Gerson and Guglielmo (2011a,b) have demonstrated that when flying for a mean duration of 2.7 ± 0.3 h in conditions of low relative humidity (13%), Swainson's thrushes (*Catharus ustlatus*) have a lean mass (protein) loss of 3.55 ± 0.91 mg/min, whereas when flying in high relative humidity (80%) air, there was no relationship between lean mass loss and flight duration. The greater rate of loss of lean mass when flying in relatively dry conditions led to a 21.7 ± 4.9% increase in endogenous water production. These data demonstrate that when flying in dry conditions, the rate of water loss induces greater metabolic water production by increasing protein catabolism. However, for those species that do not complete their migration in one nonstop flight, relatively high rates of reductions in flight muscle and the digestive system may result in reduced ability to fly and to process food during the first day of stopover.

39.7 THE CARDIOVASCULAR SYSTEM

A major role of the cardiovascular system is to deliver metabolic substrates and oxygen to the tissues undergoing aerobic metabolism and to remove the waste products of that metabolism. Thus, the cardiovascular system in general, and the heart in particular, must be capable of meeting the demands of the flight muscles during sustained, flapping flight.

TABLE 39.3 Mean Values of Oxygen Uptake and Cardiovascular Variables Measured in the Pigeon *Columba livia* and Emu *Dromaius novaehollandiae*[1]

	Pigeon (0.442 kg)		Emu (37.5 kg)	
	Rest	Flying	Rest	Flying
Oxygen uptake (mL/min STPD)[2]	9.0	88.4	156.7	1807
Heart rate (beats/min)	115	670	45.8	180
Cardiac stroke volume (mL)	1.44 (1.14)	1.58	57	102.7
Oxygen content of arterial blood (vol%)	15.1	13.7	15.2	15.2
Oxygen content of mixed venous blood (vol%)	10.5	5.4	9.0	4.6

[1]*Measurements taken at rest and after 6 min of steady level flight in a wind tunnel at a speed of 10 m/s for the pigeon and after 20 min running on a treadmill at a 6-degree incline and a speed of 1.33 m/s for the emu (from Butler, 1991). Value for cardiac stroke volume in parentheses is recalculated from Butler et al. (1977), as discussed by Bishop and Butler (1995).*
[2]*STPD, Standard temperature and pressure, dry.*

39.7.1 Cardiovascular Adjustments during Flight

The pigeon (*C. livia*) is the only species in which all but one of the variables of the Fick equation (see above) have been determined during flight (Butler et al., 1977; Peters et al., 2005). In the study of Butler et al. (1977), $\dot{V}o_2$ in the pigeons was 10 times the resting value (Table 39.3) when flying in a wind tunnel at 10 m/sec. The respiratory system maintained C_aO_2 at slightly below the resting value, but $C_{\bar{v}}O_2$ was halved, giving a 1.8-fold increase in $(C_aO_2 - C_{\bar{v}}O_2)$. There was no significant change in V_s, so the major factor in transporting the extra oxygen to the muscles was the 6-fold increase in f_H. Unfortunately, all of these variables were not measured simultaneously on the same birds, and Bishop and Butler (1995) have argued that the original calculation of V_s at rest may have been inappropriate. This being the case, there would have been a 1.4-fold increase in V_s during flight. As mean arterial blood pressure did not change, total peripheral resistance must have declined by the same proportion as cardiac output (V_b, which is $f_H \times V_s$) increased.

In general, birds have larger hearts and lower resting heart rates than those of mammals of similar body mass (Lasiewski and Calder, 1971; Grubb, 1983). The higher V_b in birds is

an important factor in their attaining a higher maximum $\dot{V}o_2$ ($\dot{V}o_{2,max}$) during flight than similar-sized mammals do when running. Bats have larger hearts and a higher blood oxygen-carrying capacity than other mammals of similar size (Jurgens et al.,1981), and their $\dot{V}o_2$ during flight is similar to that of birds of similar mass (Butler, 1991). Among birds, those that are not capable of sustained flight, such as Galliformes, tend to have slightly lower hematocrit (Hct, packed cell volume) and hemoglobin concentration (Hb) than those of good fliers (Balasch et al., 1973), and weaker fliers have a slightly lower Hct than stronger fliers (Carpenter, 1975). Wild barnacle geese migrating from their breeding grounds in the high Arctic to their wintering grounds in southern Scotland have surprisingly low heart rates during flight (see earlier), which means either that the energy cost of migratory flight is lower than was previously thought (maybe as a result of formation flight, which will be discussed later) and/or that ($C_aO_2 - C_{\bar{v}}O_2$) is greater in migrating geese than was assumed from the data obtained from pigeons flying in a wind tunnel (see Butler et al., submitted-a).

39.7.2 The Cardiac Muscles

Studies of exercising animals have indicated that both the locomotor and cardiac musculature are dynamic structures that can vary in mass seasonally and in direct response to demand (Hickson et al., 1983; Marsh, 1984; Dreidzic et al., 1993; Bishop et al., 1996). Thus, it might be anticipated that where additional energetic costs occur seasonally (e.g., due to migratory fattening or the development of secondary sexual characteristics), then the relevant cardiac and locomotor musculature might also be regulated seasonally. Bishop et al., (1996) showed that both cardiac and pectoralis muscles hypertrophy during the premigratory fattening period of the barnacle goose.

Bishop and Butler (1995) suggest that heart mass (M_h) can be used to model the availability of oxygen to the flight muscles of birds. Assuming that the adaptations of the flight muscles are appropriately matched to the cardiovascular system, then the relative M_h of birds of a similar body mass should be a good indicator of the relative aerobic power input available to the flight muscles. Bishop (1997) calculated that the $\dot{V}o_{2,max}$ of birds should scale with respect to body mass as $230\ M_b^{0.82}$ mL/min^{-1}, and that maximum aerobic power input (aerobic $P_{i,max}$) should scale as $11\ M_h^{0.82}$ (W). Thus, for studies of the prolonged aerobic flight performance of birds, the estimates of $\dot{V}o_{2,max}$ or $P_{i,max}$ based on relative M_h should be of more practical value than the use of general scaling equations based on body mass alone.

The mean values for M_h from selected avian families are plotted in Figure 39.26(A) (data from Hartman, 1961) and Figure 39.26(B) (data from Magnan, 1922) and indicate the interfamily adaptive diversity in aerobic capacity. The very small M_h of all three species of tinamou indicate that the members of this family have the lowest aerobic ability of all bird species. Other relatively sedentary forest birds with small M_h include the guans, motmots, puffbirds, and antbirds. This contrasts with the relatively large M_h of other bird families that live predominantly in forest, such as the parrots, trogons, kingfishers, and hummingbirds. Interestingly, Figure 39.18(B) shows that the M_h values of the bustard family (Otidae) appear to range above the general allometric trend. The relative M_h of the 0.83 kg little bustard and the 8.95 kg great bustard are 1.8 and 1.4%, respectively. These relative M_h values are even larger than those of the Anatidae, which typically range from 0.8% to 1.1%. Two other observations appear to substantiate this finding. Crile and Quiring (1940) gave the following values for the relative heart masses of the African Kori bustard; a 5.54 kg female Kori bustard (1.1%) and a 10 kg male Kori bustard (1.0%). In addition, Stickland (1977) shows that while 100% of the area of the pectoralis muscle of the African helmeted guinea-fowl is made up of "white" anaerobic muscle fibers (i.e., FG fibers), 82% of the area between the pectoralis muscle of the similarly sized white-bellied bustard is made up of "red" aerobic fibers (i.e., FOG fibers). This author also comments on the fact that the European species of bustards undergo local migrations, which is a further indication that they are capable of a "prolonged" mode of flight.

There are also some interesting intrafamily differences in aerobic capacity indicated in the M_h data of Hartman (1961) and Magnan (1922). The different genera of the Columbidae (pigeons and doves) have relative M_h means ranging from 1.29% to 0.57%, while among the genera of the Falconidae (falcons) these range from 1.14% to 0.6%. In both these families, the genera with the relatively small hearts occur predominantly in tropical forests and are likely to be relatively sedentary. As intrafamily pectoralis muscle mass is fairly constant in these examples, it is reasonable to assume that the relatively sedentary species are more dependent on anaerobic metabolism to support their flight activity and that their flight muscles consist of a relatively greater proportion of FG fiber types.

39.8 THE RESPIRATORY SYSTEM

The respiratory system is not only concerned with gas exchange (i.e., the supply of oxygen to and the removal of carbon dioxide from the circulatory system and the metabolizing tissues) but also with the control of body temperature and evaporative water loss.

39.8.1 Ventilatory Adjustments during Flight and Ventilatory/Locomotor Coupling

As for the cardiovascular system, there is a variation of Fick's formula for convection that describes the relationship between $\dot{V}o_2$ and the various components of the respiratory system:

$$\dot{V}o_2 = f_{resp} \times V_T \times (C_IO_2 - C_EO_2),$$

where f_{resp} is respiratory frequency (breaths/min), V_T is respiratory tidal volume (mL), and ($C_IO_2 - C_EO_2$) is the difference in the oxygen content in the inspired and expired gas (milliliter of O_2 per mL of gas). Data on ventilation are given in Table 39.4 for five species of birds at rest and during forward flapping flight in a wind tunnel. At relatively low ambient temperatures (<23 °C), minute ventilation volume V_I ($=f_{resp} \times V_T$) increases by a similar proportion as $\dot{V}O_2$ and the proportion of oxygen extracted from the inspired gas ($O_{2,ext}$ effectively equal to $C_IO_2 - C_EO_2/C_IO_2$) during flight is similar to that in resting birds. The relative contributions of f_{resp} and V_T to the increase in V_I during flight vary between species. In white-necked ravens (*Corvus leucocephalus*), V_T does not change at all, whereas in fish crows and black-billed magpies it doubles and in starlings there is a fourfold increase. Thus, in the first three species, f_{resp} makes the greater contribution, but in the fourth, volume predominates. Respiratory frequency and V_T in the fish crow (Bernstein, 1976) and f_{resp} in the barnacle goose (Butler and Woakes, 1980) are independent of flight speed. This could mean that, like the starling and the fish crow, $\dot{V}O_2$ of the barnacle goose is also largely independent of flight speed. However, in the budgerigar, both $\dot{V}O_2$ and f_{resp} change with speed in a U-shaped fashion (Tucker, 1968b).

Despite the apparent matching between the increases in V_I and $\dot{V}O_2$ during flight in the four species listed in Table 39.4, there does appear to be an increase in effective lung ventilation above that required by metabolic rate (hyperventilation) during flight in starlings, as indicated by a decrease in the partial pressure of CO_2 (PCO_2, hypocapnia) in the anterior and posterior airsacs (Torre Bueno, 1978a). It can also be seen from Table 39.4 that $O_{2,ext}$ for the hovering hummingbird, *C coruscans*, is similar to those for the four birds during forward flapping flight, whereas that for *Amazilia fimbriata fluviatilis* is 50% or less.

Ever since Marey's (1890) pioneering studies on bird flight, it has been known that f_{resp} may be coordinated with the beating of the wings, and Marey himself suggested that the flapping of the wings during flight might have some impact on the airsacs. In crows (*C. brachyrhynchos*) and pigeons there is a 1:1 correspondence between f_{resp} and the frequency of wingbeating (f_{wb}), whereas ratios as high as 5:1 (f_{wb}:f_{resp}) have been reported for the black duck *Anas rubripes*, quail *Coturnix coturnix*, and ring-necked pheasant *Phasianus colchicus* (Hart and Roy, 1966; Berger et al., 1970b). However, as mentioned above, the flights reported by these authors were of only a few seconds duration, and

it was concluded that coordination was not obligatory. During flights of up to 10-min duration, pigeons in a wind tunnel showed a very close relationship between these two activities. Wingbeats occurred in bursts and, although f_{resp} was often either slower or faster than f_{wb} between bursts of wingbeating, there was always close coordination between the two when the wings were flapping (Figure 39.27(A)). Almost immediately upon landing, the pigeons panted at a frequency identical to the mean resonant frequency of the respiratory system (i.e., 10 Hz, Kampe and Crawford, 1993). During flapping flight, however, f_{resp} was slower, at approximately 7 Hz (i.e. the same as f_{wb}).

With a 1:1 correspondence, it is possible to imagine how contractions of the flight muscles could assist respiratory airflow, but with higher ratios this is not always so obvious. Nevertheless, a correspondence of 3:1 has been found in free-flying barnacle (1.6 kg) and Canada (3.8 kg) geese (Butler and Woakes, 1980; Funk et al., 1993), and it is clear that the wingbeat is tightly locked to fixed phases of the respiratory cycle during flights of relatively long duration (Figure 39.27(B)). These phase relationships can be maintained, even following transient changes in one of the activities (Butler and Woakes, 1980). As Tucker (1968b) comments, "It is hard to believe that the contractions of the flight muscles have no influence in ventilation…." More recent studies have attempted to investigate this intriguing possibility.

Banzett et al. (1992) recorded respiratory airflow and the timing of each wingbeat for three starlings flying at 11 m/s for up to 5 min in a wind tunnel. Triggering on wingbeat and using the technique of ensemble averaging, these authors found that there was usually a 3:1 ratio between f_{wb} and f_{resp}, but that the effect of wingbeat on V_T ranged from 3% to 11%. They concluded, therefore, that wingbeat and breathing in starlings are essentially mechanically independent. A problem with ensemble averaging is that it examines the systems when they are out of synchrony; that is, when there would be a low influence of locomotion on ventilation. On the other hand, Jenkins et al. (1988) took high-speed X-ray cine films of starlings flying in a wind tunnel and suggested that the lateral movement of the furcula during the downstroke of the wing and the recoil during the upstroke may facilitate inflation and deflation, respectively, of the clavicular airsac. They also found, however, that the sternum is moved in an expiratory direction during the downstroke and in an inspiratory direction during the upstroke. As the action of the sternum will influence the more posterior airsacs, these authors proposed that the combined action of the movements of the furcula and of the sternum, which are caused by the beating wings, is to produce a secondary respiratory cycling mechanism between the airsacs and the lungs that performs independently of (the slower) inhalation and exhalation.

Boggs et al. (1997a,b) recorded pressures in, and simultaneous cineradiographic images of, the anterior and posterior

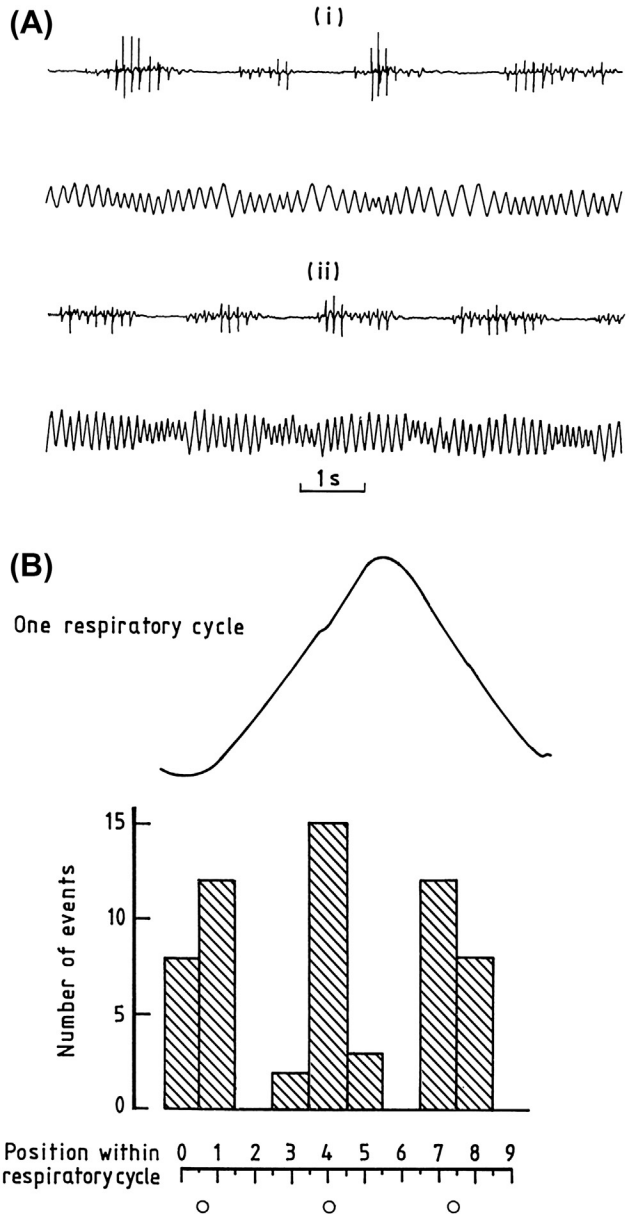

FIGURE 39.27 (A) Traces from a pigeon, *Columba livia* (0.45 kg), flying at a speed of 10 m/s in a wind tunnel, showing changes in respiratory frequency associated with periods of wingbeating and with periods of gliding (i) at the beginning of a flight (1 min after takeoff) when respiratory frequency decreased during the gliding period and (ii) later in the flight (6 min after takeoff) when respiratory frequency increased during the gliding period. In each series, the traces from top to bottom are electromyogram from the pectoralis muscle, respiratory movements (up to trace, inspiration). (*From Butler et al. (1977), Company of Biologists, Ltd.*) (B) Histogram showing the positions during the respiratory cycle at which the wings were fully elevated (called "events") during the flight of a barnacle goose, *Branta leucopsis,* trained to fly behind a truck. Data are from 20 respiratory cycles, which were divided into 10 equal parts. Below the histogram is plotted the mean position of each group of events (○). Above the histogram is a trace of one of f_{resp}, the respiratory cycles (inspiration, up). *From Butler and Woakes (1980), Company of Biologists, Ltd.*

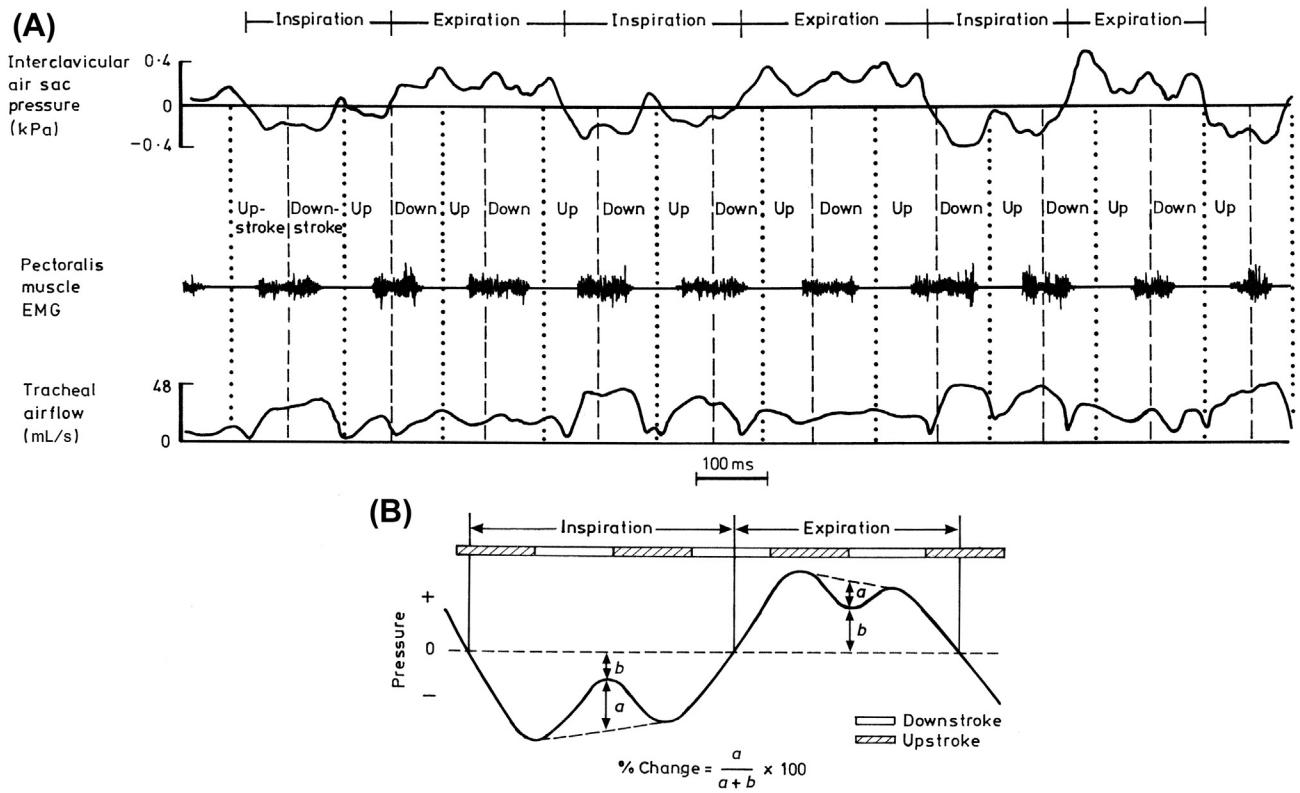

FIGURE 39.28 (A) The relationships between interclavicular airsac pressure, tracheal airflow, and electromyogram (EMG) of a pectoral muscle during flight of a black-billed magpie, *Pica pica,* in a wind tunnel. As the flow signal is not directional, inspiration is taken as that period during which pressure is subatmospheric (below 0) and expiration is that period during which pressure is above atmospheric (above 0). The EMG of the pectoral muscle indicates the upstrokes and downstrokes of the wings. When a downstroke occurs during inspiration, the subatmospheric pressure is driven up toward or above zero and when upstroke occurs during expiration, the supraatmospheric pressure is reduced toward zero (*from Boggs (1997); with permission*). (B) Diagram to indicate how the average changes in airsac pressure shown in (A) were quantified in terms of the percentage change in pressure caused during inspiration or expiration by downstroke or upstroke of the wings, respectively. *From Boggs et al. (1997a), Company of Biologists, Ltd.*

airsacs, airflow in the trachea, and EMGs of the pectoral muscles in black-billed magpies during short (10–20 s) flights in a wind tunnel (Figure 39.28(A)). Although they found similar patterns of movements of the furcula and sternum in the magpie during flight as Jenkins et al. (1988) described for the starling, they did not find that the pressure changes in the anterior and posterior airsacs are consistent with the internal, secondary cycling between the airsacs and the lungs, as postulated by Jenkins et al. (1988). However, the downstrokes and upstrokes of the wings do have compressive and expansive effects, respectively, on the thoracoabdominal cavity, most probably by way of inertial mechanisms. It was only possible to quantify the effect of these influences when the movements of the wings were opposing the action of the respiratory muscles (Figure 39.28(B)). Thus, the average change in airsac pressure caused when a downstroke occurred during inspiration was 94%, whereas the average change caused by an upstroke occurring during expiration was 41%. The corresponding average changes in flow and volume were 75% and 23%, and 35% and 11%, respectively. The conclusion is, therefore, that when the effects of the wings and the respiratory muscles are acting together (i.e., when downstroke occurs during expiration and upstroke during inspiration), ventilation of the lung is substantially enhanced. With the normal 3:1 ratio between f_{wb} and f_{resp}, the pattern of phasic coordination means that there are two upstrokes during inspiration (cf. Figure 39.27(B)) and two downstrokes during expiration, thus giving a net assistance to inspiration during the former and a net assistance to expiration during the latter. This phasic coordination is not disrupted when the birds breathe 5% CO_2 during flight. When they spontaneously switch to a 2:1 ratio, they shorten inspiratory time to ensure that upstroke occurs during most of inspiration and that downstroke corresponds with the transition to expiration (Boggs et al., 1997b). Both of these phenomena indicate that such coordination is probably of fundamental functional significance.

Studies with decerebrate Canada geese (Funk et al., 1992a,b) indicate that, in the absence of peripheral feedback from the flapping wings, there is predominantly a 1:1 ratio between f_{resp} and f_{wb} and that peripheral feedback is required to create the patterns of coordination seen in free-flying birds.

39.8.2 Temperature Control

At least 70% of the total energy expended during forward flapping flight is wasted as heat, and this heat load has to be dissipated in some way. One possible route is by evaporative heat loss via the respiratory system. The hyperventilation that occurs in starlings during forward flapping flight (Torre Bueno, 1978a) could be the result of the increase in body temperature (T_b), by at least 2 °C, that occurs in all birds so far studied, even at low (0 °C) ambient temperatures (T_a) (Torre-Bueno, 1976; Hudson and Bernstein, 1981; Hirth et al., 1987). However, when the usual elevation in T_b during running is prevented in ducks and domestic fowl, there are still signs of hyperventilation (Kiley et al., 1982; Brackenbury and Gleeson, 1983). In ducks, there was an increase in lactic acid and hence slight acidosis that could have stimulated ventilation, and in the fowl, hyperventilation seemed only to occur at higher workloads. Thus it appears as if factors other than hyperthermia contribute to the overall hyperventilation in birds during exercise.

At relatively low T_a (<23 °C), T_b does not change with varying T_a at constant speed in starlings, white-necked ravens, and pigeons flying in a wind tunnel (Torre-Bueno, 1976; Hudson and Bernstein, 1981; Hirth et al., 1987). Above a T_a of 23 °C, however, T_b does increase with increasing T_a in the same three species. In the raven, V_I increases with increasing T_b so that, in this species and in the fish crow flying at constant speed, V_I progressively rises above that required by the metabolic demands of the bird as T_a increases above about 23 °C. Thus, $O_{2,ext}$ falls from a value of 0.19 at a T_a of 20 °C to 0.13 at a T_a of 25 °C in the flying fish crow (Figure 39.29).

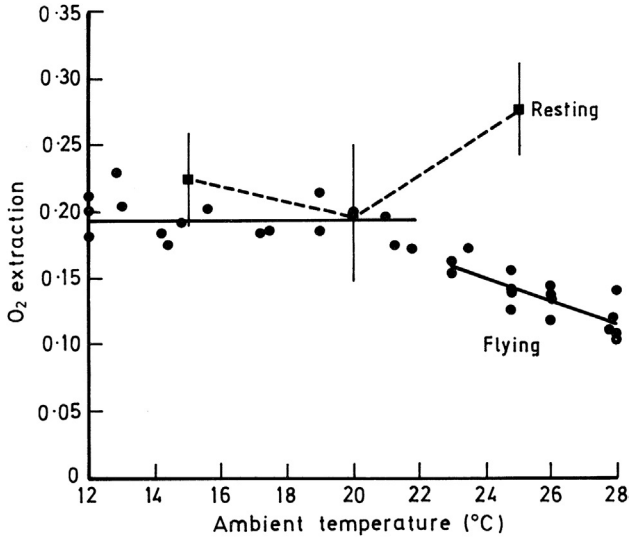

FIGURE 39.29 The relationship between ambient temperature and steady-state oxygen extraction of fish crows, *Corvus ossifragus,* while at rest and while flying in a wind tunnel. *Reprinted from Bernstein (1976), Copyright 1976 with permission from Elsevier Science–NL, Sara Burgerhartstraat 25, 1005 KV Amsterdam, The Netherlands.*

The increased hyperventilation at higher T_a would tend to cause further hypocapnia (seeTorre-Bueno, 1978a) and thus alkalosis. It has been demonstrated that the white-necked raven resorts to so-called compound ventilation when flying at high T_a. A high-frequency, shallow ventilatory component is superimposed upon a deeper, lower-frequency component and may serve to reduce hypocapnia during thermal panting (Hudson and Bernstein, 1978).

The physiological significance of the hyperthermia during flapping flight, even at low T_a, is uncertain, although Torre-Bueno (1976) concluded that birds adjust their insulation to allow a certain increase in T_b during flight in order to improve muscle efficiency and to increase maximal work output. Hudson and Bernstein (1981) point out that, assuming an overall efficiency of 25%, the almost 3 °C increase in T_b in white-necked ravens while flying at a speed of 10 m/s reflects the storage up to half of the metabolic heat produced during a flight of 5 min duration. At lower overall efficiencies, more heat would be produced, so the proportion stored under the above conditions would be less. A similar situation exists for the calculations of the proportion of metabolic heat lost by respiratory evaporation (see below).

Whatever the significance of the increase in core temperature during flapping flight, brain temperature is maintained at a lower level. In fact, even in birds under resting, thermoneutral conditions, there is approximately a 1 °C difference between brain and body temperatures (Bernstein et al., 1979a). This difference is at least maintained as kestrels (*Falco sparverius*) become hyperthermic during flapping flight and may even increase (Figure 39.30). The structure that appears to be largely responsible for this phenomenon is the *rete mirabile ophthalmicum* (RMO) (Kilgore et al., 1979; Bernstein et al., 1979a,b). It is closely associated with the circulatory system of the eye and warm arterial blood from the body is thought to be cooled by the countercurrent exchange with venous blood returning from the relatively cool beak, evaporative surfaces of the upper respiratory tract, and eye (Midtgård, 1983).

Hyperventilation during flight no doubt serves a thermoregulatory function, and as T_a increases, a greater proportion of total heat loss during flight is by respiratory evaporation. However, even at a T_a of 30 °C, this proportion is only approximately 20% of total heat loss for the budgerigar and fish crow (Tucker, 1968b; Bernstein, 1976) and 30% for the white-necked raven and pigeon (Hudson and Bernstein, 1981; Biesel and Nachtigall, 1987). In the hummingbird *Amazilia fimbriata*, maximum respiratory heat loss of 40% of the total occurred at a T_a of 35 °C (Berger and Hart, 1972). So, most metabolic heat must be dissipated by means other than respiratory evaporation. Indeed, herring gulls can lose up to 80% of total heat production through their webbed feet during flight (Baudinette et al., 1976). In

the pigeon, the value is probably less, but nonetheless significant, at 50–65% (Martineau and Larochelle, 1988).

39.8.3 Respiratory Water Loss

During flapping flight at T_a above 18 °C for the budgerigar and 7.5 °C for the pigeon, water is lost at a greater rate than it is produced metabolically (i.e., the birds are dehydrating; Tucker, 1968b; Biesel and Nachtigall, 1987). The starling is in water balance only at T_a below 7 °C (Figure 39.31; Torrre-Bueno, 1978b). However, because of the uncertainty regarding the rate of metabolic water production during flight, the author points out that the critical temperature lies between 0 and 12 °C. Only below a T_a of 0 °C was the hovering hummingbird *A. fimbriata* in water balance (Berger and Hart, 1972). Torre-Bueno (1978b) suggested that during migrations, birds ascend to altitudes where the air is cool enough to enable a greater proportion of heat to be dissipated by nonevaporative means, thus keeping them in water balance.

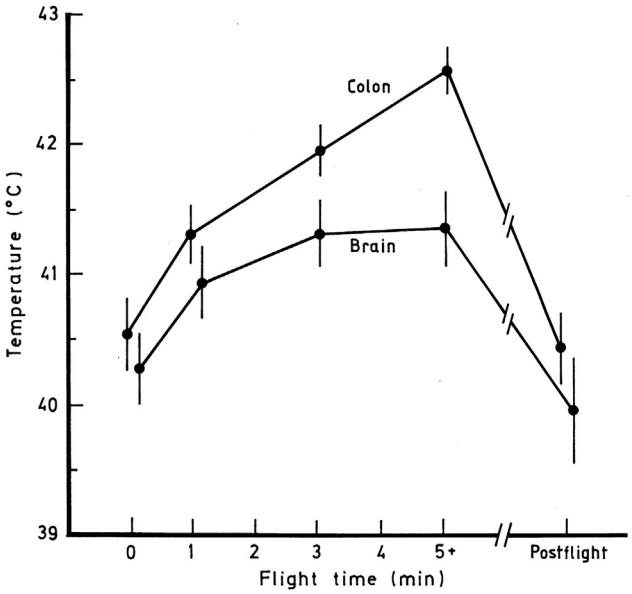

FIGURE 39.30 Mean (±2 SE) temperatures in the colon and brain of American kestrels, *Falco sparverius*, before, during, and after flying at a speed of 10 m/s and at an ambient temperature of 23 °C. Data at 5+ min were obtained as mean values over the period between 5 and 15 min after the onset of flight and represent steady-state values. Postflight values are those obtained after reestablishment of steady-state following each flight. *From Bernstein et al. (1979a) with permission.*

Some of the larger species of birds do indeed appear to migrate at high altitudes, in excess of 8000 m (Swan, 1970; Stewart, 1978). However, Carmi et al. (1992) used program one from Pennycuick (1989) to calculate P_i and concluded that smaller species might be better off staying below 1000 m because of the greater ventilation (and hence increased water loss) required by the reduced air density and partial pressure of oxygen (PO_2) associated with higher altitudes. These authors also emphasize the importance of $O_{2,ext}$ and the temperature of the exhaled. air (T_{exp}) in water conservation during flight. The greater the $O_{2,ext}$, the lower the V_I for a given $\dot{V}o_2$, and the lower the T_{exp}, the less water will be lost in expired air, provided the birds have an effective countercurrent heat exchanger in their respiratory passages (Schmidt-Nielsen et al., 1970). Thus, it should be advantageous for small migrants crossing the Sahara to fly at low altitude at night and to rest during the day. However, a study of the behavior of nocturnal migrants in a desert area indicates that only tailwind speed is closely related to the altitude at which the birds fly (Bruderer and Liechti, 1995). Thus, in autumn, that the birds make use of the northerly winds at relatively low altitudes, despite the implication for water balance, may not be surprising, but

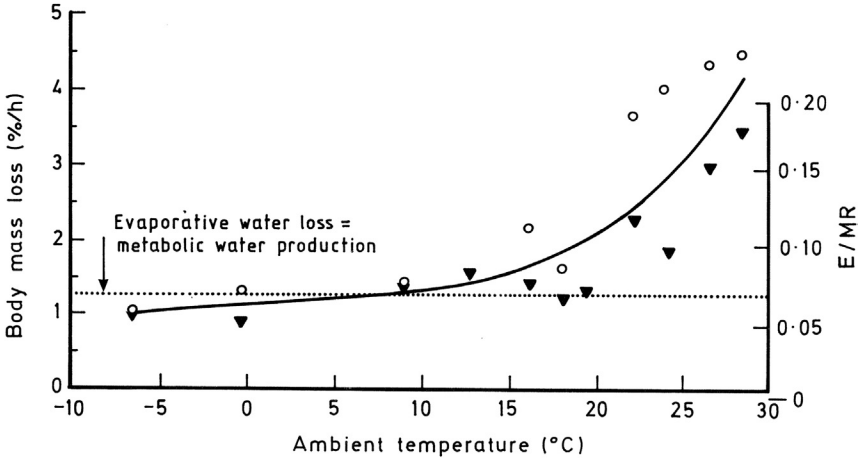

FIGURE 39.31 Data showing the rate of loss of body mass and the ratio of the rate of evaporative cooling to the metabolic rate (E/MR) as a function of ambient temperature in two starlings, *Sturnus vulgaris*, flying in a wind tunnel at between 9 and 14 m/s. *From Torre-Bueno (1978b), Company of Biologists, Ltd.*

how nocturnal migrants are able to detect wind direction is a fascinating question.

Carmi et al. (1993) also demonstrated that when at rest or during flight, birds have an ability to maintain plasma volume, despite significant reductions in body mass that are largely the result of water loss. This is of obvious significance during flight, particularly during long-distance migratory flights, when a reduction in plasma volume would result in an increase in viscosity of the blood, which in turn would increase the workload of the heart, resulting in an inadequate cardiac output and supply of oxygen to the metabolizing tissues.

39.9 MIGRATION AND LONG-DISTANCE FLIGHT PERFORMANCE

39.9.1 Preparation for Migration

As discussed by Fry and Ferguson-Lees (1972), it is a reasonable expectation that there will be correlated physiological adaptations associated with the extra power required to fly due to the laying down of fat as fuel for long-distance flights. Their work indicated that early in the fattening process of the yellow wagtail (*Motacilla flava*), the flight muscles showed a small hypertrophy. Other studies have also found muscle hypertrophy during fattening for both the pectoralis muscles (Marsh, 1984; Driedzic et al., 1993; Bishop et al., 1996; Jehl, 1997) and the cardiac muscles of birds (Driedzic et al., 1993; Bishop et al., 1996; Jehl, 1997). Thus, as protein as well as lipid is metabolized during long-duration flights, it is also replaced during stopovers, so the increase in body mass before a migration and during stopovers should be described as "fueling" rather than "fattening" (Piersma, 1998).

There has to be a close relationship between the amounts of fuel and flight muscle that are deposited before migration, as the greater the fuel load, the greater the mass of flight muscle required to carry that load. A study by Piersma (1998) indicates that the proportions of fat-free tissue and fat that are deposited before long-distance (>1500 km) migration of shore birds vary between similar-sized species depending on the duration and nature of their impending flights. Just before departure, the pectoral muscles and heart tend to hypertrophy whereas the stomach, intestine and liver tend to atrophy. Figure 39.32 indicates that the greater fat deposition and atrophy of the visceral organs (such as the liver) are most pronounced in those species that have the longest migrations and especially in those that have little or no opportunity for an emergency landing (e.g., by flying over an ocean). Of particular interest are the two subspecies of bar-tailed godwit. Although the distances of their migrations are vastly different (4500 km versus 11,000 km), they both have high fat fractions and low liver to pectoral muscle mass ratios. What they have in common is their inability to make emergency landings during their migrations.

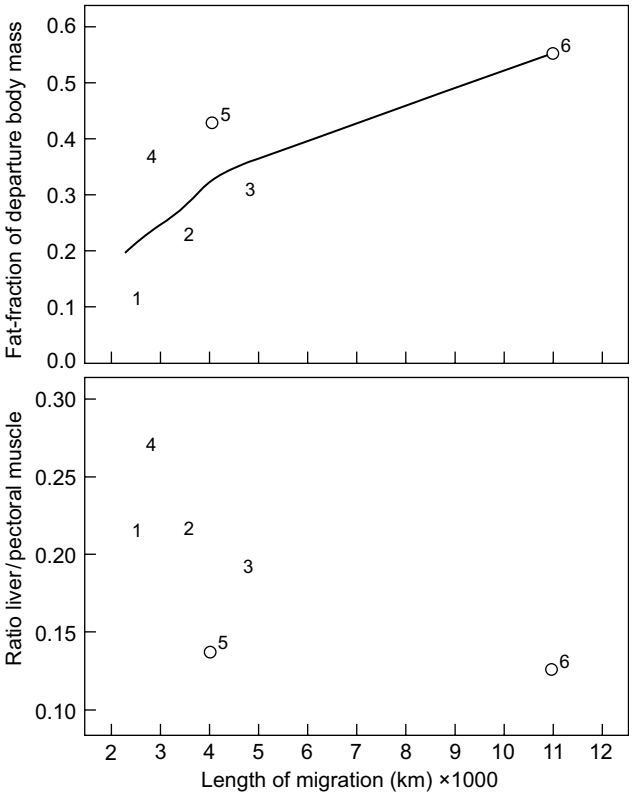

FIGURE 39.32 Fat loads and relative organ sizes before departure of six species of long-distance migrants. Top. The amount of fat as a fraction of body mass in relation to the distance of the migration to be undertaken. Bottom. The ratio of liver mass to pectoral muscle mass in relation to the distance of migration. Closed circles indicate species that would be able to make stopovers during their migration and open circles indicate subspecies that would not. Bishop et al. (1998) compared the development of a captive population of barnacle geese with that of the wild migratory population in order to investigate to what extent some of the migratory specializations of the cardiac and locomotory muscles might be determined by developmental processes and to what extent they might be modulated by differences in relative levels of activity. Postflight increases in the masses of the pectoralis muscles of both wild and captive geese tend to show an appropriate amount of hypertrophy in response to changes in body mass (Figure 39.33(A) and (B)). Regression equations were calculated for both the wild adult premigratory geese $\left(\text{pectoralis mass} = 0.5\, M_b^{0.86},\ r^2 = 0.93\right)$ and captive adult geese $\left(\text{pectoralis mass} = 0.3\, M_b^{0.92}\right)$. The body mass exponents (or slopes) of the two regression equations are not significantly different between the two populations, although the coefficients are slightly smaller in the captive geese. Thus, approximately 92% of the pectoralis muscle mass of

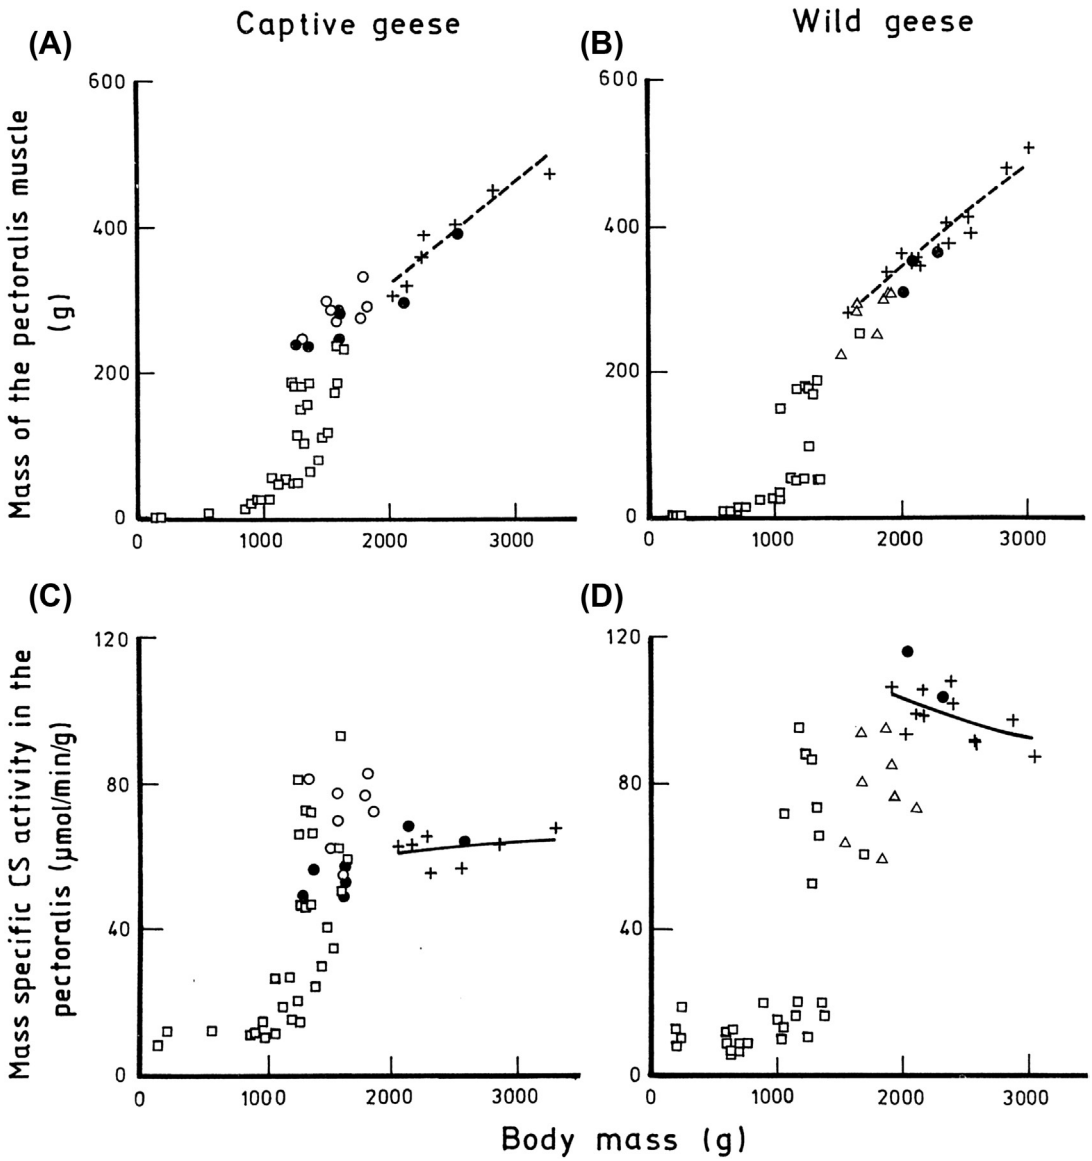

FIGURE 39.33 Scatter diagram of the masses of the pectoral muscles (g) and the mass-specific activity of citrate synthase (CS) in the pectoral muscles (μmol/min g wet wt) of captive (A and C) and wild (B and D) barnacle geese, *Branta leucopsis*, plotted against body mass (g). Goslings of 1 to 7 weeks of age (□), goslings of 12–20 weeks of age (●), adults at 7 weeks after the population hatch date, (Δ) and premigratory adults >10 weeks post–hatch (+). *From Bishop et al. (1998), with permission from The University of Chicago Press. © University of Chicago Press.*

premigratory barnacle geese appears to be almost independent of the experience of flight *per se*. Indeed, wild adult barnacle geese showed no increase in the amount of time they spent flying before their autumn and spring migrations (Portugal et al., 2012), and Portugal et al. (2009) found that hypertrophy of the pectoralis muscles of captive barnacle geese actually began even before their body mass increased.

Gaunt et al. (1990) studied the flight muscle changes of the eared grebe (*P. nigricollis*) during a staging period at Mono Lake, California, where the food resources were not limiting. Following a postbreeding molt at the lake, the birds become flightless and their flight muscles show a slight atrophy, but due to an abundance of food the birds put on a large amount of fat and body mass greatly increases. Just prior to departure for the winter grounds, the birds metabolize much of the fat, and it is at this time that the flight muscles hypertrophy. In this example, flight muscle atrophy occurs when the birds have plenty of food, while subsequent hypertrophy occurs while the birds are actually reducing in body mass. Marsh and Storer (1981) had originally suggested that the correlation between flight muscle mass and body mass in Cooper's hawk (*Accipiter cooperii*) was a natural analog of "power" training during flight. Subsequent studies have found no obvious mechanistic link between hypertrophy of the flight muscle and body mass, although the authors did associate increased wing flapping with the flight muscle

hypertrophy. Dietz et al. (1999) found that two subspecies of red knots (*Calidris canutus*), which were kept under a constant photoperiod, showed similar increases in pectoral muscle hypertrophy (44%) during premigratory fattening, and that this represented between 29% and 39% of the total mass increase. This suggested that there was no direct photoperiodic control, and that the mechanism was likely to be endogenous, possibly with some kind of circannual regulation. It still remains an outside possibility that the relatively infrequent bouts of wing-flapping and occasional takeoffs exhibited by captive birds might provide a sufficient mechanistic link by which the birds are able to maintain the flight muscle to body mass relationship. However, as mentioned above, Portugal et al. (2012) showed that wild migratory barnacle geese did not show any change in the time spent flying during a 3 week premigratory period, thus, ruling out any overt evidence for flight training prior to the actual migration.

Figure 39.33(C) and (D) show the change in maximum mass-specific CS activity in the same barnacle geese (Bishop et al., 1998) for the data on pectoralis muscle mass (Figure 39.33(A) and (B)). There is little difference between the two populations up to 7 weeks of age. Specific activities of CS in the pectoralis muscles of the two wild 11.5 week old juveniles are, at 103 and 116 μmol of substrate/min g, outside the range of that for the 12 week old captive birds (55–59 μmol of substrate/min g) and the captive adult birds (56–58 μmol of substrate/min g) but similar to the range of wild adult birds (92–106 μmol/min g). The main conclusion from these results is that the captive adults have mass-specific values of activity for CS (mean = 62.1 ± 1.7 μmol/min g) that do not scale with body mass $\left(\mathrm{CS} = 20\, M_b^{0.14},\ r^2 = 0.11\right)$ and are substantially below those of the wild premigratory birds (mean = 98.6 ± 1.9 μmol/min g, $p < 0.0001$). Results from captive goslings aged between 12 and 20 weeks also appear to be closely associated with the regression line resulting from the data from captive adult geese.

Peak values for the activity of CS in the pectoralis muscles of wild barnacle geese are found in the premigratory birds, although there is a tendency for the mass-specific activity to decline with increasing body mass $\left(\mathrm{CS} = 862\, M_b^{-0.28},\ r^2 = 0.33\right)$. Thus, the activity of CS in the pectoralis of adult captive geese, and captive goslings over 11 weeks of age, is only around 60% of that measured in wild geese. In addition, CS activity in the pectoralis muscles of a group of postmolting, wild, adult geese was similar to that of long-term captive birds. Thus, it is suggested that the rise in the activity of CS in the premigratory birds may be a reaction to the increase in flight activity *per se,* while the rise in CS activity during development of the goslings up to fledging could be primarily under endogenous control. In addition, heart ventricular mass is reduced in captive and postmolt wild adults compared to that in wild premigratory birds, and is qualitatively similar to the reduction shown in the aerobic capacity of the pectoralis muscle. It is suggested that this reduction in ventricular mass is also likely to be a direct result of the lower activity levels experienced by captive birds (Bishop et al., 1998).

One of the factors that may be important in the development of the aerobic capability of the pectoral muscles of barnacle geese is thyroxine (T_4). Circulating levels of T_4 show a similar developmental profile as mass and mass-specific activity of CS of the pectoral muscles (Bishop, 1997). While artificially accelerating the increase in circulating T_4 did not have a significant effect on either relative mass or on the mass-specific CS activity of these muscles (Deaton et al., 1997), hypothyroidism during development, induced by administration of the drug methimazole, did result in the retardation of their growth, mass-specific CS activity, fractional volume of mitochondria, and capillarity (Deaton et al., 1998). There was no such effect on the mass of the muscles of the leg.

If the mass-specific CS values for the pectoralis muscles of premigratory geese are generalized to the whole muscle, then the largest birds will have the lowest mass-specific aerobic capacity despite requiring the highest relative power outputs (Pennycuick, 1989). Consequently, during sustained flight, the larger birds may have to fly nearer to their minimum power speeds than smaller geese. This conclusion is also supported by the data on the heart ventricular mass (Bishop et al., 1996), which indicates that there is a tendency for relative heart mass to decline slightly with increasing body mass. Thus, given that maximum oxygen consumption is likely to be closely correlated with heart mass (Bishop and Butler, 1995; Bishop, 1997, 1999, 2005), it is suggested that during premigratory fattening, P_i available is likely to scale relative to body mass with an exponent value considerably lower than that of the P_o exponent theoretically required $\left(M_b^{1.59}\right)$ for flight performance to be maintained at a similar level according to aerodynamic theory (Rayner, 1990). However, a number of studies have questioned whether the allometric exponent for the scaling of P_i with increasing body mass is similar to that predicted for P_o. Tucker (1972) measured the rate of oxygen consumption, from a single gull flying in a wind tunnel at 10.8 m/s, on 13 different occasions and with body mass naturally varying from 0.328 to 0.420 kg. He determined that the cost of carrying the extra body mass was quite small, with a body mass exponent of only $M_b^{0.325}$ but 95% confidence limits of 0.05–0.6. A very similar result was reported by Kvist et al. (1998) using the DLW technique to determine the energy expenditure of red knots flying in a wind tunnel on different days while they naturally put on body mass during the autumn. They calculated a body mass exponent of only $M_b^{0.325}$, with 95% confidence limits of 0.08–0.62. Subsequently, quite low exponents of $M_b^{0.55}$ and $M_b^{0.58}$ were also calculated for flying rose-colored starlings, *Sturnus roseus*, and barn swallows, *Hirundo rustica*, also using

DLW (Engel et al., 2006; Schmidt-Wellenburg et al., 2007). Kvist et al. (1998) suggest that birds may be able to change the mechanochemical conversion efficiency of their flight muscles as they fuel up for the migration. However, it might be expected that birds should maximize muscle efficiency at all times.

39.9.2 Migratory Behavior

When migrating, it might be more appropriate for the bird to minimize the time of migration (T_{min}), rather than the energy consumed, particularly if it is important for it to arrive at its destination before most of its competitors (Alerstam and Lindstrom, 1990). In this case, the optimal flight speed will be greater than U_{mr}. In an analysis of data in the literature for 48 species during migration, Welham (1992) concluded that lighter species do, indeed, fly faster than U_{mr}, and heavier species tend to fly slower. However, in an even more comprehensive study of 138 species (Alerstam et al., 2007), this apparent allometric compression of the expected speed range could be partially explained through the lack of geometric similarity with increases in body mass (e.g., aspect ratio of the wings scales positively). Flight speed was found to be strongly influenced by wing loading and phylogenetic relationships, but some of the variation could not be fully accounted for.

It is now possible to track individual birds of many different species on their migratory flights, some of which cover many thousands of kilometers over land and sea. One of the fastest flights recorded is that of great snipe (*Gallinago media*), despite the fact that it is mostly conducted over land (Klaassen et al., 2011). This species made nonstop flights from Sweden to Central Africa and back again, covering between 4000 and 6800 km at estimated air speeds of 16–26 m/s. Bar-tailed godwit (*Limosa lapponica*) makes an even longer nonstop flight, largely over the Central Pacific Ocean, while traveling between Alaska and New Zealand (Gill et al., 2009). They averaged 10,153 km in 7.8 days, equivalent to an air speed of around 15 m/s. Other species of wading birds have also been shown to make impressive and rapid migratory flights (Minton et al., 2011; Niles et al., 2012; Johnson et al., 2012) in which they have to greatly increase their body mass before departure (Gudmundsson et al., 1991). More specialized pelagic species of seabird, such as those within the orders Procellariiformes and Charadriiformes, regularly make quite long foraging trips during the breeding season. In the winter months they frequently disperse around the oceans of the world on massive migrations, such as that of the sooty shearwater, *Puffinus griseus* (Figure 39.34; Shaffer et al., 2006) and Arctic tern, *Sterna paradisaea* (Egevang et al., 2010).

It has been suggested that some species of birds, such as geese, may be able to reduce induced drag by flying in V-formation (Lissaman and Scholenberger, 1970; Hummel, 1995). This would entail their maintaining positions so that the tips of the wings on the inside of the V are close to the centers of the trailing vortices from the wings on the outside of the bird ahead (Hainsworth, 1987). Assuming a fixed wing at maximum span, Hainsworth (1987) found considerable variability in wing tip spacing (WTS) of between

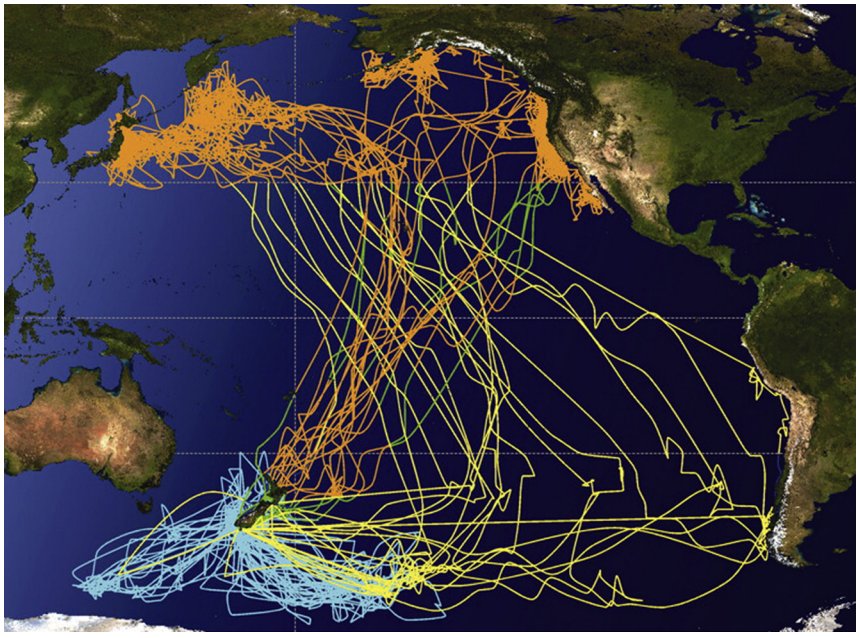

FIGURE 39.34 Geolocation tracks of sooty shearwater, *Puffinus griseus*, flights originating from breeding colonies in New Zealand. Interpolated geolocation tracks of 19 sooty shearwaters during breeding (light blue) and subsequent migration pathways (yellow, start of migration and northward transit; orange, wintering grounds and southward transit). *From Shaffer et al. (2006).*

−128 and 289 cm, both between and within formations of Canada geese (*B. canadensis*), but found that the median WTS for 55 geese (−19.8 cm) was close to the theoretical optimum (−16 cm) and corresponded to an estimated saving in induced power of 36%. Even so, in order to achieve such savings with beating wings, there would have to be a high degree of synchrony in wingbeat frequencies, as there is little variation in depth (the distance between adjacent birds' body centers, parallel to the flight path) between individuals (Hainsworth, 1988). This author found close synchrony (a difference of <0.1 beat/s) to be present in 48% of the birds he studied and, because of the calm conditions at the time, concluded that this probably represents an upper limit. Indeed, even when not taking wingbeat frequency into account, Cutts and Speakman (1994) calculated mean saving in induced power for 54 skeins of pink-footed geese (*Anser brachyrhynchus*) to be only 14% and concluded that the relationship between depth and WTS supported the communication hypothesis (Gould and Heppner, 1974). This contends that the birds position themselves so as to avoid collisions and to maintain flock unity. Although not on migration, Weimerskirch et al. (2001) studied the flight performance and heart rate of great white pelicans (*Pelecanus onocrotalus*) while they were flying alone and when they were flying in V-formation. Mean wingbeat frequency was reduced by up to 50% for pelicans flying behind the first two birds in formation, as a result of an increase in the time spent gliding. Heart rate was reduced by 14% for pelicans in formation compared to birds flying alone. If we apply the allometric trend that $\dot{V}_{O_2}$ is proportional to f_H^2 (Bishop and Spivey, 2013), then this would suggest that the mean energetic saving for flying in V-formation was around 27% relative to unaccompanied flight.

39.10 FLIGHT AT HIGH ALTITUDE

The majority of avian migratory flights occur below 1 km above the ground (Liechti and Schaller, 1999; Berthold, 1993); thus migrations where birds climb to higher altitudes to select for favorable wind directions, or where traditional flyways route birds over large mountain barriers, are of particular interest. Early studies indicated that most small passerines migrating at night fly below 2 km above sea-level (Lack, 1960; Nisbet, 1963), although it was demonstrated by Bruderer and Liechti (1995) that wind direction may cause the majority of birds crossing the Negev desert in the south of Israel to fly above 1.8 km in spring, but with 90% below 3.5 km. Occasionally, when a low-level jet offered tailwinds that were particularly strong, birds flying over Israel reached heights between 5 km up to almost 9 km (Liechti and Schaller, 1999), and with ground speeds >25 m/s and up to 50 m/s. Even more rarely, some accidental observations of various species of birds have been reported at similarly extreme high altitudes (>6 km). A flock of 30 swans (probably whooper, *Cygnus cygnus*) was located by radar off the west coast of Scotland at an altitude of 8–8.5 km, where the temperature was −48 °C (Stewart, 1978; Elkins, 1979), but it is unclear how these birds managed to reach such high altitudes (Pennycuick et al., 1996a). Bar-headed geese, *A. indicus,* have also been reported as flying at altitudes of well over 8 km (where PO_2 is around 6.7 kPa, approximately one-third of the sea-level value) during their migration across the Himalayas (Swan, 1961). However, these anecdotal observations have never been substantiated by any scientific evidence, while the highest ever directly recorded flight for a bar-headed goose was 7290 m (Hawkes et al., 2012), using a GPS satellite tag. Thus, birds can certainly fly at altitudes at which non-acclimatized mammals find walking difficult (Tucker, 1968a). Unfortunately, there have been few physiological studies on birds flying at high altitude, real or simulated, although Tucker (1968a) did train a budgerigar wearing a $\dot{V}_{O_2}$ mask to fly in a hypobaric wind tunnel for 30 s at the equivalent of 6.1 km. Two particular aspects of flying at high altitude (low air temperature and evaporative water loss) have already been mentioned. Other aspects are the effect of the decrease in air density and in the partial pressure of oxygen with increasing altitude, which will have both physiological and biomechanical influences on flight performance. Pennycuick (1975) argues that, as birds fly higher, they must fly faster in order to obtain sufficient lift from the wings. However, as speed increases with height, so does the power required to maintain it. Also, because the rate of gas exchange will be affected by the value for PO_2, there will be a particular altitude at which the bird can only just obtain O_2 at a rate sufficient to maintain even its minimum power speed, at which point it will not be able to climb any higher under its own power.

Gudmundsson et al. (1995) studied the migration of brent geese (*Branta bernicla*) from Iceland to Greenland and tracked them by satellite as they flew up and across the Greenland ice cap. These authors found that the brent geese (fitted with 60 g satellite transmitters) were not able to fly continuously over the Greenland ice cap and had to make frequent and long rests during the climb. Gudmundsson et al. (1995) concluded that this evidence supported the biomechanical predictions of Pennycuick (1989) that these birds were up against the limit of the biomechanical power available from the flight muscles due to negative scaling of wingbeat frequency with respect to body mass. However, the analyses of Bishop and Butler (1995) and Bishop (1997, 2005) suggest that the limit to the sustained climbing performance of birds, such as brent geese, is more likely to be related to the biomechanical performance of the heart. As geese have both FG and FOG fiber types in their flight muscles (Rosser and George, 1986a), the net effect is that during "prolonged" activity the mass of the flight muscle is effectively reduced to that of the "aerobic" FOG fibers and the P_o available becomes proportional to the ability of the

cardiovascular and respiratory system to supply the working (aerobic) muscle tissue. With a small additional contribution from the FG fibers, the brent geese would have the potential to fly up the steeper slopes using anaerobic power, but the birds would require regular stops (as was observed). The empirical data of Gudmundsson et al. (1995) indicate that it is not the biomechanical power available from the whole flight muscles *per se* that is limiting, but the power available from the mass of the FOG fibers, which is likely to be closely matched to the ability of the cardiovascular system to perfuse the flight muscle with blood. Pennycuick et al. (2011) also tracked brent geese flying over the Greenland ice cap and arrived at the same conclusion.

Due to its iconic migration over the Himalayan mountains and across the Tibetan-Qinghai plateau (Figure 39.35), the bar-headed goose has been the subject of many studies concerned with the physiological adaptations for flying at high altitude (reviewed in Butler, 2010; Scott, 2011). Unlike Pekin ducks, bar-headed geese do not increase their Hct and Hb when exposed to simulated high altitude (Black and Tenney, 1980). This means that there is no increase in the viscosity of the blood, thus preventing a possible reduction in its circulation. This is more than counterbalanced by the higher affinity for oxygen (low P_{50}) of the Hb of the goose (P_{50} for blood of the bar-headed goose at pH 7.5 is approximately 5 kPa compared with 7.5 kPa for the duck), which allows the maintenance of a higher C_aO_2 (and hence $C_aO_2 - C_{\bar{v}}O_2$) at high altitudes than in the duck.

A comparison between the bar-headed goose and the plain-dwelling graylag goose, *Anser anser*, indicates that their Hb differs by only four amino acid substitutions, one of which (α^{119} Pro→Ala) may, by altering the contact between the α1 and β1 chains, confers a small increase in the O_2 affinity of the Hb from the bar-headed goose (Perutz, 1983), and this is then amplified by the interaction with inositol pentaphosphate (Rollema and Bauer, 1979). The complementary substitution (β^{55} Leu→Ser) at the same position may have a similar effect on the P_{50} of the Hb of the Andean goose *Cloephaga melanoptera* (Weber et al., 1993). Temporary movements to high altitude in some other species may

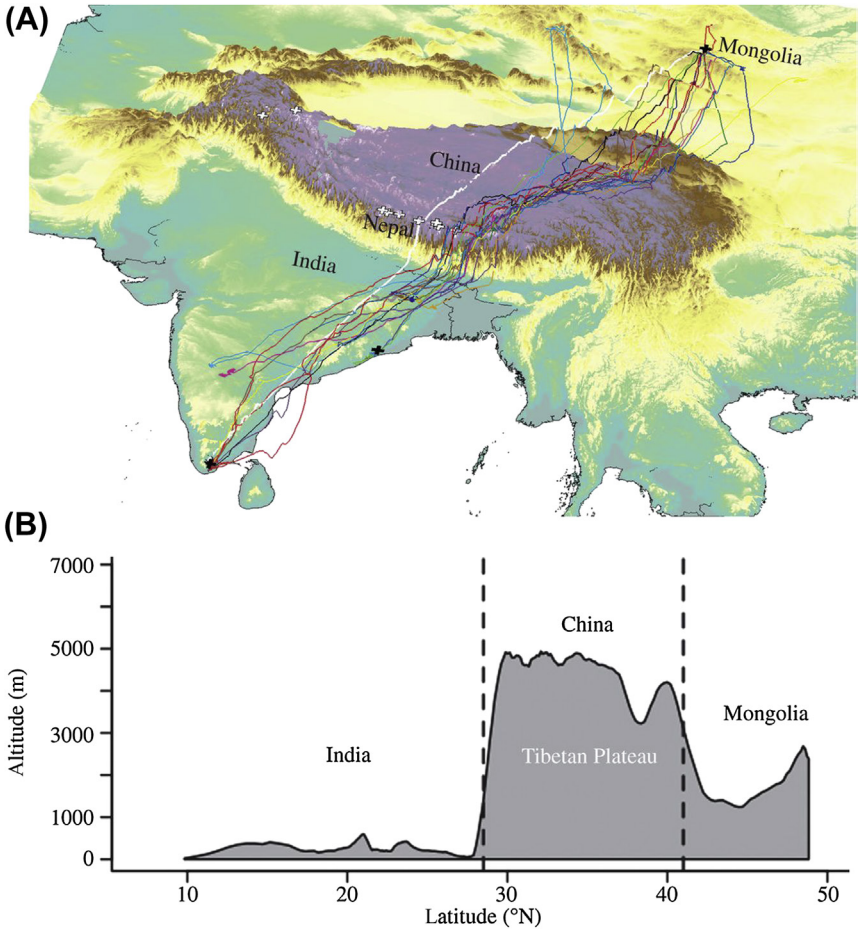

FIGURE 39.35 Satellite tracks of migrating bar-headed geese, *Anser indicus*: (A) three-dimensional map showing release locations (black crosses) of bar-headed geese in India ($n=2$ sites) and Mongolia ($n=1$ site). Colored lines represent 16 individual geese, and colored background shading indicates elevation. Solid thick white line shows the great circle route. White crosses show locations of the mountains peaks over 8000 m in elevation. (B) Cross-section of land elevation underlying the route of the northwards migration, based on the arithmetic mean of all flights. *From Hawkes et al. (2013).*

have different effects. The natural annual movements of wild quail from 200 to 1200 m in Catalonia is accompanied by an increase in Hb of 24% but a decrease in the affinity of Hb for O_2 (P_{50} from 3.6 to 4.2 kPa, Prats et al., 1996). Thus, there is an increase in O_2-carrying capacity of the blood and an enhancement of its ability to release O_2 to the tissues.

It is clear from the data of Black and Tenney (1980) that the respiratory system of bar-headed geese is able to maintain a very small difference between the PO_2 of inspired air (P_IO_2) and that in the arterial blood (P_aO_2), when at high altitude. For example, when at sea level, $P_IO_2 - P_aO_2$ in bar-headed geese is approximately 7 kPa, whereas at a simulated altitude of 10.67 km it is only 0.5 kPa. The large increase in respiratory minute volume $(\dot{V}_I)$ that is required to maintain such a small difference between P_IO_2 and P_aO_2 also causes a decline in P_aCO_2 and associated increase in arterial pH (pHa); the bird becomes hypocapnic and alkalotic. Scott and Milsom (2007) showed that the increase in $\dot{V}_I$ in bar-headed geese was the result of a larger increase in tidal volume and a correspondingly lower increase in respiratory frequency than that of the lowland-living graylag goose (*A. anser*) or Pekin duck.

In a number of mammals (dog, monkey, rat, human) the hypocapnia induced by hyperventilation causes a reduction in cerebral blood flow. This is not the case in ducks and bar-headed geese (Grubb et al., 1977; Faraci and Fedde, 1986). Also, hypoxia causes a greater increase in cerebral blood flow in ducks than it does in dogs, rats, and man (Grubb et al., 1978). At high altitude, of course, both of these factors occur together (hypocapnic hypoxia) and under these conditions hypocapnia appears to attenuate the increase in cerebral blood flow caused by hypoxia (Grubb et al., 1979). However, these authors found that blood flow is similar at a given O_2 content in both normocapnic and hypocapnic ducks. This is because during hypocapnia and alkalosis, there is a leftward shift of the O_2 equilibrium curve, as a result of the Bohr effect, so that a given O_2 content is achieved at a lower PO_2. In fact, in bar-headed geese, the alkalosis during severe hypoxia is greater than that in Pekin ducks, which together with the higher affinity of their Hb for O_2, means that at a given (low) P_aO_2, C_aO_2 is much (at least two times) greater in the geese (Faraci et al., 1984a). In addition, the pulmonary vasoconstrictor response to hypoxia is smaller in the bar-headed goose than in other birds and mammals (Faraci et al., 1984b). Thus, similar (or even greater) O_2 deliveries to the brain and heart can be achieved in hypoxic bar-headed geese at lower cerebral and coronary blood flows than in hypoxic ducks. Indeed, this species of goose is able to maintain, or even to increase, its perfusion of all tissues during severe hypocapnic hypoxia (Faraci et al., 1985).

Delivery of O_2 to the locomotory muscles are also influenced by the architecture of the capillaries. Capillary density and capillary:fiber ratio are greater in the skeletal muscle (gastrocnemius) of bar-headed geese than in that of Canada geese (Snyder et al., 1984), and this is a genetic adaptation that is not dependent on exposure to low atmospheric oxygen during development. Perhaps surprisingly, there was only a 24% increase in the capillary:fiber ration of the bar-headed goose flight muscle compared with that of the barnacle goose and no significant difference in capillary density (Scott et al., 2009). All of these factors are, no doubt, very important features when the bar-headed geese need to fly at higher altitudes. Scott and Milsom (2006) suggested that adaptations to decrease the value for hemoglobin P_{50} and to increase tissue diffusion capacity might be the most beneficial for high-flying birds.

It has been suggested that the more effective lungs of birds, compared with those of mammals, may contribute significantly to the ability of birds better to tolerate high altitude (Scheid, 1985). However, Shams and Scheid (1989) concluded that, although the parabronchial lung of birds does confer an advantage at a PO_2 equivalent to that at the top of Mt. Everest, at the highest simulated altitude (11.58 km) tolerated by their ducks, there was no advantage at all. The authors concluded that the major difference between birds and mammals at these extreme altitudes is the ability of the former to tolerate lower P_aCO_2, thus enabling the respiratory system to maintain P_aO_2 at as high a level as possible. In a subsequent paper, the same authors (Shams and Scheid, 1993) reported that when hypoxia is accompanied by the appropriate hypobaria (reduced atmospheric pressure), V_I and P_aO_2 are slightly, but significantly greater. Although the authors have no explanation for these differences, they would allow a bird at the elevation of Mt. Everest to gain another 700 m in height before the "increase" in P_aO_2 was eliminated. Gas exchange across the *rete mirabile ophthalmicum* is thought to enhancing the supply of oxygen to the brain (Bernstein et al., 1984), and improvement in gas transport as a result of acclimation to high altitude (Weinstein et al., 1985) may be another way in which birds are adapted for survival and activity at high altitudes.

Despite all of these apparent adaptations to life at high altitude, as mentioned at the beginning of this section, there is very little accurate information with regard to the heights that these birds typically fly at during their migrations. Hawkes et al. (2011) tracked bar-headed geese flying North out of India and climbing up and through the Himalayan mountains, on their way to breed in China and Mongolia (Figure 39.36). The birds typically climbed between 4 and 6 km in 7–8 h in a single day, with regular sustained climb rates of between 0.2 and 0.6 m/s. Over the whole migratory period, the data suggested that bar-headed geese normally minimize flight altitude by traveling through the mountain valleys and only flying as high as the terrain dictates (Hawkes et al., 2012). Maximum altitudes reached were 7290 and 6540 m, for southbound and northbound geese, respectively, but with 95% of locations recording <5489 m.

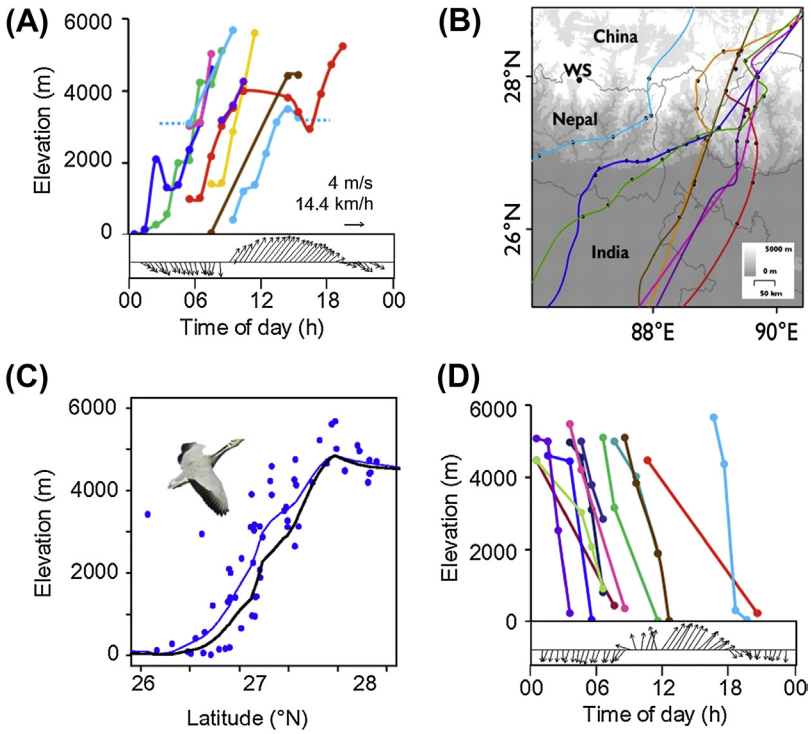

FIGURE 39.36 Timing of migrations with 30-min average wind speed and direction from the Nepal Climate Observatory at Pyramid station for bar-headed geese, *Anser indicus*, migrating (A) northward ($n=8$) and (D) southward ($n=12$) over the Himalayas. Arrows show cardinal direction (north pointing up to 0°) in which the wind was blowing and arrow length (indicated in (A)) is proportional to wind speed in (A and D). (B) Map showing the northward migration routes; weather station (WS) location is indicated. (C) Elevation of the mean northward track across the Himalayas (for all crossing locations from all eight geese); blue circles show individual data points and blue line shows Lowess smoother for mean ground elevation under the track (black line). *From Hawkes et al. (2011).*

Blum (1980) reports seeing bar-headed geese flying over the summit ridge of Annapurna I at >7622 m and took photos of them. Clearly, it is possible that occasional rare flights to very high altitudes could occur, but it is not clear if these flights are only possible if assisted by favorable wind conditions in the mountains or whether they are sustained entirely by the various physiological adaptations for flight at high altitude.

Experiments on bar-headed geese running on a treadmill under hypoxic conditions, similar to those at the top of Mt. Everest, indicated possible severe limitations to oxygen uptake (Fedde et al., 1989). Under normoxic conditions, running at 0.6 m/s and at a 2-degree incline caused a doubling of $\dot{V}o_2$ and of cardiac output. Under the severe hypoxic conditions of only 7% atmospheric O_2, there was a decline in resting $\dot{V}o_2$ and, surprisingly, $\dot{V}o_2$ did not increase significantly during the subsequent 6 min of exercise. Cardiac output also apparently remained unchanged during exercise, although there was a significant reduction in V_s. The authors suggest that there may be a hypoxic depression of cardiac contractility, but clearly this cannot occur when the birds are flying at high altitude. It may be that the birds used in this study were stressed by the surgical techniques associated with the cannulations and so on (Woakes and Butler, 1986). Certainly, their resting heart rate was almost three times higher than that of resting barnacle geese (Butler and Woakes, 1980; Ward et al., 2002). A similar study of bar-headed geese (Hawkes et al. submitted) obtained similar blood gas and metabolite values to those of Fedde et al. (1989) but significantly lower resting heart rates during normoxia and hypoxia. They also used accelerometry to indicate that the cost of locomotion and found that the requirement for oxygen was not different between running in hypoxia and in normoxia. Finally, it was noted that, while lactate levels had risen significantly in the geese running in hypoxia (Fedde et al., 1989; Hawkes et al., submitted), it could only account for a maximum of 10% of the locomotory costs after 6 min of running, which was incompatible with the 50% reduction in $\dot{V}o_2$ measured by Fedde et al. (1989) in severely hypoxic geese. Put together, these results suggest that there was a problem with the experimental determination of $\dot{V}o_2$ by Fedde et al. (1989) under hypoxic conditions during running, and that the maximum running speeds of bar-headed geese are not significantly affected by severe hypoxia (Hawkes et al., submitted).

These recent studies of bar-headed geese in the wild (Takekawa et al., 2009; Hawkes et al., 2011, 2012) are beginning to reveal the true nature of their migration across

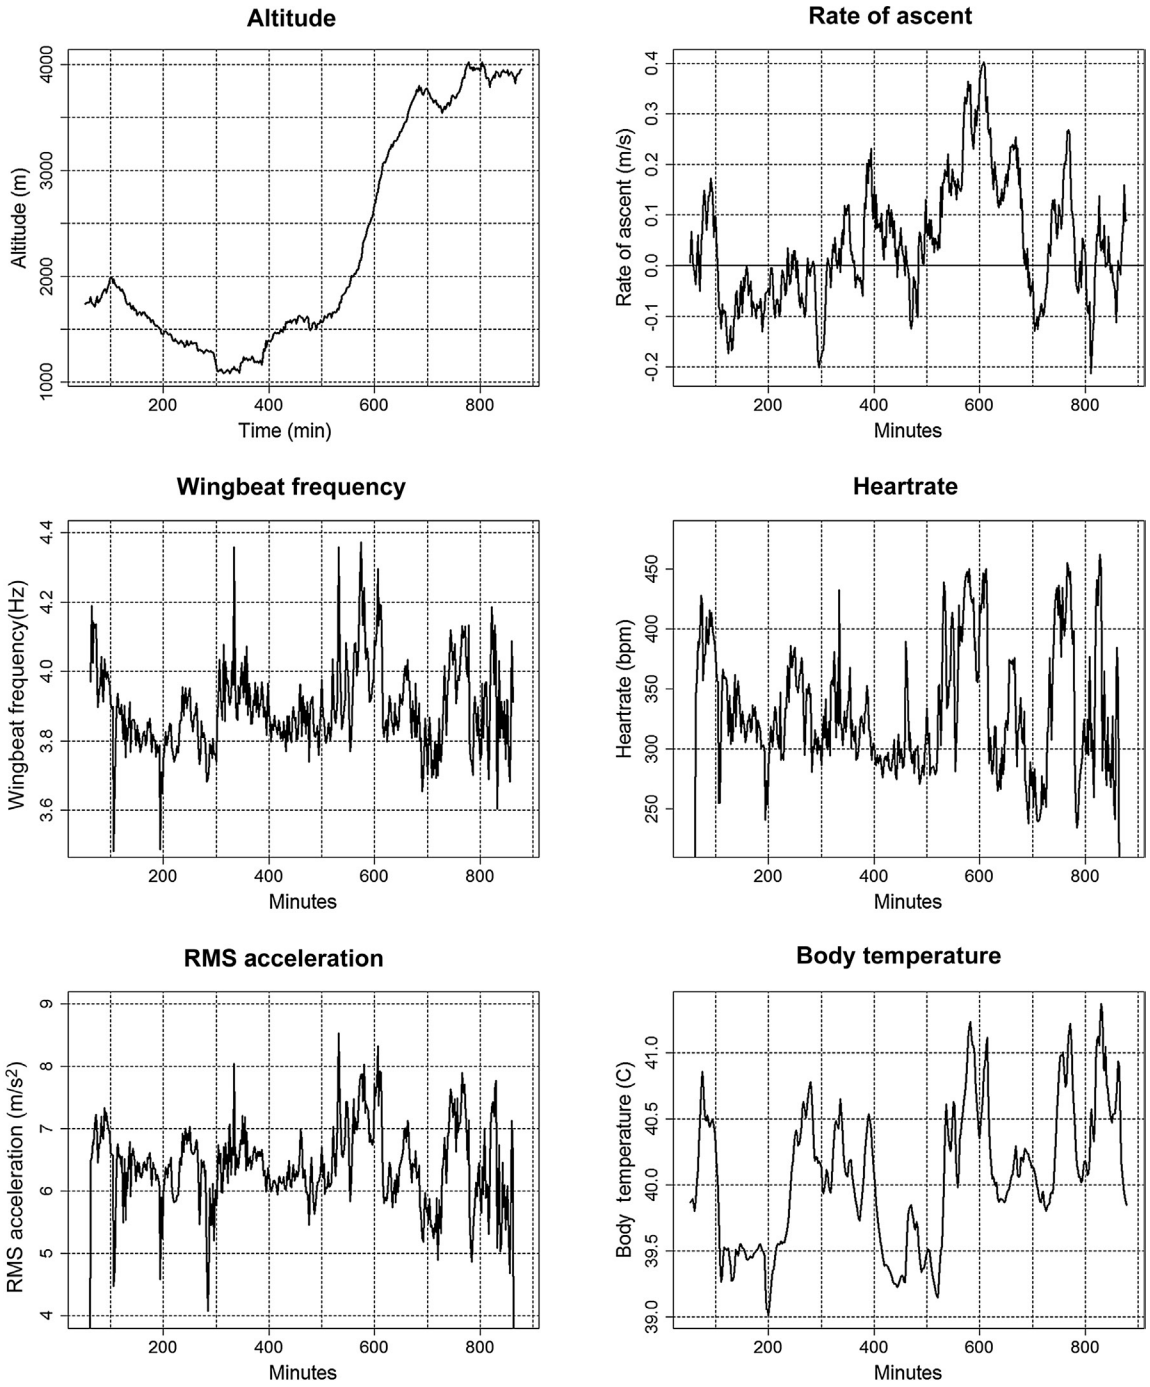

FIGURE 39.37 Simultaneous recording of heart rate, body temperature, wingbeat frequency, and root mean squared ventral-dorsal acceleration, from a wild bar-headed goose, *Anser indicus*, on its autumnal, southward migration from Mongolia up onto the edge of the Tibetan-Qinghai Plateau. All four variables are very well correlated with each other and, in particular, body temperatures fluctuate between 1 and 2 °C in direct association with changes in flight costs, as the geese alter their rate of ascent and descent during flight. *From Bishop, C.M., Spivey, R.J., Hawkes, L.A., Butler P.J., Unpublished data.*

the Himalayan Mountains and Tibetan-Qinghai plateau. Technological approaches are allowing the simultaneous recording of altitude, heart rate, and accelerometry during their migratory flights (Figure 39.37; Bishop, Hawkes, Butler et al. unpublished data). These data indicate that even a comparatively gentle climb rate of around 0.1 m/s, between an altitude of 3600 to 4000 m, required a heart rate of well over 400 beats/min, compared to a maximum heart rate of around 500 beats/min (Ward et al., 2002). However, overall the mean heart rates are remarkably low and indicate that there is still much to discover with regard to the maximum flight performance of these high-flying birds.

Chapter 40

Physiological Challenges of Migration

Eldon J. Braun

Department of Physiology, College of Medicine, University of Arizona, Tucson, AZ, USA

40.1 GENERAL CONCEPTS

There are a number of theories suggesting why birds migrate and the evolutionary origin of this phenomenon, but the fundamental premise is that this type of mass movement over long distances at predictable times of the year does occur (Salewski and Bruderer, 2007). This very complex phenomenon must be supported by a metabolism that is equally complex. Theories vary a great deal as to the way birds move. Do birds migrate towards breeding territories that provide necessary resources for reproduction and rearing of young, then return to "home" areas to avoid harsh climates that occur with annual cycles (Zink, 2011)? It has been suggested that birds gradually expand ranges toward more favorable territories. As this expansion continues or grows with changing seasons, the farthest points of the range become less favorable and birds return to home territory where conditions are more favorable (Zink, 2011).

40.2 EVOLUTION OF MIGRATION

Most avian species may have had their origin in tropical regions or were forced to the tropics by glaciation events (Klaassen et al., 2012). Such events may have may have markedly increased competition for resources in southern regions and forced species to gradually expand to more favorable regions to ensure breeding success and the rearing of offspring. These activities may have lead to mass movements of species in bidirectional movements (i.e., patterns of migration).

40.3 COST OF MIGRATION

No matter the evolutionary source of migratory patterns, they do exist. These long-distance—and at times, uninterrupted—flights must be supported by the metabolism of substrates stored in the bodies of birds. Through a process of evolution, the metabolic fuel of choice of all migratory birds appears to be lipids or fatty acids, which can be stored within the body without the accompaniment of water (Guglielmo, 2010). The source of this high-energy metabolite substrate is variable, as is the manner in which it is stored in the body of birds. This storage is dependent on the body mass of the species and the distance of the migratory route. Very small birds (body mass <25 g) accumulate lipid reserves prior to departure, but in some cases have to "come down" to refuel (Jenni and Jenni-Eiermann, 1998). However, other small species sustain migratory trips without refueling. Good examples are hummingbirds, which may have a body mass of 8 g before departure and arrive at their destination with body masses of less than 5 g (Calder, 1987). Small European garden warblers with body masses of approximately 20 g accumulate lipids prior to departure for sub-Saharan Africa, but they do not sustain flight for the entire trip (Klaassen and Biebach, 1994). They stop to refuel two or three times before their final destination is reached. The refueling is of the lipid stores. These birds, as all avian species, do not metabolize carbohydrates (glucose) as a metabolic fuel, as is suggested by a lack of change in plasma glucose concentration during the migration. Either the glucose is not metabolized or it is constantly replenished as it is used. Parenthetically, all birds have high plasma glucose concentrations compared to other vertebrates, particularly mammals and reptiles, when compared on the basis of body mass. It is not clear why this is the case. The high levels of plasma glucose may serve functions unrelated to being consumed as metabolic fuel.

Although the metabolism of lipids is the most important metabolic fuel for birds undergoing sustained flight, there is increasing evidence that the breakdown of body protein also serves as an important resource during migration. Not only can protein be catabolized for energy, but the metabolism of it produces much more water than the metabolism of lipid. The catabolism of protein produces five times more water per unit of energy produced than does the metabolism of lipid (Jenni and Jenni-Eiermann, 1998). In a study using garden warblers (*Sylvia borin*) as an experimental animal, Bauchinger et al. (2005) examined the mass changes of 13 organs during spring migration. In preparation for the journey

Sturkie's Avian Physiology.

across the Sahara, some organ masses increased 1.5 times. After the flight, most organs (including the heart and flight muscles) lost mass. The liver, spleen, kidney, and the gastrointestinal tract decreased in mass by 50%. During refueling stopovers, the mass of the organs was restored. Interestingly, the testes mass increased fourfold, probably in preparation for reproduction. Because there are no special tissues to store protein, the change in mass of the normal organs facilitates the storage of protein as a supplemental energy and water source. Therefore, protein is a multifunctional substrate that can facilitate long-distance flight.

Using computer simulations, field data, weather, and global positioning system tracking data, Pennycuick et al. (2011) estimated fuel reserves for three species of geese along several migratory routes: from Iceland to Arctic Canada, from Scotland to Greenland, and from Scotland to northern Norway. The major result of the study (other than employing a combination of technologies) was the prediction that the geese would arrive on their breeding grounds with sufficient energy reserves that could be used for breeding activities.

Another observation that strongly supports the use of lipid storage and reserves for long-distance flight is that of several species of plovers that use the Bay of Fundy as a stopover on their way to their wintering grounds in northeastern South America, a journey that takes about 72 h nonstop (Turcotte et al., 2013). The bay is a rich source of the invertebrate *Corophium volutator*, commonly known as the mud shrimp. The body mass of these small mud shrimp is 43% lipids (Napolitano and Ackman, 1989). The birds remain in the bay area for 10–20 days to rest and feed on the shrimp and markedly increase their body mass primarily as result of lipid storage.

The reliance on lipids as metabolic fuel presents problems. Their lack of aqueous solubility means that they not only have to be transported from fat depots to cells, but they must cross cell membranes to be metabolized. They are carried in the plasma by serum albumin, and evidence suggests that they are transported into cells by a protein FAT/CD36 (fatty acid translocating protein) not by simple diffusion. Once inside cells, they are bound to the fatty acid binding protein (FABP), which serves as a sink to facilitate their continued entry into cells. The role of FABP has been demonstrated in heart muscle of western sandpipers (*Calidris mauri*), where its concentration about 10-fold greater than in mammalian heart muscle and its concentration 70% higher during migration than in winter resident populations of sandpipers (Guglielmo et al., 1998).

The role of protein, not only as an energy source but also as a water source, was demonstrated in studies on Swainson's thrush (*Catharus ustulatus*). In controlled wind tunnel experiments, birds flown in dry air lost 3.55 mg/min lean body mass, whereas birds flown in moist air did not lose lean body mass (Gerson and Guglielmo, 2011). This study suggested lean body mass (muscle) was metabolized to produce water lost to the dry air.

The emerging pattern appears to be that lipids are the primary energy source for the demands of long-distance flight, with protein serving as the energy reserve and a source of water to prevent marked changes in osmolality of total body water. Lipids have a negative feature of low aqueous solubility; however, this can be viewed as positive because, as an energy storage source, lipids do not require water. In an overall balance, lipids supply approximately 90% of the energy for flight and protein supplies approximately 10%. The third metabolic substrate carbohydrate (glucose) appears to play no role as a source of energy for long-distance flight. The physiological role of the high plasma glucose concentrations is undetermined at this time.

Adaptations of birds to fly at high elevations during migration are exemplified by bar-headed geese (*Anser indicus*), which fly over the Himalayas as they move from their wintering grounds in the low lands of India to their breeding areas on the high-altitude plateaus of central Asia (Koppen et al., 2010). The flight to the breeding grounds last about 8 h, but the return flight is accomplished in about one-half that time. Although there are limited data in the literature on body mass changes or the metabolic fuel consumed, the principal adaptations exhibited by the bar-headed geese appear to be at the level of the muscle microcirculation and the mitochondria (Scott et al., 2011). The capillary density appears to be higher in both cardiac and skeletal muscle (to reduce diffusion distance) and the nature of cytochrome oxidase is altered compared to geese whose lifespan is at low altitudes.

The mass movement of large numbers of birds of a given species (migration) is an interesting and complex area of study; the evolutionary bases for it are not completely understood. Nonetheless, the phenomenon does occur and birds have evolved strategies to use primarily lipids as metabolic substrates to support this endurance activity.

41.1 INTRODUCTION

The use of chemicals has been critical in crop production, pest control, health and beauty products, and in industrial systems crucial in our global economies. Plastics and industrially produced compounds have been essential to our lifestyle and are key factors in the efficiency of production systems, packaging, and storage. Not surprisingly, as we learn more about the chemical components used in many of these processes, in storage and production, and for control of pests and our environment, adverse effects have come to light. One of the earliest findings indicative of potential adverse effects of industrial chemicals and pesticides was the thinning of eggs in bald eagles in response to exposure to dichlorodiphenyltrichloroethane (DDT), which dramatically illustrates the potency of these chemicals in wild birds. Since that time, there have been a series of workshops aimed at assessing the actions and risks associated with exposure to environmental chemicals across vertebrate and invertebrate species. Workshops, including the Wingspread Meetings and research publications, have documented impacts of EDCs and toxicants in laboratory studies and in wild populations of avian species (Berg et al., 1999; Bowerman et al., 2007; Brunstrom et al., 1991; Cohen-Barnhouse et al., 2011; Corbitt et al., 2007; Custer et al., 2010a,b; Custer and Read, 2006; Hotchkiss et al., 2008; Kavlock et al., 2005; Rattner, 2009; Rattner et al., 2000, 2010, 2001; Safe et al., 1985; Levengood et al., 2007). In general terms, the potential for deleterious results have been supported by observations of endocrine-related effects to organisms in areas in which dioxin, PCB, or other chemicals occurred. Furthermore, the exposure of wildlife to environmentally relevant levels is often at sublethal concentrations, making the determination of effects of EDCs challenging, especially when attempting to separate other interacting factors in the animal's environment. Additional variables may include environmental conditions, food availability, disease, or confounds such as simultaneous exposure to several chemicals. It is therefore important to develop reliable and sensitive measures that are appropriate for the endocrine or organ system that are the targets of the EDCs. This chapter will consider toxicants that affect avian species, with emphasis on environmental chemicals that attack endocrine systems through similarities in structure and/or function to hormones and growth factors. Background will be provided on some of the early studies to circumscribe the potential for adverse impacts of these toxicants and underpin the testing paradigms required

Sturkie's Avian Physiology.

for the commercial use of these chemicals. The impacts of these environmental chemicals will be considered in terms of broad categories of compounds, based on their characteristics and targets. Finally, mechanisms of action will be described in the context of the variety of avian species, their habitats and reproductive strategies, and characteristics that make them unique among vertebrates.

41.2 ENDOCRINE-DISRUPTING CHEMICALS: UTILITIES AND HAZARDS?

A number of factors must be considered when evaluating the cost/benefit for the use of environmental chemicals. The productivity of our agricultural systems is outstanding, in part due to the use of chemical treatments that limit pests and make applications, storage, and preparation more efficient. The use of chemicals has dramatically increased as our knowledge of chemistry and biochemistry has enabled the development of designer chemicals for specific applications. However, many of these chemicals are effective because they specifically interact with endocrine-related processes or other physiological functions in pest species. For example, an effective pesticide for gypsy moths is tebufenozide, which is an ecdysone inhibitor that acts on the timing of molting in larvae. Because these compounds were developed specifically to act on physiological targets in insects, coincident effects on other vertebrate classes are generally regarded as minimal risk compared to benefits.

The U.S. Environmental Protection Agency (EPA) formed the Endocrine Disruptor Screening and Testing Advisory Committee (EDSTAC), a committee of scientists and stakeholders that was charged by the EPA to provide recommendations on how to implement its Endocrine Disruptor Screening Program (EDSP). The EDSP is critical for assessing the potential for EDCs to impact vertebrate species, with the added benefit that identifying EDCs with adverse effects in vertebrates and banning them from use would then prevent human exposure. Upon recommendations from the EDSTAC (Harvey and Everett, 2006), the EPA expanded the EDSP using the Administrator's discretionary authority to include the androgen and thyroid hormonal systems as well as the reproductive endocrine systems of wildlife (see http://www.epa.gov/endo/pubs/edspoverview/edstac.htm). Following broader international concerns and the creation of similar programs in other countries, the Organisation for Economic Co-operation and Development (OECD) established the Endocrine Disrupters Testing and Assessment (EDTA) Task Force in 1998 within its Test Guidelines Programme, with the charge of developing an internationally harmonized testing strategy for the screening and testing of EDCs.

To address possible effects in birds, the Tier 2 Japanese quail (*Coturnix japonica*) Avian Toxicity Test was developed to detect potential disruption of the endocrine system by EDCs; this and other tests will be reviewed later in this chapter. One of the primary challenges, given the diversity of chemicals considered potential EDCs is to ascertain risk across vertebrate classes. Because birds have a broad range of life histories and unique developmental characteristics, there are differential sensitivities across avian species with changing lifetime vulnerability. Further, migratory birds have enormous metabolic demands, requiring highly functional metabolic and thyroid endocrine systems. As such, EDCs that impact metabolic and in particular the thyroid systems pose risk to migratory avian species. Furthermore, sexual differentiation of reproductive and other endocrine systems is unique to birds, being driven by primarily estradiol-mediated mechanisms. Developmentally, songbirds and other passerine species are altricial, while ducks, galliforms, and ground-dwelling species are precocial. This developmental difference appears to relate to the extent and timing of sensitivity to EDCs, because precocial species are fully functional and relatively independent at hatch. They undergo sexually differentiation *in ovo;* similarly other physiological systems are also well developed at hatch as compared to altricial birds that require intensive parental care. Finally, the potential for adverse effects of EDCs on long- or short-lived birds is unknown, especially in the context that long-lived birds tend to have small clutches and raise fewer chicks per year compared to short-lived birds (Holmes and Ottinger, 2003; Ottinger et al., 2009a; Ottinger, 2005).

Historically, there are many studies in wild birds that document cases of exposures with higher concentrations of toxicants originating from chemical applications and industrial spills. Often these occurrences were associated with high mortality, thereby prompting federal and regional responses aimed at protecting human and wildlife health. However, less is known about nonlethal impacts of EDCs on wild birds and the potential for adverse effects translating even to the level of a risk to the population. The deleterious effects of DDT was a recognized adverse effect of a pesticide acting as an EDC in bald eagles, with endocrine actions on females that resulted in eggshell thinning (Lundholm, 1997). As a consequence, embryonic eagles failed to develop to hatch. In addition, there are extensively documented cases, such as incidences of avian impacts from the Great Lakes, PCBs released into the Housatonic and Hudson Rivers, and high concentrations of munitions and other contaminants that indicate impacts on birds (Best et al., 2010; Bowerman et al., 2007; Custer et al., 2010a; Darnerud, 2003; Franceschini et al., 2008). Data collected from some extraordinary datasets also exist or are emerging from long-term monitoring and research programs, including the Great Lakes region; many of these studies have considered physiological and reproductive impacts of exposure to chemicals found in those areas. Laboratory studies have provided additional insights into potential mechanisms of

action of EDCs as well as periods of sensitivity throughout the life-cycle. Information from many of these studies will be discussed below in order to put the proposed two-generation test into the context of testing in avian species. Furthermore, it is important to consider unique characteristics of the avian physiology with emphasis on sexual differentiation, hormonal modulation of endocrine and behavioral components of reproduction, and functional impacts of EDCs on neuroendocrine regulatory systems, especially considering potential adverse outcomes.

41.3 LIFE-CYCLE OF EDCS IN THE ENVIRONMENT

There are many sources of EDCs in the environment and there are excellent resources available to search for information and distribution about many of these compounds. For example, the United States Geological Service has a Contaminant Exposure and Effects—Terrestrial Vertebrates Database that provides over 20,000 searchable records that provide information on taxonomy and chronology of ecotoxicological exposure and effects as well as geographic location of contaminants (see http://www.pwrc.usgs.gov/contaminants-online/pages/ceetv/ceetvintro.htm). In considering the use and fate of environmental chemicals, it is useful to consider the life-cycle of a chemical or compound (Figure 41.1). The fate of a compound in the environment relates to both the movement in soil, water, and air as well as the metabolism of the parent or original chemical. Some chemicals enter directly into the air as a consequence of the manufacturing process, as in the case of airborne chemicals through smokestacks or steam. Moreover, chemicals in the environment become metabolized with exposure to air, sun, heat, and microbial metabolism. Metabolites of parent compounds are often bioactive and in some cases impact different physiological targets with even greater toxicity than the parent compound. Alternatively and more frequently, chemicals are manufactured for a specific purpose such as in the case of DDT, which as an effective insecticide became ubiquitous in the environment with wide use as a pesticide and in the battle against malaria-carrying mosquitos (Asawasinsopon et al., 2006; Borga et al., 2007; Braune et al., 2005; Rattner, 2009). As may be seen in Figure 41.2, DDT applied to fields as an insecticide then migrates into the water via rain events and run-off. In the rivers and streams, DDT becomes part of the food chain by ingestion into invertebrates, which are eaten by fish and eventually by organisms higher on the food chain. This brings to attention the effects. In the DDT example, effects were observed in bald eagles and more recently in herons at Lake Michigan on eggshell thinning (Lundholm, 1997; Rattner, 2009). The life-cycle of DDT also includes metabolism into DDE (dichlorodiphenyldichloroethylene), an antiandrogenic compound in vertebrates (Bowerman et al., 2007; Quinn et al., 2008). Despite years of banning, significant concentrations of DDT and its metabolites are found in agricultural areas and in wildlife living and breeding in proximity to areas that had wide use of DDT as an insecticide (Weseloh et al., 1990).

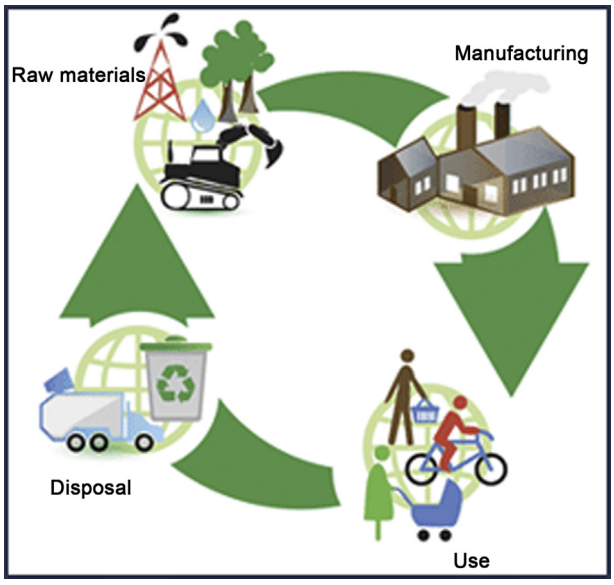

FIGURE 41.1 Diagrammatic representation of the life-cycle of compounds; once manufactured, they are used and then disposed allowing reentry into the environment. *From Environmental Protection Agency "Risk Management Sustainability Technology", http://www.epa.gov/nrmrl/std/lifecycle.html.*

In the case of industrial compounds such as lubricants, plastics, flame retardants, and nanofibers, there may be purposeful or inadvertent release into the environment, especially at the time of usage or disposal. This is the case with the release of polychlorinated biphenyls (PCBs) into the environment, which occurred both as a consequence of the manufacturing practices for electrical transformers containing Aroclors® and affected the Housatonic River in western Massachusetts (Custer and Read, 2006; Custer et al., 2012a; Barnthouse et al., 2003). Similarly, General Electric's Hudson Falls and Fort Edward plants discharged PCBs into the upper Hudson River from 1947 until 1952 (http://www.darrp.noaa.gov/northeast/hudson/index.html). This, in combination with leakage of these compounds from the manufacturing process for capacitors, resulted in long-term contamination of the river and continued persistence of PCBs in the environment (Erickson et al., 2005; Butcher and Garvey, 2004; Cho et al., 2002; Foley, 1992; Man et al., 2011). Not only do PCBs have a very long half-life in the environment, they also remain chemically stable in the sediment and become available when the sediment is disturbed. Further, measurements in tree swallow and sandpiper eggs revealed that there were two mixtures present in the Hudson River environs, reflecting both released congeners and other congeners associated with metabolism (Echols et al., 2004; Nichols et al., 2004). As such, there are dynamics in

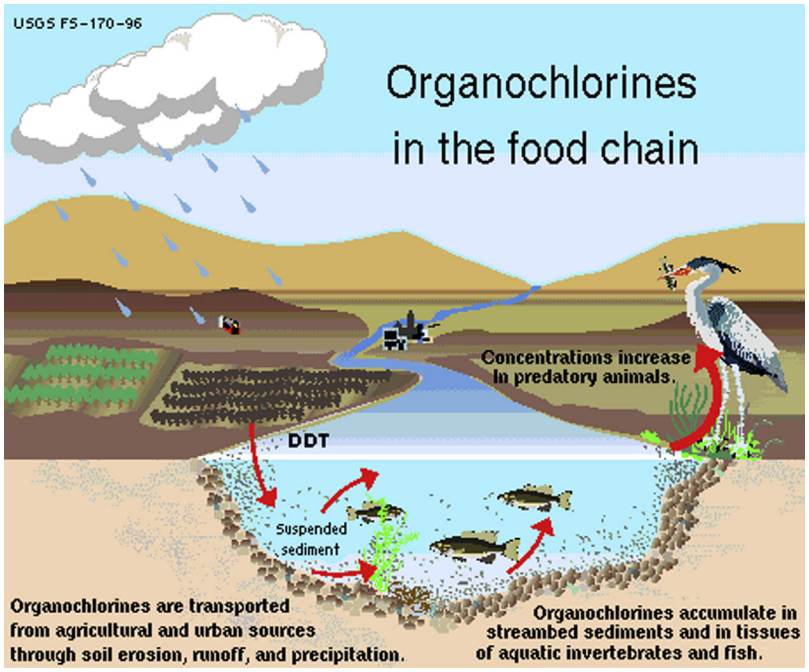

FIGURE 41.2 The life-cycle of DDT in the environment, from application on fields, transport to aquatic environments, and uptake by invertebrates and fish that are eaten by vertebrates higher on the food chain.

the environment including rainfall events as well as climate change that will impact the movement and potential for exposure across living organisms.

41.4 CLASSES OF EDCs

As the potential risk from EDCs became more apparent, the Environmental Protection Agency formed a federal advisory committee, the EDSTAC in 1996 and charged the members to carefully consider the issue of EDCs and to recommend appropriate regulatory measures (see http://www.epa.gov/endo/pubs/edspoverview/edstac.htm). Over two years, the EDSTAC members considered the complexities of potential and recognized EDCs, and risks to vertebrate and invertebrate organisms, and recommended a series of testing paradigms to be developed and verified (see http://www.epa.gov/endo/pubs/edspoverview/finalrpt.htm for the EDSTAC final report). These tests would include screening and testing, utilizing cell-based screens and bioassays sensitive to endocrine disruption of the reproductive and thyroid endocrine systems. The tests were separated into Tier 1 containing *in vitro* high throughput screens to allow rapid assessment and identification of endocrine active compounds and *in vivo* specific assays to target known EDC mechanisms of action (Table 41.1). The mechanisms of action considered in these Tier 1 tests focus on estrogenic, androgenic, or thyroid active compounds (Table 41.2). These Tier 1 assays are intended to precede more extensive Tier 2 assays that would serve as an in-depth test of risk for selected compounds that may be endocrine disrupting over the life-cycle. Tier 2 assays are multigenerational, including stages over the life-cycle and as such intended to capture periods of vulnerability to EDC effects. With the exception of the two-generation rat reproduction test, testing protocols are undergoing technical validation and refinement. Other two-generation tests under consideration include the medaka multigeneration test, Japanese quail two-generation test, mysid two-generation toxicity test, and larval amphibian growth and development test. All tests are being subjected to review by expert panels (FIFRA Science Advisory Panels) and have strengths and weaknesses that are being evaluated for reliable detection of EDCs of concern for regulatory oversight (Touart, 2004).

41.4.1 Categorizing Potential Endocrine Disruptors According to Structure and Function

Clearly, there are many factors to be considered in order to understand the passage of chemicals through the environment and to assess the potential for exposure to living organisms. Moreover, individuals are generally exposed to multiple environmental chemicals concurrently, and all living organisms carry some burden within their body. In order to deal with the potential for an estimated 80,000+ chemicals to be endocrine active, there have been attempts to organize potential and proven EDCs into classes of chemicals; chemicals have been grouped by mechanism of action, physiological target, and relative activity including capacity for toxicity. These groupings are based on structure–function relationships, and when available, on experimental findings in the

TABLE 41.1 List of Assays Proposed by the Endocrine Screening and Testing Advisory Committee

Assays Recommended for Consideration for the Tier 1 Screening Battery	
Assay	**Reason for Inclusion**
Estrogen receptor binding or transcriptional activation assay	An *in vitro* test to detect chemicals that may affect the endocrine system by binding to the estrogen receptor.
Estrogen receptor transcriptional activation assay	An *in vitro* test to detect chemicals that may affect the endocrine system by binding to the estrogen receptor.
Androgen receptor binding assay	An *in vitro* test to detect chemicals that may affect the endocrine system by binding to the androgen receptor.
In vitro steroidogenesis assay	An *in vitro* test to detect chemicals that interfere with the synthesis of the sex steroid hormones.
Placental aromatase assay	An assay to detect interference with aromatase.
Uterotrophic assay	An *in vivo* assay to detect estrogenic chemicals.
Hershberger assay	An *in vivo* assay to detect androgenic and antiandrogenic chemicals.
Pubertal male assay	An *in vivo* assay to detect chemicals that act on androgen or through the hypothalamic-pituitary-gonadal (HPG) axis that controls the estrogen and androgen hormone systems. It is also enhanced to detect chemicals that interfere with the thyroid system. This assay could in part substitute for the female pubertal assay.
Pubertal female assay	An *in vivo* assay to detect chemicals that act on estrogen or through the HPG axis that controls the estrogen and androgen hormone systems. It is also enhanced to detect chemicals that interfere with the thyroid system.
Amphibian metamorphosis assay	An *in vivo* assay for detection of chemicals that interfere with the thyroid hormone system.
Fish screening assay	An *in vivo* assay for detection chemicals that interfere with the HPG axes.

From EPA publication October 21, 2009; Tier 1 Screening Battery; http://www.epa.gov/endo/pubs/assayvalidation/tier1battery.htm.

literature for a specific or similar compound (Le Page et al., 2011; Newbold et al., 2008; Safe et al., 1998; Watanabe et al., 2002; Zacharewski, 1998; Foster, 1998; Kavlock and Ankley, 1996). A great deal of emphasis has gone into understanding the actions of estrogen active or xenoestrogens, because much of the initial recognition of endocrine-disrupting activities emerged from estrogenic effects of environmental chemicals. However, it has become clear that many compounds and mixtures are androgen active, either having androgen-like activity or antiandrogenic actions. In addition, many compounds including polybrominated biphenyls (PBDEs) and PCBs have thyroid-axis activities, with several physiological targets. Finally, there is increasing recognition of a wide range of other actions due to EDCs, which include impacts on the stress axis, growth factors modulating development of organs and organ systems, epigenetic actions associated with alterations at the genetic level, and lifetime effects on immune function and metabolism. At this time, most EDCs are considered as estrogenic, androgen active, or thyroid modulators. There are data emerging that also show EDC effects via other mechanisms on the stress axis and growth factors, and exerting epigenetic effects. Therefore, it will be critical to continue to modify testing methods to detect endocrine disruption as more data become available that provide insights into the varied actions of these compounds.

Analysis of the chemical structure of a compound provides valuable insight into the potential actions and physiological targets. In the case of PCBs, there is increasing toxicity associated with the number and molecular placement of chlorine atoms. Extremely toxic compounds such as dioxins provide a "yardstick" for comparison of toxic effects from other toxicants. As pointed out earlier, it is challenging to discern frank toxicity from endocrine disruption. Therefore, it has become important to utilize approaches, such as Adverse Outcomes Pathway (AOP; see below) that describe the suite of effects associated with exposure to a compound or mixture. Because the presumed targets of EDCs have been the reproductive axis and more specifically via interaction with steroid hormone

receptors, many of the strategies for high-throughput screening have utilized cell-based systems that detect interactions with these steroids (Fisher, 2004; Hartig et al., 2002; Kase et al., 2009; Kusk et al., 2011; D'Ursi et al., 2005). However, these *in vitro* approaches must be integrated with information about physiological and toxicological effects. As a consequence, computer-based predictive models have been developed that provide a rapid method for ascertaining potential endocrine activity based on structure–function and known mechanisms of action (Wambaugh et al., 2013; Knudsen et al., 2013; Kavlock et al., 2012; Martin et al., 2009; Dix et al., 2007). As more information becomes available, these approaches provide a powerful technique for assessing the potential for emerging chemicals to be endocrine disruptors.

41.4.2 General Mechanisms of Action of EDCs in Vertebrates

In addition to the development of extensive databases and mechanism-based models, a number of investigations have explored the mechanisms of endocrine-disrupting activity (Stoker et al., 2000; Zacharewski, 1998; Watanabe et al., 2002; Le Page et al., 2011; Janer et al., 2005; Gore, 2010; Harvey and Everett, 2006). Findings have revealed that EDCs can be endocrine active; however, the primary targets are not as clear. A number of EDCs that are estrogen mimics interact with estradiol receptors and/or with estrogen-responsive systems as agonists or antagonists (Watson et al., 2013; Hall and Korach, 2002; Marino et al., 2012). Conversely, androgen-active compounds are now gaining more attention, with DDE, trenbolone, and other EDCs acting as potent EDCs on endocrine systems (Hartig et al., 2007; Manikkam et al., 2013; Soto and Sonnenschein, 2010; Guerrero-Bosagna and Skinner, 2009; Prins, 2008; Skinner, 2007; Maffini et al., 2006; Bigsby et al., 1999; Santti et al., 1998). Many of the assays developed have taken advantage of the mechanisms revealed by these studies, for example the vitellogenic effects of EDCs in fish (Wang et al., 2011; Larkin et al., 2002). It is also important to recognize that there are a number of additional effects of EDCs, some of

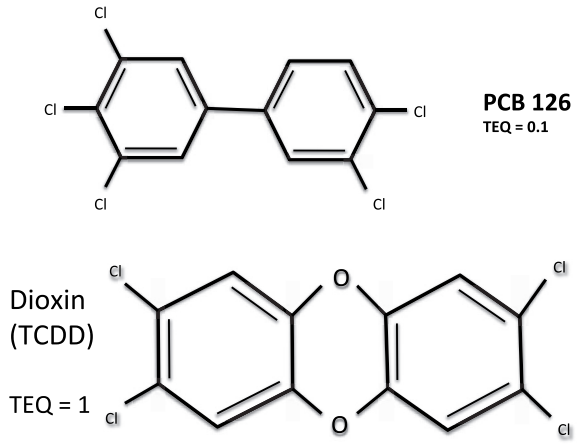

FIGURE 41.3 Structures of polychlorinated biphenyl 126 (PCB 126) with a toxic equivalency quotient (TEQ) of 0.1 compared to dioxin with a TEQ of 1.

which may be due to direct toxicological effects of these compounds in addition to endocrine effects (Fucic et al., 2012; Carro et al., 2013a,b; Quinn et al., 2007b). In some cases, induction of cancer in reproductive organs has also been linked to EDC exposure, especially during vulnerable life stages such as embryonic development (Ohlson and Hardell, 2000; Fucic et al., 2012).

There is an extensive literature now available that clearly demonstrates the interaction of EDCs with steroid hormone receptors, particularly those specific for estrogens, androgens, and thyroid hormones (Kusk et al., 2011; Zhang and Trudeau, 2006; Masuyama et al., 2002). This literature show similar mechanisms of action in birds compared to other classes of organisms, including mammals. However, the outcomes from exposures may differ widely, as will be reviewed in later sections of this chapter. Interactions with receptors depend on the structural characteristics of the EDC. In the case of polychlorinated biphenyls (PCBs), the toxicity and relative effect relates to the number and location of chlorine molecules on the ring structure (Figure 41.3) (Fischer et al., 1998; Hennig et al., 2002). Primary effects of EDCs rely on the ability to interact with steroid or thyroid hormone receptors, which then exert competitive inhibition or antagonistic effects or in some cases may be agonistic and stimulate the system. The up or down-regulation of cellular processes via interaction with these receptors then has the capacity to alter a host of physiological functions that are modulated through steroid hormone or thyroid hormones. Although less is known about the potential for EDCs to act on the stress axis, a stressed individual would be predicted to be more vulnerable to other insults such as those from EDC exposure (Fairbrother et al., 2004; Fernie et al., 2005a; Grasman, 2002; Grasman et al., 1998; Franceschini et al., 2008). Data are emerging that demonstrate effects of EDCs on multiple growth and differentiation factors, which in turn affect the ontogeny of that organ system as well as impact function in the mature individual (Thackaberry et al., 2005; Walker and Catron, 2000; Head et al., 2008). For example, effects of EDCs on the ryanodine receptor have been shown to impact calcium signaling, which in turn alters neural function, neurodevelopment, and neurodegenerative processes (Pessah et al., 2010). EDCs have the potential to affect immune function both short- and long-term in individuals and can be especially potent if there are other environmental stressors (Schug et al., 2011; Ottinger et al., 2005a; Quinn et al., 2007b; Lavoie et al., 2010). At a more cellular level, dioxins and other EDCs have been shown to affect oxidative damage processes, with potential to impact mitochondrial function (Pereira et al., 2013).

41.4.3 Predicting Risk: Adverse Outcomes Pathways

A number of approaches have been developed to conceptualize the myriad effects associated with endocrine disruption, with the overall intent to span molecular and cellular effects to the whole organism and eventual population-level impacts (Figure 41.4). A comprehensive approach has been developed and termed Adverse Outcomes Pathways (AOP). This approach has been conceptualized as well as applied to aquatic species (Lalone et al., 2013; Villeneuve et al., 2013; Ankley et al., 2010; Currie et al., 2005). Subsequent studies will utilize this and other approaches to establish probable outcomes with exposure to EDCs and model the potential for population level effects. In addition, it will be critical to integrate data collected from these and future studies to further refine the mechanisms that are responsible for both short- and long-term impacts upon individuals and potentially for wildlife and human populations (Ottinger et al., 2013; Villeneuve et al., 2013; Zawatski and Lee, 2013).

41.4.4 Predicting Impact: Toxic Equivalency Factor and Toxic Equivalence Quotient

There is a large body of literature on the role of the aryl hydrocarbon receptor (AhR) in response to exposure to toxicants. The signaling pathway showing activation of the AhR by dioxin or dioxin-like compounds involves interaction of an EDC with the AhR, which then binds to Hsp 90 followed by translocation into the nucleus. After dimerization, the aryl hydrocarbon nuclear translocator complex binds to the xenobiotic response element on the DNA with transcription of mRNA for translation into CYP proteins (Figure 41.5). As this is a well-characterized response to dioxin-like compounds, an accepted method for assessing the potential activity of a toxicant utilizes the relative activation of the AhR toxicological measure for environmental chemicals, the toxic equivalency factor (TEF), and the

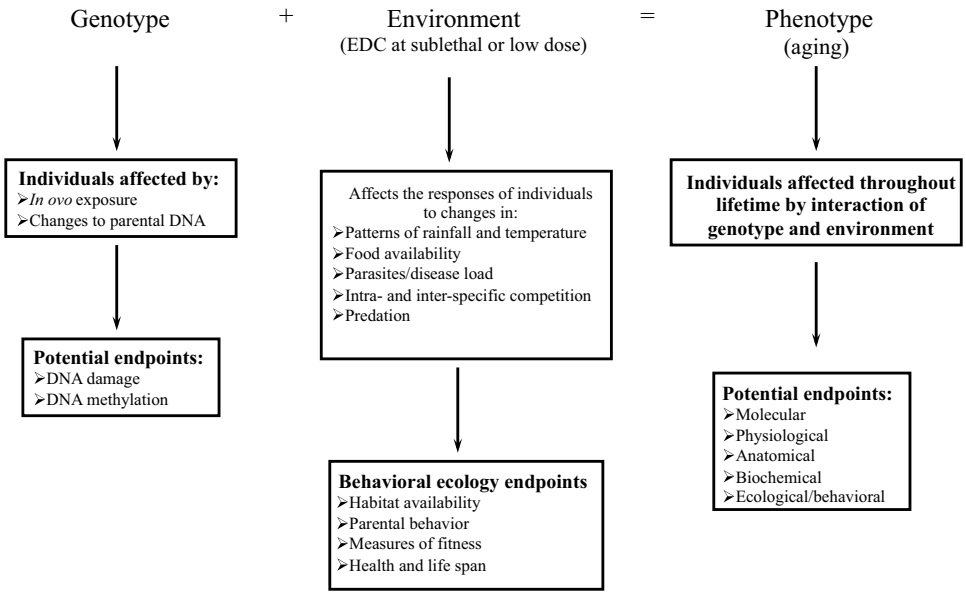

FIGURE 41.4 **Conceptual range of effects of EDCs range from effects on individuals relative to altered gene expression.**

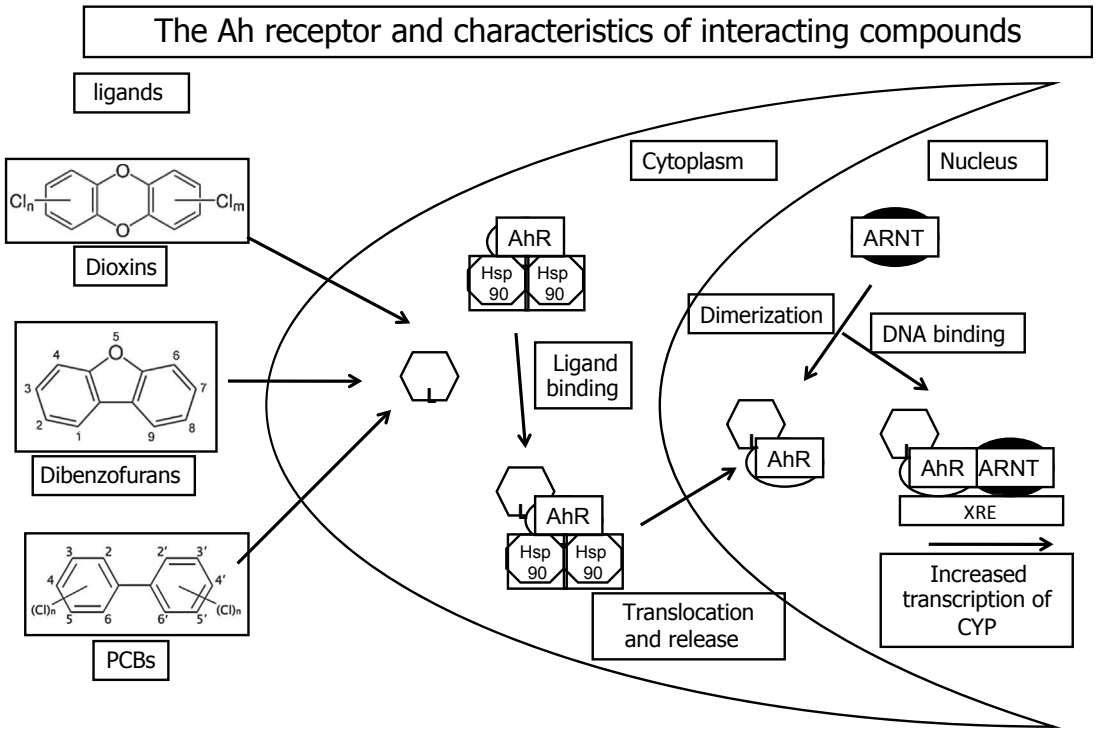

FIGURE 41.5 Aryl hydrocarbon receptor (AhR) signaling pathway is comprised of interaction of EDCs with affinity to AhR, translocation of the complex to the nucleus, dimerization, and binding of the aryl hydrocarbon nuclear translocator complex to the xenobiotic response element on the DNA, ultimately leading to increased transcription of CYP mRNA for translation to CYP enzymes.

added toxicity potential for a mixture or compound that is termed the toxic equivalency quotient (TEQ). This measure utilizes the literature and other information derived from functional similarities to compare toxicity against dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD)) (Van Den Berg et al., 2013). In birds as well as other vertebrates, a range of adverse physiological outcomes have been documented with exposure to dioxin (Hervé et al., 2010; Hsu et al., 2007; Kuil et al., 1998; Watanabe et al., 2009). There has been a series of studies that have focused on the relative sensitivity and response to a range of EDCs using activation of the AhR as a relative measure among

avian species (Head et al., 2008). These studies have demonstrated a wide variation in the vulnerability of avian species to toxicants, with molecular differences at the level of the AhR structure and function (Farmahin et al., 2012; Karchner et al., 2006; Manning et al., 2012; Zhang et al., 2013). It is clear that as in mammals, EDCs can exert wide-ranging effects on endocrine processes in birds, with the potential for lifetime effects that will impact fitness of the individual and ultimately have a potential population-level impact.

41.4.5 Why are Birds Unique?

As will be discussed in more detail below, avian species have specific attributes that distinguish them from other vertebrate classes (Table 41.3). These characteristics underpin observed differences in vulnerability to EDCs and contribute to the unique responses observed in birds compared to other vertebrate classes. A distinctive feature of avian biology is the higher body temperature, which is 105 °F. As in many other vertebrate classes, there is a large range of reproductive strategies and habitats utilized across avian species. In addition, many birds migrate seasonally often over long distances. In seasonally breeding birds, the gonads regress and reproductive function ceases; thereby allowing reducing weight and concentrating energy utilization on migration. There are documented seasonal changes in metabolism that also relate to energetics, exposure to environmental chemicals, and endocrine modulators (Broggi et al., 2003; Hallanger et al., 2011; Hurlbert and Haskell, 2003; Majewski et al., 2005; Wilson and Reinert, 1999). There is a differential pattern in the development of the thyroid and metabolic regulatory systems in altricial and precocial birds; precocial birds have a relatively functional hypothalamic–pituitary–gonadal axis at hatch (Mcnabb, 2007; Mcnabb and Fox, 2003; Wada et al., 2009; Webb and Mcnabb, 2008; Wilson and Reinert, 1999). Further, both seasonality and exposure to environmental contaminants alter thyroid hormone system responses (Mcnabb, 2005; Nost et al., 2012; Ross et al., 2011; Webb and Mcnabb, 2008; Wilson and Reinert, 1999). Birds also differ from other vertebrate classes in the endocrine and neural mechanisms involved in sexual differentiation. Moreover, mature females have only one functional ovary. Many of these characteristics, including breeding characteristics, neural mechanisms, and lifetime impacts, will be discussed below.

TABLE 41.3 Unique Characteristics of Avian Species that Influence Response to EDCs

- Growth and metabolism
  - High body temperature (105 °F) with high metabolic rate
  - Rapid growth rate
  - Seasonal metabolic changes associated with migration
  - Seasonal shift in mobilization of lipid reserves
  - Differential developmental patterns in altricial versus precocial birds
  - Thyroid system critical for pre-migratory fattening
- Reproductive system
  - Female has one functional ovary
  - Altered gonadal differentiation results in ovotestes
- Hormones and behavior
  - Males adversely impacted by xenoestrogens and androgenic compounds
  - Females less sensitive to xenoestrogens
- Sexual differentiation
  - Males are the homogametic sex (ZZ); females (ZW)
  - HPG axis relies on relative exposure to estradiol and testosterone
    - Males experience relatively higher exposure to testosterone
    - Females experience relatively higher exposure to estradiol
  - Song system differentiation occurs in passerines with potential role of steroids
- Lifespan
  - Long-lived birds produce few offspring annually over many years.

41.4.6 Discerning EDC Impacts in Field Birds

Much of the documentation for effects of toxicants that affect wild populations of birds has been associated with spills and critical exposures that resulted in the death of a number of individuals. Conversely, it is often difficult to detect nonlethal effects in wild populations due to the lack data for individuals and the difficulty in tracking birds, especially through migration. There are large datasets on wild birds from the USGS (United States Geological Service) Bird Banding lab and from annual surveys species and individual counts. However, there are few consolidated reports that begin to bring together potential long-term effects of exposure to environmental chemicals, especially those that are endocrine disruptors, because the effects may be subtle and occur over an individual's lifetime. As such, it is a challenge to develop reliable and sensitive measurement endpoints that can serve as indices of exposure in birds. Inherent in the selection of endpoints to be used as bioindicators is having an understanding of the association of an adverse impact on the individual and risk to populations as a whole. Exposure to steroid hormones or EDCs disrupt embryonic development including organ development, sexual differentiation, reproduction and immune function, reproductive behavior, and metabolic processes (Best et al., 2010; Berg et al., 1999; Darnerud, 2003; Ottinger et al., 2005a,b; Fernie et al., 2005a; Franceschini et al., 2008; Fox and Grasman, 1999). Biomedical and epidemiological data reveal clear linkages between EDC exposure, particularly early events and later disease or even epigenetic effects. In addition to biomedical data, field studies have correlated EDC exposure to immunosuppression in a number of taxa

demonstrating that the effects of these compounds have conserved mechanisms and impact across a range of species, including invertebrates. Laboratory studies have been successful in establishing clear effects of various classes of EDCs on a number of physiological systems (Berg et al., 1998; Halldin et al., 2005). Because many early EDCs of concern such as methoxychlor, dioxin, and some polychlorinated biphenyls (PCBs) have estrogenic activity, attention focused on reproductive impact of these compounds in comparison to estradiol. However, at any one time, wildlife species are actually exposed to many different types of EDCs (e.g., androgenic, thyroid active) as well as other toxicants often with potentially different mechanisms of action (e.g., metals) (Levengood et al., 2007; Hotchkiss et al., 2008). As a result, it has been difficult to develop comprehensive risk-assessment models. Furthermore as mentioned above, some EDCs such as DDE are androgen receptor (AR) blockers, whereas other compounds such as trenbolone are androgenic (Mura et al., 2009; Panzica et al., 2007; Quinn et al., 2007a; Quinn et al., 2008). As in mammals, EDCs are physiologically active on a variety of pathways, including not only steroid-sensitive pathways but also pathways involving thyroid, metabolic, stress, and immune systems (Head et al., 2008; Fairbrother et al., 2004; Fernie et al., 2005a; Fox and Grasman, 1999; Mcnabb and Fox, 2003; Kavlock and Ankley, 1996; Knudsen et al., 2009). Therefore, use of the AOP (Hotchkiss et al., 2008) is an important tool for conceptualizing effects of EDCs including fundamental actions and molecular targets underpinning effects on the organism and population-level impacts.

Much of the available documentation on wild birds is from cases of highly concentrated exposures associated with toxicants originating from chemical applications and industrial spills. Often these occurrences are associated with high mortality; thereby prompting federal and regional responses aimed at protecting human and wildlife health. However, less is known about nonlethal impacts of EDCs on wild birds and the potential for adverse effects translating even to the level of a risk to the population. There are extensively documented cases, such as incidences of avian impacts from the Great Lakes, PCBs released into the Housatonic and Hudson Rivers, and high concentrations of munitions and other contaminants that indicate impacts on birds (Custer et al., 2010a, 2012a,b; Custer and Read, 2006; Custer et al., 2010d; Franceschini et al., 2008; Levengood et al., 2007). Data collected from some extraordinary datasets contain long-term monitoring and research programs, including the Great Lakes region and many of these studies have considered physiological and reproductive impacts of exposure to chemicals found in those areas. Laboratory studies provide the controlled conditions to filter out some of the myriad confounding factors challenging field birds, thereby allowing us to discern potential mechanisms of action of EDCs as well as periods of sensitivity throughout the life-cycle. Information from both types of studies is critical to conduct informed risk analysis for specific chemicals. Furthermore, it is important to consider unique characteristics of the avian physiology with emphasis on sexual differentiation, hormonal modulation of endocrine and behavioral components of reproduction, and functional impacts of EDCs on neuroendocrine regulatory systems, especially considering potential adverse outcomes.

Further, EDCs in the environment seldom often appear in combination and exert their actions the background of endogenous steroids. As such, EDCs may interfere with endogenous processes critical for sexual differentiation, maturation, breeding, and parental behavior. It is against this backdrop that exogenous EDCs act, with variations in specific mechanism(s) of action and targets for a particular compound. Although much of the emphasis of EDC studies has been on the reproductive axis, it is clear that the thyroid, immune, and stress axes are also potential targets of endocrine disruption. Toxicological effects are also observed with many of the EDCs, and some measures of activation of the liver detoxification processes, such as ethoxyresorufin-*O*-deethylase (EROD) activity, are excellent indicators of exposure. Elegant studies have also shown that subtle differences in the sequence of the aryl hydrocarbon receptor contribute to observed variations in the sensitivity of wild birds species to EDCs (Head et al., 2008; Head and Kennedy, 2007a,b). Finally, behavior is a sensitive measure, and more work is needed to establish methods to assess behavioral impairment related to EDC exposure. It is known from laboratory studies that EDCs do impair male sexual behavior in male quail and that diminished behavioral responses often parallel effects on other physiological responses (Mura et al., 2009; Ottinger et al., 2013; Panzica et al., 2007). Behavioral measures also provide useful indicators of effects, including sensory deficits, stress responses, and impaired reproductive function. Finally, behavioral measures may prove to be very revealing in songbirds in which the neural circuitry is steroid dependent and in distinguishing EDC effects on altricial versus precocial birds.

41.4.6.1 Altricial versus Precocial Birds: Developmental Patterns and Vulnerable Stages

Avian species rely on genetically based sexual differentiation with well-characterized developmental events occurring during ontogeny for both precocial and altricial birds. The genetic basis for gender is reversed from that of mammals in that the male is the homozygotic sex (ZZ) and the female is the heterozygotic (ZW). Two developmental strategies occur in birds; altricial chicks require extensive parental care whereas precocial chicks are well developed at hatch. The song system is steroid dependent, with elements that are sexually differentiated primarily post-hatch, and remains plastic throughout the life-cycle, showing

seasonal regression and hormone-induced seasonal neurogenesis (Adkins-Regan and Watson, 1990; Adkins-Regan et al., 1990; Adkins-Regan and Ascenzi, 1990; Wade and Arnold, 2004; Fusani and Gahr, 2006; Ball and Balthazart, 2010). This neuroplasticity contributes to an apparent lifelong vulnerability yet potential resilience to EDC exposure (Iwaniuk et al., 2006; Rochester et al., 2010; Rochester and Millam, 2009). Adverse effects of EDCs have also been observed in finches and the dark-eyed junco (Hoogesteijn et al., 2008; Satre et al., 2009).

Precocial birds have often been the subject for toxicological studies and regulatory testing, such as Japanese quail (*C. japonica)*, which are well developed at hatch, with sexual differentiation of the reproductive endocrine system and functional competency of other physiological systems already relatively complete (Adkins-Regan, 2009; Balthazart et al., 2009; Ottinger et al., 2005b; Ottinger and Dean, 2011). These studies have shown that the male Japanese quail is exquisitely sensitive to exogenous steroids, with both estradiol and androgen treatments resulting in impaired male reproductive behavior. As such, estradiol is very useful as a positive control and as a means of comparison for the relative activity of EDCs with varying impacts on endocrine, neural, and behavioral components of reproduction (Berg et al., 2001; Halldin et al., 1999; Berg et al., 1998; Adkins-Regan and Watson, 1990; Panzica et al., 2007). Japanese quail have a 17 day incubation period, and during development, each level of the reproductive (hypothalamic–pitutitary–gonadal; HPG) axis develops and begins to function as early as embryonic day 5 (gonadal differentiation), embryonic days 12–14 (hypothalamus and pituitary gland), and later in embryonic development (accessory structures). Gonadal function is initiated as early as embryonic day 5, with differential patterns of circulating steroid hormones in males and females (Figure 41.6). Estradiol is a critical element in sexual differentiation in quail. During embryonic development, females have relative high concentrations of estradiol/androgen whereas males have a relative low estradiol/androgen ratio. Moreover, there are sex-related differences in the patterns of plasma steroid levels during embryonic development. In female embryos, plasma E_2 rose until hatch and decreased post-hatch (Ottinger et al., 2008, 2005a). In males, plasma androgen peaked at embryonic days 14–17 (E14–E17), during the 17 day incubation period, and declined post-hatch. In addition, yolk steroid hormone content reflects embryonic steroid hormone levels. These steroid hormones are present and available to the embryo during sexual differentiation of multiple organ and endocrine systems throughout incubation. Once the embryonic gonads and adrenal glands begin to produce steroid hormones, circulating concentrations rise to make the gender-related pattern in changes more evident, especially during the last half of embryonic development. Both genders experience increased steroid hormones after embryonic days 10–12 in males and embryonic days 10–16 in females. Sexual differentiation of endocrine and behavioral components of reproduction occur during this time, organizing the HPG axis and gender-specific behaviors (Adkins-Regan and Watson, 1990; Ottinger et al., 2005a). There is a large literature that links steroid hormones, brain regions that modulate reproductive behavior, onset of reproduction during maturation, and adult reproductive function. The primary hypothalamic hormone that regulates the HPG axis is gonadotropin releasing hormone-I (GnRH-I), which is produced by the cell bodies located in the preoptic-septal region of the hypothalamus. Hypothalamic GnRH-I levels rise between embryonic days 10–15; followed by a sharp drop that appears associated with activation of the function of the HPG axis and feedback regulation of GnRH-I (Li et al., 1991). Both the endocrine and behavioral components of reproduction in Japanese quail are sexually differentiated during embryonic development.

In concert with the changing steroid hormones during embryonic development, the adrenal axis and the thyroid axis develop and achieve function. Circulating concentrations of adrenal and thyroid hormones rise during embryogenesis to peak at about the time of hatching in precocial birds, with a slight delay in this pattern for altricial birds. Additionally, the steroid hormones circulating during embryonic development also impact the immune system, with circulating testosterone in males inducing regression in the bursal tissue in males (Grasman, 2010; Lavoie et al., 2007; Lavoie and Grasman, 2007). Clear effects of EDCs have been observed for the immune system, especially for

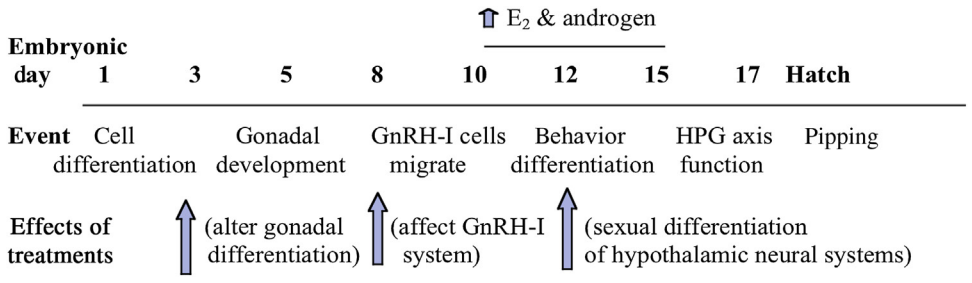

FIGURE 41.6 Stages in embryonic development. Diagram shows timing of developmental events during embryogenesis with indications of endogenous endocrine change and potential periods of vulnerability.

the response of the bursa, which is exquisitely sensitive to steroid hormones during embryonic development. Additionally, it has been well documented that the thyroid axis is also a primary target for many EDCs, including PCBs, flame retardants, and other compounds. Effects of EDCs exerted during embryonic development may also impair the thyroid axis, which is critical for hatching as well as overall metabolic function (Mcnabb and Fox, 2003).

Maternal deposition of steroids and EDCs into the egg. A primary mode of exposure to the avian embryo is from maternal deposition of steroids and EDCs into the egg. There is increasing recognition of the important role of maternally deposited steroid hormones, as well as corticosterone and thyroid hormones (Almasi et al., 2012a,b; Hayward and Wingfield, 2004). Mounting data point to both direct and epigenetic effects of maternally deposited hormones, which vary according to the condition of the female, health, reproductive status, and stressors. These steroids can affect viability as well as developmental characteristics of the chicks (Lipar et al., 1999; Schwabl, 1993,1996a,b). Deposition of EDCs is layered on top of these endogenously produced hormones from the hen. Moreover, most maternally transferred compounds and EDCs are lipid soluble, thereby deposited primarily into the egg yolk; whereas, water soluble compounds such as atrazine may be more evenly distributed throughout the egg compartments. There is significant deposition of EDCs into the eggs of field birds (Custer et al., 2010a,b,c,d). Similarly, laboratory studies have demonstrated that EDCs, including exogenous estradiol, methoxychlor, and soy phytoestrogens (see Figure 41.7 for phytoestrogens), all readily transfer from the hen into the egg and partition in the egg compartment according to lipid solubility (Lin et al., 2004; Ottinger et al., 2005b).

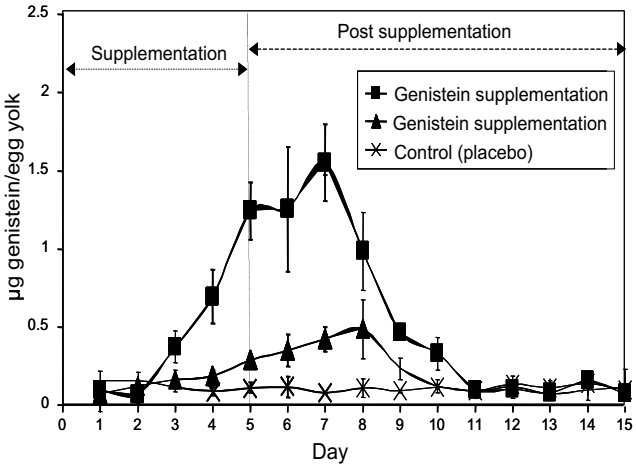

FIGURE 41.7 Maternal deposition of the phytoestrogen, genistein by the quail hen into eggs. Concentrations of Genistein in Japanese Quail egg yolks supplemented with genistein (aglycone), genistin (glucoside) or placebo capsules. Data points represent average of 4 replicates for treatment groups and 2 replicates for the control group. *Modified from Lin et al. (2004).*

Post-hatch growth and maturation are periods that are vulnerable to interference from EDCs. Steroid hormones continue to decline from the late embryonic and post-hatch levels associated with sexual differentiation to remain at low quiescent concentrations until the onset of sexual maturation. During sexual maturation, reproductive endocrine and behavioral responses are initiated earlier in males, so that they mature by 6–8 weeks of age (Ottinger and Brinkley, 1979, 1978). Females begin to mature slightly later than males, with onset of egg production by 8–10 weeks of age. This dimorphism is reflected in hypothalamic GnRH-I levels, which increase in males earlier than females (Ottinger et al., 2004). Organizational effects of steroids in quail are also reflected morphologically in the sexually dimorphic preoptic region of the quail, which is larger in males and testosterone sensitive in the adult; high levels of aromatase metabolize testosterone to estradiol, which is essential for sexual behavior. Because this area in known to be important in modulating courtship and mating behavior, a number of studies have focused on the neural systems contained in this area in Japanese quail; this area is potentially vulnerable to the effects of EDCs (Panzica et al., 2007). In addition, the preoptic-septal region (POA-SL) contains many of the gonadotropin releasing hormone (GnRH) cell bodies; these cells project to the median eminence of the hypothalamus, making the POA-SL critical in the regulation of both endocrine and behavioral components of reproduction. All these characteristics of the HPG axis and sexually dimorphic neuroendocrine systems are vulnerable to EDC exposure, especially during organization of the reproductive axis during embryonic sexual differentiation.

41.4.7 Developing Testing Paradigms to Reveal Endocrine Disruption in Birds

41.4.7.1 Investigating EDCs in an Avian Model: The Japanese Quail Two-Generation Test

Laboratory tests provide important information about EDC actions and impacts in birds and have used several experimental approaches. Most studies on the actions of steroid hormones have used egg injection, with treatment with known concentrations in order to understand the role of steroids in ontogeny and sexual differentiation. Many of the studies on EDC effects have used a similar approach, and these studies have been conducted in domestic chick embryos, mallard duck, and Japanese quail. The U.S. EPA oversees the safety of chemicals in use by industry, agricultural practices, recreational application, and individual residences. The Japanese quail two-generation test (JQTT) is under consideration to provide a multigenerational test to assess the impacts of EDCs on all life stages, both separately and as a continuum. Current testing for registration of chemicals may require Ecological Effects Studies, including

Avian Acute Oral Toxicity, Avian Subacute Dietary Toxicity, Avian Reproduction, or Simulated or Actual Field Testing (http://www.epa.gov/oppefed1/ecorisk_ders/toera_analysis_eco.htm) to ascertain safety for birds. These tests are conducted on a variety of species according to the test and are conducted in tandem with tests in other vertebrate and invertebrate species.

As discussed in the introduction to this chapter, EDCs may be difficult to detect, especially their nonlethal effects that have more subtle and long-term impacts on organisms. As a result, a series of testing protocols has been developed to address potential effects on vertebrates and invertebrates over the life-cycle. These two-generation testing protocols consider a range of measurement endpoints to assess effects and potential risks to selected organisms. In birds, there is consideration of a multigeneration test using Japanese quail, which contains each primary phase in the life-cycle with isolated exposure at that phase as well as cumulative exposure over the multiple life stages. Initial exposure in the current testing protocol occurs in proven breeders followed by continuous exposure to F1 offspring to evaluation of their F2 offspring as the final step in the testing protocol. As will be described below, there are a number of measures considered to assess health, toxicity effects, and endocrine disruption. The general list of measurement endpoints include measures of health and overt toxicity (food consumption, body weights, secondary sex characteristics, activity, chick health, growth and maturation, lethargy, morbidity or other clinical signs of toxicity, mortality); reproductive measures (sexual differentiation, sexual maturation, egg production, egg quality, fertility, embryo death, hatchability, chick survival and condition, sex ratio, reproductive behavior and reproductive hormones, testes histology and sperm counts, cloacal gland size and foam); endocrine and physiological endpoints (weight and histology of liver, testes, thyroid, adrenals, gonads, and brain, fecal steroid hormones, serum hormones and vitellogenin, glandular thyroid hormone). The reasoning for use of these endpoints in assessing EDCs is briefly discussed below to provide a more complete overview of the response of the endocrine and physiological systems to EDCs.

41.4.8 Pertinent Endpoints for Assessing Potential Endocrine Disruption

The selection of endpoints depends on the dosing regimen (i.e., amount of compound administered and the timing of administration), projected dose–response, the window of exposure (i.e., life-stage), projected mechanisms of action, potential endocrine activity or induction of vitellogenin or other biochemical responses, and mode of exposure; these are all critical variables in evaluating potential EDCs. As more information becomes available on EDC actions, it will be possible to use the structure proposed in the framework offered by the AOP to elucidate both the targeted physiological systems vulnerable to a chemical/chemical class and the potential for significant impacts to avian species. This approach is not currently integrated into the testing paradigm, but may prove useful for providing structure to interpreting the observations and findings. For example, the developing embryo is much more sensitive to the effects of EDCs than the adult, and developmental defects (i.e., permanent central and peripheral disruption) often persist into maturation and adult life stages. Conversely, adult exposure does not generally have as much impact or effects appear to be more transient, especially in precocial species. Advances in our understanding of molecular mechanisms have revealed that EDCs often exert epigenetic effects. This has changed our understanding of both the activational and organizational effects of EDCs, allowing for the possibility that exposure can cause lasting effects in multiple generations (Skinner et al., 2011; Hochberg et al., 2011). Therefore, it is extremely important to understand the physiology of the model (i.e., Japanese quail) and the species-specific endocrine mechanisms behind the selection of endpoints.

41.4.8.1 Survival

Survival is a basic endpoint for acute and chronic toxicity testing of compounds. Determining the median lethal dose that will kill 50% of the population being tested (LD50) is an important value for traditional toxicology studies. In dietary studies, survival must be monitored in order to assess health effects. In the context of endocrine disruption studies, it is unlikely that the doses will approach lethal concentrations because circulating concentrations of endogenous hormones are in the pico- or femtograms. Nonetheless, sublethal treatments are important in ascertaining potential risk from endocrine disruption. For example, 50 μg/kg/day of BPA has been determined to be a safe exposure by classic toxicology testing (Myers et al., 2009). However doses 100 to 1000 times lower than that have been shown to induce feminization of the gonads in Japanese quail, with no changes in survivability among groups (Oshima et al., 2012). Monitoring survival provides toxicological information and this important measure has not been generally reported in basic studies focused on understanding mechanisms. As such, the literature has a critical gap that ignores potential individual variability in response and the range of responses across a population including survivor effects.

41.4.8.2 Food Consumption and Body Weight

Food consumption is a basic measure of the general health; changes in food intake can indicate acute or chronic toxic effects of a compound. Additionally, if the route of chemical exposure is through the feed, it is important to monitor the consumption carefully to determine the exact exposure. It is also important to measure the stability of treatment

compounds. Reduced food consumption has been associated with EDC exposure in Japanese quail (Yamashita et al., 2011). Similarly, body weight is closely linked with food intake and overall health and can be indicative of toxicological effects. For example, perchlorate, a thyroid hormone system disruptor, significantly reduced the growth (measured in body mass) of zebra finches dosed for the first two weeks of life (Rainwater et al., 2008). These birds also exhibited altered begging and fledging behaviors indicating that other endpoints may be linked to altered body weight, depending on the mechanism of disruption.

41.4.8.3 Accessory Sex Characteristics and Sexual Maturation

A number of secondary sex characteristics are gender-specific and provide excellent hormone-dependent response indices. Plumage differs in males and females; these sexual dimorphisms first appear as early as three weeks of age. Ultimately, the male has a rust-hued chest, which is even in color; females have a buff-colored chest with small dark areas in a dappled pattern. In general, feather color, especially in more brightly colored species such as bluebirds, depends on dietary carotenoids as well as being related to overall health. In addition, males often have sexually dimorphic characteristics that are testosterone dependent. In Japanese quail, the cloacal gland produces a glycoproteinaceous secretion, termed cloacal gland foam, that is critical for sperm transfer to the female (Ottinger and Brinkley, 1979). Measurements of the cloacal gland area have provided a reliable correlated measure for the sexual maturation and reproductive status of an individual male, and the foam produced can be estimated on a scale of 1–5 or a similar ordinal subjective measurement scale. Since Japanese quail are ground dwellers and males establish territories during breeding season, cloacal gland foam provides a marker delineating their territory; the foam has been called the "topping on the dropping" (Schleidt and Shalter, 1973). Monitoring the effects of EDCs on sexual maturation provides insight into the mechanisms of action. In males, monitoring for presence of cloacal gland foam in males provides an initial indicator of testicular activity and production of androgens. Further, depending on an EDC's action(s), there may be differential effects in males and females with males maturing slightly earlier than females. By 5–6 weeks of age, testicular activity initiates and begins to produce increasing concentrations of testosterone, leading to increasing expression of reproductive endocrine function, courtship and mating behavior, whereas females initiate egg production by 9–10 weeks of age.

41.4.8.4 Behavioral Indicators

Although the female Japanese quail exhibits a range of sex-specific behaviors, these behaviors are not readily quantifiable. Males and females both exhibit aggressive behavior, which can be quantified (Ramenofsky, 1985). Male courtship and mating behavior provide excellent bioindicators of reproductive competency. Sexual behaviors are steroid-hormone dependent; meaning that there must be sufficient circulating concentrations of androgens to enable the expression of male sexual behavior. Moreover, male sexual behavior is an exquisitely sensitive endpoint for embryonic exposure to estrogenic and highly active androgen-active compounds. A three minute test is conducted in which a receptive female (control diet female that is from the same population; non-experimental) is introduced into the male's home cage. Latency to mount, mount attempts, and cloacal contacts by the male are recorded. An individual may be tested on three successive days if it is important to determine the effects of experience on behavioral responses. Interpretation of the outcomes of behavioral testing relates to the potential mechanisms of action of compounds under testing. More specifically, the female quail requires exposure to estradiol during embryonic development and is masculinized by exposure to androgens between embryonic days 12–18. Conversely, males are demasculinized as evidenced by impaired male sexual behavior as adults, if they have been exposed to either estrogens or androgens during this critical period. As such, the male Japanese quail is exquisitely sensitive to exposure to EDCs during sexual differentiation.

41.4.8.5 Egg Production, Shell Quality, Fertility, and Embryo Viability

Egg production and onset of laying are important measures of reproductive function in birds, and are easily monitored by checking cages daily and marking eggs. EDC exposure has related to reduced egg production as well as delayed onset of egg production by acting on the gonads, gametes, or sperm-host glands, potentially resulting in decreased fertilization success. Similarly, the fertilized egg may not develop properly due to interference from an EDC and the embryo may not survive beyond the first few hours or days of development. During this time, the uptake of yolk (white and yellow yolk) is minimal and as such reflects primarily a toxic effect of a compound or specific effects impairing the function of homeobox genes and disruption of cellular lineages contributing to the formation of organ systems, such as in the case of heart effects (Carro et al., 2013b). Eggshell thickness, strength, and gross abnormalities can affect embryo viability. As early as the 1960s, exposure to DDT and DDE was linked to eggshell thinning and population decline in many wild bird species (Rattner, 2009).

Later embryonic effects and lethality are more likely to relate to disruption of essential physiological systems, such as impacting the thyroid endocrine axis and other systems

essential for the development and synchronization of endocrine and other physiological systems. It has also been shown that a combination of early and late embryo mortality is a stronger indicator of toxicity that either alone. Moreover, there are distinct strain differences in Japanese quail, and there is an extensive literature that deals with a variety of physiological responses in Japanese quail that have been selected for multiple generations (Blohowiak et al., 1984; Bursian et al., 1983; Marks, 1996; Marks and Siegel, 1980). The Japanese quail chick begins to pip at ED15 in preparation for hatching at ED17. Once pipped, the chick is able to vocalize and often there is synchronizing in hatching of chicks in proximity. Pipping is followed by the chick pecking a hole, similar to an escape hatch, and requires a great deal of energy. The hatching success of chicks has been shown to be highly sensitive to chemical perturbation, and thus hatchability is an important endpoint in EDC studies.

41.4.8.6 Histopathology

Many organ systems are highly sensitive to hormonal perturbations, particularly if exposed during development. This includes reproductive organ (i.e., testes/ovaries/oviduct) weight, gross disruption of organ morphology, and microscopic disruption (i.e., disrupted follicular function or spermatogenesis). Thyroid glands, liver, bursa, and other organs should be examined, depending on the projected target(s) for the EDC. Because sexual differentiation of the avian female involves regression of one of the two primordial ovaries with its accompanying oviduct, the presence/regression of the right ovary and oviduct provides initial information about appropriate sexual differentiation of the female reproductive axis. There are sperm-host glands in the oviduct of the avian female, in which sperm may reside for some weeks; however, there are no data available for a potential impact of EDCs on these glands. The ovary in the ovulating female showed multiple follicles in varied stages of recruitment and maturation. Histological analyses will provide information as to the status of ovarian function, and linking ovarian morphology to these components of ovarian function provides insight into potential EDC targets and actions. Early exposure to EDCs in males can impact gonadal development in a genetic male; however, there is less information about this type of long-term impact. In some studies, EDC exposure resulted in transient presence of ovotestes, which are found in the hatchling but generally do not persist into the adult. Liver histology can provide information on any abnormalities associated with toxic effects. In addition, the activation of detoxification enzymes are excellent markers for initiation of these enzyme systems; conduct of the ethoxyresorufin-*O*-deethylase (EROD) assay on liver subsamples can provide supporting evidence for histopathology findings.

There is a link between embryonic exposure to PCBs and cardiac malformations, and kidney histology can provide information about toxicological impacts of EDCs due to the critical role of the kidneys in detoxification and elimination of water-soluble toxicants. Pathophysiological measurements of the bursa provide a powerful tool to assess endocrine disruption affecting the immune system. The bursa of Fabricius is exquisitely sensitive to steroid hormones, especially during development, with testosterone having an immunosuppressive effect (Ottinger et al., 2005b). As shown in Table 41.4, embryonic exposure to trenbolone acetate resulted in persistent effects on bursal morphology with fewer, smaller follicles (Quinn et al., 2007b). Conversely, estradiol treatment resulted in larger bursal size (Table 41.5); there was evidence of histopathology in treated individuals (Quinn et al., 2009). Many of these studies have also found a consistent relationship between bursal morphology and immune response. As such, bursal histopathology appears to be a reliable measure of impact upon the immune system, especially assessing impacts during embryonic treatment and the persistence of these effects into adulthood.

41.4.8.7 Neuroendocrine Systems Regulating Reproduction, Metabolism, and Stress

Embryonic exposures to steroids or compounds that are estrogen- or androgen-active result in impaired behavior in male behavior in adult quail (Ottinger et al., 2005a; Panzica et al., 2007; Ottinger et al., 2009b, 2008). Further, it has been shown that specific neural systems, including neurotransmitters (norepinephrine, dopamine, serotonergic) and neuropeptides (vasotocinergic), are modified in response to embryonic exposure to steroid hormones and to EDCs. Assessing the effects of embryonic exposure to EDCs on neurotransmitters and neuropeptides can provide information about direct effects of these compounds on regulatory systems that modulate reproductive, thyroid, and adrenal endocrine axes. Gonadotropin-releasing hormone (GnRH-I) neurons are located in the preoptic/lateral septal region of the hypothalamus. Although redundant, this system may be vulnerable to endocrine disruption (Ottinger et al., 2009b). Impact to neurotransmitter systems such as acetylcholine esterase (ACHase) has been used as a measure of toxicant exposure (Rattner et al., 1986).

Songbirds and other altricial birds also show impacts of EDC exposure on avian brain morphology (Iwaniuk et al., 2006; Millam et al., 2001). Further, there is a large literature about the impacts on steroid hormones on the sexual differentiation and function of the nuclei that direct and modulate song control in songbirds (Wade et al., 2004; Grisham et al., 2008; Arnold and Itoh, 2011; Wade and Arnold, 2004; Gilbert et al., 2007). Because of the neuroplasticity in songbirds, EDC effects may be more transient in songbirds;

TABLE 41.4 Summary of Significant ($p < 0.05$) Effects of Trenbolone Acetate and p,p-DDE on Immune, Reproductive, and Behavioral Measures

Endpoint Group	Endpoint	Trenbolone Acetate (Androgen)	p,p-DDE (Anti-androgen)
Immune measures	Bursa-body weight index	Decreased	Increased
	Bursal follicle number	Decreased in hatchlings and adults	Decreased in chicks
	Bursal follicle size	Increased at 0.05 μg/g, decreased at 50 μg/g	NA
	Spleen-body weight index	NA	NA
	Humoral response to chukar red blood cells	NA	NA
	Cell-mediated response to phytohemagglutinin	NA	NA
	Hatchling plasma immunoglobulin G	Increased at only 0.05 and 0.5 μg/g	NA
	Hatchling total leukocyte counts	NA	Increased in chicks
	Hatchling differential leukocyte counts	Increased heterophil : lymphocyte ratio	NA
Physiological reproductive measures	Gonad-body weight indices	NA	NA
	Testes morphology	NA	NA
	Ovarian follicle count	NA	NA
	Proctodeal foam gland weight	Decreased	NA
	Onset of puberty	Prolonged in males	Shortened in females
	Sperm penetration of perivitelline layer	NA	NA
Male copulatory behavior	Number of attempts to mount female	Decreased	Decreased
	Number of successful copulations	Decreased	NA
	Time to initial mount attempt	NA	NA
	Time to achieve first successful copulation	NA	Increased

"NA" denotes measures that were not affected by treatments.

however, there are insufficient data to ascertain if this is the case. Nonetheless, there are clearly documentations of EDC effects on brain regions that modulate singing and other behaviors that are steroid dependent in both precocial and altricial birds.

In addition, metabolic systems have been investigated in detail in birds, especially for domestic poultry. The thyroid system in birds has proven vulnerable to specific types of endocrine disruption in which this endocrine system is a target. Specifically, polychlorinated biphenyls, flame retardants, and other classes of EDCs have been implicated in having thyroid system actions that impact birds, both in the laboratory and in field birds (Scanes and Mcnabb, 2003; Mcnabb and Fox, 2003; Mcnabb, 2005; Chen et al., 2008; Webb and Mcnabb, 2008; Fernie et al., 2005b). It is not clear if histological methods provide a sensitive method for revealing these EDC effects; however, impaired production and release of thyroid hormones would be observed in abnormal thyroid gland follicles size and distribution and in differences in circulating thyroxine (T4) and the more bioactive form, triiodothyronine (T3) (please refer to Chapter 24). Finally, the hypothalamic–pituitary–adrenal axis is another endocrine system potentially responsive to EDC challenges. Measuring corticosterone in feathers may be an interesting technique to determine if long-term stress has occurred using a noninvasive technique. Seasonality and migration also complicate responses by birds to EDCs. Birds often exhibit seasonal patterns in reproduction, and species that migrate often show complete regression of the reproductive axis with cessation of function followed by restimulation of the reproductive system, or seasonal recrudescence for the next breeding cycle. Initial stimulation of reproductive function in birds relies on environmental triggers, termed zeitgebers, and in the case of temperate-zone species this environmental cue is often photoperiod. Birds are generally long day breeders due to their relatively short

TABLE 41.5 Summary of Responses to Estradiol or Trenbolone with Day of Egg Injection from the Studies Reviewed Above

	Hatchling Effects Summary[1]			
Endpoint	Estradiol ED4	Estradiol ED11	Trenbolone ED4	Trenbolone ED11
Embryo mortality	(↑)	–	(↑)	(↑)
Hatchability	(↓)	–	(↓)	(↓)

incubation and relatively quick maturation times for their offspring. As such, most photoperiodic birds become reproductive with day length longer than 12 h. There is a very large literature on this subject that deals with the neural mechanisms, response via the eyes and pineal gland, and the hypothalamic response to regulate reproductive function; review of this literature is beyond the scope of this chapter, but it is important to recognize seasonal variations in energy demands due to reproduction, migration, and environmental challenges, especially as EDCs impact critical endocrine systems involved in these seasonal and adaptive responses.

41.5 CONCLUSIONS

Estradiol and estrogen-active compounds are potent disruptors early in embryonic development in birds. Effects in females may be due to direct effects on the ovary as well as on other physiological systems. Males are exquisitely sensitive to impacts from xenoestrogens, with impaired endocrine and behavioral components of reproduction, altered immune responses, and modifications in other physiological systems. Androgen-active compounds and EDCs that impact thyroid system function alter reproductive, metabolic, and immune responses. Further, EDC impacts on stress responses place individuals at risk from multiple environmental challenges. It is clear that early exposure has greater overall impacts on precocial species, which have relatively developed and functional physiological systems at hatch. Altricial birds follow another developmental pattern and as such may differ in the timing and relative vulnerability to EDC exposure. Nonetheless, there are distinct and documented effects of EDCs in birds that must be considered for effective conservation of field populations of birds and to protect these populations from adverse effects from these environmental compounds.
