The two major arms of the adaptive immune response—T-dependent and B-dependent immune responses (more commonly called cell-mediated and humoral immune responses, respectively)—were first described in the chicken before they were described in any other vertebrate species. The bursa of Fabricius was first described in the seventeenth century by Hieronymous Fabricius. The existence of cell-mediated immune responses (involving macrophages and lymphocytes) and humoral immune responses (involving antibodies) was generally accepted by the 1960s, but it was not clear if the cells that produced antibodies and drove cell-mediated responses were the same or distinct populations. Through a series of bursectomy experiments carried out for other reasons, Glick et al. (1956) realized that lymphocytes from the bursa controlled antibody production; it

Sturkie's Avian Physiology.

was later confirmed that the bursa is the site of development of the B cell receptor repertoire in birds. Other workers then realized that cells from the thymus controlled cell-mediated immunity (Szenberg and Warner, 1962). Cooper et al. (1965) then proposed, because of the similarities between the immune systems and lymphoid tissues of birds and mammals, that there must be a mammalian equivalent of the bursa of Fabricius (later shown to be the bone marrow). Therefore, T cells are so-called because they develop in the thymus, and B cells because they develop in the bursa of Fabricius.

17.2.1.1 The Thymus, T Cells, and T Cell Receptors

The avian thymus lies in the neck, parallel to the vagus nerve and the internal jugular veins, and consists of 7–8 separate lobes on each side of the neck running from the third cervical vertebra to the upper thoracic vertebrae. The lobes reach a maximal size of 10–12 mm in diameter by 3–4 months of age and thereafter they begin to involute. Each lobe is surrounded by a fine fibrous connective tissue capsule and is embedded in adipose tissue. Each lobe is divided into a central medulla surrounded by a cortex. The thymus contains mostly T cells, fewer macrophages, which are scattered throughout both the cortex and medulla, and epithelial reticular cells. The subcapsular zone of the cortex is thought to be the major site of T cell proliferation. During T cell maturation, the cells migrate towards the corticomedullary border, where thymic dendritic cells (DCs) and macrophages select the thymocytes, before the latter enter the medulla and then the circulation.

T cells recognize antigens presented in the context of major histocompatibility complex (MHC) molecules (see later) via the heterodimeric T cell receptor (TCR). Like mammals, chickens have both αβ and γδ TCRs (Chen et al., 1991). Each TCR is composed of two immunoglobulin (Ig) superfamily domains—a membrane-distal variable (V) region and a membrane-proximal constant (C) domain. The latter defines the class of the TCR. The Ig domains are anchored in the cell membrane by a connecting peptide and a transmembrane domain, followed by very short cytoplasmic regions that do not contain signaling motifs. Rather, signaling for all TCRs is mediated by the CD3 complex—a complex of five different proteins first identified in the chicken by Chen et al. (1986). There are two Vβ gene families in the chicken, Vβ1 and Vβ2, which are recognized by the antibodies TCR2 and TCR3, respectively (Chen et al., 1991). T cells expressing αβ TCR are also subdivided by their expression of two other surface molecules, CD4 and CD8. CD4 is a co-receptor for MHC class II and CD8 for MHC class I. TCR-$\alpha\beta^+CD4^+$ T cells are described as T helper (Th) cells and TCR-$\alpha\beta^+CD8^+$ T cells as cytotoxic T (Tc) cells, and both shall be discussed in more detail later.

Precursor hematopoietic cells enter the thymus in three waves, and all three lineages are present in the first two waves (Chen et al., 1991). However, TCR-$\gamma\delta^+$ and TCR-$\alpha\beta_1^+$ mature T cells migrate to the spleen by 15 and 19 days of embryonic development (DE), respectively, whereas TCR-$\alpha\beta_2^+$ cells do not appear in the spleen until after hatching (Chen et al., 1991).

17.2.1.2 The Bursa of Fabricius

The bursa of Fabricius is essentially a diverticulum of the cloaca. In the chicken, it reaches its maximum size around 8 weeks of age and then, like the thymus, involutes. By sexual maturity, most bursae have largely disappeared. The bursa is surrounded by a thick coat of smooth muscle. Inside, the bursa is composed of 15–20 longitudinal folds, each containing many follicles, with total follicle numbers in a mature bursa being estimated at 8,000–12,000 (Olah and Glick, 1978a). The bursal anlage appears at 3–5 DE. Buds, which are the forerunner of the bursal follicles, begin to form thereafter and each goes on to be the medulla of a bursal follicle. The surface epithelium of each bud is made up of follicle-associated epithelium (FAE) and interfollicular epithelium (IFE). IFE produces a mucin-like substance that is released into the bursal lumen and lubricates the surface of the folds. FAE provides a direct connection between the follicular medulla and the bursal lumen. FAE can both take up antigen or particles from the lumen (e.g., Bockmann and Cooper, 1973; Olah and Glick, 1978a; Schaffner et al., 1974) and products of the bursal secretory DCs (BSDCs) in the opposite direction (Nagy et al., 2001). The bursal follicles themselves, like the thymic lobes, have both a cortex and a medulla (Figure 17.1).

17.2.1.3 B Cells

B cells colonize the bursa between 8 and 14 DE (Le Douarin et al., 1975; Houssaint et al., 1976), migrating there through the blood. Mature B cells expressing rearranged B cell receptors leave the bursa posthatch. There are at least three populations of B cells in the periphery posthatch. A short-lived (approximately 3 days) population expressing the LT2 antigen (Paramithiotis and Ratcliffe, 1996) comprise about 60% of peripheral B cells in the newly hatched bird but largely disappear by 3 weeks of age. A further 30–35% of peripheral B cells that do not express LT2 then disappear, having a lifespan of about 3 weeks (Paramithiotis and Ratcliffe, 1993, 1994, 1996). A third population (approximately 5% of peripheral B cells in the newly hatched bird) of short-lived B cells appear to be derived from rapidly dividing extrabursal precursors. These may also be the source of peripheral B cells in older birds after bursal involution.

The majority of the lymphoid cells in the bursa are B cells (98%), with only a scattering of T cells (2%). Macrophages are also present in both the cortex and medulla,

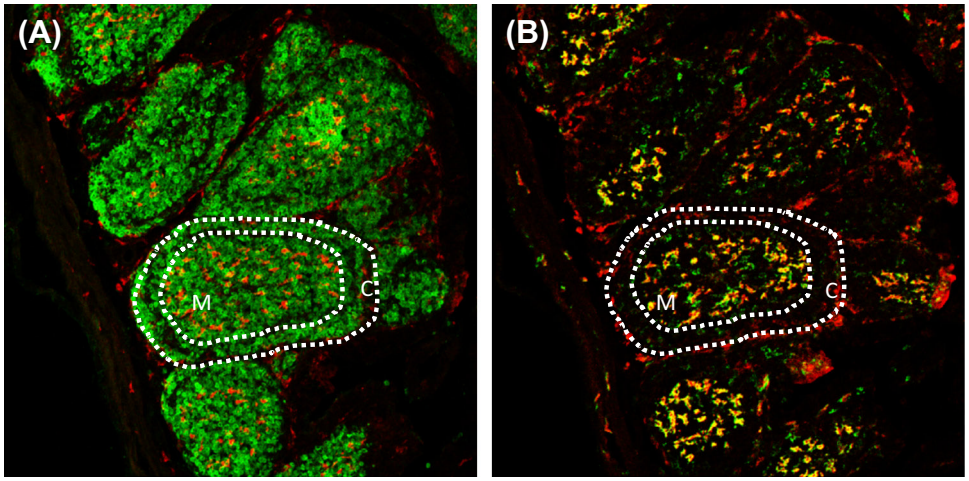

FIGURE 17.1 Mononuclear phagocyte subsets in the bursa of Fabricius. Immunofluorescence staining for Bu-1$^+$ B cells (A, green) or putative CD11 (B, green) and red fluorescent protein (RFP)$^+$ mononuclear phagocytes (red) in an 8 day old MacReporter chicken (a transgenic bird in which fluorescence is expressed in all cells of the macrophage lineage, driven by the CSF-1R promoter; Balic et al., unpublished). The structure of the B cell follicle in cross-section is shown (dotted lines). The B cell follicle medulla (M) contains a mononuclear phagocyte subset, the bursal secretory dendritic cell, that is positive for CD11. In contrast, the interfollicular mononuclear phagocyte subset adjacent to the B cell follicle cortex (C) expressed low levels of CD11.

as well as macrophage-like cells in the FAE. BSDCs, first identified by Olah and Glick (1978b), are found only in the medulla where they interact with lymphocytes; BSDCs are thought to play a role in promoting the education of B cells by controlling their interaction with antigens.

17.2.1.4 The B Cell Receptor/Antibody

Generation of the antibody repertoire (or more correctly, of the B cell receptor repertoire), of which the antibody represents a secreted form, in mammals takes place predominantly via gene rearrangement. For each immunoglobulin chain, there are multiple contiguous V (variable) segments, multiple D (diversity) segments for the heavy chains, and between 4 and 6 J (joining) segments; these are joined by recombination to produce functional VJ (light chain) or VDJ (heavy chain) Ig. This combinatorial diversity is augmented by junctional diversity at the joints between the different gene segments; the recombination mechanisms are not precise and nucleotides can be added or subtracted. Together, these mechanisms produce the B cell receptor and antibody repertoire, with as many as 10^8 different immunoglobulin specificities in an individual at any time.

In the chicken, the mechanism is somewhat different and is known as gene conversion. The chicken only has a single copy of functional V and J segments for both the light and heavy chains. Rearrangement of these would yield little or no diversity. However, both loci contain clusters of pseudogene V segments upstream of the functional V segment. VJ or VDJ rearrangement occurs in B cells in the bone marrow and spleen in chickens. B cells exhibiting this rearranged B cell receptor on their surface then migrate to the bursa of Fabricius. In the bursa, gene conversion involves random recombination between the pseudogene sequences and the canonical rearranged sequences, which leads to a B cell receptor/antibody repertoire similar in size to that of mammals.

Most mammals contain five classes of immunoglobulins: IgD, IgM, IgG (which undergoes subclass switching), IgA, and IgE. Three classes of avian Ig have been identified and represent the functional homologues of mammalian IgM, IgA, and IgG. IgD and IgE appear to be absent in all birds.

Chicken IgM is structurally and functionally homologous to its mammalian counterpart; during embryonic development, it is the first isotype expressed. Physical determinations of chicken IgM under various conditions have suggested a molecular weight (MW) of 823–954 kDa, with an average value of 890 kDa. The H chain has an MW of 70 kDa and the L chain 22 kDa, suggesting that chicken IgM is more likely to be tetrameric rather than pentameric; it could be a mixture of the two.

The avian homologue of mammalian IgG has similarities with both mammalian IgG and IgE and probably functionally shares the properties of both. It is the predominant form in sera, produced after IgM in the primary antibody response, and is the main isotype produced in the secondary response. It is described variously in the literature as IgY or avian IgG, but IgY in our opinion is preferable because the avian molecule appears to be the evolutionary predecessor of both IgG and IgE (Parvari et al., 1998; Bengten et al., 2000), sharing homology with each of the two mammalian isotypes. This nomenclature is also now well established for all nonmammalian vertebrates. The major difference between chicken IgY and mammalian IgG is that the H chain is longer in the chicken molecule. Avian IgY has five domains (V, C1–C4), as opposed to the four in mammalian

IgG, and the avian molecule does not possess a hinge. Instead, there are "switch" regions with limited flexibility at the C1-C2 and C3-C4 interfaces. Chicken IgY in serum is monomeric, with an MW of 165–206 kDa.

The predominant form of antibody activity in bodily secretions, such as tears, saliva, or bile, is IgA. In mammals, IgA is a dimer linked by a J chain that binds to its receptor on the surface of epithelial cells (Underdown and Schiff, 1986; Kerr, 1990). This receptor becomes integrated into the IgA molecule as a secretory component (SC), and the IgA complex is then transported through the epithelial cell and secreted into the lumen of the organ in question (Solari and Kraehenbuhl, 1985). SC promotes adhesion of IgA to the epithelial surface and protection from proteolytic degradation within cells. Chicken IgA, extracted from secretions such as bile, is usually larger than the IgA found in mammalian secretions, suggesting that the avian form is a trimer or a tetramer (Watanabe and Kobayashi, 1974). It also has a J chain and SC.

17.2.2 Secondary Lymphoid Tissues

17.2.2.1 The Spleen

In the chicken, the spleen is round/oval and lies behind and to the left of the proventriculus. It has an important role in embryonic lymphopoiesis; B cell progenitors undergo rearrangement of their Ig genes here before colonizing the bursa of Fabricius (Masteller and Thompson, 1994). At hatch, the spleen becomes a secondary lymphoid organ, providing an indispensable microenvironment for interactions between lymphoid and nonlymphoid cells. In fact, the contribution of the avian spleen to the immune system as a whole may be more important than it is in mammals because of the poorly developed lymphatic vessels and nodes in birds.

Mammalian and chicken spleens share the same basic structure, consisting of red and white pulp (Figure 17.2). The latter contains predominantly lymphocytes with few erythrocytes. Both lymphoid and nonlymphoid cells are found in the red pulp. $CD8^+TCR\gamma\delta^+$ T cells are plentiful in the sinuses, although $CD4^+TCR\alpha\beta1^+$ or $CD4^+TCR\alpha\beta2^+$ cells are also present.

In adult birds, most of the $TCR\gamma\delta^+$ cells are $CD8\alpha\beta^+$ (Tregaskes et al., 1995). Plasma cells expressing all three Ig isotypes are also present in the red pulp, especially near the large blood vessels. The red pulp also contains many macrophages, which are strongly acid-phosphatase positive and stain with the monoclonal antibodies 68.1 and 74.2 (Jeurissen et al., 1994) and KUL01 and MHC class II (Mast et al., 1998). Heterophils are also scattered throughout the red pulp sinuses.

The spleen is the largest lymphoid organ. It lacks afferent and efferent lymphatics, and it can therefore only obtain antigen from the blood. The white pulp surrounds the blood vessels in the spleen and has morphologically distinct areas. Periarteriolar lymphoid sheaths (PALS) surround the central arteries. Periellipsoid lymphoid sheaths (or PELS) analogous to the mammalian marginal zone, surround the penicillary capillaries. Germinal centres are found at the bifurcation of arteries, at the origin of the PALS.

The PALS contain predominantly T cells, mostly $CD4^+TCR\alpha\beta1^+$, but also some $CD4^+TCR\alpha\beta2^+$ and $CD8^+TCR\alpha\beta1^+$ cells. Chicken CD4 T cells are T helper cells and presumably play a role in B cell maturation as they surround the germinal centers. The PALS also contain KUL01+ MHC class II+ cells, which have been called

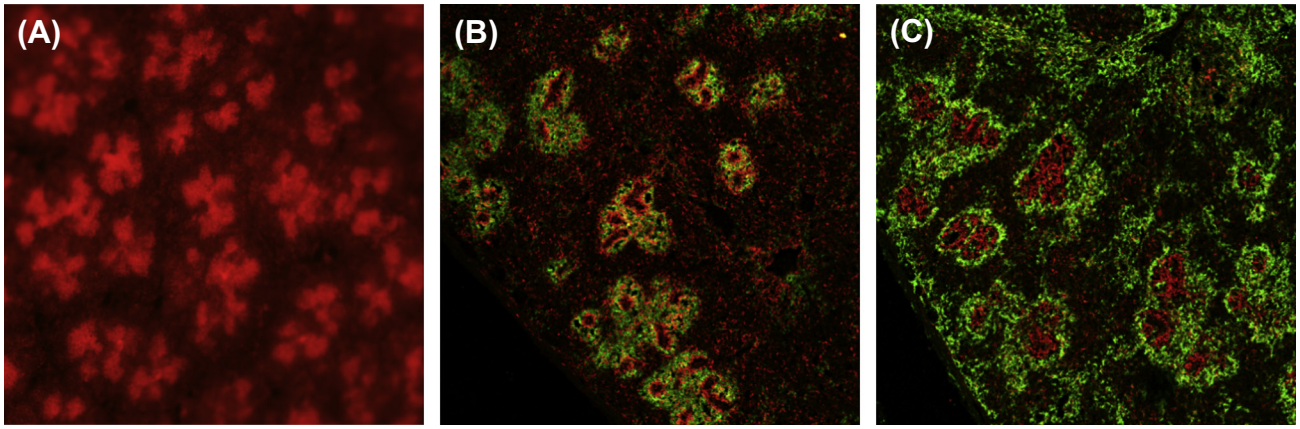

FIGURE 17.2 Whole-mount visualization (A) and immunofluorescence staining (B and C) of the spleen in a MacReporter chicken. (A) Whole mount visualization of the surface of the spleen, with mononuclear phagocytes expressing red fluorescent protein (RFP). RFP^+ cells are located throughout the spleen, but are particularly concentrated in the periellipsoid white pulp (PWP). The distinctive flower-like clustering of RFP^+ cells in the PWP reflects the structure of the penicillar capillaries as they branch off the central artery. (B) Immunofluorescence staining for Bu-1^+ B cells (green) and RFP^+ mononuclear phagocytes (red). RFP^+ mononuclear cells are concentrated in the B cell-rich periellipsoid lymphoid sheaths (PELS) and within the ellipsoid. (C) Immunofluorescence staining for CVI-ChNL-74.2 (green), which recognizes red pulp macrophages and a ring of macrophages surrounding the PELS and RFP^+ mononuclear phagocytes (red).

interdigitating dendritic cells (Igyarto et al., 2007). These cells are presumably the precursors of follicular dendritic cells (FDC), as they are either scattered or in aggregates approximately the size of germinal centers (Jeurissen et al., 1994; Igyarto et al., 2007; Olah and Glick, 1982; Gallego et al., 1993).

In the PELS, the penicillary capillaries are surrounded by ellipsoid-associated reticular cells. Ellipsoid-associated cells (EAC) are highly phagocytic and found at the surface of the ellipsoid (Olah and Glick, 1982). They are recognized by the monoclonal antibody 68.2 (Jeurissen, 1991) and are responsible for the clearance of antigens from the circulation. The ring of EAC is surrounded by Bu-1$^+$ B cells (Nagy et al., 2005; Mast and Goddeeris, 1998; Igyarto et al., 2008). B cells in the PELS primarily express IgM or IgA, but less IgY. Around the EAC, another ring is formed by 74.2$^+$ KUL01$^+$ macrophages (Nagy et al., 2005; Jeurissen et al., 1992; Mast et al., 1998).

Both innate and adaptive immune responses can be efficiently mounted in the spleen; it is therefore an important immune regulatory organ. Based on the localization of various lymphocyte and nonlymphoid cells in the spleen, the PALS seem most involved in adaptive immune responses, whereas the PELS are involved in both innate and adaptive immune responses.

17.2.2.2 The Harderian Gland

The Harderian gland (HG) is an immune-endocrine organ located in the orbit behind the eye. It produces secretions that lubricate and maintain the nictitating membrane via an excretory duct. The gland is divided into two areas based on differences in the surface epithelium and the organization of the underlying lymphoid tissues (Olah et al., 1996). The head of the gland has the structure of a typical secondary lymphoid organ with B cell-dependent germinal centers, FAE, and T cell-dependent interfollicular regions with scattered T cells and macrophages. The body of the gland contains many B and plasma cells and B and T cells cluster in separate areas in more mature glands.

The HG in young chicks contains CD45$^+$ cells, B cells, macrophages, interdigitating cells, and heterophils (Jeurissen et al., 1989; Bang and Bang, 1968). In older birds, the majority of T cells are CD4$^+$ and TCR$\alpha\beta1^+$, with a few scattered CD8$^+$TCR$\gamma\delta^+$ cells. The number of plasma cells increases dramatically with age, and uniquely they can proliferate in situ (Savage et al., 1992; Scott et al., 1993). IgM-, IgY- and IgA-producing plasma cells have all been described (Jeurissen et al., 1989; Olah et al., 1996; Jalkanen et al., 1984), reflecting the fact that all three Igs are found in tears.

17.2.2.3 The Cecal Tonsils

Cecal tonsils are located at head of the ceca near the ileocecal junction (Figure 17.3). The cecal tonsil primordium appears at about 10 DE, and lymphocytes are present by 18 DE (Payne, 1971). Posthatch lymphocyte numbers increase and germinal centers can be seen from the second week, increasing in number with age. The general structure of a cecal tonsil is comparable with that of a Peyer's patch, including a specialized lymphoepithelium, a subepithelial zone, germinal centers, and interfollicular areas. The subepithelial zone contains mainly IgM$^+$ B cells (with fewer IgY$^+$ B cells and occasional plasma cells) and a few CD4$^+$ and

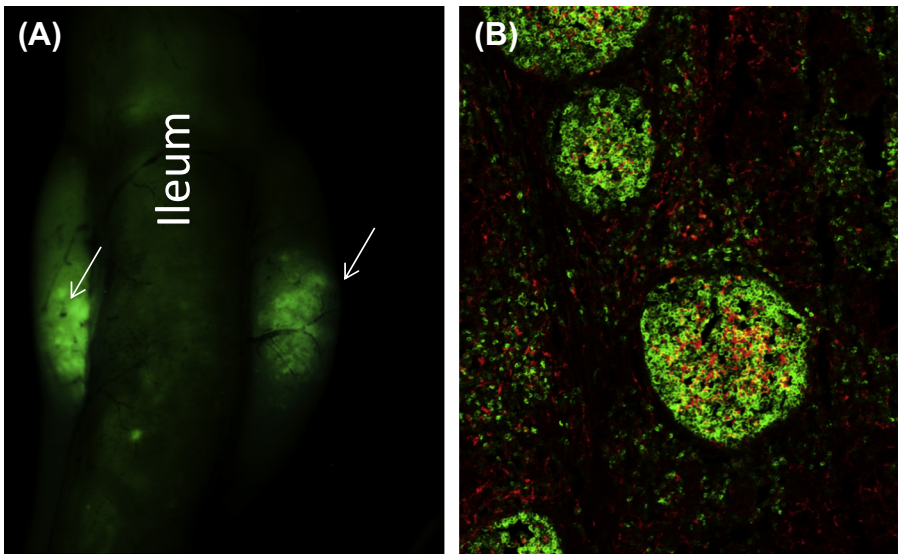

FIGURE 17.3 Whole-mount visualization (A) and immunofluorescence staining (B) of the cecal tonsil in a MacReporter chicken. (A) Whole-mount visualization of the surface of posthatch MacGreen cecal tonsils (arrows) with mononuclear phagocytes expressing green fluorescent protein (GFP). The cecal tonsil is composed of an extensive lymphoid tissue. (B) Immunofluorescence staining for Bu-1$^+$ B cells and mononuclear phagocytes (red) in the MacRed cecal tonsil identifies scattered B cells and mononuclear phagocytes, as well as germinal centers containing an extensive network of mononuclear phagocytes identified as avian follicular dendritic cells.

$CD8^+$ T cells expressing either TCRγδ or TCRαβ1. Monocytic cells are found throughout the tonsils but are mainly concentrated underneath the epithelium. The interfollicular areas are T cell-dependent and are mainly $CD4^+TCR\alpha\beta1^+$ cells (Olah and Glick, 1987; Bucy et al., 1988).

17.2.2.4 Peyer's Patches

Lymphoid aggregates with characteristics of mammalian Peyer's patches are present in the chicken intestine (Burns, 1982; Befus et al., 1980) (Figure 17.4). The exact number and distribution of chicken Peyer's patches is highly variable. The number of individual Peyer's patches peaks at 6–16 weeks of age, wherein they undergo involution, with the exception of one that is consistently found just before the ileocecal junction (Befus et al., 1980). This suggests that, as has been found in some mammals (Reynolds and Kirk, 1989), the chicken Peyer's patch may in fact include lymphoid structures of different ontogeny and function. Similarly to mammalian Peyer's patches, those in the chicken have widened villi, a follicular structure, a specialized epithelium containing M cells, active antigen uptake development in the embryo, and age-associated involution. Germinal centers, the subepithelial zone, and the interfollicular areas are similar to those in the cecal tonsils (see above). The subepithelial zone, where macrophages are more prevalent, is B cell dependent, and all B cells express the Bu-1/chB6 antigen (Jeurissen et al., 1989). The interfollicular zone is T cell dependent, and almost all T cells are $TCR\alpha\beta1^+$, with the majority being $CD4^+$ (Bucy et al., 1988). Only a few $TCR\gamma\delta^+$ cells (<5%) are present. The germinal centers and interfollicular areas contain mainly IgY^+ cells, with fewer IgA^+ and IgM^+ plasma cells.

17.2.2.5 Meckel's Diverticulum

The precise role of Meckel's diverticulum (MD) and its contribution to the bird's immune response remain to be determined. It is the remnant of the yolk stalk and is found halfway along the jejunum as an appendage of the small intestine. The wall of MD consists of four distinct layers. A serosa covers a thick layer of connective tissue. Next come bundles of smooth muscle. On the lumenal side of the muscle, the connective tissue contains large vessels and ganglions. This layer folds into the lumen of MD, and its surface is covered by columnar epithelium containing mucus-producing goblet cells. At hatch, MD contains no lymphoid cells. However, as the yolk sac regresses in the

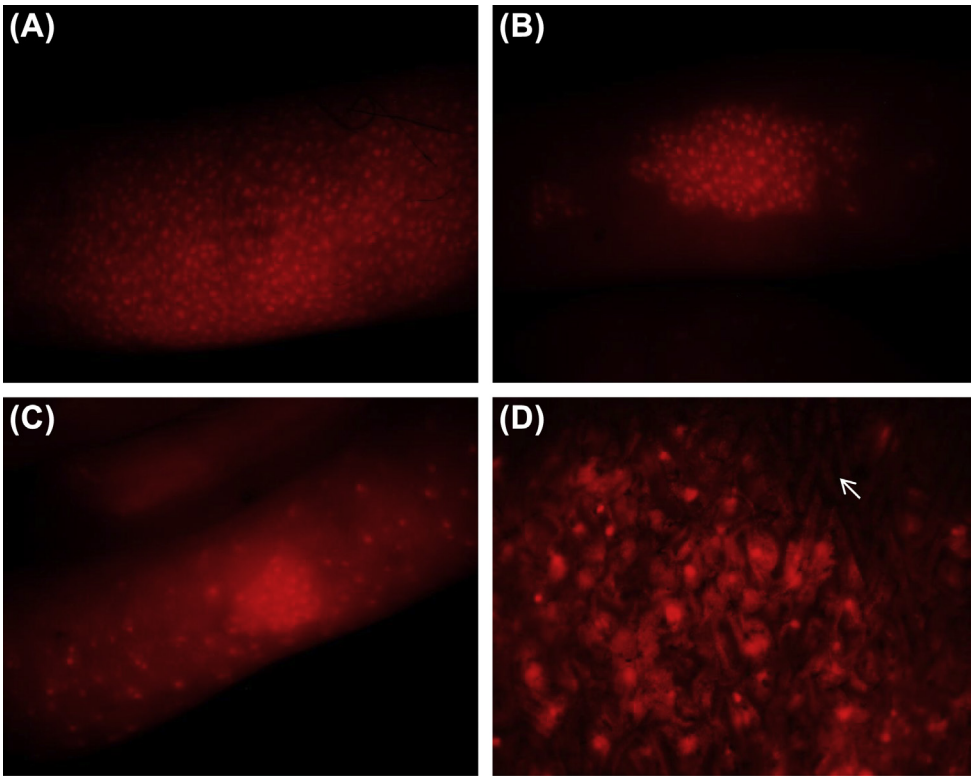

FIGURE 17.4 Whole-mount visualization (A–D) of Peyer's patches (PPs) in a 10-week-old MacReporter chicken. RFP expression in mononuclear phagocytes allows visualization of chicken gut-associated lymphoid tissues. Three different PP from the same individual shown at the same magnification (1.8×) demonstrate the wide range of sizes of chicken PPs. Individual PPs may contain tens to thousands of lymphoid follicles. Scattered non-PP lymphoid aggregates can also be seen in (C). (D) Ileum PP as seen from the mucosal surface. The normal chevron arrangement of intestinal villi (arrow) is disrupted by the lymphoid tissues of the PP.

first two weeks post-hatch myelopoietic and lymphopoietic tissues begin to appear. In the former tissue, there are three different zones. That closest to the yolk sac lumen contains monocytic cells, followed by a zone with large numbers of blast cells, and finally one containing immature granulocytes. Mature granulocytes are rare (Olah and Glick, 1984). In the lymphopoietic tissues, $CD45^+$ cells including IgM^+ B cells infiltrate the epithelium and connective tissue. Mononuclear phagocytes are found throughout the MD. The lymphoid tissue in MD gradually increases with age and fills the folds. As a result, the number of goblet cells is reduced, the epithelium is infiltrated by lymphocytes, and clusters of lymphoblats form around the antigen-presenting cells. Two to three months posthatch, germinal centers appear in large numbers located close to the muscle layer (Olah et al., 1984; Jeurissen et al., 1988). Dispersed throughout MD are IgA and IgY plasma cells. Later, B and T cell areas can be distinguished. The T cell areas are adjacent to germinal centers, whereas the B cell areas are generally beneath the epithelium (Jeurissen et al., 1988).

17.2.2.6 Other Mucosal Lymphoid Tissues and Cells

The combined mucosal surfaces of the gut, respiratory, and reproductive tracts represent by far the largest surface area in contact with the external milieu. They can also be considered the largest organ system in vertebrates, with each tract involved in diverse physiological functions, such as digestion and gas exchange. These functions come along with the continuous movement of external substances—nutrients and air, respectively—and the need to transport or exchange essential molecules across the mucosal surface. Hence, there is a continual challenge from new materials and microorganisms, including pathogenic microorganisms, which pass through the system. To prevent the entry of pathogens through the mucosal tissues, a wide variety of protective mechanisms has evolved. These range from barrier functions (e.g., keratinized skin, ciliated cells in the trachea, mucus secretion) to highly specialized immune cells (e.g., Langerhans cells in the skin) and organized lymphoid structures. In particular, the mucosal immune systems of the respiratory, gut, and reproductive tracts have highly developed lymphoid tissues, such as bronchus-associated lymphoid tissues and gut-associated lymphoid tissue (Figure 17.5), along with Peyer's patches, cecal tonsils, and lymphoid follicles.

In addition, the lamina propria harbors a wide range of immune cells, such as intraepithelial and lamina propria lymphocytes, macrophages, and dendritic cells. In mammalian species, the gut contains more lymphocytes than all secondary lymphoid tissues collectively. It is likely that this is also the case in avian species (reviewed in Schat and Meyers, 1991), particularly because birds lack lymph nodes. Numerous lymphoid follicles are found throughout the gut; typically these consist of one or more B cell follicles and a surrounding T cell zone. It is not clear if these structures represent secondary or tertiary lymphoid tissues; however, given the increasing number of different classes (Baptista et al., 2013) of similar structures that have been identified in mammals, it is likely that the lymphoid follicles of the chicken gut represent lymphoid tissues of diverse ontogenies and functions. Finally, the epithelial cells of the mucosal surfaces are able to sense pathogens and actively shape the response of the immune cells underneath.

For many years, research in mucosal immunology has focused on the question of how these cells become activated and interact to protect the host from invasion and dissemination of pathogenic microorganisms. Immunologists only recently began to appreciate that the gut harbors, and is in

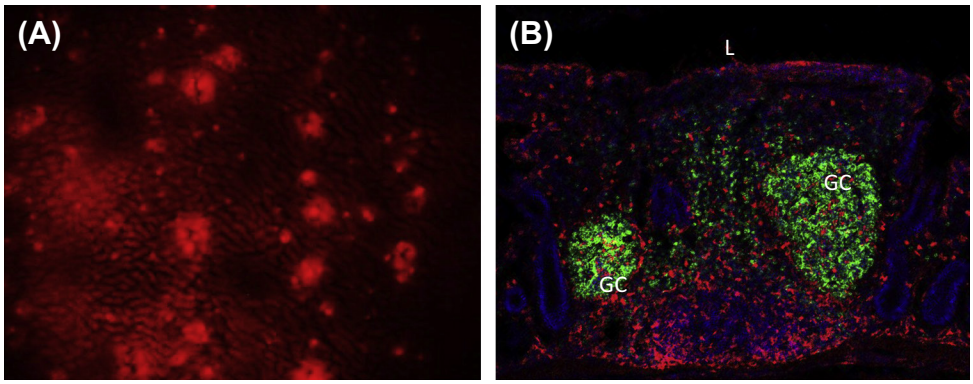

FIGURE 17.5 Whole-mount visualization (A) and immunofluorescence staining (B) of the rectal mucosa in a MacReporter chicken. (A) Whole-mount visualization of the rectum, as viewed from the mucosal surface, with mononuclear phagocytes expressing RFP. RFP^+ cells are located in the lamina propria of all mucosal villi, but are also concentrated in aggregates of variable size. (B) Immunofluorescence staining of a rectal mucosal lymphoid aggregate for Bu-1^+ B cells (green), RFP^+ mononuclear phagocytes (red) and cell nuclei (blue). RFP^+ mononuclear cells are found throughout the lamina propria, but are particularly associated with germinal centers (GC). L = lumen of the rectum.

constant contact with, trillions of commensal microorganisms that closely interact with the mucosal immune system (Molloy et al., 2012). This microbiome not only plays an important role in nutrient digestion; it is also a critical player in the development and function of the immune system and maintenance of intestinal integrity.

Under physiological conditions, the mucosal immune system has to remain tolerant of the microbiome to avoid chronic mucosal inflammation while at the same time being able to respond quickly and appropriately to pathogenic challenge. As a consequence, dysregulation of the cross-talk between the microbiome, the epithelium, and the mucosal immune system may result in local and systemic diseases. Although research on epithelial barrier biology has been a major topic in mammalian immunology in recent years, comparative studies in birds are only now being initiated (Mwangi et al., 2010).

17.3 REGULATION OF THE IMMUNE RESPONSE

17.3.1 Molecules and Cells of the Innate Immune Response

The chicken differs from mammals in its repertoire of lymphoid tissues, cells, and molecules, although many members of all three are the same. Arguably, the academically most interesting areas for study are where they differ, although it is vital to understand the similarities also.

As already discussed, the site of B cell development in the chicken is the bursa of Fabricius, which is not found in mammals. Chickens also lack lymph nodes, the primary site of antigen presentation in mammalian species. To date, the site of antigen presentation in the chicken has yet to be formally demonstrated, although it is thought to occur locally to the site of infection, probably in the many lymphoid aggregates found in the chicken's mucosal tissues. These aggregates include some unique structures, including Meckel's diverticulum and the cecal tonsils. Little has been published on immune responses in the former, but it is clear that the latter represent important sites at which immune responses are generated, particularly to pathogens such as *Campylobacter jejuni*, *Salmonella*, and *Eimeria tenella*.

Although one can detect cells from chicken blood that have the morphology of eosinophils, these have yet to be demonstrated to be functional. Eosinophils in mammals are key components of allergic and antihelminthic reactions (traditionally described as humoral immune responses)—in other words, of Th2 responses. There are many components of the mammalian Th2 response, particularly those that control the response and function of eosinophils, which are absent in the chicken. Th2 responses in mammals involve the cytokines IL-4, IL-13, and IL-5, all of which are upregulated following infection with an extracellular pathogen. Amongst other functions, they drive antibody isotype switching towards IgA and IgE, with the latter being crucial in eosinophil function because it binds the Fc-εR on eosinophils, triggering their degranulation. IgE production is driven by IL-5, after IL-4 induces isotype switching to IgE. In the chicken, IL-13 and IL-4 (the former up to 100-fold more than the latter) are both induced following infection with extracellular pathogens (Degen et al., 2005; Powell et al., 2009), but IL-5 expression is switched off (Powell et al., 2009). IgE is not produced in birds: chickens only have IgM, IgY (the functional equivalent of mammalian IgG, which does not have subtypes), and IgA. The eotaxins (chemokines) and the eotaxin receptor, which control migration of eosinophils in mammals, are absent in the chicken genome.

The other major immune cell type that is absent in the chicken is the neutrophil. These cells in mammals are essential effector cells of the induced innate response. In the chicken, they are replaced by heterophils; as yet, we lack the tools to determine if heterophils are a single set of cells with identical functions or if the term heterophil encompasses functionally different subsets of cells.

17.3.1.1 The CHIR Family

All pathogens (probably) have immune intervention/evasion mechanisms to manipulate the host's immune response to gain sufficient time to replicate. Viruses are particularly deft in this respect. To alert the adaptive immune system to viral infection, viral peptides are presented to CD8+ T cells in the context of MHC class I molecules. Many viruses use a variety of mechanisms to downregulate MHC class I expression in the cells they infect, to avoid triggering CD8+ T cells. In turn, the host has mechanisms to survey the levels of MHC class I expression on the surface of its cells, specifically by natural killer (NK) cells, which will target host cells with reduced surface MHC class I expression. In turn, some viruses have devised mechanisms to mimic MHC class I expression, either by encoding their own MHC class I mimics, selectively regulating host cell MHC class I expression, interfering with NK cell signaling, or modulating cytokine pathways that influence NK cells (reviewed in Orange et al., 2002).

The mechanism by which NK cells survey MHC class I expression levels and become activated is quite exquisite. In essence, a variety of receptors on the surface of NK cells recognize MHC class I and deliver a balance of activatory and inhibitory signals to the NK cell. Simply put, lack of detection of MHC class I on a host cell leads to a lack of inhibitory/suppressive signal for the NK cell, leading to NK killing of that cell.

In the human and mouse, these NK receptors are called KIR receptors (originally killer-cell immunoglobulin-like receptors for human, but now standing for killer-cell inhibitory receptors; the mouse uses a different family of receptors, dimeric lectins, to carry out the same function).

Immunoglobulin-like receptors form a superfamily and are involved in virtually all arms of the immune response. The human KIR receptors form part of a leukocyte receptor complex (LRC) on chromosome 19 that also include the leukocyte Ig-like receptor family (LILR). The equivalent LRC loci in the mouse are on chromosome 7.

The chicken LRC is located on microchromosome 31, and the genes have been given the name chicken immunoglobulin-like receptors, or CHIR (excellently reviewed in Viertlboeck and Gobel, 2011). In fact, the whole microchromosome seems only to encode the LRC, with no other genes yet assigned to it. Overall, the CHIR genes look equally like the mammalian KIR and LILR genes, and in terms of features look similar to both. CHIR genes are expressed on various leukocytes, like LILR genes, but are very diverse, like KIR genes. In humans, there are up to 17 KIR genes and 13 LILR genes. In the chicken, there are over 100 CHIR genes, a massive expansion compared with mammals, and the proteins encoded by the genes can be activatory, inhibitory, or bifunctional. The ligands for the vast majority of the CHIRs remain to be determined. The sole exception is CHIR-AB1, which binds to chicken IgY (Viertlboeck et al., 2007).

It is difficult to explain the reasons underlying this large expansion of genes in the chicken compared with mammals, and it remains the only major exception to the rule that chickens have the same immune gene families as mammals, but with fewer members. Further characterization of CHIR ligands will help to elucidate function, and it is tempting to speculate that this expansion of CHIR genes in some ways compensates for apparent contractions in the number of genes for other molecules, such as the MHC.

In comparison to mammals, chickens have different repertoires of Toll-like receptors (Boyd et al., 2007; Temperley et al., 2008; Cormican et al., 2009), defensins (Lynn et al., 2007), cytokines (Kaiser et al., 2005), chemokines (Kaiser et al., 2005; Hughes et al., 2007), antibodies (as discussed above), and other immune molecules (Kaiser, 2007, 2010). As can be seen from the references quoted, most of this knowledge postdates the sequencing of the chicken genome (ICGSC, 2004).

17.3.2 The Major Histocompatibility Complex

The adaptive immune response is only triggered when pathogen antigens are presented to T cells in the context of molecules called the major histocompatibility complex (MHC). The region of the genome that encodes the MHC is highly polymorphic and in mammals includes approximately 300 genes. The most relevant for antigen presentation are the class I genes, which present antigens from intracellular pathogens, mainly to CD8+ T cells, and the class II genes, which present antigens from extracellular pathogens, mainly to CD4+ T cells. MHC class I proteins are expressed on most cell types, whereas MHC class II proteins are mainly expressed on antigen-presenting cells such as dendritic cells (DC), macrophages, and B cells.

In contrast to the mammalian MHC, the chicken has a minimal essential MHC (Kaufman et al., 1999). In mammals, there are several class I and class II genes; precise numbers vary from species to species and in some cases between individuals of the same species. In contrast, in the chicken, the minimal essential MHC contains only two class I genes and two class IIβ genes, with only one of each dominantly expressed (reviewed in Kaufman, 2000). This has some striking consequences, particularly for the chicken's ability to mount an immune response to a pathogen, especially a virus.

Viral infections are cleared by cell-mediated immune responses, triggered by presentation of viral antigen via MHC class I. If a chicken expressed a single MHC class I gene, whose product will only fit certain peptides, then in order for an adaptive immune response to be triggered, the virus must encode a peptide that fits into that MHC class I molecule. Otherwise, the virus will not be seen by the adaptive immune response and will not be cleared. Most large viruses will encode so many peptides that the chances of none fitting the particular MHC class I gene in an individual is small. With smaller viruses, this chance becomes far greater. This has best been illustrated with Rous sarcoma virus (RSV) (Kaufman, 2000; Hofmann et al., 2003), which only encodes four genes. RSV is a transforming retrovirus that causes tumors, which progress and are fatal for some lines of chickens but are resolved in others. With this virus, the ability of an MHC class I gene product to bind a peptide from RSV (line B12) or not (line B4) absolutely defines the progression of the disease, with B12 birds regressing tumors and surviving and B4 birds succumbing to tumors.

17.3.3 Cytokines and Chemokines

Cytokines and chemokines are the molecules that control the precision of the immune response to disease or vaccination. Our understanding of the repertoire of cytokines and chemokines in the chicken was limited until recently, compared to those of mammalian species. A decade ago, only the type I interferon (Sekellick et al., 1994; Sick et al., 1996) and TGF-β family (Jakowlew et al., 1998, 1990; Burt and Jakowlew, 1992) had been characterized in the chicken. In general, chicken cytokines have only 25–35% amino acid identity with their mammalian orthologues. As a result, there are few, if any, cross-reactive monoclonal antibodies or bioassays. Moreover, cross-hybridization or degenerative (reverse-transcriptase) polymerase chain reaction approaches have been unsuccessful. Prior to the release of the chicken genome sequence (ICGCS, 2004), some progress had been made through a combination of expression cloning from expressed sequence tag (EST) libraries (Digby and Lowenthal, 1995; Sundick and Gill-Dixon,

1997; Weining et al., 1998), systematic sequencing of EST libraries (Lillehoj et al., 2001; Min and Lillehoj, 2002, 2004; Rothwell et al., 2004; Schneider et al., 2000, 2001) and genomics approaches based on the conservation of synteny (Avery et al., 2004; Balu and Kaiser, 2003). However, the availability of the chicken genome sequence has radically altered our ability to understand both the repertoire (Kaiser et al., 2005) and thereafter the biology of avian cytokines and chemokines.

Many of the cytokines and chemokines identified in mammals are also present in the chicken. The exceptions are in multigene families of cytokines and chemokines, where the chicken seems to have fewer members than do equivalent families in mammals. The absence of some of these multigene family members may explain some of the fundamental differences in the organs and cells of the avian immune system. Rather than give an exhaustive list of differences between the mammalian and chicken cytokine repertoires, we here focus on three multigene families—the chemokines, the tumor necrosis superfamily and the interleukin-1 family—where there are interesting differences that raise intriguing biological questions.

17.3.3.1 Chemokines

Chemokines are small chemical messengers that control the traffic of immune cells, both during inflammatory responses to infection and also to populate immune tissues and maintain homeostasis. As such, they are crucial to immune defense. They are broadly subdivided by structure into two main families (CC and CXC) and two much smaller families (XC and CX3C). A more useful division is arguably made by function; some chemokines have primarily a homeostatic role, and others are more involved in inflammatory responses. For the homeostatic chemokines, there is a single ligand-single receptor relationship. For the inflammatory chemokines, a single ligand can interact with several receptors, and a single receptor can have several ligands. The inflammatory chemokine genes and those of their receptors are grouped in multigene families at different loci in the genome. There is a single family of CXCL chemokines, and there are two families of CCL chemokines—the MCP and MIP families.

The chicken has slightly fewer homeostatic chemokines than mammals (Kaiser et al., 2005). For example, the eotaxins (CXCL9-11) and the eotaxin receptor (CXCR3) are absent, as discussed earlier, but for those present there are clear homologous relationships, which suggest similar functions. The one exception is CXCL13, which is a single copy gene in humans and mice, but at the same locus in the chicken genome there are three genes (CXCL13L1, CXCL13L2, and CXCL13L3). Of these, two interact with the cognate receptor, CXCR5, but the third (CXCL13L3) does not (Victoria Waters and Pete Kaiser, unpublished results).

The picture is less clear for the inflammatory chemokines and their receptors (Table 17.1). The mouse and human inflammatory CXCL families have five and ten

TABLE 17.1 Inflammatory Chemokine-Ligand Receptor Relationships in Humans and Chickens

Human		Chicken	
Receptor[1]	**Ligands**[2]	**Receptor**[3]	**Ligands**[4]
CXCR1	CXCL8, CXCL6	CXCR1	CXCLi1, CXCLi2 (Poh et al., 2008)
CXCR2	CXCL1–5, CXCL7	Unknown	CXCLi3
CCR1	*CCL4*, *CCL5*, *CCL6*, *CCL14*, *CCL15*, *CCL16*, *CCL23*	CCRa	CCLi1-10?
CCR2	**CCL2**, **CCL8**, *CCL16*	CCRb	CCLi1-10?
CCR3	**CCL11**, *CCL26*, **CCL7**, **CCL13**, CCL15, *CCL24*, *CCL5*, CCL28, *CCL18*		
CCR5	**CCL2**, *CCL3*, *CCL4*, *CCL5*, **CCL11**, **CCL13**, *CCL14*, *CCL16*		
CCR8	**CCL1**, *CCL16*	CCR8	Unknown
CCR4	*CCL3*, *CCL5*, CCL17, CCL20	CCRc	Unknown

[1]The CCR genes are all found on human chromosome 3. CCR1, CCR2, CCR3, and CCR5 are at a single locus, CCR8 and CCR4 are at an increasing distance from this locus.
[2]Bold font indicates MCP family, whereas italic font indicates MIP family.
[3]At the locus in the chicken genome equivalent to that in the human genome where CCR1, CCR2, CCR3 and CCR5 are encoded, there are three chicken genes, CCRa, CCRb, and CCRc. In phylogenetic analysis, CCRa and CCRb cluster with human CCR1, CCR2, CCR3, and CCR5, whereas CCRc clusters with human CCR8.
[4]We hypothesize that CCLi1-10, the chicken MCP and MIP family chemokines, use CCRa and CCRb.

members respectively, whereas the chicken family only has three members. Human IL-8 (CXCL8) is a member of this family; the mouse has no CXCL8 orthologue; in the chicken, there are two homologues, CXCLi1 and CXCLi2, which both share biological functions with human CXCL8 (Poh et al., 2008). The third chicken inflammatory CXCL, CXCLi3, has no direct mammalian orthologue. In mammals, the inflammatory CXCL chemokines signal through two receptors, CXCR1 and CXCR2, which are encoded at a single locus. The equivalent locus in the chicken genome only encodes a single receptor, CXCR1.

There are six members of the MCP family in humans, mice, and chickens. However, human and mouse MCP families share five members, and there are no direct orthologous relationships between the mammalian and chicken MCP families (Kaiser et al., 2005). The MIP families show greater differences across species, with eleven, five, and four members in the human, mouse, and chicken families, respectively. The human and mouse families share three members only. The chicken family appears to have an orthologue of mammalian CCL5, a potential orthologue of human CCL16, with no obvious orthologous relationship for the other two family members (Hughes et al., 2007). In mammals, the MCP and MIP family chemokines signal through four receptors (CCR1, CCR2, CCR3, and CCR5), which again are encoded at a single locus. At the equivalent locus in the chicken genome, there are only three genes. Two (CCRa and CCRb) look equally like all four mammalian receptors. The third (CCRc) clusters with the homeostatic CCR8 in phylogenetic analysis.

The general rule for chemokines is that the chicken has fewer members than mammals. Is this a "minimal essential chemokine repertoire"?

17.3.3.2 Tumor Necrosis Factors

The tumor necrosis factors form a superfamily (TNFSF) as do their receptors (TNFRSF). These molecules have crucial roles in all arms of immune responses, including induced innate responses and inflammation, apoptosis, and cell proliferation. The vast majority of the members of both families are membrane-bound, although certain of each can also be soluble proteins. Members of the TNFSF are primarily type II membrane proteins and function as homotrimers, whereas members of the TNFRSF are type I membrane proteins and function as monomers, although they often form higher level complexes with their ligands and other copies of themselves.

Members of the TNFSF in mammals and the chicken are present as small subfamilies in multigene loci on different chromosomes (see Table 17.2). As can be seen, the chicken has fewer TNFSF family members than mammals, and the rule seems to be that entire subfamilies are either present or absent in the chicken. Bearing in mind that the chicken genome is not complete, these absences are more likely to be real if the cognate TNFRSF members are also absent, and in general this is the case.

This has important implications for the chicken's immune response, particularly the apparent absence of the subfamily of genes encoding TNF-α and the two lymphotoxins (LT-α and LT-β). The LT genes are crucial in mammals for the development of secondary lymphoid organs including lymph nodes (reviewed in Fu and Chaplin, 1999). Their apparent absence in the chicken might explain the lack of lymph nodes. Ducks have primitive lymph nodes, but to date there is no evidence for the presence of the LT genes or TNF-α in the duck genome either. TWEAK and APRIL are involved in angiogenesis and immune regulation respectively in mammals, but both are absent in the chicken genome. 4-1BBL and LIGHT in mammals have costimulatory activity for activated T cells, enhancing T cell proliferation, secretion of IL-2, survival and cytolytic activity, as well as enhancing antitumor activity. CD27L (aka CD70) is expressed on activated T and B lymphocytes and mature DCs. Binding to its receptor, CD27, is important in priming, effector functions, differentiation and memory formation of T cells, and plasma and memory B cell generation. The absence of these latter five molecules in the chicken, but the presence of the functions which they are involved with in mammals, suggests again redundancy in the mammalian immune system. One could call the chicken TNFSF and TNFSRSF a "minimal essential TNF family."

17.3.3.3 The Interleukin-1 Family

Three members of the IL-1 family have been known for many years—IL-1α, IL-1β, and IL-1 receptor antagonist (IL-1RN). The three genes are encoded at a single locus in mammalian genomes. IL-1α and IL-1β are pro-inflammatory cytokines, whereas IL-1RN acts as a negative feedback mechanism to switch off the inflammation. A fourth member of the IL-1 family, IL-18, which drives Th1 adaptive immune responses, was discovered in 1995 at a different locus on a different chromosome. Genomic sequencing of the human and mouse identified seven more members of the family—six genes at the same locus as the original three family members and IL-33 at a third locus. The nomenclature of these genes in mammals was recently revised (Table 17.3). All members of the family are either pro- or anti-inflammatory.

To date, only four family members have been identified in the chicken. IL-1β (Weining et al., 1998) and IL-18 (Schneider et al., 2000) have been known for over a decade; they are still the only two IL-1 family members annotated in the chicken genome. We recently identified two new members of the chicken IL-1 family—IL-1RN (Gibson et al., 2012a) and IL-36RN (Gibson et al., 2012b)—from EST libraries. We have yet to identify the chromosomal

–	–		TRAIL-L	4	?

location of the two novel chicken family members, but we have shown that they do not lie at the same locus as IL-1β. The large mammalian multigene locus, which encodes nine IL-1 family members, therefore seems to be absent in the chicken. This suggests that the family has undergone differential evolution since birds and mammals diverged from a common ancestor. It makes determination of the complete repertoire of chicken IL-1 family members challenging, especially as the two novel members are still not present in the genome sequence, suggesting they lie in regions of the genome that are refractory to sequencing.

The biological effects of the IL-1 family ligands are exerted through members of the IL-1 receptor (IL-1R) family, which are expressed on the surface of target cells or secreted as soluble receptors. In mammals, the family is comprised of 12 members (Figure 17.6) that are characterized by an IgG-like extracellular domain and a cytoplasmic Toll/IL-1R (TIR) domain. Despite the apparent paucity of IL-1 family members identified to date in the chicken, all of the IL-1R genes found in the human genome are present in the chicken at conserved loci (Gibson, Fife, and Kaiser, unpublished observations), suggesting that it is highly likely that more members of the chicken IL-1 family remain to be identified.

17.4 SUMMARY AND CONCLUSIONS

Birds live in the same geographical niches as mammals; share similar diets, ranges of body mass, and longevity; and are challenged with the same range of pathogens (e.g., viruses, bacteria, protozoan parasites, worms, ectoparasites). Birds and mammals share many general features of their immune responses, yet it is fair to say that birds' immune systems are somewhat simpler than those of mammals. It is difficult to hypothesize as to the selective pressures that have led to this increased complexity in mammals. It is hard to imagine that pressure being due to a particular pathogen challenge. Perhaps instead it has something to do with the nature of pregnancy in mammals and the requirement for nonrejection of the fetus by

TABLE 17.3 The Interleukin (IL)-1 Families in Humans and Chickens Differ Dramatically in Their Repertoires, with That of the Chicken Much Reduced

Human		Chicken	
Gene	Chromosome	Gene	Chromosome
IL-1α (IL-1F1)	2

IL-33 (IL-1F11)	9		

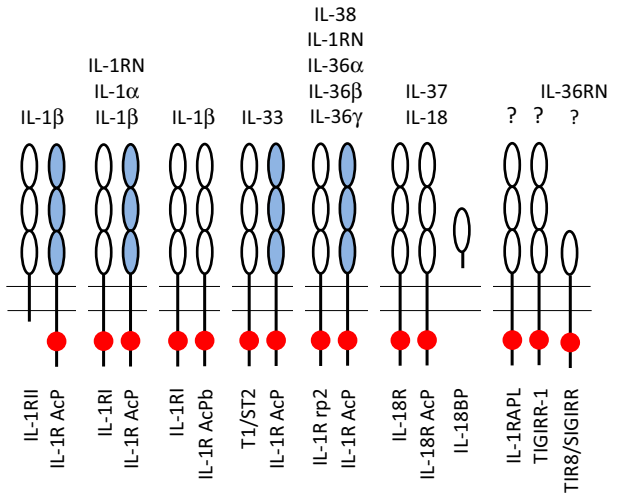

FIGURE 17.6 The IL-1 receptor family in humans, with their ligands shown above the molecules. The majority of the receptors contain cytoplasmic TIR domains (red circles), and several share the IL-1R accessory proteins (IL-1R AcP, shaded in blue). In the chicken, all 12 receptor family members are present, but only four of the IL-1 family members (IL-1β, IL-1RN, IL-36RN, and IL-18) have been identified.

the mother. However, that increased complexity seems to come with the price of increased prevalence of autoimmune disease in mammals—or have we simply failed to catalogue the same in birds?

It is an exciting time to be an avian immunologist. The chicken genome sequence and those of more than a hundred other avian species, either completed or in progress, and the rapid development of new tools and reagents to study host–pathogen interactions in birds, open the door to an improved understanding of avian immunophysiology.

Chapter 18

Carbohydrate Metabolism

Colin G. Scanes

Department of Biological Sciences, University of Wisconsin, Milwaukee, WI, USA

18.1 OVERVIEW OF CARBOHYDRATE METABOLISM IN BIRDS

Carbohydrate metabolism in birds has close similarities to that in mammals. Glucose is absorbed in the small intestine. Glucose can be used for energy via glycolysis, the citric acid cycle, or the pentose pathway. Some tissues only use glucose, being incapable of using fatty acids. Glucose can be stored as the polysaccharide glycogen in the liver, muscles, and other tissues or used as a substrate to produce fatty acids (lipogenesis). Glucose can be synthesized from lactate, amino acids, and other glucogeneogenic precursors in the liver and kidneys. The differences between avian and mammalian carbohydrate metabolism include the following:

- The very high circulating concentrations of glucose in birds (discussed in more detail in Section 18.2)
- The site of lipogenesis being the liver

Several caveats need to be introduced. The energetic needs for extended flight are met using fatty acids, not glucose. Discussion of carbohydrate metabolism in birds is hampered by the preponderance of evidence coming from studies in domesticated birds, particularly from a single species, the chicken. The control of carbohydrate metabolism of (and hence circulating glucose concentrations by) the pancreatic hormones, glucagon, and insulin is addressed elsewhere in this volume.

The respiratory quotient (RQ) (carbon dioxide released divided by the oxygen consumed) informs as to the major substrate being used by an animal for energy. If the RQ is 1.0, carbohydrate (glucose) is the major substrate. If the RQ is 0.7, triglyceride (fatty acids) is the major substrate. If amino acids are being used for energy, the RQ is 0.8–0.9. Table 18.1 summarizes the RQ for a number of avian species. Birds seem to have an RQ of either 0.7 or 1.0, indicating that they are using either triglyceride/fatty acids or glucose. An RQ of 1.1 and greater, as reported in young chickens (Geelissen et al., 2006), reflects glucose utilization for energy production and fatty acid synthesis together with triglyceride deposition. When there is a shift from use of glucose to fatty acids predominantly, there is a decrease in RQ. For instance, the RQ decreases to 0.7 during fasting in the house sparrows (*Passer domesticus*), hummingbirds, and chickens during the nocturnal fast from ~0.9 to <0.7 (see Table 18.1).

18.2 CIRCULATING CONCENTRATIONS OF CARBOHYDRATES

18.2.1 Introduction: Circulating Concentrations of Glucose across Avian Species

The major circulating carbohydrate in birds is glucose. The mean circulating concentration of glucose in birds is 15.4 ± 0.32 (standard error of mean (SEM); number of species (n) = 139; Table 18.2). There are higher circulating concentrations of glucose in *Neognathae* than in the flightless rattites. There are marked differences between circulating concentrations of glucose between wild birds and mammals, with avian concentrations more than double those in mammals; for instance, plasma concentrations of glucose in fed and fasting rats were respectively 7.9 and 4.9 mM (Simon et al., 2011). The control of circulating concentrations of glucose by the pancreatic hormones, glucagon and insulin, is addressed elsewhere in this volume.

In mammals, there is a relationship between circulating concentration of glucose and body weight: the circulating concentration of glucose in mM = 7.6 − 0.44 log body mass in kilograms (Beuchat and Chong, 1998; Braun and Sweazea, 2008). In birds, a similar relationship was reported by Braun and Sweazea (2008): the circulating concentration of glucose in mM = 15.3 − 0.44 log body mass in kilograms. For birds, the y-intercept of the line at 1 kg is 15.3 mM (or 275 mg/dL) in wild birds (Braun and Sweazea, 2008). The basis for this relationship between circulating concentrations of glucose and body weight is not clearly established. No such relationship was observed by Beuchat and Chong (1998). There is frequently a dichotomy in the literature between research on wild and domesticated species. The analysis of circulating concentrations of glucose included only wild species.

TABLE 18.1 Examples of Respiratory Quotients (RQ) Reported in Birds

Species	RQ	Reference
Chicken (*Gallus gallus*) fed	~1.0 or 1.1 or greater	Brackenbury and El-Sayed, 1985; Geelissen et al., 2006
Chicken exercising	0.97	Brackenbury and El-Sayed, 1985
Chicken fasted	0.7	Boshouwers and Nicaise, 1981
House sparrow (*Passer domesticus*) fed	0.9 or ~1.0	Walsberg and Wolf, 1995
House sparrow fasted	0.7	Walsberg and Wolf, 1995; Khalilieh et al., 2012
Rufous hummingbirds (*Selasphorus rufus*) or Anna's hummingbirds (*Calypte anna*) upon feeding on nectar	1.0	Welch et al., 2007; Suarez et al., 2011
Rufous or Anna's hummingbirds fasted	0.7	Suarez et al., 1990, 2011; Welch et al., 2007
Carnivorous birds: Sparrow hawks (*Falco sparverius*), long-eared owls (*Asio otus*), saw whet owl (*Aegoliusa cadicus*)	0.74–0.78	Gatehouse and Markham, 1970

TABLE 18.2 Circulating Concentrations of Glucose Across the Class *Aves*

	Plasma/Serum Glucose mM (mmol/L) + SEM (Number of Species)
Order *Accipitriformes*	17.8 + 1.18 (11)
Order *Anseriformes*	12.2 + 1.34 (13)
Order *Apodiformes*	16.0 + 0.47 (3)
Order *Charadririiformes*	17.8 + 1.12 (8)
Order *Columbiformes*	16.4 + 0.94 (8)
Order *Ciconiformes*	14.5 + 1.01 (3)
Order *Falconiformes*	20.1 + 0.65 (8)
Order *Galliformes excluding poultry*	17.3 + 0.79 (14)
Order *Gruiformes*	13.1 + 0.57 (4)
Order *Passeriformes*	16.8 + 1.29 (12)
Order *Pelicaniformes*	14.6 + 0.90 (5)
Order *Phoenicopteriformes*	10.8 + 0.52 (4)
Order *Procellariiformes*	13.5 + 1.89 (5)
Order *Psittaciformes*	14.9 + 0.46 (20)
Order *Sphenisciformes*	14.1 + 0.83 (6)
Order *Suliformes*	10.6 + 1.32 (6)
Super-order *Neognathae*	15.5 + 0.32 (136)
Super-order *Palaeognathae*	11.1 + 1.18 (3)
Class *Aves*	15.4 + 0.32 (139)

18.2.2 Domestication and Circulating Concentrations of Glucose

There is conjecture that domestication and intensive selection have influenced glucose metabolism and circulating concentrations of glucose, although there is also some against this theory. The circulating concentrations of glucose in wild turkeys (*Meleagris gallopavo*) are more than 50% greater than those in domestic turkeys (Lisano and Kennamer, 1977; Anthony et al., 1990; see Table 18.3). In contrast, the circulating concentrations of glucose were higher in domestic than wild geese (Gee et al., 1981; Sitbon and Mialhe, 1979; see Table 18.3). A small study directly compared red jungle fowl (*Gallus gallus*, from which chickens are thought to have been domesticated), Asian village fowl, and commercial broiler chickens (Soleimani and Zulkifli, 2010). No differences were found between circulating concentrations of glucose between red jungle fowl and domesticated chickens (Table 18.3). Moreover, there are no discernible differences between the circulating concentrations of glucose in wild or domestic pigeons or ducks (Table 18.3). At present, there are no comprehensive studies comparing chickens with red jungle fowl or domestic turkeys, ducks and geese with wild turkeys, ducks and geese respectively. These should encompass multiple ages. Moreover, they should be performed in the same laboratory with circulating concentrations of glucose determined by the same methods to ensure consistency.

18.2.3 Fasting and Circulating Concentrations of Glucose

In some species of birds, circulating concentrations of glucose are depressed by fasting, such as in chickens (Dupont et al., 2008; Christensen et al., 2013), domestic ducks (*Anas platyrhynchos*; Zhang et al., 2005), domestic geese (*Anser anser*; Sitbon and Mialhe, 1979), house sparrows (*P. domesticus*; Khalilieh et al., 2012), hummingbirds (Anna's hummingbird (*Calypte anna*)), Costa's hummingbird (*Calypte costae*) and Ruby-throated hummingbirds

TABLE 18.3 Comparison of Circulating Concentrations of Glucose in Domesticated Birds and Wild Birds of the Same Species

Species	Plasma/Serum Concentration of Glucose (mM)	Reference
Red jungle fowl (*Gallus gallus*)	13.3	Soleimani and Zulkifli, 2010
Village chickens (*Gallus gallus domesticus*)	12.7	Soleimani and Zulkifli, 2010
Commercial broiler chickens (*Gallus gallus domesticus*)	15.0	Soleimani and Zulkifli, 2010
Fed chickens (15 studies)	13.0	Scanes, 2008
Fed chickens	13.2	Simon et al., 2011
Fasted chickens	12.6	Simon et al., 2011
Turkey (*Meleagris gallopavo*)		
Wild turkey	19.7	Lisano and Kennamer, 1977
Domestic turkey fasted	10.6	Anthony et al., 1990
Domestic turkey re-fed	11.5	Anthony et al., 1990
Duck (*Anas platyrhynchos*)		
Wild or mallard duck	11.5	Fairbrother et al., 1990
Domestic duck	10.0	Mean Applegate et al., 1999 & Zhang et al., 2005
Goose (*Anser anser*)		
Wild or Embden goose	12.3	Gee et al., 1981
Domestic goose	15.6	Sitbon and Mialhe, 1979
Pigeons (*Columba livia*)		
Wild or rock pigeon	15.5	Gayathri et al., 2004
Domestic or racing pigeon	16.1	Lumeij and de Brujne, 1985

(*Archilochus colubris*); Beuchat and Chong, 1998), and yellow-legged gulls (*Larus cachinnan*; Alonso-Alvarez and Ferrer, 2001). For instance, circulating concentrations of glucose are depressed by 25.3% in adult house sparrows fasted for 24 h (Khalilieh et al., 2012). Similarly, circulating concentrations of glucose decreased by fasting in late juvenile/adult domestic geese, being decreased by 25.4% in birds fasted for 24 h and by 32.5% in geese fasted for 4 days (Sitbon and Mialhe, 1979). In contrast, circulating concentrations of glucose were not depressed by fasting in other species/studies, such as adult ring doves (*Streptopelia* risoria; Lea et al., 1992), Japanese quail (*Coturnix japonica*; Sartori et al., 1996), Adélie penguins (*Pygoscelis adeliae*; Vleck and Vleck, 2002), Emperor penguins (*Aptenodytes forsteri*; Groscolas and Rodriguez, 1981), Garden warbler (*Silva borin*; Totzke et al., 1998), and juvenile herring gulls (*Larus argentatus*; Jeffrey et al., 1985); on the contrary, concentrations were increased in female ring doves (*Streptopelia risoria*; Lea et al., 1992).

18.2.4 Influence of Feeding

As might be expected, circulating concentrations of glucose are influenced by feeding. For instance, plasma concentrations of glucose are depressed at night in chickens when feeding is not occurring (Christensen et al., 2013). Moreover, concentrations of glucose are markedly increased following eating in hummingbirds, with circulating concentrations rising from already high concentrations to >26.5 mM—levels way into the diabetic range in mammals (Figure 18.1). This is not surprising with the consumption of nectar, which is high in both glucose and fructose. Plasma concentrations of glucose decline rapidly from 41 mM to basal (17 mM) within 1.5 h following feeding in, for instance, Anna's hummingbird (*Calypte anna*) (Beuchat and Chong, 1998). Similarly, oral loading with monosaccharides increases circulating concentrations of glucose in passerine birds (Figure 18.1) and chickens (Figure 18.2). Circulating concentrations of glucose return to basal within an hour (Sinsigalli et al., 1987; Figure 18.2).

18.2.5 Shifts in Circulating Concentration with Age, Reproductive State, and Migration

Circulating concentrations of glucose increase during the second half of embryonic development (Willemsen et al., 2011). There is a decrease in circulating concentrations of glucose immediately after hatching, followed by a gradual rise over 12 h (chickens: Rinaudo et al., 1982). Circulating concentrations of glucose decline during posthatch growth and development in chickens (*Gallus gallus*; Sinsigalli et al., 1987; Figure 18.2). The rate of clearance of glucose after a glucose challenge is slower in older but still juvenile birds, as shown in chickens by Sinsigalli et al. (1987; Figure 18.2).

There are some small sex differences in circulating concentrations of glucose in some birds. For instance, in adult

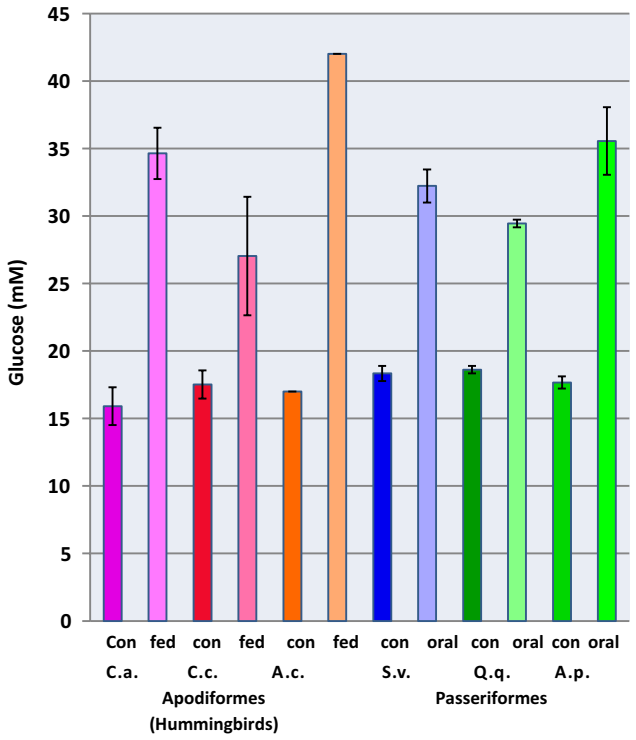

FIGURE 18.1 Effects of nectar-feeding hummingbirds and administering an oral load of 1:1 glucose:fructose (intubated) to Passeriform birds (30 min later). C.a., Anna's hummingbird (*Calypte anna*); C.c., Costa's hummingbird (*Calypte costae*); A.c., ruby-throated hummingbirds (*Archilochus colubris*); S.v., European starlings (*Sturnus vulgaris*); Q.q., common grackles (*Quiscalus quiscula*); A.p., red-winged blackbirds (*Agelaius phoeniceus*). Vertical bars: S.E.M. *Data calculated from Beuchat and Chong (1998) and Martinez del Rio et al. (1988).*

sexually mature quail, there is a small but consistent sex difference in circulating concentrations of glucose, being decreased 6.7% (Itoh et al., 1998) and 17.0% (Scholtz et al., 2009) in females in different reports. In contrast, circulating concentrations of glucose were lower in male than female mallards (Fairbrother et al., 1990; see Table 18.4).

Some changes have been reported in the circulating concentration of glucose during the breeding cycle. For instance, circulating concentrations of glucose are reduced by 53% in adult pigeons in the middle of period of incubating their eggs, but they recover late in incubation and then rise further after incubation is terminated (Gayathri et al., 2004). Similarly, in ring doves, circulating concentrations of glucose are increased after incubation and when the young squabs are receiving parental care (Lea et al., 1992). A similar reduction in circulating concentrations of glucose is reported in ducks (mallard duck (*A. platyrhynchos*); Fairbrother et al., 1990).

Prelaying circulating concentrations of glucose correlate well with later reproductive success in raising at least one chick in the greater sage grouse (Dunbar et al., 2005). What is not clear is the physiological basis of the circulating glucose concentrations having a predictive value for reproductive success.

There was little difference in the circulating concentrations of glucose in Canada geese (*Branta canadiensis interior*) irrespective of whether it was before or after the spring migration, during the breeding season, or in the period before the fall migration (Mori and George, 1978). An increase was observed after the fall migration (Mori and George, 1978). Circulating concentrations of glucose are markedly increased in Emperor penguins undergoing both fasting and

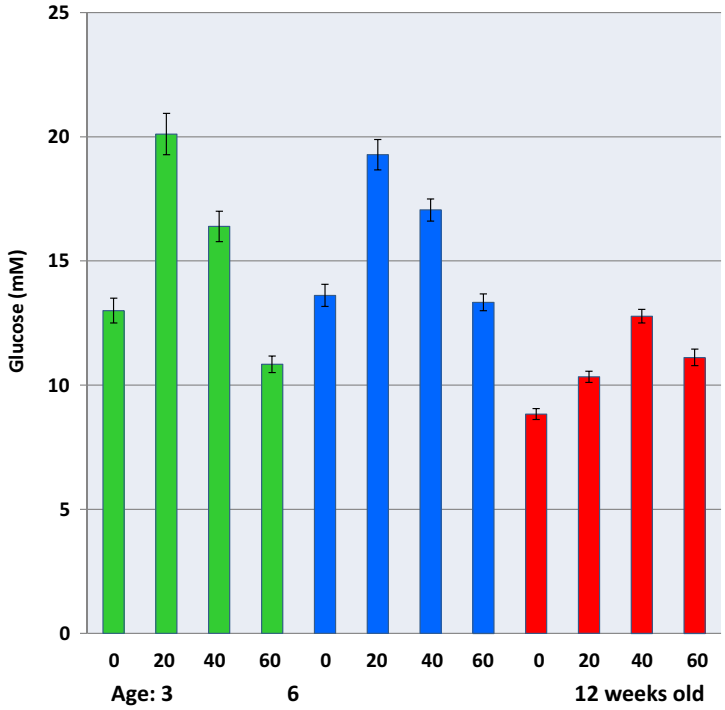

FIGURE 18.2 Effect of glucose load (2 g glucose intubated per kg or 11.1 mmol/kg) on circulating concentrations of glucose at 3, 6 and 12 weeks of age in chickens prior to (0 min) and 20, 40, and 60 min after challenge. *Data from Sinsigalli et al. (1987).*

TABLE 18.4 Effect of Reproductive Status on Serum Glucose Concentrations in Mallard Ducks (*Anas platyrhynchos*)

Reproductive Status	Serum Concentration of Glucose mM (mmol/L) ± SEM (*n*)
Pre-egg-laying females	13.2 ± 0.2 (34)[1]
Egg-laying females	14.3 ± 0.9 (10)[1]
Incubating females	11.7 ± 0.7 (20)[2]
Molting females	11.0 ± 0.5 (11)[2]
Nonreproductive females	11.9 ± 0.3 (34)[2]

[1,2]Different superscript numbers indicate significant difference $p < 0.01$.
Data from Fairbrother et al. (1990).

molting, increasing from a mean (SEM) of 19.7 ± 2.4 mM to 28.4 ± 6.5 mM (Groscolas and Rodriguez, 1981).

18.2.6 Shifts in Circulating Concentrations of Glucose due to Disease, Toxicants, and Husbandry Practices

There are pathological changes in the circulating concentration of glucose, with decreases with infectious disease and increases with exposure to toxicants. In the common pheasant, the circulating concentrations of glucose are depressed by severe infection with spironucleosis (Lloyd and Gibson, 2006). Similarly, in chickens with spiking mortality, there are extremely low circulating concentrations of glucose (Davis et al., 1995).

Environmental toxicants can elevate, depress, or have no effect on circulating concentrations of glucose. There is a marked increase in circulating concentrations of glucose in parakeets receiving the organophosphate insecticide quinalphos (roseringed parakeet, *Psittacula krameri*; Anan and Maitra, 1995). Circulating concentrations of glucose were depressed in mallard ducks exposed to the polychlorinated biphenol mixture Aroclor 1254 (Fowles et al., 1997). In contrast, there was no change in circulating concentrations of glucose in ducklings with toxicosis due to furazolidone (Webb et al., 1991).

Force feeding is used in some counties to produce *pate de fois gras* in ducks and geese. Circulating concentrations of glucose are increased by force feeding in geese (Sitbon and Mialhe, 1979) and ducks (Zhang et al., 2005).

18.2.7 Temperature and Circulating Concentrations of Glucose

There are effects of environmental temperature on circulating concentrations of glucose. Not only does fasting for 16 h depress circulating concentrations of glucose (Boussaid-Om Ezzine et al., 2010) but the effect is greater in birds exposed to elevated temperatures (32 °C for a week in broiler chickens; Boussaid-Om Ezzine et al., 2010). Moreover, glucose plus arginine administration to birds with free access to feed evoked a larger increase in circulating concentrations of glucose in the chickens at a higher environmental temperature (Boussaid-Om Ezzine et al., 2010).

18.3 GLUCOSE UTILIZATION

Glucose utilization can be very high in birds (see Table 18.5). For instance, in foraging hummingbirds, hovering flight is maintained by utilization of ingested sugars in rufous (*Selasphorus rufus*) and Anna's (*Calypte anna*) hummingbirds (Welch and Suarez, 2007). In contrast during migration, fats are employed as the energy source, with the Ruby-throated hummingbird (*Archilochus colubris*) losing most of the triglyceride stored in the adipose tissue during a 20 h flight over 960 km (600 miles; Hargrove, 2005). There are very high respiration rates of mitochondria from skeletal muscles of hummingbirds (7–10 mL O_2/cc/min); the rates are twice the maximum found in mammals (Suarez et al., 1991). This may be associated with increased mitochondrial surface area (Suarez et al., 1991). There is an increase in glucose turnover with exercise in chickens (Brackenbury and El-Sayed, 1985).

There are marked differences in glucose uptake by different organs (summarized in Table 18.6). The highest uptake is by the brain and heart. Insulin induced large increases in glucose uptake by the liver and some skeletal muscles. In contrast, glucose uptake is depressed in the brain of the chicken (Tokushima et al., 2005).

There are marked changes during the day in glucose uptake by tissues in chickens on a 12 h light/12 h dark cycle (Karaganis et al., 2009).

18.3.1 Developmental Changes

There is little glucose utilization for lipogenesis (fatty acid synthesis) in the liver of avian embryos and at hatching. They rise to a substantial plateau level within 8 days after hatching due to feeding, as shown in chickens (Goodridge, 1968a,b; Table 18.7).

18.3.2 Fasting and Glucose Utilization

There is reduced glucose utilization during fasting in birds. For instance, irreversible glucose turnover is depressed 32% by fasting (either associated with breeding or forced starvation) in Emperor penguins (*Aptenodytes forsteri*; Groscolas and Rodriguez, 1981):

- Fed 44.2 μmol/min/kg
- Fasted 30.1 μmol/min/kg

Similarly, there is a 57.6% decrease in glucose utilization in Japanese quail (*C. japonica*) fasted for 2 days (Sartori et al., 1996) and 64% in chickens fasted for 1 day (Belo et al.,

TABLE 18.5 Glucose Metabolism in Chickens

Parameter	Age	Method	Estimated Glucose Metabolism (μmol glucose/min/kg)	Reference
Total body glucose loss (utilization)	8 days	Disappearance of radioactive deoxyglucose from the blood	102	Calculated from Tokushima et al. (2005)
Total body glucose utilization	4 weeks	Heat produced	174	Calculated from Buyse et al. (1993)[1]
	5 weeks		112	
Total body glucose disappearance	5–6 months	Disappearance of radioactive glucose from the blood	79.4	Belo et al., 1976
Average			116	

[1]This assumes that the respiratory quotient (RQ) of 1.0 with glucose being utilized for energy rather than either fats or amino-acids. Geelissen et al. (2006) reported RQ in similar-aged animals of 1.1 or greater. Data are calculated based on body weights of the same aged birds in the same laboratory (Buyse et al., 2004) and on catabolized energy from carbohydrate = 16.7 kJ/g substrate (3008.67 kJ per mole glucose) with RQ of 1.00 (Walsberg and Wolf, 1995).

16	**120.8 ± 12.5**	**105.1 ± 24.5**	**144.2 ± 29.0**

Bolded data are at plateau.
[1]Determined by utilization of [U-^{14}C] glucose.
[2]Plateau conversion to CO_2: 1261 dpm/mg calculated from Goodridge (1968a).
[3]Plateau conversion to glycogen: 647 dpm/mg calculated from Goodridge (1968a).
[4]Plateau conversion to fatty acids: 582 dpm/mg calculated from Goodridge (1968a).
Based on Goodridge (1968a).

1976). The decrease in glucose utilization is due to the following:

- Reduced glucose utilization by peripheral tissues such as skeletal muscles (Table 18.8)
- Reduced glucose utilization by the liver for:
  - lipogenesis, with as little as 2 h fasting (Figure 18.3). Rates of fatty acid synthesis are further decreased to 6.4% of control with 1 day fasting and to 0.2% of control with 3 days starvation (data from Yeh and Leveille (1971a,b)). Expression of genes for enzymes in lipogenesis is depressed by fasting in chickens (Désert et al., 2008; Sherlock et al., 2012).
  - Glycolysis (Goodridge, 1968a).

18.4. GLUCOSE TRANSPORT

Glucose enters cells due to glucose transporters. There are five glucose transporter (GLUT) genes/proteins (chicken: Wagstaff et al., 1995; Kono et al., 2005) in birds, namely:

- *GLUT1*: Solute carrier family 2 facilitated glucose transporter member 1 (Wang et al., 1994) (chicken: Gene bank CGNC ID CGNC:49664)

TABLE 18.8 Glucose Generation/Utilization as Assessed from Venous-Arterial Differences in 8 Week Old Chickens either Fed or Starved for 6 Days

Venous-Arterial Difference (nmol blood/mL)		
	Fed	Starved (6 days)
Liver	+940[1]	+1450

[2]Liver glucose generation calculated as the product of venous arterial difference and blood flow to the liver (1.92 mL/min; Tinker et al., 1986).
[3]Kidney glucose generation calculated as the product of venous arterial difference and arterial blood flow to the kidneys (9 mL/min/g; Merrill et al., 1981).
[4]Net glucose utilization by hindquarters calculated as the product of venous arterial difference and arterial blood flow to the skeletal muscle (50 μL/min/g; Merrill et al., 1981), using skeletal muscle as a surrogate for hindquarters.
[5]Assumes skeletal muscle represents 55% of body weight.
Data from Tinker et al. (1986).

- *GLUT2*: Solute carrier family 2 facilitated glucose transporter member two GLUT3 (chicken: GenBank: Z22932.1)
- *GLUT3*: Solute carrier family 2 facilitated glucose transporter member 3 (SLC2A3) (chicken: Gene bank NM_205511.1)
- *GLUT5*: Solute carrier family 2 facilitated glucose fructose transporter member 5 (chicken: Gene bank CGNC ID1764)
- *GLUT8*: Solute carrier family 2 (facilitated glucose transporter member 8 (chicken: Gene bank CGNC ID378802))

There does not appear to be a homologue of the mammalian insulin dependent GLUT4 in birds (chickens: Seki et al., 2003; house sparrows *P. domesticus*: Sweazea and Braun, 2006). There is high expression of GLUT1 in adipose tissue and the brain (chicken: Kono et al., 2005) together with fibroblasts (Wagstaff et al., 1995). High GLUT2 expression is only found in the liver and kidneys (chicken: Kono et al., 2005; Lee et al., 2006), with low expression in the small intestine (chickens: Duarte et al., 2011). Epidermal growth factor (EGF) decreases GLUT2 protein levels in chicken hepatocytes (Lee et al., 2006). There is high GLUT3 expression in the brain (chicken: Kono et al., 2005) with chicken fibroblasts also expressing GLUT3 (Wagstaff et al., 1995) and all tissues expressing GLUT3 (house sparrows: Sweazea and Braun, 2006). Although GLUT1 is insulin independent in mammals, insulin stimulates glucose uptake along with both GLUT1 expression and protein content in avian myoblasts (chicken: Zhao et al., 2012). An insulin dependent GLUT8 is expressed in the chicken (high: adrenal, brain, kidney, lung, pancreas, spleen and testis; low: adipose tissue, liver, heart, skeletal muscle; chickens: Seki et al., 2003; Kono et al., 2005). GLUT expression decreases during the development of the avian erythrocyte (chicken: Johnstone et al., 1998) with only 200 copies of GLUT1 per mature erythrocyte (pigeon: Diamond and Carruthers, 1993). There is high expression of GLUT2 in the liver of the young chickens, together with some expression of both GLUT1 and GLUT3 (Humphrey et al., 2004). Skeletal muscle also exhibits high expression of GLUT3, with some expression of GLUT1 but no detectable expression of GLUT2 (Humphrey et al., 2004).

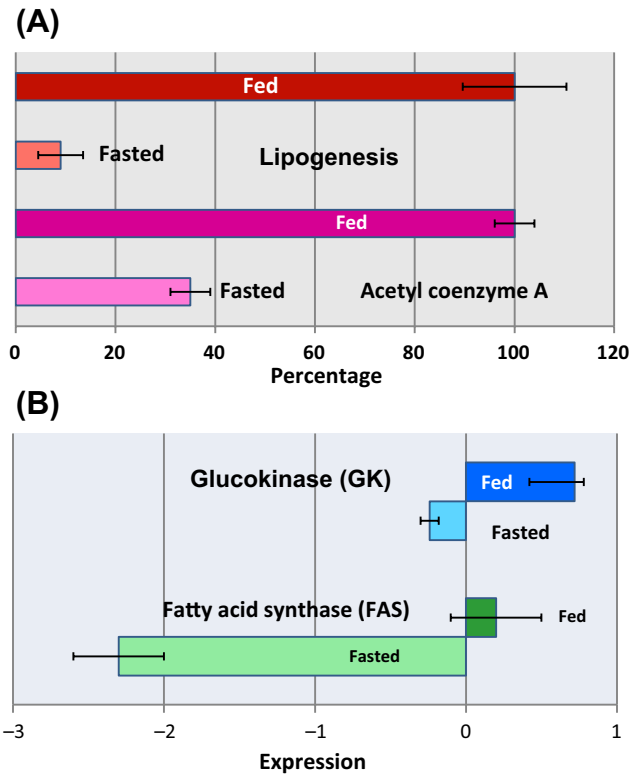

FIGURE 18.3 Effects of fasting on carbohydrate metabolism in the liver. (A) Effect of fasting (2 h) on rate of lipogenesis in the chicken liver and on the liver concentration of acetyl coenzyme A. Data are expressed as a percentage of the control (fed) ± SEM. Calculated from Yeh and Leveille (1971a,b). (B) Effect of fasting for 5 h on the hepatic expression of key enzymes in carbohydrate metabolism in the chicken. *Based on data from Dupont et al. (2008).*

18.5 INTERMEDIARY METABOLISM

18.5.1 Glucose Phosphorylation and Dephosphorylation

Glucose 6-phosphate plays a major role in the control of metabolism (Figure 18.4). There are rapid increases in hepatic concentrations of glucose 6-phosphate after hatching (turkeys: Rosebrough et al., 1979).

18.5.1.1 Glucose Phosphorylation to Glucose 6-Phosphate

Glucose is phosphorylated to glucose 6-phosphate catalyzed either by glucokinase or hexokinase:

$$\text{Glucose} + \text{ATP} \rightarrow \text{Glucose 6-phosphate}$$

18.5.1.1.1 Enzyme: Glucokinase/Hexokinase

Glucokinase has been partially characterized both from chickens and mule ducks with 99% identity (Berradi et al., 2005, 2007). There is increased expression in the liver of mule ducks with overfeeding (Berradi et al., 2004) and feeding in chickens (Berradi et al., 2007). Fasting depresses glucokinase expression by 66% in chickens (Dupont et al., 2008). Low Michaelis constant (Km) hexokinase activity is present in the chicken liver and reduced with fasting (O'Neill and Langlow, 1978; Klandorf et al., 1986). High Km hexokinase activity is found in the mitochondria of the liver (chicken: Borrebaek et al., 2007). Hexokinase is present also in the muscles of hummingbirds (Suarez et al., 1990).

18.5.1.2 Glucose 6-Phosphatase

Glucose 6-phosphatase plays a critical role in glucose homeostasis:

$$\text{Glucose 6-phosphate} \rightarrow \text{Glucose} + \text{Phosphate}$$

18.5.1.2.1 Glucose 6-Phosphatase

Glucose 6-phosphatase activity is present in the avian liver (chicken: O'Neill and Langlow, 1978). Thus, glucose 6-phosphate generated from glycogenolysis and glucogenesis is released from the liver into the circulation for peripheral use. There does not appear to be glucose 6-phosphatase in skeletal muscle; hence, muscle glycogen is not a source of circulating glucose. Along with elevated glycogenolysis and glucogenesis with fasting, there is increased glucose 6-phosphatase activity in the liver (chicken: O'Neill and Langlow, 1978).

18.5.2 Glycolysis

Glycolysis is summarized in Figure 18.4. The glycolytic pathway precedes carbohydrate metabolites entering the citric acid cycle and also allows the anaerobic metabolism of glucose.

18.5.2.1 Developmental Changes

There are low rates of hepatic glycolysis in the liver of avian embryos, rising quickly after hatching to a plateau level achieved after about a week (chicken: Goodridge, 1968a; Table 18.4).

18.5.2.2 Effects of Feeding and Fasting

The posthatch increase in glycosylation is induced by feeding (chicken: Goodridge, 1968b). Hepatics rates of glucose utilization for glycolysis and conversion to carbon dioxide are depressed by fasting. For instance, in young chickens, rates of glucose oxidation to carbon dioxide by liver slices are decreased by the following (Goodridge, 1968b):

- 1 day: 59.5% of control
- 3 days: 17.5%

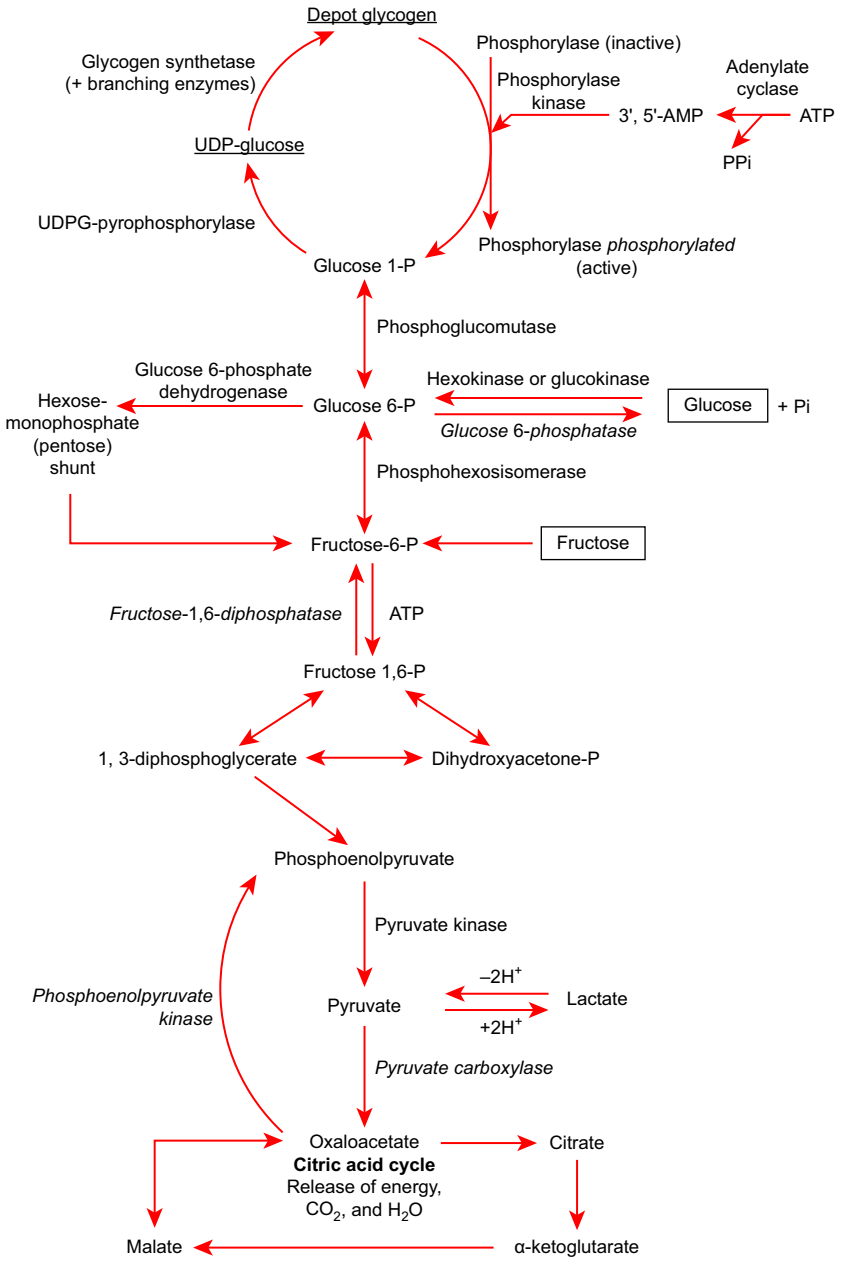

FIGURE 18.4 Overview schematic diagram of carbohydrate metabolism (glucose phosphorylation/dephosphorylation, glycolysis, glycogenesis, glycogenolysis, and pentose phosphate shunt).

Expression of genes for enzymes in the glycolytic pathway is depressed by fasting in chickens (Sherlock et al., 2012).

18.5.2.3 Erythrocytes

Glycolysis and pentose phosphate shunt are the pathways to obtain energy from glucose in the erythrocyte (pigeon: Kalomenopoulou et al., 1990). Phosphofructokinase activity, pyruvate kinase activity, and hexokinase activity are present in the erythrocyte (pigeon: Kalomenopoulou et al., 1990).

18.5.3 Citric Acid or Tricarboxylic Acid Cycle

18.5.3.1 Overview

Figure 18.5 summarizes the citric acid or tricarboxylic acid (TCA) cycle. There were increases in mitochondrial capacity (citrate synthase activity) at the end of embryonic and in early posthatch development (chicken: Walter et al., 2010). Citrate synthase (CS) and pyruvate kinase (PK) activities are found in skeletal muscle from chukar, pheasant, domestic turkey, and wild turkey (Shea et al., 2007). Citrate synthase activity in hummingbirds is similar to that

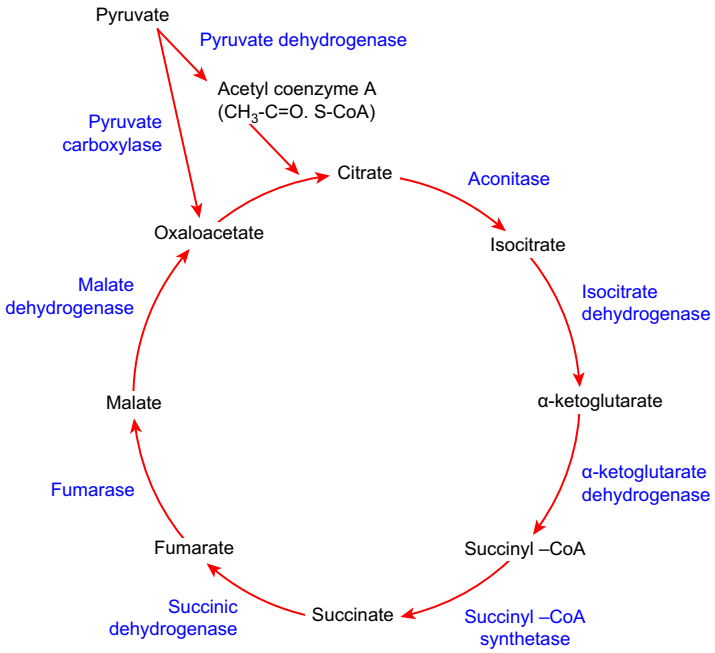

FIGURE 18.5 **The citric acid or tricarboxylic acid (TCA) cycle.**

TABLE 18.9 Comparison of Citrate Synthase Activity between Hummingbirds and Chickens

Species	Citrate Synthase Activity (nmol/min/g wet wt)	Reference
Hummingbird	448	Suarez et al., 2009
Chicken	21	Azad et al., 2010

in mammalian mitochondria (Suarez et al., 1991) but higher than that of the chicken (Table 18.9). PK has been identified by proteomics in pectoralis muscle with dietary protein deprivation (chicken: Corzo et al., 2006).

18.5.3.2 Erythrocytes

The citric acid cycle is absent in erythrocytes (pigeon: Kalomenopoulou et al., 1990).

18.6 GLUCONEOGENESIS

The gluconeogenic pathway is summarized in Figures 18.4 and 18.6. The major organs for gluconeogenesis in birds are the liver and kidneys (see below). There appears to be marked gluconeogenic potential for the yolk sac in the developing embryo, with high expression of fructose 1,6-bisphosphatase and phosphoenolpyruvate carboxykinase together with glucose 6-phosphatase (chicken: Yadgary et al., 2011). Muscle- and liver-type phosphofructokinase-1 (PFK-M and PFK-L) have been characterized in the chicken (Seki et al., 2006). Chicken PFK-L is expressed at a low level in the liver, skeletal muscle, and brain (Seki et al., 2006). Chicken PFK-M is expressed in skeletal muscle (Seki et al., 2006).

18.6.1 Gluconeogenesis and Fasting

Fasting increases gluconeogenesis in some but not all birds. There is greatly increased net release of glucose from both the liver and kidneys (Table 18.8), together with elevated hepatic glucose 6-phosphatase, phosphoenolpyruvate carboxykinase, alanine aminotransferase, and aspartate aminotransferase activities (chickens: Veiga et al., 1978). There are marked increases in gluconeogenesis during fasting in the Japanese quail (*C. japonica*), with increases in the rate of glucose formation from ^{14}C bicarbonate *in vivo* (Sartori et al., 1996, 2000). Moreover, with 2 days fasting (phase 2), there were increases in the activity of cytoplasmic phosphoenolpyruvate carboxykinase in the kidney (Sartori et al., 2000). Similarly, fasting increases gluconeogenesis in duckling liver-based perfusion studies in which the medium contains the gluconeogenic precursor, lactate (Bedu et al., 2001). Expression of genes for enzymes in the gluconeogenic pathway is increased by fasting (chicken: Désert et al., 2008; Sherlock et al., 2012). However, gluconeogenesis is depressed in fasted carnivorous birds (black vulture *Coragyps atratus*: Veiga et al., 1978).

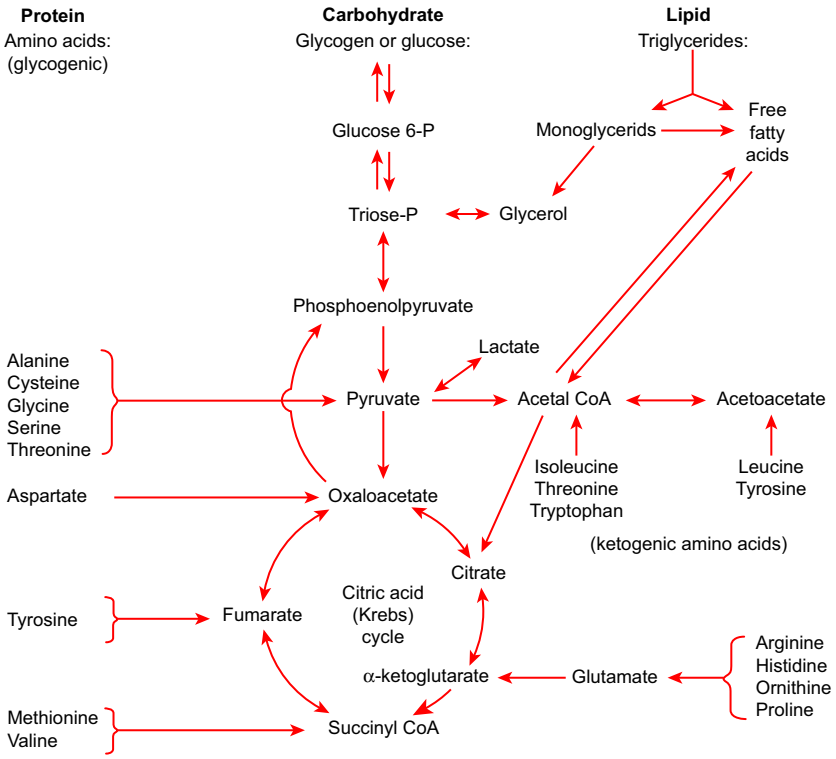

FIGURE 18.6 **Overview schematic diagram of the relationships between lipid and protein metabolism with carbohydrate metabolism.**

18.6.2 Relative Importance of the Liver and the Kidney

Gluconeogenesis occurs in both the liver and kidneys. The relative contribution is estimated from arteriovenous differences in fed and fasted birds, with the liver producing about 70% of the glucose and kidney about 30% in the fasted state (chicken: Tinker et al., 1986; Table 18.8). In fed carnivorous birds, there is high rates of gluconeogenesis (black vulture *C. atratus*: Veiga et al., 1978; also see Figure 18.9). There is likely to be some hepatic gluconeogenesis in graniferous birds. This is supported by studies of arterial-venous differences in glucose and lactate (Table 18.8). It is presumed that much of the lactate originates from gastrointestinal tract, with 37% of glucose converted to lactate in the chicken gastrointestinal tract (Riesenfeld et al., 1982).

18.7 GLYCOGEN

18.7.1 Overview

Glycogen is a branched polysaccharide composed of glucose monomers. It is the major storage form for carbohydrates, particularly in the liver and skeletal muscle. The synthesis and degradation of glycogen is summarized in Figure 18.4 (also see Figure 18.9). Glycogenolysis also plays an important role in astrocyte functioning (chicken: Gibbs et al., 2006).

This can be catalyzed by the enzyme glucokinase (expressed in the liver).

18.7.2 Synthesis and Breakdown

18.7.2.1 Glycogenesis (Synthesis)

Glycogenesis is synthesis of glycogen from glucose:

$$\text{Glucose 6-phosphate} \rightarrow \text{Glucose 1-phosphate}$$

18.7.2.1.1 Phosphoglucomutase

$$\text{Glucose 1-phosphate} + \text{Uridine triphosphate (UTP)} \rightarrow \text{Uridine diphosphoglucose}$$

18.7.2.1.2 UDP-Glucose Pyrophosphorylase

$$\text{Glycogen } (n) + \text{Uridine diphosphoglucose} \rightarrow \text{Glycogen } (n+1) + \text{UDP}$$

18.7.2.1.3 Glycogen Synthase

Glycogen synthase (GS) is expressed in pectoralis muscle (chicken: Sibut et al., 2008; Simon et al., 2012).

18.7.2.2 Glycogenolysis (Breakdown)

Glycogenolysis is the breakdown of glycogen to glucose 1-phosphate:

$$\text{Glycogen}\,(n)+\text{ATP}\rightarrow\text{Glycogen}\,(n-1)+\text{Glucose 1-phosphate}$$

18.7.2.2.1 Glycogen Phosphorylase

Glycogen phosphorylase is expressed in pectoralis muscle (chicken: Sibut et al., 2008; Simon et al., 2012).

18.7.2.3 Glycogenesis (Breakdown)

There is little difference in hepatic phosphorylase activity between late avian embryos and newly hatched chicks (turkeys: Rosebrough et al., 1978b). As might be expected, cAMP increases phosphorylase activity in turkey liver tissue (Rosebrough and Von Vleck, 1990).

There are increases in AMP-activated protein kinase (AMPK) protein, the expression of regulatory and catalytic AMPK subunits, and phosphorylation of AMPK in the liver and skeletal muscle at the end of embryonic and in early posthatch development (chicken: Walter et al., 2010).

18.7.2.4 Developmental Changes

There are marked changes in the importance of glycogen predominantly during posthatch development of birds. Glycogen levels are low in the avian embryo with changes reported in some studies. For instance, liver glycogen is decreased between 15 and 19 days of embryonic development (chicken: Pulikanti et al., 2010) and between 19 days and prior to hatching (chicken: Zhai et al., 2011). These are shifts in the low levels of the storage form of glucose. In contrast, it is speculated that the increase in glycogen in the pipping muscle between 15 and 19 days of embryonic development is provide a ready source of easily mobilized glucose for the process of hatching (chicken: Pulikanti et al., 2010). At least in galliform birds, there are large increases in the amount of glycogen stored in the liver following hatching (turkey: Foye et al., 2006; see Table 18.10).

There are increases in liver glycogen during the second half of embryonic development to a maximum that occurs prior to the beginning of the process of hatching in the chicken (*Gallus gallus*):

- Glycogen concentrations increasing threefold between 11 days of embryonic development to a maximum at day 18 (Hamer and Dickson, 1987)
- Glycogen concentrations increasing 51% between 16 days of embryonic development to a maximum at day 18 (Willemsen et al., 2011)
- Glycogen content increasing between 18 days of embryonic development to a maximum at day 20 (Kornasio et al., 2011; see Table 18.11).
- A decrease (58%) decrease in the hepatic glycogen concentration was reported between internal pipping and hatching (chicken *Gallus gallus*: Willemsen et al., 2011) with glycogenolysis was calculated to yield 21 µmol glucose during the process of hatching.

After hatching, there are marked increased in liver glycogen in chicks receiving feed early (Kornasio et al., 2011; see Table 18.11). Before and after hatching, hepatic glycogen are increased by *in ovo* feeding (nutrient supplementation to the embryo; Kornasio et al., 2011).

Pectoralis muscle glycogen shows only small similar pattern to that of liver but with smaller changes, with a 33% increase between days 18 and 20 (Kornasio et al., 2011). Muscle glycogen is increased by *in ovo* feeding (Kornasio et al., 2011).

The rate of hepatic glycogenesis is very low in avian embryos, but it rises immediately after hatching to achieve a plateau at approximately 2 weeks old (chicken: Goodridge, 1968a; Table 18.4). The rise in glycogenesis does not occur in newly hatched chicks until after feeding, suggesting

TABLE 18.10 Changes in Liver Glycogen during Early Posthatch Embryonic Development of the Turkey

	Liver Glycogen

that nutrients induce expression of critical carbohydrate enzymes (chicken: Goodridge, 1968b). There are analogous increases in the activity of hepatic glycogen synthase in the first week of life after hatching (turkeys: Rosebrough et al., 1979).

18.7.2.5 *Effect of Feeding and Fasting*

There are marked effects of nutrition on liver glycogen concentrations. An example where hepatic glycogen storage is high is in chickens fed meals. Table 18.12 summarizes the hepatic glycogen concentrations and the daily estimated contribution of glycogenolysis in the postabsorptive period between meals to whole body metabolism. Moreover, the relatively high rates of glycogenolysis will be similar to those of glycogenesis in the fed state. Hepatic glycogen synthase activity is increased by glucose and, particularly, sucrose supplementation (turkeys: Rosebrough et al., 1979). There are also increases in skeletal muscle glycogen after hatching, reflecting increased glycogen synthase activity (turkeys: Rosebrough et al., 1979). Glycogen concentrations in the liver, kidneys, and skeletal muscle are depressed by fasting, as shown in chickens (Tinker et al., 1986; see Table 18.13) and turkeys (Rosebrough et al., 1978a).

18.7.3 *In ovo* Feeding

Liver glycogen concentrations rise in late embryonic development to a peak at day 20, with a subsequent decline before hatching (Kornasio et al., 2011). *In ovo* feeding increases glycogen concentrations in both the liver and skeletal muscle (Kornasio et al., 2011). There is a large increase in the concentrations of glycogen in both the liver and skeletal muscle after feeding (Kornasio et al., 2011).

18.7.4 Glycogen Body

The glycogen body is a gelatinous ovaloid organ found in dorsal area of the lumbosacral region of the spinal cord in birds (Watterson, 1949). It is composed of what was initially described as uniform glycogen body cells (Watterson, 1949). These are astroglial-like cells (Louis, 1959, 1993; De Gennaro, 1993). These cells have a high capacity to store glycogen and contain deposits of glycogen in the cytoplasm (Imagawa et al., 2006a). A second cell type has been identified based on co-incubation of glycogen body cells with cerebellar neurons. These have processes that extend and attach to neurons (Imagawa et al., 2006a). The glycogen body is derived from anterior section of the lumbosacral neural tube (De Gennaro, 1991). The lobes of Lachi have many metabolic similarities to glycogen bodies with glycogen synthase, glycogen phosphorylase, glucose 6-phosphate dehydrogenases, and 6-phosphogluconate dehydrogenase together with a lack of glucose 6-phosphatase (Benzo and DeGennaro, 1981).

Glycogen bodies contain multiple metabolic enzyme activities, including the following: glycogen synthase,

TABLE 18.13 Changes in Glycogen (μmol glucose equivalents/g) with Starvation in Chickens

	Glycogen (μmol glucose equivalents/g)	
Organ	**Fed**	**Starved 6 Days**
Liver	84.4	18.5
Muscle	54.4	25.8
Kidneys	2.8	1.3

Data from Tinker et al. (1986).

TABLE 18.12 Changes in Liver Glycogen with Meal Feeding in the Chicken, Allowing Determination of the Rate of Glycogenolysis

Time Relative to Feeding	Meal Fed	Liver Glycogen (mmol glucose equivalents per kg body weight)	Delta Liver Glycogen (mmol glucose equivalents per kg body weight)	Estimated Release of Glucose by Glycogenolysis (μmol glucose per min per kg body weight)
+12 h following meal	Once daily	7.7	4.2	5.8
Prior to feeding	Once daily	3.5		
+24 h following meal	Once on alternate days	15.9	9.0	6.2
Prior to feeding	Once on alternate days	6.9		

From De Beer et al. (2007).

glycogen phosphorylase, glucose 6-phosphate dehydrogenases, and 6-phosphogluconate dehydrogenase (Benzo and DeGennaro, 1974, 1981). There is lactate dehydrogenase (LDH) activity and LDH-B expression in the glycogen body (Imagawa et al., 2006b). It is suggested that the glycogen body consumes lactate body (Imagawa et al., 2006b). The glycogen level within the glycogen body cells is refractory to both nutritional status, being unchanged by starvation, and by hormones such as insulin, glucagon, and adrenocorticotropic hormone (Imagawa et al., 2006a). There is a small effect of norepinephrine on glycogenolysis with reduced glycogen levels in the glycogen body cells *in vitro* (Lee et al., 2001). It is suggested that the glycogen body and the lobes of Lachi function to provide precursors via the pentose phosphate pathway for myelin synthesis (Benzo and DeGennaro, 1981).

18.8 CARBOHYDRATE DIGESTION AND ABSORPTION

Carbohydrate digestion and absorption will be discussed in three parts: starch digestion, disaccharide digestion, and glucose absorption.

18.8.1 Starch Digestion

Starch is digested by amylase, which is produced by the small intestine (see Table 18.14) and exocrine pancreas (chicken: Osman, 1982). About 97% of corn starch in the diet is digested in the chicken (Riesenfeld et al., 1980). The sites of starch digestion in the chicken small intestine are the following (calculated from Riesenfeld et al., 1980):

- Duodenum 63%
- Jejunum 19%
- Ileum 12%

However, there is markedly higher proportion of digestion of other starches, for instance from legumes, in both the duodenum and ilium of chickens (Weurding et al., 2001). There is secretion of amylase in the upper gastro-intestinal tract and from the liver reported in some birds: from salivary glands (e.g. *spotted dove* (Streptopelia chinensis) and house crow (Corvus splendens)), the proventriculus (e.g. house sparrow (Passer domesticus)) (Bhattacharya and Ghose, 1971) and from the liver in bile (chicken: Farner, 1943).

TABLE 18.14 Enzymatic Activities in the Chicken Small Intestine

Enzyme	Duodenum	Jejunum
Amylase	13.4	19.0
Maltase	1.5	4.8
Sucrose	1.4	3.2

Based on Liu et al. (2008).

18.8.2 Disaccharide Digestion

Maltase cleaves the disaccharide maltose into its two constituent glucose moieties, whereas sucrose cleaves the disaccharide sucrose into its two constituent monosaccharide moieties, glucose and galactose. There is both maltase and sucrase activity in the duodenum and jejunum (chicken: Liu et al., 2008). Although maltase activity is higher than that of sucrose in a passerine bird, the rufous-tailed plantcutter (*Phytotoma rara*), there is a similar distribution along the small intestine (Meynard et al., 1999). Similarly, there is somewhat lower expression of isomaltase in the jejunum then duodenum (Liu et al., 2008). There are little changes in expression of isomaltase during embryonic development (Yadgary et al., 2011).

18.8.3 Glucose Absorption

There is active absorption of glucose in the small intestine, cecum and colon of birds (chickens: Riley et al., 1986; Vinardell and Lopera, 1987; Moreno et al., 1996; De La Hora et al., 1998, 2001). The major site of glucose absorption is the duodenum, accounting for more than 80% of glucose absorbed in young chickens fed a diet high in glucose (Riesenfeld et al., 1980). The very high glucose absorption from the intestines of hummingbirds is due to active, mediated transport (rufous (*Selasphorus rufus*) and Anna's (*Calypte anna*) hummingbirds) (McWhorter et al., 2006).

Glucose absorption from the lumen of the gastrointestinal tract into enterocytes is achieved by active transport, predominantly by sodium D-glucose and galactose co-transporter 1 (SGLT1). The SGLT1 protein has a high affinity for glucose (Gal-Garber et al., 2000) and is exclusively found in the brush border of enterocytes (chickens: De La Hora et al., 1998; Barfull et al., 2002). Expression of SGLT1 is high in the small intestine, being greatest in the jejunum as seen from the following values for the chicken (calculated from Gilbert et al., 2008, with expression shown as a percentage of that in the jejunum):

- Duodenum 77%
- Jejunum 100%
- Ileum 65%

Jejunal expression of sodium glucose transporter 1 is increased in fasted chickens (Gal-Garber et al., 2000; Duarte et al., 2011) and further elevated with re-feeding (Gal-Garber et al., 2000). During embryonic development expression of SGLT1 is increased (chicken: Yadgary et al., 2011; Speir et al. 2012; pigeon: Dong et al., 2012). During growth, the surface area increases but expression of SGLT1 declines (Barfull et al., 2002). Aldosterone influences expression of SGLT1 (chickens: De La Hora et al., 2001). There is also expression of sodium independent glucose (galactose and

fructose) transporter 2 (GLUT2) in the small intestine. Jejunal expression of GLUT2 is unaffected by either fasting or re-feeding in young chickens (Duarte et al., 2011).

18.8.4 Gastrointestinal Storage of Ingesta

There is temporary storage of feed in the crop and gizzard of at least some graniferous birds (e.g., in the order *Galliformes*). For instance, substantial stores of feed are found in crop of in sexually immature meat-type chickens adapted to either daily or alternate day meal feeding (De Beer et al., 2008) (Figure 18.7). In chickens, feeding is restricted to the hours of light (day). There is a marked peak in consumption prior to lights off, with concomitant filling of both the crop and gizzard (Scanes et al., 1987; Buyse et al., 1993; Figure 18.7). Nocturnal energy needs are accommodated by reduced metabolic rate and the release of the stored ingesta (Buyse et al., 1993; Figure 18.8).

18.8.5 Intestinal Fermentation

Limited information is available on gastrointestinal fermentation in birds.

18.8.5.1 Cellulose

18.8.5.1.1 Foregut

A neotropic bird, the hoatzin (*Opisthocomus hoazin*), is said to be unique in having foregut fermentation (Grajal et al., 1989). The microbial communities in the muscular crop have been characterized and include methanogens as in the mammalian rumen (Wright et al., 2009; Godoy-Vitorino et al., 2012).

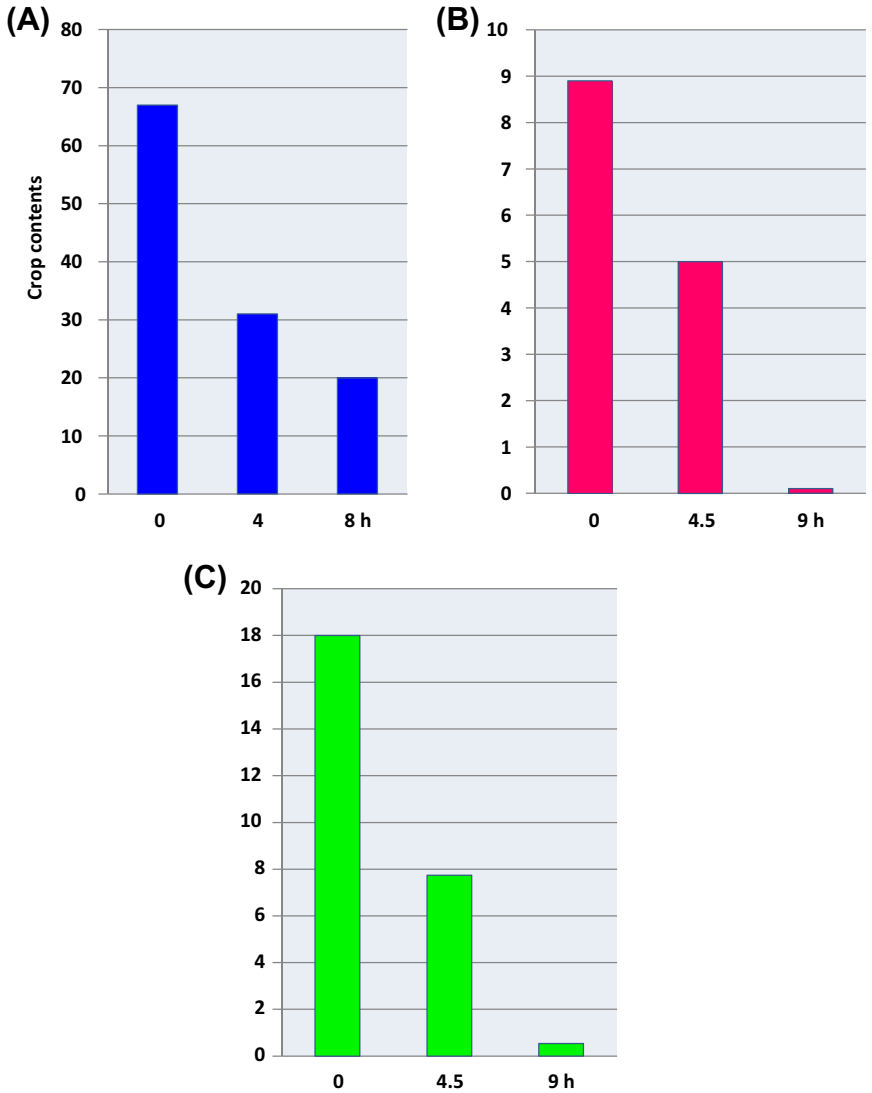

FIGURE 18.7 Mechanical storage of ingesta in the crop (g) of chickens. (A) Following meal feeding in broiler breeder pullets (sexually immature females) (De Beer et al., 2008) and (B) during the night following increased feeding prior to lights-off in young broiler chickens (Buyse et al., 1993) and during the night following increased feeding prior to lights-off in laying hens (Scanes et al., 1987).

18.8.5.1.2 Hindgut

Cellulose fermentation to volatile fatty acids in the ceca has been demonstrated in a galliform bird, rock ptarmigan (*Lagopus muta*) (Gasaway et al., 1976a,b,c).

18.8.5.2 Starch

There is evidence for fermentation of starch in the crop of domestic poultry. During the nocturnal storage of feed in the crop, there are marked increases in lactate acid concentrations but little increase in volatile simple fatty acids, except valeric and caproic acids (turkey: Johannsen et al., 2005). About 37% of glucose converted to lactate in the chicken gastrointestinal tract (Riesenfeld et al., 1982).

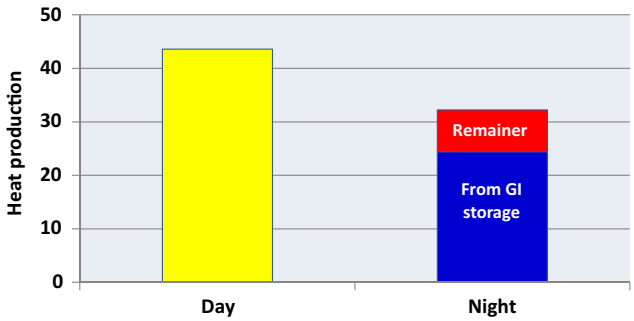

FIGURE 18.8 Comparison of heat production/energy consumption (kJ $kg^{0.75}$ h) during the day and night in young chickens. Also shown are the contributions of ingesta held (short-term stored) in the crop, gizzard, and proventriculus for nocturnal needs. *Data from Buyse et al. (1993).*

18.9 CONCLUSIONS

Figure 18.9 summarizes glucose flow in the metabolism in birds.

Although carbohydrate metabolism in birds is similar is that in mammals, there are distinct differences:

1. There are marked differences between circulating concentrations of glucose between wild birds and mammals, with avian concentrations double those in mammals.
2. Birds are very resistant to diabetes, with neither pancreatectomy nor insulin administration evoking large changes in circulating concentrations of glucose. However, chickens received passive immunization with antisera to insulin exhibit a diabetic-like shifts in metabolism, with circulating concentrations of glucose of 747 mg/dL reported 5 h after antisera administration (Dupont et al., 2008; Simon et al., 2012). Identical extremely high concentrations of glucose are observed following feeding in hummingbirds without adverse effects (Beuchat and Chong, 1998).
3. The glucose transporter GLUT4 is missing in birds.
4. The principal site of lipogenesis is the liver (compared with adipose tissue in mammals).

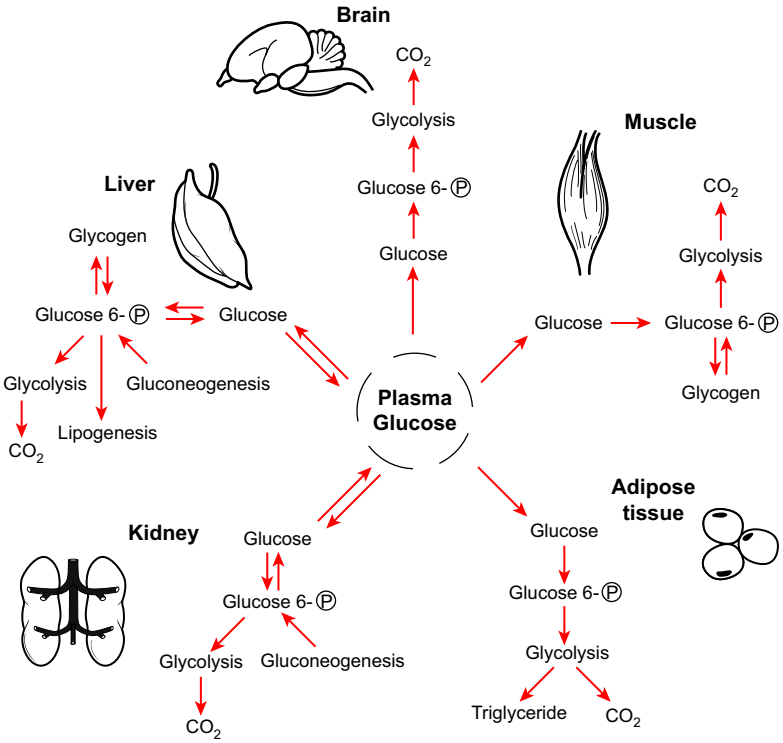

FIGURE 18.9 Overview schematic diagram summarizing the flow of glucose to and from plasma to major organs.

18.9.1 In starvation and metabolism

It is assumed that there are four metabolic phases:

- An absorptive phase following feeding, until ingesta carbohydrates in the gastrointestinal tract are completely depleted
- A postabsorptive phase or short-term fasting
- Phase 2 starvation: protein sparing and utilization of fatty acids
- Phase 3 starvation: fatty acids depleted and a shift to amino acids.

The absorptive phase is when glucose and other simple carbohydrates are being absorbed. It encompasses both the passage of ingesta with digestion, and any storage of ingesta in the foregut (crop, gizzard, and proventriculus) prior to digestion/absorption (Figure 18.7). In at least chickens and turkeys, there is nocturnal foregut storage of ingesta (laying hen: Scanes et al., 1987; young chicken: Buyse et al., 1993). This has been calculated to meet over 70% of energy requirements (Figure 18.8).

It has been generally assumed that, during the postabsorptive phase, glycogen is employed as the energy source. In contrast, during phase 2 starvation, there is protein sparing and fatty acids from the breakdown of adipose triglyceride used. During phase 3 starvation, there is a shift to muscle and other protein catabolism using amino acids for gluconeogenesis as triglyceride stores are exhausted (Goodman et al., 1980; Bernard et al., 2002).

During the postabsorptive phase, together with phase 2 and 3 starvation, there is a progressive decrease utilization of glucose for glycolysis, such as by muscle (see Table 18.8) and hepatic lipogenesis (Figure 18.3). The decrease precedes the end of absorptive phase as, for instance, the metabolic rate is decreased 26% in chickens during the nocturnal period (Figure 18.8), when feeding has essentially stopped. Hepatic glycogenolysis only meets a small proportion of body glucose during the postabsorptive phase. Table 18.12 shows hepatic glycogen contents in meal-fed chickens; it was assumed that the hepatic glycogen contents approach maximal in chickens fed meals either daily or on alternate days. Hepatic glycogenolysis in the postabsorptive phase between meals was calculated as follows:

- 6 μmol/min/kg compared with
- 55 μmol/min/kg total glucose utilization (Belo et al., 1976) or 116 μmol/min/kg total glucose utilization (Table 18.5).

Thus, only about 10% of whole body glucose utilization comes from hepatic glycogenolysis. This would indicate that hepatic gluconeogenesis is increased and hepatic glycolysis and lipogenesis are decreased during the postabsorptive phase and phase 2 starvation. Evidence for an immediate increase in gluconeogenesis and/or a decline in hepatic glycolysis comes from the observed reduction in the hepatic concentration of lactate with 2 h fasting (chicken: Yeh and Leveille, 1971b).

The glycogen content in both the liver and muscle decline during fasting, being depressed by respectively 78% and 53% with 6 days of starvation in the chicken (see Table 18.12; Tinker et al., 1986).

The conceptual framework for phases 2 and 3 starvation is supported in king penguins (*Aptenodytes patagonicus*), where body fat reverses are almost exhausted with markedly decreased circulating concentrations of fatty acids (Bernard et al., 2002). Evidence for increased gluconeogenesis comes from the increase in circulating concentrations of uric acid (Bernard et al., 2002). Moreover, in chickens, starvation for 6 days is accompanied by increased net release of glucose into hepatic and renal veins (Tinker et al., 1986); indicating elevated gluconeogenesis (see Table 18.8). This is calculated as gluconeogenesis providing 70 μmol glucose/min/kg.

Arterial venous differences demonstrate that there is a concomitant increase uptake of glucogenogenic precursors (amino acids and lactate) by the liver and kidney together with release from the hindquarter muscles (Tinker et al., 1986). Increased gluconeogenesis is indicated by the depressed circulating concentrations of glycine in chickens fasted for 24 h (Belo et al., 1976).

Chapter 19

Adipose Tissue and Lipid Metabolism

Johan Buyse and Eddy Decuypere
Laboratory of Livestock Physiology, Department of Biosystems, Faculty of Bioscience Engineering, KU Leuven, Leuven, Belgium

ABBREVIATIONS

ACC acetyl-CoA carboxylase
ATGL adipose triglyceride lipase
FAS fatty acid synthase
FTO fat mass and obesity-associated (FTO) gene
GH growth hormone
HDL high-density lipoproteins
IGF insulin-like growth factor
LDL low-density lipoproteins
LPL lipoprotein lipase
ME metabolizable energy
NEFA nonesterified fatty acids
PPARγ peroxisome proliferator-activated receptor γ
SREBP sterol regulatory element binding protein
TAG triacylglycerol
VLDL very-low-density lipoproteins
VLDLy yolk-targeted very-low-density lipoproteins

19.1 INTRODUCTION

The presumed predominant function of adipose tissue is to maintain energy homeostasis. In times of feed excess, energy is stored as hydrophobic triglycerides or triacylglycerols (TAGs) in expansive lipid droplets within the adipocytes. Triacylglycerols are very well suited for this as they contain a large amount of energy per unit of weight. In times of feed deprivation, however, adipocyte TAGs are mobilized (lipolysis) and the generated fatty acids are subsequently oxidized by various tissues to yield chemical energy. Adipose tissue is the most variable carcass component, and the amount that is deposited depends on genetic as well as on exogenous factors. However, it has become clear that adipose issue is more than only a storage buffer for energy as it also functions as an important endocrine and paracrine tissue involved in many bodily processes.

19.2 DEVELOPMENT OF ADIPOSE TISSUE

Adipose tissue cellular development consists of an increase in cell number (hyperplasia) and an increase in cell volume (hypertrophy). Both adipocyte number and volume increase with age and are positively correlated with fat pad weight and with body mass (Cartwright, 1991). Hence, both hyperplasia and hypertrophy of adipose cells contribute to the accumulation of fat in the chicken. However, the magnitude of the contribution of each of these two factors to the final size and weight of the distinct fat tissues is not equal.

At younger ages, increases in weight of fat depots would be mainly attributable to an increase in fat cell number, whereas at later ages, lipid accumulation in fat cells would be the major determinant. Literature data are not consistent about the age at which hypertrophy becomes the most important contributor to adipose tissue growth. It was first observed that in broiler chickens of a commercial strain, the number of abdominal adipocytes increased until about 12–14 weeks of age, whereas adipocyte volume only increased slowly. After this age, the filling of the existing adipose cells was then the predominant factor responsible for the increase in weight of the abdominal fat pad (Hood, 1982; March et al., 1984; Cartwright, 1991). In contrast, more recent studies revealed that at about 7 weeks of age, increases in fat deposition were primarily due to adipocyte hypertrophy in broiler chickens (Guo et al., 2011). The modern, growth-selected, meat-type chickens are proportionally fatter compared with the random-bred, unselected, or even growth-selected chickens of some decades ago. Therefore, it is reasonable to assume that the age at which hypertrophy becomes the major determinant for body fat accumulation is shifted to a younger age and even to a lower degree of maturity. Fast-growing chickens will probably also attain their genetically determined final number of fat cells earlier than slower growing chickens. Furthermore, sex (Hood, 1982), nutritional status (March et al., 1984; Cartwright, 1991), and surely direct and indirect divergent selection for fatness (Hood and Pym, 1982; Guo et al., 2011) all affect the age- or body weight-dependent developmental pattern of adipose cellularity. As a consequence of the increase in

Sturkie's Avian Physiology.

adipocyte number and size but with a different velocity, a bimodal frequency distribution (proportional number of cells per diameter class) is present in the abdominal fat pad of broilers by 7 weeks of age. With increasing age up to 22 weeks, the number of fat cells in the population of "large" cells increased slowly and the mean diameter shifted to larger values. In contrast, the number of cells in the population of "small" cells increased more rapidly, but the mean cell diameter remained unchanged (March et al., 1984). The same phenomenon was observed by Merkley and Cartwright (1989) for abdominal, thigh, back, and neck fat pads. It can be concluded that differences in fatness between populations, even when considered on a same-body-weight basis, are attributable to both the number and the size and volume of adipocytes, whereas reductions in body fat content by, for example, dietary manipulations are mainly caused by delipidation of adipocytes (hypotrophy).

19.3 ADIPOCYTE PROLIFERATION AND DIFFERENTIATION

The first step in adipogenesis is the differentiation of chicken embryonic stem cells into white preadipocytes, a process that is induced by insulin and dexamethasone (Li et al., 2011). The resulting adipocyte precursors are present in the stromal-vascular fraction of adipose tissue. These preadipocytes proliferate and then undergo differentiation to multilocular immature white adipocytes. When becoming filled with lipids, unilocular mature adipocytes appear that are characterized by distinct morphological and metabolic features (Butterwith, 1988; Evans, 1977). A mature avian fat cell (with an average diameter of 150 μm) is characterized by the presence of a large lipid droplet that occupies more than 80% of the total cell volume. As a consequence, all other cell organelles are displaced to the periphery, where the cytoplasm appears as a narrow rim. Another morphological feature of avian adipocytes is the presence of microfilaments at the interface between the cytoplasm and lipid droplet, which may provide structural support to the adipocyte (Evans, 1977; Hood, 1982).

Most of the studies concerning adipogenesis were done using cell culture systems with cell lines from mammalian and, to a much lesser extent, from avian origin and were mainly focused on its endocrine regulation. It was observed that the proliferation of chicken preadipocytes grown in culture was stimulated when insulin was added to the medium. When the medium was supplemented with 10% dialyzed chicken serum or when insulin was deleted from the medium, proliferation was retarded. Moreover, it was found that chicken preadipocyte proliferation *in vitro* was stimulated by insulin-like growth factor-1 and -2 (IGF1 and IGF2), fibroblast growth factor-1 and -2, epidermal growth factor, transforming growth factor-α and -β, and platelet-derived growth factor (reviewed by Butterwith (1997)). However, most of these growth factors also inhibit preadipocyte differentiation. These data suggest that these growth factors may be important autocrine, paracrine, and endocrine regulators of preadipocyte proliferation and differentiation. In addition, glucose (Qi et al., 2012), dexamethasone, and insulin (Ramsay and Rosebrough, 2003) also stimulate preadipocyte differentiation. Finally, insulin, heparin, chicken serum, dexamethasone, and the transcription factor peroxisome proliferator-activated receptor-γ (PPARγ) are involved in the maturation (lipid filling) of adipocytes.

19.4 DISTRIBUTION OF BODY FAT

The modern meat-type chickens contain between 150 and 220 g of lipids per kilogram of body weight at commercial slaughter age. Adipose tissue is distributed over several fat depots, of which the abdominal fat pad is the largest, followed by neck, thigh, back, and gizzard fat pads. These fat depots represent about 20% of the total body fat content. The skeleton and the skin contain, respectively, 15% and 19% of the total body lipid content, whereas several smaller fat depots represent about 8% of the total body fat content. The rest of the carcass, then, contains about one third of the total body lipid content. As avian striated muscle is characterized by only small amounts of inter- and intramuscular fat (1.5%), the remaining lipids must be located in the intestines, lungs, kidneys, glands, and so on (Nir et al., 1988).

The abdominal fat pad weight is highly positively correlated with total body fat content, and as it is rather easy to dissect it quantitatively, abdominal fat pad weight has been used extensively as an excellent estimator of total body fat content (Sonaiya, 1985). Indeed, selection against fatness in meat-type chickens by means of selection against abdominal fat content has been proven to be very successful (Leclercq, 1984; Baéza and Le Bihan-Duval, 2013).

The growth of higher vertebrates consists of not simply an increase in weight but also changes in body conformation and composition due to the differential growth rate of the constituent parts and of their functional abilities (Pálsson, 1955). The relationship between the weight of a part (Y) of the body in relation to total body weight (X) can be described by the Huxley equation:

$$Y = aX^b$$

Or, after logarithmic transformation:

$$\ln Y = \ln a + b \ln X$$

The regression coefficient b is also referred to as the allometric coefficient. When $b = 1$, the weight of the dependent variable Y increases proportionally with the weight of the independent variable X (isometric). When $b \neq 1$, the proportionality of absolute weights is not maintained, but the ratio

between the relative growth rates of both *Y* and *X* remains constant during the growth trajectory.

As in mammals, the allometric coefficient for the growth of body fat in relation to body weight is also greater than unity in avian species. However, not all adipose tissues, including intramuscular and physiologically necessary fat, mature at the same rate as indicated by their different allometric coefficients. Merkley and Cartwright (1989) reported greater weight gains in abdominal and back fat than in neck and sartorius fat depots between 8 and 16 weeks of age in commercial female broilers. Nir et al. (1988) observed that in broiler lines selected for or against abdominal fat content, the allometric coefficients (pooled for both lines) of several fat depots increased in the following order: sartorial ≈ neck fat (0.83) < gizzard fat (1.030) < abdominal fat (1.17) < mesenteric fat (2.51). The allometric coefficients were higher for the high-fat-line chickens (average 1.24) compared to the low-fat-line chickens (average 1.02). From our studies on commercial broilers reared under continuous illumination, the following allometric coefficients were calculated: sartorial fat (1.137) ≈ scapular fat (1.171) < heart fat (1.284) < abdominal fat (1.615) ≈ stomach fat (1.623). It can also be concluded that the abdominal fat pad is relatively more affected by genetic and nongenetic factors than other fat depots and even the fat deposited in the rest of the carcass. However, the mechanisms involved in the differential allometric growth of adipose tissues and in the regulation of the discriminative effects of genetic and exogenous factors, according to their location in the body, remain to be elucidated further.

19.5 LIPID METABOLISM

19.5.1 Lipoprotein Metabolism

19.5.1.1 Portomicrons

After hydrolysis, simple sugars (hexoses and pentoses) and amino acids are transported by active or diffusion processes from the lumen of the small intestine into the blood circulation. Dietary lipids are first hydrolyzed by lipases, and the resulting free fatty acids are absorbed by the mucosa cells. Within the enterocytes, most fatty acids are re-esterified with glycerol to form new TAGs. These TAGs are then associated with phospholipids, cholesterol (esters), and specific apolipoproteins (mainly apoB100) to form lipoproteins. In mammals, these lipoproteins are transported via the lymphatic system and are therefore termed chylomicrons. In birds, however, the lymphatic system is poorly developed and these newly formed lipoproteins are released into the portal vein. It was therefore proposed to term these lipoproteins (average diameter of 150 nm) from dietary origin as portomicrons (Bensadoun and Rothfeld, 1972). The main characteristics as well as the lipid composition of these lipoproteins and other lipoprotein classes and remnants are given elsewhere (Sato et al., 2009; Alvarenga et al., 2011). It is worthy to note that lipoproteins of birds have no apoB48 and apoE (Walzem, 1996). However, the re-esterification of the dietary free fatty acids is not complete and the nonesterified fatty acids (NEFAs) are also released to the portal system, bound to albumin, and carried to peripheral tissues. The portomicron concentration in the blood is mainly dependent on the nutritional status of the bird and of the dietary fat content (Griffin and Hermier, 1988). After the portomicrons are released into the portal vein, they are transported to the liver. However, they are not metabolized by the liver (probably because they are too large to penetrate the cellular sieve of the hepatic capillary bed; Hermier (1997)) but pass through the liver to the extrahepatic tissues where they are partially hydrolyzed by lipoprotein lipase (LPL). The resulting portomicron remnants are taken up by the liver, probably by an apoB100-dependent lipoprotein remnant receptor as apoE is lacking in chickens (Sato et al., 2009). The endocytosed TAG can then be used to resynthesize new TAG-rich lipoproteins.

19.5.1.2 "De novo" Lipogenesis and Very-Low-Density Lipoprotein (VLDL) Synthesis

"De novo" lipogenesis refers to those metabolic pathways that are involved in the synthesis of TAGs from nonlipid precursors (e.g., carbohydrates from dietary origin, or from glycogenolysis or gluconeogenesis from glucogenic or ketogenic amino acids and metabolites such as lactate and glycerol). In contrast to most mammals, in which *de novo* lipogenesis predominantly takes place in the adipocytes, in avian species, the liver has been traditionally considered as the main site of *de novo* lipogenesis (Leveille et al., 1975). However, there are indications that the role of the liver in lipogenesis might be overestimated and that the contribution of other tissues (e.g., bones, skin, and intestines) must also be reconsidered (Griffin and Hermier, 1988; Nir and Lin, 1982).

Acetyl-CoA, formed from pyruvate by pyruvate dehydrogenase, plays a central role in *de novo* lipogenesis. Acetyl-CoA is then irreversibly converted to malonyl-CoA. This reaction is catalyzed by Acetyl-CoA carboxylase (ACC), and this step is considered to be rate limiting for fatty acid synthesis. Elongation of malonyl-CoA is catalyzed by the multienzyme complex fatty acid synthase (FAS). The newly formed fatty acids are then esterified with glycerol to form TAGs. These TAGs are then assembled with phospholipids, cholesterol (esters), and specific apolipoproteins (mainly apoB100) to form very low density lipoproteins (VLDLs). The newly synthesized VLDLs are then stored in vesicles and released into the bloodstream. As for mammals, many apolipoproteins have already been identified in birds, but the roles of the individual avian apolipoproteins are not yet fully elucidated (Griffin and Hermier, 1988; Walzem, 1996;

Sato et al., 2009). Insulin stimulates *de novo* hepatic lipogenesis and VLDL synthesis, whereas thyroxine, glucagon, and epinephrine have opposite effects. Plasma VLDL concentrations are highly positively correlated with total body fat content and can be used successfully as selection criteria for or against fat deposition in broiler lines (Whitehead, 1988; Guo et al., 2011).

19.5.1.3 LPL: A Key Enzyme

TAG-rich lipoproteins from the intestine (portomicrons) and from the liver (VLDL) secreted in the bloodstream are substrates for several lipase enzymes, of which LPL is by far the most important. LPL is synthesized by fat and by muscle cells and migrates to the luminal surface of the surrounding blood capillaries, where it becomes functional after being anchored to the capillary wall by heparin and must be activated by specific apolipoproteins on the surface coat of the lipoproteins (Butterwith, 1988; Griffin and Hermier, 1988). In mammals, apoCII is transferred from high-density lipoproteins (HDLs) to VLDLs and then activates LPL. In birds, however, the equivalent activator of LPL needs to be identified (Walzem, 1996) but is present on VLDLs from immature hens and portomicrons from mature and immature hens and HDLs (Griffin et al., 1982). LPL hydrolyzes TAGs from the core of the lipoprotein, after which the liberated free fatty acids are taken up by the cells. In muscle cells, fatty acids are then oxidized to yield energy, whereas in adipocytes, fatty acids are again incorporated into TAGs for storage. LPL activity is influenced by the age and, to some extent, nutritional state of the bird and is under the major stimulatory control of insulin (Griffin and Hermier, 1988).

19.5.1.4 Lipoprotein Catabolism

As the hydrolysis of the TAGs of the lipoproteins progresses, apolipoproteins are also lost and the lipoproteins decrease in size but increase in density. The partially metabolized VLDLs can be recovered from chicken plasma as intermediate-density lipoproteins (IDLs, or VLDL remnants). The IDL is remodeled in cholesterol-rich LDLs. The remaining VLDL remnants and portomicron remnants are substrate for hepatic lipase. LDLs are taken up by receptor-mediated endocytosis in the liver and other tissues. Premature HDLs probably originate in liver and intestines and receive cholesterol and phospholipids from VLDLs and after interaction with LDLs. As in mammals, HDLs are considered to be the main transporters of cholesterol and phospholipids in avian species.

19.5.1.5 Lipoproteins in Laying Hens

Plasma lipoprotein metabolism in laying hens differs substantially compared to that in immature hens or male chickens. As the ovary has very little capacity for lipid synthesis, all egg yolk lipids are synthesized mainly by the liver (stimulated by steroid hormones, i.e., estrogens and progesterone) and transported to the ovary in special yolk-targeted TAG-rich VLDLs (VLDLy) and in phospholipid-rich lipoproteins termed vitellogenins (Walzem, 1996). Compared with immature hen and normal VLDLs, laying hen VLDLy are 50% smaller in size (30 nm), contain relatively more TAGs and phospholipids but lower proportions of cholesterol (esters), have an unusual apoprotein composition (only apoB and apoVLDLII), and are sparely hydrolyzed by peripheral intravascular LPLs (Griffin et al., 1982; Griffin and Hermier, 1988). The sequence leading to the incorporation of lipoproteins into the oocytes starts with passing through the pores of the granulosa basal lamina (which acts as a sieve to exclude larger lipoproteins) and ends with the uptake of the lipoproteins into the developing oocytes by receptor-mediated endocytosis (the oocyte-specific apoB receptor, in contrast to the somatic apoB receptor). Apparently, apoB acts as the ligand and not apoVLDLII (Walzem, 1996). This oocyte-specific VLDL–vitellogenin receptor or LR8 receptor was then identified as a member of the LDL receptor superfamily (Bujo et al., 1994). In this way, only lipids of hepatic origin (except for polyunsaturated fatty acids) can be deposited in the egg yolk. Besides its role in mediating the diameter of VLDLy, it has been shown that the estrogen-dependent apoVLDLII acts as an inhibitor of LPL activity and in this way prevents TAGs from VLDLy to be hydrolyzed by LPLs (Schneider et al., 1990).

19.5.2 Hormonal Control of Lipid Metabolism

The earliest "endocrinological" observation that already had practical implications concerning growth of avian species was caponization. Since then, systematic studies of the hormonal system have revealed substantial effects of these endogenous molecules on protein, carbohydrate, and lipid metabolism. In addition to pancreatic hormones, two major axes can be identified: the somatotrophic axis and the thyrotrophic axis. These two axes seem to be very much interrelated in birds and especially in the determination of growth and body composition.

19.5.2.1 Somatotrophic Hormones

The pituitary hormone, growth hormone (GH), is a potent stimulator of growth in mammals. In the young, it promotes overall body growth, and in the adult, it stimulates the growth of the extremities. Therefore, it was obvious to suppose that this hormone had also a primary effect on growth in poultry (Scanes et al., 1984). The anabolic effects of GH in relation to its pulsatile secretory pattern are discussed elsewhere (Buyse and Decuypere, 1999).

Based on these observations, it became clear that GH is not the only determinant of growth and body composition in poultry. Also, other endogenous regulatory substances such as thyroid hormones and IGF must be considered. There is ample evidence for a positive relationship between plasma GH and IGF-I levels, which are known to stimulate several anabolic processes. Moreover, IGF-I stimulates adipogenesis while it inhibits the GH-induced lipolysis. Continuous administration of IGF-I reduces abdominal fat content (Buyse and Decuypere, 1999). Data on plasma IGF-II concentrations are scarce and its biological significance is unclear, except that IGF-II administration to broilers augmented fat deposition (Buyse and Decuypere, 1999). This also holds for the role of IGF-binding proteins in avian growth, development, and body composition.

Various sources of GH have been reported to affect the lipolytic activity of chicken adipose tissue explants *in vitro*. GH alone stimulates glycerol release but is also known to inhibit glucagon-induced lipolysis, although by different cellular mechanisms (Campbell and Scanes, 1988). The physiological importance of the observed effects of GH on lipolysis *in vitro* can be linked with a homeostatic role of GH in nutrient metabolism.

19.5.2.2 Thyroid Hormones

There is abundant evidence that thyroid hormones are important not only for embryogenesis but also for normal posthatch growth in birds. Thyroid hormones also affect body composition and fatness. A hyperthyroid status in chickens is associated with a decreased fat content, while in hypothyroid chickens, fat deposition is greatly enhanced (Decuypere and Buyse, 1988). Triiodothyronine has been shown to increase basal lipolytic activity and glucagon-induced lipolysis in cultured broiler adipocytes (Harden and Oscar, 1993). In addition, triiodothyronine stimulates hepatic malic enzyme activity, and hence lipogenesis.

19.5.2.3 Pancreatic Hormones

The pancreatic hormones (insulin, glucagon, avian pancreatic polypeptide, and somatostatin) are important in the regulation of carbohydrate, protein, and lipid metabolism and hence for normal growth and development of birds. The structure, secretion, and peripheral control of these pancreatic hormones are reviewed elsewhere (Simon, 1989). In brief, insulin acts to decrease circulating levels of glucose by increasing glucose uptake by several cell types and by inhibiting glycogenolysis and gluconeogenesis while glycogen synthesis is stimulated. Glucagon has the opposite effect on these processes. Therefore, it is suggested that the glucagon–insulin ratio would be more important in regulating nutrient metabolism. Insulin also stimulates hepatic lipogenesis mainly by stimulating the synthesis of lipogenic enzymes. In addition, insulin may increase the hydrolysis of VLDLs at the adipocyte level by stimulation of LPL activity (Simon, 1989). With respect to the role of insulin and glucagon on lipid mobilization, several profound differences between mammals and birds are apparent. First, in mammals, catecholamines are the main effectors of lipolysis, while in birds, glucagon is the most potent stimulator of lipolysis. Furthermore, in mammals insulin is clearly antilipolytic, while this is not the case in birds.

19.5.2.4 Other Hormones

There is ample evidence that adrenal glucocorticoids (mainly corticosterone in birds) depress body weight and increase fat deposition in birds as glucocorticoids exert a direct catabolic action and stimulate lipogenic activity in avian hepatocytes. The pituitary hormone prolactin is also known to be a lipogenic effector, and a possible temporal synergistic effect between corticosterone and prolactin on fat deposition has been demonstrated in broilers and wild-type birds (Decuypere and Buyse, 1988). The role of sex steroids in the hormonal control of growth in birds is not well established except that estrogens stimulate lipogenesis, whereas testosterone has the opposite effect.

19.5.2.5 Endocrine Control of Premigratory Hyperphagia and Fattening in Wild Birds

A peculiar feature of many bird species is the annual migration, which is a high-energy-demanding process. In preparation of vernal or autumnal migration over long distances, the occurrence of premigratory hyperphagia and fattening is well documented. The onset of premigratory morphological, behavioral, and body compositional changes is predominantly induced by alterations in day length and environmental temperature as principal Zeitgebers, and suggests a neuroendocrine involvement. It has been reported that besides gonadal hormones, both corticosterone and prolactin are involved in premigratory hyperphagia and fattening in wild-type birds (e.g., *Zonotrichia gambelii*: Meier and Farner (1964); and *Zonotrichia albicollis*: Meier and Martin (1971)). More in particular, the increased premigratory fat deposition is dependent on a temporal synergism between corticosterone and prolactin (Meier and Farner, 1964; Meier and Martin, 1971). The most potent lipolytic agent, glucagon, is also strongly implicated in premigratory and winter fattening (e.g., in red-winged blackbirds: Hintz, 2000). Indeed, significantly reduced glucagon levels were measured in the plasma of birds exposed to outdoor winter (from September to May, Ontario, Canada) conditions compared to birds maintained in summer conditions. It was concluded that the low glucagon levels are meant to preserve the deposited lipid stores. In addition, seasonal variations in adipocyte glucagon receptors and concomitant reduction

in adipocyte sensitivity to glucagon may be involved in the preservation of body weight and fat.

19.6 FUNCTIONS OF ADIPOSE TISSUE

It has always been believed that the role of white adipose tissue is rather strictly limited to storing energy as TAGs and releasing these lipids for oxidation (primarily by skeletal muscle), and this has been known for many decades. Although their hydrophobic lipid content is variable between fat depots, it can amount to up to 90% of the fresh tissue weight (Evans, 1977; Nir et al., 1988). Taking into account the high energy content of lipids (±39 kJ/g) compared to protein (±23 kJ/g) and carbohydrates (±18 kJ/g), adipose tissue is indeed an appropriate reservoir of energy. In addition, fat tissue (e.g., subcutaneous fat) can play a role in insulation and can act as a protective shield for internal organs. More recent studies, however, have revealed that adipose tissue is also involved in numerous other processes and biological functions such as appetite regulation, reproduction, angiogenesis, coagulation, fibrinolysis, vascular tone control, and immunity.

Adipose tissue is not just equal to a sum of adipose cells. In adipose tissue, 90% of adipose mass may account for roughly 25% of the total cell population, the other cells being fibroblasts, blood cells, endothelial cells, pericytes, mesenchymal cells, and preadipocytes, all being targets for an extensive autocrine–paracrine cross-talk with each other and involved in adipogenesis (Frühbeck and Gómez-Ambrosi, 2005).

At least in mammals, and probably also in birds, new adipocyte formation is still possible even when a positive energy balance is maintained after hypertrophy; then hyperplasia resumes and a greater than normal number of adipose cells is developed. Moreover, adipocytes have been also reported to dedifferentiate: mature adipocytes lose their lipid-filled morphology, and they assume a fibroblast-like appearance and regain preadipocyte characteristics (Kokta et al., 2004). Especially the signaling interactions between muscle and fat cells are important to understand the relative fat and lean deposition and the efficiency of energy utilization in the complex processes of growth, development, and body composition. These signaling interactions are based on the notion of adipose tissue as a multifunctional organ as opposed to a passive organ for the storage of excess energy in the form of fat. This is linked with the ability of fat cells to secrete a large number of hormones, growth factors, cytokines, and matrix proteins collectively termed adipokines or adipocytokines (Table 19.1). At the same time, adipocytes have receptors for many of these adipokines as well as for several systemic hormonal factors (e.g., pituitary and pancreatic hormones).

Intra- and intermuscular fat is regulated by different factors than those regulating fat deposition in other tissues such as omental, mesenteric, and perirenal fat, which are not in close proximity to muscle and may therefore lack some specific paracrine signaling.

TABLE 19.1 Tentative List of Demonstrated Expression of Genes Involved in Lipid Metabolism of Avian Species[1] and Potential Avian Adipokines

Gene Expressions	Potential Adipokines
Stearoyl-CoA desaturase	Leptin
Hormone-sensitive lipase	Adiponectin
Adipose triglyceride lipase	Visfatin
AMP-activated protein kinase	Resistin
Adiponectin receptors R1 and R2	Adipsin
Insulin receptors (IRs)	Acylation-stimulating protein
IR-substrate protein	Adiponutrin
Peroxisome proliferator-activated receptor-γ	Interleukin-6
Sterol regulatory element binding protein-1 and -2	Tumor necrosis factor-α
Leptin receptor?	Transforming growth factor-β
Agouti-signaling peptide	Apelin
Melanocortin receptor	Angiotensinogen
Pro-opiomelanocortin	
Neuropeptide Y	
Fat mass and obesity-associated gene	
Lipoprotein lipase	
Fatty acid synthase	
Growth hormone receptor	
Interleukin-18	
Visfatin	
Hydroxy-3-methylglutaryl-CoA reductase	

[1]*A more comprehensive list of genes expressed in the adipose tissue of 7 week old fat- and lean-line broilers is provided by Wang et al. (2007).*
Source: After Richards et al., 2010.

The responsiveness of fat cells to neurohormonal signals may vary according to the adipose cell stage at the moment of exposure; this, together with local differences in the expression and presence of these numerous factors involved in the control of adipogenesis, may contribute to affecting the pattern of distribution of fat in birds, and this is in a species-specific way.

Fat tissue is central in energy substrate partitioning as it acts as a reservoir as a result of lipogenesis, on the one

hand, and substrate mobilization, on the other hand. However, in energy balance equilibrium, lipogenesis and lipolysis are still going on continuously, making fat tissue a rather dynamic tissue with a turnover rate that is relatively high (e.g., the half-life of depot lipids in rodents is about 8 days; Frühbeck and Gómez-Ambrosi (2005)). NEFA mobilization (lipolysis) is followed by its uptake by diverse cell types for subsequent oxidation. In most cases, uptake of NEFAs is much faster than their oxidation except during heavy and/or prolonged exercise. Between 80% and 90% of the NEFAs used in muscle for oxidation comes from plasma NEFAs (coming from the diet and fat tissue), while only ±10% comes from muscle lipid itself. AMP-activated protein kinase plays a central role as energy sensor and positively affects cell processes that produce energy (NEFA oxidation and glucose uptake) while negatively affecting cell processes that consume energy (lipogenesis, protein synthesis, and gluconeogenesis). These processes are governed by endocrine factors as well as by adipokines.

The regulation of lipolysis in chicken adipose tissue is almost exclusively exerted by glucagon. No antilipolytic effect of insulin has been demonstrated in chicken adipocytes in culture, and only avian pancreatic polypeptide, somatostatin, and gut-glucagon-like immunoreactivity have antilipolytic effects (Dupont et al., 2012). Lipolysis in chicken adipose tissue is realized by a lipase (adipose triglyceride lipase (ATGL)) exclusively found in subcutaneous and abdominal fat (Lee et al., 2009), and this lipase is highly present after hatching and before feed is given. Hormone-sensitive lipase is also present in chicken (Anthonsen et al., 1997), and LPL, hepatic lipase, and endothelial and carboxylester lipase are all highly conserved in mammalian and bird (chicken) species (Sato et al., 2010). ATGL is stimulated by corticosteroids in broilers (Serr et al., 2011).

Adiponectin as well as its receptors (R_1 and R_2) are expressed in many tissues, including adipose tissue in the chicken (Hendricks et al., 2009; Ghazanfari et al., 2011). It stimulates NEFA oxidation in muscle, hence decreasing plasma NEFA as well as glucose levels (due to enhanced insulin sensitivity, at least in mammals). Fasting in chicken is known to decrease adiponectin receptor expression in adipose tissue (Ghazanfari et al., 2011), while plasma adiponectin is inversely related to abdominal fat pad weight in chicken (Hendricks et al., 2009), especially the plasma heavy-molecular-weight adiponectin isoform.

The insulin-signaling cascade in chicken adipose tissue, although similar in its downstream components (see Dupont et al. (2012)), is quantitatively markedly different from that operating in mammals. It has been shown that levels of IR (insulin receptor) and IRS1 (IR-substrate protein) in chicken are lower compared to those of mammals (rat), contributing to a certain insulin insensitivity or refractoriness.

PPARγ is a central regulator of adipogenesis, and it is expressed in fat tissue and even more in liver but not in muscle. Levels are affected by nutrition and are also higher at the onset of egg laying in layers in the liver and ovary, while it is then decreased in adipose tissue (Sato et al., 2004). Moreover, a single intraperitoneal injection of troglitazone, a synthetic PPARγ ligand, to newly hatched broiler chicks resulted in a reduction of the absolute and proportional abdominal fat pad weight at 48 days of age (Sato et al., 2008).

Sterol regulatory element binding protein-1 and -2 (SREBP1 and SREBP2) chicken genes, on two separate chromosomes and nearly perfectly conserved compared to their mammalian homologs (Assaf et al., 2003), also play a role in the regulation of lipogenesis in liver. SREBP1 is linked to FAS protein content or activity in adipose tissue and/or liver. Therefore, SREBP1/2 are key regulators in lipogenesis in both mammals and avian species, and their differential expression in different tissues is a major determinant of the site of fatty acid synthesis in the body (Gondret et al., 2001; Yen et al., 2005).

Visfatin is another adipokine hormone involved in immune system and glucose metabolism. Chicken visfatin is 92–94% homologous to mammalian visfatin and mainly expressed in skeletal muscle rather than in abdominal and subcutaneous fat in chicken; therefore it is rather a myokine than an adipokine (Krzysik-Walker et al., 2008; Li et al., 2012). Nevertheless, fat-line chickens selected for high abdominal fat have a higher expression of visfatin in adipose tissue compared to their lean-line counterparts (Cogburn et al., 2011).

There is controversy as to the leptin receptor expression in chicken adipose tissue. According to Wang et al. (2007), no leptin receptor expression in chicken adipose tissue was found, whereas Hausman et al. (2012) reported leptin receptor expression in broiler adipose tissue.

Also, local agouti-signaling peptide and melanocortin receptor expression were found in chicken adipose tissue, as well as pro-opiomelanocortin (Yabuuchi et al., 2010) and neuropeptide Y (Hausman et al., 2012), indicating that hypothalamic regulatory pathways for feed intake regulation, also in birds, may also play a role, locally, in adipose tissue metabolism.

In mammals, the fat mass and obesity-associated (FTO) gene is known to be implicated in the regulation of energy balance, more in particular in food intake and energy expenditure (Wang et al., 2012b). In chickens, FTO gene mRNA is present in many tissues, with high levels in the hypothalamus, cerebellum, liver, and visceral fat. However, the expression levels are dependent on breed (broiler versus layer), age, and nutritional status. More studies are needed to determine the functional role of FTO in avian species.

A specific role for other factors that were found as adipokines in mammalian species still have to be elucidated in birds and chicken in particular (e.g., resistin, adipsin, and plasminogen activator inhibitor-1; see Richards et al. (2010)).

19.7 FACTORS AFFECTING FAT METABOLISM AND DEPOSITION

Nutrition has a major impact on animal performance and body composition. Nutrition is a very broad term and includes quantitative (e.g., *ad libitum* versus feed restriction programs) and qualitative (e.g., metabolizable energy (ME), macro- and micronutrients, and toxins) aspects as well as feeding programs (e.g., sequential feeding or "skip-a-day" feeding).

It is common knowledge that feed deprivation–refeeding cycles are associated with fluctuations in intermediary metabolism induced by endocrine factors such as thyroid hormones, GH, and pancreatic hormones (Buyse et al., 2001). During feed deprivation, hepatic lipogenic activity is drastically reduced and the release of NEFA from adipose tissue is stimulated, whereas the opposite is true after refeeding. The reader is referred to recent elegant studies for detailed information from feed deprivation–refeeding schedules on the dynamics of hepatic mRNA levels of lipogenic genes and transcription factors (e.g., Wang et al., 2012a; Richards et al., 2003; Saneyasu et al., 2013). In addition, such feeding schedules also have a marked effect on hypothalamic orexigenic and anorexigenic neuropeptides and lipogenic genes such as FAS and ACC (Higgins et al., 2010; Song et al., 2013). A discussion of the relevance of these findings in the framework of the control and regulation of voluntary feed intake of avian species is, however, beyond the scope of this chapter.

With respect to diet quality, the impact of ME levels and macronutrient (lipids, carbohydrates, and proteins) ratios on performance and body composition has been widely investigated, mainly with broiler chickens. In general, diets with high ME levels (but normal protein levels) promote fat deposition in broiler chickens, but genetically determined body weight gain is rather maintained. This augmented fat deposition is the result of an excess in energy intake ("luxus" energy consumption) relative to the energy needed for maintenance and production. This luxus energy is then largely diverted to body fat deposition, although it is also dissipated as heat to some extent (Buyse et al., 1992). Widening of the ME–protein ratio due to a reduction in protein level results in not only a higher fat deposition but also a reduced growth rate. The higher fat deposition is caused by an enhanced hepatic lipogenesis (demonstrated *in vivo* and *in vitro*), as reflected in the increased expression and activity of lipogenic enzymes such as malic enzyme, ACC, and FAS (e.g., Donaldson, 1985; Adams and Davis, 2001; Rosebrough et al., 2011). The reader is referred to the work of Rosebrough, Richards, and coworkers with respect to short-term adaptations in hepatic lipogenesis when switching from high- to low-protein diets and vice versa (Rosebrough et al., 2011). The underlying causal mechanisms at the biochemical level of the hepatic intermediary metabolism are discussed in detail elsewhere (Swennen et al., 2007a). Such diets with a relative protein shortage also induce marked endocrine alterations (reviewed by Buyse et al. (2001), Rosebrough et al. (2011)). Indeed, protein-restricted chickens are characterized by an enhanced pulsatile GH secretion, lower plasma IGF-I and thyroxine levels, but higher 3,3′,5-triiodothyronine concentrations. Feeding broilers with diets with a too-high protein content (above requirements) will result in lean broilers (decreased *de novo* lipogenesis and expression and activity of lipogenic enzymes), but growth is likely to be stunted because of the energetic costs of nitrogen waste excretion. The effects of dietary fat level on body fat accretion and lipid metabolism are less unambiguous (Swennen et al., 2007a). The interpretation of studies focusing on dietary fat level is sometimes complicated by the fact that it is not clearly indicated whether the dietary fat is iso-energetically substituted with protein or carbohydrates or both. In general, increasing the dietary fat level will reduce hepatic lipogenic activity, probably due to the inhibitory effect of long-chain acyl-CoA on ACC activity (Leveille et al., 1975). Finally, high carbohydrate levels in broiler diets will enhance glycolysis and hence provide plenty of reducing equivalents for hepatic fatty acid production (Tanaka et al., 1983). However, these dietary fat and carbohydrate-induced changes in hepatic lipogenic activity do not necessarily result in changed body fat accretion (Swennen et al., 2007a).

Intensive selection of broiler chickens for high growth rate and feed efficiency has resulted in a tremendous progress in body weight gain and feed efficiency (direct selection response). However, several adverse indirect selection responses such as augmented fat deposition, leg problems, and metabolic diseases such as ascites and sudden death syndrome have also occurred. Havenstein and coworkers (Havenstein et al., 1994a,b) have elegantly assessed the differential impacts of selection for growth rate and of diet regimen by comparing a typical 1957 broiler strain (Athens-Canadian random-bred control strain) with a modern 1991 broiler strain (Arbor Acres) and feeding both on a typical 1957 or 1991 diet. A similar comparative study was done between the random-bred 1957 strain and a commercial 2001 (Ross 308) strain, with both fed on a typical 1957 or 2001 diet (Havenstein et al., 2003). These studies clearly revealed that genetics were the major contributing factor for the progress in performance and yield of carcass parts but also that carcass fat content increased due to selection for growth rate. In view of this augmented fat deposition and its associated negative consequences, divergent experimental fat and lean broiler lines were established in several poultry research institutes. Different selection strategies were used: divergent selection for or against abdominal fat content (France and Israel), selection for high body weight gain (fat line) or feed efficiency (lean line) (the Netherlands and Denmark), and divergent selection for high (fat line) or low (lean line) plasma VLDL concentration (United Kingdom). Detailed information on heritability estimates, genotypic

and phenotypic correlations, as well as performance characteristics, energy, lipid and protein metabolism, endocrine profiles and intermediary metabolism, and breeder performance is provided elsewhere (Leclercq, 1988; Whitehead, 1988; Buyse et al., 1999; Baéza and Le Bihan-Duval, 2013). It is clear that either direct or indirect selection resulted in fat and lean broiler lines. With respect to lipid metabolism, all fat-line broilers were characterized by a higher hepatic lipogenic capacity compared to their lean-line counterparts, irrespective of the selection criteria. However, some indirect selection responses as well as the underlying endocrine mechanisms were different according to the selection strategy. Indeed, lean broilers produced by selection for feed efficiency had a higher basal as well as glucagon-stimulated lipolytic activity compared to their fat counterparts selected for high body weight gain. In contrast, direct selection for high or low abdominal fat content had apparently no effect on the lipolytic capacity of adipose tissue. These differences in lipolytic activity, amongst other parameters, according to the selection strategy can be related to the differential selection-induced alterations in endocrine profile. Indeed, direct selection rather triggered the thyrotrophic axis and pancreatic hormones, whereas indirect selection primarily affected the somatotrophic axis (Buyse et al., 1999). Another interesting genetic model to study the regulatory mechanisms of lipid metabolism is the selection model for the high (R+: fat line) or low (R−: lean line) residual feed intake of laying hens, which markedly differ in appetite; heat production, including diet-induced thermogenesis; body conformation; and composition (Bordas et al., 1992; Swennen et al., 2007b).

19.8 SUMMARY AND CONCLUSIONS

Adipose tissue is the most variable carcass component and is traditionally being considered as a rather inert storage tissue for energy under the form of lipids. Most of the fat in chickens is located in adipose depots, which are all late maturing. At the cellular level, preadipocyte differentiation and proliferation are under the control of multiple hormones and transcription factors. The growth of fat tissue is initially due to hyperplasia followed by hypertrophy of the mature adipocytes, and the amount of fat deposited depends on genetic and nutritional factors. Recent research has, however, revealed that adipose tissue must now be regarded as a dynamic tissue that secretes a considerable number of adipokines and hence plays a role in a multitude of bodily processes.

Chapter 20

Protein Metabolism

Colin G. Scanes
Department of Biological Sciences, University of Wisconsin, Milwaukee, WI, USA

20.1 INTRODUCTION

20.1.1 Protein Metabolism: Overview

Proteins play critical roles in birds, as in other animals, including the following: as structural elements, such as keratin in skin and feathers, collagens in connective tissue and cellular proteins (e.g., those of the cell membrane), cytoskeleton, protein synthetic machinery, and DNA-associated proteins (e.g., histones); as contractile elements in muscles (see Chapter 15); as oxygen-binding proteins, such as hemoglobin in erythrocytes and myoglobin in muscle; as receptors; as hormones, cytokines, and other messengers; as antibodies; as transporters; as nutrients for embryonic development in the yolk and egg albumin proteins (see Chapter 31); and as enzymes. Table 20.1 summarizes the protein composition of a young chicken as estimated by dissection and correction for muscles and associated connective tissue adhering to bone.

Proteins are synthesized from amino acids:

$$\text{Plasma amino acid pool} \leftrightarrow \text{Intracellular amino acid pool} \leftrightarrow \text{Intracellular proteins}$$

The essential amino acids in avian diets for protein production are as follows:

- Arginine, histidine, isoleucine, lysine, methionine (with a higher requirement if cysteine is not present), threonine, tryptophan, and valine.

Other important amino acids for protein production are the following:

- Alanine, aspartate, asparagine, cysteine, glutamate, glutamine, glycine, leucine, proline, phenylalanine, serine, and tyrosine.

Lysine and methionine are the first limiting amino acids for growth (Bornstein and Lipstein, 1975). Amino acids are synthesized in birds, predominantly in the liver. There is interconversion of some amino acids. For instance, glutamate can be converted to glutamine, catalyzed by glutamine synthase, while glutamine can be converted to glutamate by glutaminase. There are also extranutritional effects of amino acids (see Section 20.5), with amino acids converted to glucose in gluconeogenesis (see Chapter 17), to purines, to uric acid, to neurotransmitters, and to pigment (see Section 20.5).

Posttranslational modification of amino acids in proteins occurs, including:

- Methylation: Histidine residues in myofibrillar proteins (e.g., actin and myosin) are methylated (see Table 20.1).
- Phosphorylation: Phosphorylating serine, threonine, or tyrosine residues is essential for activating or deactivating enzymes.
- Glycosylation: This is to form glycoproteins.
- Acetylation: This forms lipoproteins.

20.1.2 Muscle

Over 20% of the wet weight of skeletal muscles is protein. The major proteins are myosin and actin of the thin and thick filaments, together with sarcoplasmic proteins.
Thin filaments:

- Actin
- Tropomyosin
- Troponin

Thick filaments:

- Myosin

Skeletal muscles are made of fibers. There are different types of fibers:

- Slow oxidative (SO) fibers; also called slow-twitch or type I fibers
- Fast oxidative glycolytic (FOG, or type IIA) fibers
- Fast glycolytic (FG, or type IIB) fibers
- Tonic (types IIIA and IIIB) fibers

These are characterized by their functional characteristics and biochemistry. Flight muscles, including pectoralis muscles, are FOG fibers capable of sustained rapid contraction in Anna's

Sturkie's Avian Physiology.

TABLE 20.1 Importance of Various Organs to Body Weight, Total Protein, and Myofibrillar Protein as Indicated by 3-Methyl-Histidine in Young Chickens

Organ	Weight (g) (% of body weight)	Protein as % of Total Body	3-Methyl-Histidine as % of Total Body
Skeletal muscle (and associated connective tissue)[1]	99.3 (37.7%)	48.6	84.0
Bone[1]	77.7 (29.2%)	22.9	1.6
Gastrointestinal tract	34.2 (13.0%)	11.9	9.8
Skin and feathers	33.3 (12.4%)	9.3	1.7
Liver	10.4 (3.9%)	5.3	1.0
Heart	3.2 (1.2%)	1.3	1.4
Kidneys	2.3 (0.8%)	0.9	0.0
Lung	2.2 (0.8%)	0.7	0.2
Brain	1.5 (0.6%)	0.4	0.1

[1]*Corrected for muscle and other soft tissues adhering to bones.*
Source: Calculated from data in Jones et al. (1986).

TABLE 20.2 Fiber Composition of Selected Chicken Muscles

Muscle	Fiber Types
Pectoralis	99% FG (type IIB)
Posterior latissimus dorsi	~90% FG (type IIB) and ~10% FOG (type IIA)
Sartorius white	~15% FOG (type IIA) and ~85% FG (type IIB)
Sartorius red	~40% SO (type I), ~40% FOG (type IIA), and ~20% FG (type IIB)
Tonic muscles such as anterior latissimus dorsi, plantaris, and adductor profundus	Almost entirely type III fibers (~70% type IIIA and ~30% type IIIB)

Source: Barnard et al. (1982).

hummingbirds (*Calypte anna*) and zebra finches (*Taeniopygia guttata*) (Welch and Altshuler, 2009). Table 20.2 summarizes the fiber types in various chicken muscles. There are multiple muscle fiber types in the gastrocnemius muscle, as seen in Anna's hummingbirds (*C. anna*: Welch and Altshuler, 2009), English sparrows (*Passer domesticus*: Marquez et al., 2006), ostrich (*Struthio camelus*: Velotto and Crasto, 2004), and zebra finches (*T. guttata*: Welch and Altshuler, 2009).

Multiple forms of myosin are expressed with differences between fiber types and during embryonic development and posthatch growth (Rosser et al., 1996, 1998). For instance, in adult chickens, pectoralis expresses fast myosin heavy chain (MyHC1), with slow myosin heavy chain (MyHC2) expressed in tonic muscles (Crew et al., 2010).

20.1.3 Feathers

Feathers make up 20–30% of body weight in wild birds (Griminger and Scanes, 1986). In contrast, they represent less than 12.4% of body weight in chickens (Table 20.1). Feathers are made of the protein β-keratin (Stettenheim, 2000). The proteins of the rachis of chicken feathers have a high content of four amino acids (Harrap and Woods, 1964):

- Serine: 13.7%
- Glycine: 13.3%
- Proline: 9.5%
- Cysteine: 7.2%

Chicken keratin genes A–D have been characterized, and these are expressed in feather tissue as early as day 14 of embryonic development (Presland et al., 1989).

Following molt (see Chapter 38), feathers are replaced. This replacement of feathers is critically important for flight. The rapidity of feather growth has been linked to feather abnormalities (Vágási et al., 2012). The time to replace feathers is longer in larger birds. Feathers scale with the body weight of birds by 0.32 power, while feather growth rate increases across species by much less, 0.17 power of body weight (Rohwer et al., 2009).

20.2 DIGESTION OF PROTEINS

Proteins are digested in the gastrointestinal tract to amino acids and dipeptides together with tripeptides. The predominant site for protein digestion is the small intestine. The amino acids and peptides are absorbed in the small intestine.

20.2.1 Protein Digestion in the Gizzard and Proventriculus

The digestion of proteins is initiated in the gizzard and proventriculus in birds by the following methods:

- Mechanical grinding by the gizzard
- Chemical denaturation by the low pH
- Enzymatic proteolysis by pepsin

Pepsinogen, a zymogen, has been purified in birds (chicken: Bohak, 1969). Avian pepsinogen is proteolytically activated to pepsin at low pH (Keilova et al., 1977). Pepsinogens A and C are expressed and secreted from the mucosal cells in the chicken proventriculus (Sakamoto et al., 1998).

20.2.2 Protein Digestion in the Small Intestine

The predominant site of protein digestion is the small intestine (Table 20.3). The digested protein (amino acids and dipeptides together with tripeptides) is absorbed in the small intestine (Table 20.3).

Proteins undergo enzymatic digestion in the small intestine by the enzymes trypsin and chymotrypsin. These are produced by the pancreas as inactive zymogens (respectively, trypsinogen and chymotrypsinogen) and transported to the small intestine in the pancreatic secretions. In the small intestine, both trypsinogen and chymotrypsinogen are activated by proteolytic cleavage:

- Trypsinogen → trypsin
- Chymotrypsinogen → chymotrypsin

In addition, there are peptidases that hydrolyze peptides generated by trypsin and chymotrypsin.

20.2.2.1 Trypsin

Avian trypsin is a 223 amino acid residue containing protein. Six members of the trypsinogen gene family have been characterized in the chicken (Wang et al., 1995), with one trypsinogen cDNA sequenced in the ostrich (Szenthe et al., 2005). These are expressed in the pancreas along with the liver, spleen, and thymus (Wang et al., 1995). Trypsinogen is proteolytically cleaved either by enterokinase or autocatalytically (ostrich: Szenthe et al., 2005). This proteolytic cleavage results in the formation of an active protease, trypsin.

20.2.2.2 Chymotrypsinogen

Chymotrypsinogen is activated in the small intestine by proteolytic cleavage, for instance by trypsin. Avian chymotrypsinogen has been isolated from pancreas (ostrich: van der Westhuizen et al., 1989; Japanese quail: Hou et al., 1990).

TABLE 20.3 Protein Digestion and Absorption in the Regions of the Chicken Small Intestine

	Protein Digestion (%)	Protein Absorption (%)
End of duodenum	60	7
End of jejunum	85	70
End of ileum	93	83

Source: Based on Hurwitz et al. (1972).

20.2.2.3 Aminopeptidases

Aminopeptidases are membrane-bound proteins of enterocytes. Most of the protein is extracellular, with a single transmembrane domain and a small intracellular domain. An avian aminopeptidase has been partially characterized (chicken: Gal-Garber and Uni, 2000). It is expressed throughout the small intestine with the highest expression in the ileum (chicken: Gal-Garber and Uni, 2000).

20.2.3 Amino Acid Absorption in the Small Intestine

Amino acids are absorbed in the small intestine (chicken jejunum and ileum: Tasaki and Takahashi, 1966). There is greater absorption of methionine in the ileum than in other regions of the small intestine (see Figure 20.1). Methionine is absorbed at the highest rate, followed by isoleucine, valine, and leucine, and glutamate is absorbed at the lowest rate, followed by aspartate, glycine, and arginine (Tasaki and Takahashi, 1966; Riley et al., 1986). There are series of amino acid transporters (10 in chickens) expressed in the enterocytes of the small intestine, with predominantly increases progressing down the small intestine from the duodenum, jejunum, and ileum (chickens: Gilbert et al., 2007). Moreover, there are increases in the expression of many amino acid transporters during the period of growth and development post hatching (chickens: Gilbert et al., 2007).

There is moderately high expression of the H^+-dependent peptide transporter-1 (PepT1) throughout the small intestine, with marked increases in the posthatch period (Gilbert et al., 2007). PepT1 functions to transport both dipeptides and tripeptides into the enterocyte.

Not only are proteins in the ingesta digested with the resultant amino acids and small peptides absorbed, but also mucosal intestinal cells are sloughed off and then digested. The turnover times for mucosal cells in the small intestine

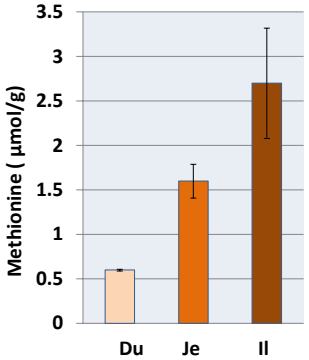

FIGURE 20.1 Absorption of methionine by different regions of the chicken intestine *in vitro*. Du, duodenum; Je, jejunum; Il, ileum; vertical lines, standard error of the mean. *Data from Knight and Dibner (1984).*

are estimated as the following (chicken: calculated from Imondi and Bird (1966)):

- Duodenum: 111 h
- Jejunum: 55 h
- Ileum: 89 h

20.2.4 Large Intestine and Protein Digestion

There is little information on the roles of the colon and ceca in protein and amino acid digestion and absorption. While most of the proteins in the ingesta are digested by the time the ingesta reaches the colon (Table 20.3), the fate of sloughed-off mucosa cells is not known. There are populations of proteolytic bacteria in the colon of birds (chicken: King et al., 2009). The impact of these proteolytic bacteria is not known. Interestingly, there is absorption of the methionine analog, 2-hydroxy-4-(methylthio) butanoic acid (Alimet), in the large intestine as well as the small intestine (chicken: Knight and Dibner, 1984; Dibner et al., 1988).

20.3 PROTEIN SYNTHESIS AND DEGRADATION

20.3.1 Whole-Body Synthesis and Degradation

Whole-body protein net synthesis (accretion)
= whole-body protein synthesis
– whole-body protein degradation/losses

Where whole-body protein losses includes in proteins in eggs or molted feathers.

If negative, whole-body protein net synthesis (accretion) is whole-body protein net degradation.

Whole-body net protein synthesis can be estimated by nitrogen balance. F nce, Kino and Okumura (1987) estimated nitrogen balance in 14–21 day old chickens as 0.29 g/day. It is also possible to experimentally determine whole-body protein net synthesis (accretion) or net degradation, and whole-body protein synthesis, using infusion of a radioactive form of a nonmetabolized amino acid such as phenyl alanine or tyrosine (see Table 20.4). As might be expected, net protein synthesis or accretion is negative in starved chicks or chicks on a diet deficient in specific amino acids (Table 20.5). Whole-body protein synthesis is markedly reduced by starvation and is depressed in birds on an amino acid–deficient diet (Kino and Okumura, 1987; Muramatsu et al., 1987b) (see Table 20.5). There is a concomitant increase in protein degradation in starved birds but not in those on amino acid–deficient diets (Kino and Okumura, 1987; Muramatsu et al., 1987b).

20.3.2 Muscle Protein Synthesis and Degradation

As with all proteins, muscle proteins are synthesized from the intramuscular amino acid pool:

TABLE 20.4 Effects of Age and Dietary Protein on Muscle Protein Synthesis and Degradation in Young Chickens

	Muscle			
	Breast (Pectoralis)		Leg	
	Fractional Protein Synthesis (% per day)	Fractional Protein Degradation (% per day)	Fractional Protein Synthesis (% per day)	Fractional Protein Degradation (% per day)

4 weeks old	24	18	–	–
6 weeks old	17	14	–	–
Control	26	10	22	9
Lysine-deficient diet	24	22	20	19
Control	24	18	–	–
Refed protein-replete diet for 2 days	41	24	–	–
Control	19	10	–	–
Protein-deficient diet	13	5	–	–

Source: Based on Maruyama et al. (1978), MacDonald and Swick (1981), Urdaneta-Rincon and Leeson (2004).

Plasma amino acid pool ↔ Muscle amino acid pool ↔ Muscle protein

There are very similar rates of protein synthesis for sarcoplasmic and myofibrillar proteins (chicken: Laurent et al., 1978a). The fractional synthesis rates of noncollagen protein in muscles from adult chickens are the following (Laurent et al., 1978a):

- Anterior latissimus dorsi: 16% per day
- Posterior latissimus dorsi: 7% per day
- Heart: 14% per day
- Gizzard: 11% per day

Given the steady state situation in the adult (no net protein accretion or delta or net protein synthesis equals zero), the above data also describe the fractional rate of protein degradation. Tables 20.4 and 20.6 provide examples of fractional rates of protein synthesis, degradation and breakdown, and accretion in young chickens. The fractional rates of protein synthesis are usually over 10% per day, while those for protein degradation are also over 10% per day. Muscle protein is obviously turning over at a rapid rate, and this is occurring in both the growing and adult bird (Table 20.4).

Connective tissue makes up a significant proportion of muscle. This is exemplified by 23% of the proteins in the chicken anterior latissumus dorsi muscle being the connective tissue protein, collagen (Laurent et al., 1978b). Examples of the fractional synthesis rates for collagen are the following (Laurent et al., 1978b):

- Heart: 0.9% per day
- Anterior latissumus dorsi: 0.6% per day
- Posterior latissumus dorsi: 0.6% per day

These rates are much lower than for myofibrillar and sarcoplasmic proteins. The fractional rates of collagen synthesis are markedly increased in anterior latissimus dorsi muscles undergoing hypertrophy, as can be seen from the following (data from Laurent et al., 1978c):

- 0 days: 0.6% per day
- 1 day: 1.2% per day
- 3 days: 4.5% per day
- 7 days: 4.2% per day

There is a decline in the fractional rates of both protein synthesis and degradation during growth (Table 20.4). The rate of protein synthesis varies between muscles (e.g., between the anterior and posterior latissumus dorsi and between the pectoralis and gastrocnemius) (Tables 20.4 and 20.6).

20.3.2.1 Effects of Nutrition on Muscle Protein Synthesis and Degradation

The highest net rates of muscle protein synthesis (i.e., muscle protein synthesis and degradation) are observed with optimal nutrition. Dietary deficiencies reduce the net rate of muscle protein synthesis, with very low or negative protein accretion being reported with the most stringent deficiencies. This is observed, for instance, in young chickens on a lysine-deficient diet (Table 20.6). The effects of nutritional deficiency or restoration of adequate diet can be mediated via effects on muscle protein synthesis (refeeding with a protein-replete diet or supplementing a methionine diet with methionine) and/or degradation (as with lysine deficiency) (Tables 20.4 and 20.6).

TABLE 20.5 Effect of Nutritional Status on Whole-Body Protein Accretion (Net Synthesis), Synthesis, and Degradation in Young Broiler Chickens

Synthesis	+41%	+67%	−16%
Breakdown	+82%	+111%	+52%

Source: Chicken, Goldspink (1978).

20.3.3.2 Effects of Stretch and Nervous Innervation on Muscle Protein Synthesis and Degradation

There are effects of both nervous innervation and stretch both on protein synthesis and on degradation and breakdown (chicken: Goldspink, 1978). For instance, denervating muscles results in shifts both in protein synthesis and in degradation and breakdown (chicken: Goldspink, 1978) (Table 20.7). Moreover, muscle hypertrophy can be induced by the application of a weight (and therefore muscle stretching). There are marked increases in muscle protein synthesis during this hypertrophy, resulting in accretion (Laurent et al., 1978c) (Figure 20.2). Surprisingly, there is a modest increase in muscle protein degradation during this hypertrophy (Laurent et al., 1978c) (Figure 20.2).

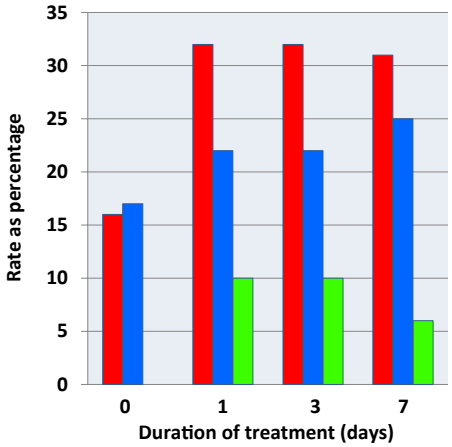

FIGURE 20.2 **Rates of protein synthesis, degradation, and accretion in anterior latissimus dorsi muscles undergoing hypertrophy due to long-term application of a weight around the humerus in adult chickens.** Red columns, protein synthesis; blue columns, protein degradation; green columns, protein accretion (net or delta synthesis). Note that at day 0, the rate of protein accretion (net or delta synthesis) is zero. *Data from Laurent et al. (1978c).*

20.3.2.3 Hormones and Muscle Protein Synthesis

Based on *in vitro* studies with myotubes derived from chicken pectoralis satellite cells, protein synthesis is stimulated by either insulin or insulin-like growth factor 1 (IGF1) (Duclos et al., 1993). Moreover, protein degradation is inhibited in the same system by both hormones (Duclos et al., 1993):

- IGF1 ↓ 32%
- Insulin ↓ 13%

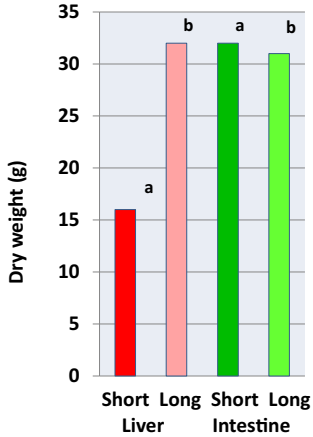

FIGURE 20.3 Effects of long versus short migration on the weight of the liver and intestine in barn swallows (*Hirundo rustica*). The letters a, b indicate significant difference $p < 0.05$. *Adapted from Schwilch et al. (2002).*

20.3.2.4 Muscle Protein Degradation

Whole-body muscle protein degradation can be measured by the excretion of 3-methyl-histidine (Saunderson and Leslie, 1983). The histidine residues in the myofibrillar

proteins of muscle are methylated (see Table 20.1) in the following manner:

Histidine residue + S-Adenosylmethionine ↔ 3-Methyl-histidine residue + S-Adenosylhomocysteine

When muscle proteins are broken down, 3-methyl-histidine is released but is not reutilized.

Measurement of whole-body muscle protein degradation has not been widely employed in birds. An exception is the study of molting. There is elevated excretion of 3-methyl-histidine in white-crowned sparrows (*Zonotrichia leucophrys*) during molting (Pearcy and Murphy, 1997):

- Nonmolting: 0.6 µmol/day
- Molting: 1.1 µmol/day

The increased degradation of muscle protein during molting is presumably to meet the needs of new feather formation. Increased excretion of 3-methyl-histidine has been reported in molting but not nonmolting white-crowned sparrows that were fed a diet deficient in sulfur amino acids when muscle protein degradation would be high (Pearcy and Murphy, 1997). In contrast, there was decreased excretion of 3-methyl-histidine in molting white-crowned sparrows fed a protein-deficient diet (Pearcy and Murphy, 1997).

20.3.3 Liver and Gastrointestinal Tract

Protein synthesis in the liver is high (see Table 20.8), representing 11% of all protein synthesis in the bird. Similarly, gastrointestinal protein synthesis is disproportionately high compared to in other tissue. For instance, in the young chick, 18.9% of protein synthesis occurs in the small intestine plus the pancreas and ceca (calculated from Muramatsu et al., 1987a) (see Table 20.9). This is in contrast to the gastrointestinal organs, which represent 5.2% of the protein in the bird or 5.9% of the body weight (see Table 20.8).

20.3.3.1 Physiological Effects on Protein Metabolism of the Liver and Intestine

There are physiological effects on the protein and weights of the liver and intestine. For instance, the weights of both the liver and intestine are decreased in pied flycatchers and in willow warblers following long migrations (Schwilch et al., 2002). This is due to amino acids from protein degradation supplying some of the energy needs of flight during migration.

Diet can influence the protein metabolism of the liver and intestine. For instance, feeding a diet that is high in fiber for 4 weeks is followed by marked hypertrophy (2.3-fold increase) of the gizzard in Japanese quail (Starck and Rahmaan, 2003). This is explicable for the following reason: there is a marked increase in the amount of feed consumed due to its lower nutritional density compared to the high-fiber diet, and this increase results in mechanical stretching of the gizzard by the volume of ingesta. Moreover, there are decreases in both the weights of the liver and small intestine and the rates of protein synthesis in these organs in chickens fed a germ-free diet

TABLE 20.8 Importance of Gastrointestinal Protein Metabolism in Young (21 Days) Chickens

			Protein Synthesis[1]		
	Weights at 23 Days (g/kg body wt.)	Protein (g/kg body wt.)	Fractional Synthesis (% per day)	Protein Synthesis (g/day/kg body wt.)	Protein Synthesis as a % of Whole-Body Protein Synthesis

(Muramatsu et al., 1987a, 1988) (Table 20.8). This would suggest that microorganisms are stimulating gastrointestinal growth.

20.3.4 Protein Metabolism in Immune Tissues

As might be expected, there are high levels of protein synthesis in immune tissues. Protein synthesis in two immune tissues of the growing chicken is summarized in Table 20.10. Immune tissues' high rates of protein synthesis are disproportionate to their percentage of the body weight. The cationic amino acid transporter-1 through -3 (CAT1–3) is responsible for the transfer of amino acids across the cell membrane into cells. These are expressed in immune tissues—the bursa of Fabricius, the spleen, and the thymus—from 7 days old (chicken: Humphrey et al., 2004, 2006).

There are interactions between immune function, on one hand, and proteins and amino acids, on the other. Lysine increases the proliferation of chicken thymocytes (Humphrey and Klasing, 2005). Acute-phase reaction, as induced by challenge with *Salmonella typhimurium* lipopolysaccharide (LPS), decreased expression of CAT1 in the bursa of Fabricius and the thymus of 11 week old chickens (Humphrey and Klasing, 2005).

20.3.5 Proteins and Reproduction

20.3.5.1 Female Reproduction

There have not been definitive studies of the relative contributions of the reproductive organs to protein synthesis and degradation in birds. However, protein synthesis related to reproduction in the female is high. Birds' eggs are high in protein. For instance, the protein composition of a chicken hen's egg (assuming a 58 g egg) is the following (calculated from Belitz et al., 2009):

- Albumin: 3.6 g
- Yolk: 3.3 g
- Shell: 0.2 g

This is equivalent to 43% of the protein required in the diet of the chicken (see Table 20.11).

Virtually all of the yolk proteins are synthesized in the liver and are absorbed into the developing oocyte in the follicle (see Chapter 27). Yolk proteins consist of the following (Moran, 1987):

- Low density (very low-density lipoproteins LDF1 and LDF2): 66%
- Granules (phosvitins and lipovitellins): 23%
- Aqueous α livetin, β livetin, and γ livetin (IgG): 11%

Both phosvitin and lipovitellin are derived from vitellogenins (VTGs) produced in the liver and secreted into the plasma. The VTG is processed to lipovitellin and phosvitin in the ovary. There are multiple VTG genes in birds (e.g., chicken VTGI, VTGII, and VTGIII: Evans et al., 1988). These are only expressed in the liver in birds either producing estrogen or receiving exogenous estrogens (chicken: Evans et al., 1988; Japanese quail: Gupta and Kanungo, 1996). Progesterone can inhibit VTGII expression (Japanese quail: Gupta and Kanungo, 1996). Interestingly, possible endocrine disrupters of chemicals such as pesticides can be evaluated using either circulating concentrations of VTG or VTG gene expression in the Japanese quail (Shibuya et al., 2005).

TABLE 20.11 Characteristics of Sexually Mature Hens

Parameter	Metric
Body weight	1.5 kg
Carcass protein	23.9%
Carcass protein	358 g
Ovary	35.5 g
Oviduct	47.1 g
Oviduct protein	8.2 g
Liver	24 g
Egg Production	
Protein requirement in diet	16.5 g/day
Protein secreted in oviduct or taken up by developing ovum in the ovary	~7.1 g/day
Sexual Maturation	
Increase in body weight during sexual maturation	252 g
Increase in body protein during sexual maturation	2.2 g/day
Increase in ovarian and oviduct protein during sexual maturation	0.5 g/day

Source: Chickens; from or calculated from Reid (1976), Renema et al. (2001), Belitz et al. (2009).

What are not known are whole-body and specific-organ rates of protein synthesis and degradation in the reproductively mature female. This includes the turnover of structural and secretory proteins in the ovary and oviduct, and those related to the production of VTG and other yolk proteins in the liver.

In the photostimulated sexually immature female chicken (17 week old pullet), the development of the ovary and oviduct occurs over about 28 days (Renema et al., 2001). Oviductal growth is occurring under the influence of estrogen (estradiol) and progesterone with marked increases in protein synthesis (Muller et al., 1970).

20.3.5.2 Male Reproduction

The importance of the male reproductive organs to overall protein metabolism has received little attention in birds. The testes of birds are considerably larger than those of mammals, as can be readily observed from the following:

- Sexually mature Japanese quail testes: 2.5 g, or 2.5% of body weight (Vatsalya and Kashmiri, 2012)
- Sexually mature chicken testes: 33 g (González-Morán et al., 2008)

It is likely that there are high demands for protein synthesis in spermatogenesis. However, protein requirements for seminal fluid are likely to be low as semen volume is modest, for instance 0.4 ml, and seminal plasma protein concentrations are only 1.9% in turkeys (Kotłowska et al., 2005). There is no information on the protein requirements for epididymal, ductal, phallic, and secondary sexual characteristic development and maintenance.

20.4 AMINO ACIDS AND METABOLISM

20.4.1 Amino Acid Transfer into Muscle and Other Cells

There are transporters transferring amino acids into muscle cells and into the cells of other organs. Amino acid uptake by cells can be determined by uptake of [^{3}H]-aminoisobutyric acid (AIB), or ^{14}C-AIB. This approach prevents the confounding of data by measuring both the uptake of amino acids and their incorporation into proteins.

Hormones, including IGF1 and insulin, stimulate AIB uptake by muscle cells. The half-maximal effective doses are the following (Duclos et al., 1993):

- IGF1: 0.27 nM
- Insulin: 35 nM

These differences in the half-maximal effective doses are consistent with insulin acting via the IGF1 receptor. Earlier studies have also reported that insulin increases AIB uptake by chick embryo cardiac cells (Guidotti et al., 1968; Santora et al., 1979). It is not clear whether insulin is acting via the insulin receptor in the heart cells or as a surrogate for IGF1. Growth hormone does not influence AIB uptake by chicken myotubes (Duclos et al., 1993).

20.4.1.1 Cationic Amino Acid Transporters

The cationic amino acid transporters (CAT1–3) are expressed in the pectoralis muscle, heart, and liver (Humphrey et al., 2004, 2006). Expression of CAT1–3 is greatly decreased in birds on lysine-deficient diet (Humphrey et al., 2006). Acute-phase reaction as induced by challenge with *Salmonella typhimurium* LPS increased expression of CAT1–3 in the pectoralis of 11 week old chickens (Humphrey and Klasing, 2005).

20.4.4 Nitrogenous Waste

Most urinary nitrogenous waste in birds is in the form of uric acid. Estimates of the relative contributions of uric acid, urea, and ammonia to nitrogenous waste in birds are the following (Stevens, 1996):

- Uric acid: ~75%
- Urea: ~5%
- Ammonia: 12%

Ammonia is only a minor component and is little affected by dietary protein status. There is no effect of dietary protein on the concentration of ammonia in pigeon excreta (*Columbia livia*: McNabb et al., 1972). There are, however, some species differences. In the small hummingbird, the black-chinned hummingbird (*Archilochus alexandri*), over a quarter of nitrogenous waste is as ammonia (McWhorter et al., 2003).

20.4.2.1 Uric Acid

The major nitrogenous waste in birds is uric acid (Milroy, 1903). Infusion of ammonia or glutamine increases circulating concentrations of uric acid in chickens (Karasawa and Tasaki, 1973). The enzymes of the uric acid cycle are found in both the liver and kidney. For instance, phosphoribosylpyrophosphate amidotransferase and xanthine dehydrogenase activities are present in both avian liver and kidneys (chicken: McFarland and Coon, 1980, 1984). Glutamine is critically important for uric acid formation (see the Section 20.4.2.3). It is not surprising that glutaminase (catalyzing glutamine to glutamate) is either not present or at very low levels in the avian liver (chicken: Wu et al., 1998).

The predominant organ responsible for uric acid formation is the liver. Chicken hepatocytes have been demonstrated to synthesize uric acid *in vitro* (McFarland and Coon, 1984). The kidney synthesizes only about 17% of the uric acid found in the urine of birds (chicken: Chin and Quebbemann, 1978).

Uric acid formed from the amino acids glutamine, glycine, and aspartate by the following pathway (based on Stevens, 1996):

1. Ribose + ATP ↔ Ribose-5-phosphate + ADP
2. Ribose-5-phosphate + ATP
   ↔ 5-Phosphoribosyl-α –pyrophosphate (PRPP) + AMP
   Pyrophosphokinase
3. PRPP + Glutamine
   ↔ 5-β-Phosphoribosyl amine + Glutamate
   Phosphoribosylpyrophosphate amidotransferase (Aminophosphoribosyltransferase)
4. Phosphoribosylamine + Glycine
   ↔ Glycinamide ribotide (GAR) [Phosphoribosylglycineamine]
   GAR synthetase
5. GAR + N-formyl tetrahydrofolate
   ↔ Formylglyinamide ribotide (FGAR) [Phosphoribosyl-N-formylglycineamine] + Tetrahydrofolate
   GAR transformase
6. FGAR + Glutamine + ATP
   ↔ Formylglycineamidine ribotide (FGAM) + Glutamate + ADP
   FGAM Synthetase
7. FGAM + HCO_3^{-1} + ATP
   ↔ Phosphoribosyl-5-aminoimidazole-4 carboxylate + ADP
8. Phosphoribosyl-5-aminoimidazole-4 carboxylate + Asparate + ATP
   ↔ Inosine monophosphate + Fumarate + ADP
9. Inosine monophosphate ↔ Xanthine + PRPP
   IMP dehydrogenase
10. Xanthine ↔ Uric acid
    Xanthine dehydrogenase

PRPP is cycled back to step 3 and hence uric acid cycle or used to generate purines.

20.4.2.2 Urea

The existence of a urea cycle in birds has been questioned (Stevens, 1996). However, birds have both uric acid and urates as well as urea in the plasma (see Chapter 11).

The urea cycle is as follows:

1. Ornithine + Carbamyl phosphate ↔ Citrulline
2. Citrulline + Asparate + ATP ↔ Argininosuccinate + Fumarate + AMP
3. Argininosuccinate ↔ Arginine
4. Arginine ↔ Urea + Ornithine (and return to step 1)

20.4.2.3 Glutamine and Ammonia Detoxification

The primary ammonia-detoxifying enzyme in the avian liver is glutamine synthase. The gene has been characterized (Pu and Young, 1989). Glutamine synthase is expressed in the liver, brain, and retina (chicken: Satoh and Matsuno, 1983; Patejunas and Young, 1987). In contrast to the situation in mammals, there is little zonation of the enzyme in the avian liver (chicken and ducks: Smith and Campbell, 1988). Moreover, while glutamine synthase is cytosolic in mammals, the enzyme is located in the mitochondria in birds (chicken and ducks: Smith and Campbell, 1988).

20.4.3 Amino Acids as Energy Sources

20.4.3.1 Glutamine as an Energy Source

Glutamine is a significant energy source for at least some tissues in birds. For instance, it is the major energy source for avian erythrocytes (chicken: Mathew et al., 1993). Glutamine is also employed as a major energy source for enterocytes (chicken: Watford et al., 1979).

20.4.4 Amino Acid Derivatives

There are multiple compounds in the animals that are derived from amino acids via biosynthetic pathways. These include the following:

- Epinephrine (hormone) from tyrosine (and phenylalanine)
- Glutamate (neuromodulator)
- Histamine (neurotransmitter and inflammatory response) from histidine
- Melatonin (hormone) from tryptophan

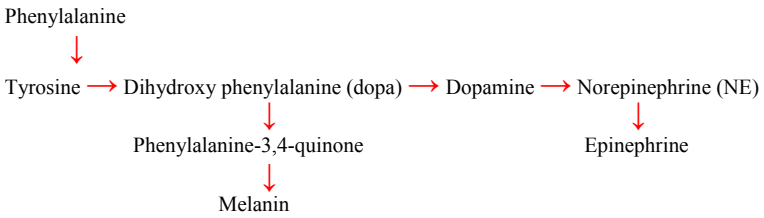

FIGURE 20.4 **Synthesis of melanin, dopamine, norepinephrine, and epinephrine from phenylalanine or tyrosine.**

- Melanin (pigment) from tyrosine
- Nitric oxide (signal molecule) from arginine catalyzed by nitric oxide synthase
- Norepinephrine (neurotransmitter and hormone) from tyrosine (and phenylalanine)
- Nucleotides (purines, e.g., adenine, and guanine together with uric acid) from glutamine, aspartate, and glycine
- Serotonin (neurotransmitter) from tryptophan
- Thyroxine and triiodothyronine (hormone) from thyroglobulin (tyrosine residues)
- Urea from arginine

An example of such biosynthetic pathways is shown in Figure 20.4.

20.5 EXTRANUTRITIONAL EFFECTS OF AMINO ACIDS

There is intriguing research supporting amino acids having regulatory roles.

20.5.1 Amino Acids in the Control of Metabolism

20.5.1.1 Glutamine and Muscle Growth

Glutamine has been proposed to be playing a role in the control of muscle protein synthesis (Wu et al., 1998). There are decreased levels of free glutamate and glutamine in leg but not pectoralis muscles from starved chickens along with the suppression of protein synthesis in leg but not pectoralis muscles (chicken: Watford and Wu, 2005) (see Table 20.12). Both glutamine synthase and glutaminase activities are reported in avian muscle. There is also much higher activity of glutamine synthase but not glutaminase in leg muscles than in pectoralis muscles (chicken and pigeon (*C. livia*): Watford and Wu, 2005).

20.5.1.2 Glutamine and Intestinal Growth

Supplementing a corn–soybean diet with glutamine increased both duodenal and jejunal mucosal villi height in young chickens despite not impacting growth (Bartell and Batal, 2007). For instance, duodenal villi height was reported to be increased by 41% with glutamine supplementation in the following manner (Bartell and Batal, 2007):

- Controls on corn–soybean diet: 652 μm
- Supplemented with 4% glutamine: 921 μm

TABLE 20.12 **Effect of Starvation on Fractional Rate of Protein Synthesis, Together with Glutamine and Glutamate, in Different Muscles in Young Chickens**

	Fed	Starved
Fractional Protein Synthesis (% per day)		
Pectoralis	11	10
Leg muscle	36	14
Glutamine (μmol/g)		
Pectoralis	1.4	1.4
Leg muscle	9.4	3.0
Glutamate (μmol/g)		
Pectoralis	0.9	0.9
Leg muscle	3.4	1.7

Chapter 21

Food Intake Regulation

D. Michael Denbow and Mark A. Cline
Department of Animal and Poultry Sciences, Virginia Tech, Blacksburg, VA, USA

21.1 INTRODUCTION

Birds, like mammals, have complex mechanisms regulating food intake. Given a choice between more than one diet, turkeys, broilers, layers, and other avian species display the ability to self-select a diet adequate for growth or production (Denbow, 1999). Although compensation may not be complete, if exposed to severe feed restriction early in life, birds compensate by increasing their intake in order to increase weight gain following the restriction. In contrast, force feeding birds twice their ad libitum food intake causes Leghorns to stop eating for 7–10 days until their fat stores approach pre-force-feeding levels. Therefore, clearly, birds have the ability to regulate food intake.

Among the strongest evidence that food intake is regulated in birds is the temporal response to dietary amino acid imbalances. Broiler chicks decrease intake of a diet deficient in lysine, methionine, and tryptophan within 24 h posthatch (Picard et al., 1993). Preferences for certain diets are evident in as little as 7 h posthatch. The ability to discriminate among diets deficient in amino acids is dependent on the genetic background of the bird (Noble et al., 1993).

Intense genetic selection of poultry has resulted in strains optimized for either meat production or egg production. Genetic selection has resulted in broilers that are five times larger than layer-type chicks at 6 weeks of age (Zhao et al., 2004). Broilers now reach market weight 50 days earlier than 50 years ago. This increased growth rate has resulted largely from increased food intake.

Food intake regulation in birds has been reviewed (Kuenzel, 1994; Denbow, 2000; Furuse et al., 2007; Richards and Proszkowiec-Weglarz, 2007; Cline and Furuse, 2012). Food intake regulation involves sites both within and outside the central nervous system (CNS), and signals are integrated within the CNS. As in mammals, the CNS, and specifically the hypothalamus, has emerged as a key site in appetite control (Hussain and Bloom, 2013). Because the bulk of the research on avian food intake regulation has used poultry as a model, this chapter focuses mainly on domestic fowl species. However, research with other avian species is reported in several tables.

21.2 PERIPHERAL REGULATION OF FOOD INTAKE

Outside of the CNS, food intake is regulated by both the gastrointestinal tract and the liver (Denbow, 1994). The crop does not appear to have a direct role in food intake regulation in that it does not appear to have receptors that modulate intake. However, it may restrict intake physically when its capacity is reached. The gastrointestinal tract has osmoceptors that, when stimulated by hyperosmotic solutions, result in reduced food intake. Infusion of hyperosmotic solutions into the duodenum reduces food intake, suggesting the existence of osmoreceptors. Intraduodenal infusions of hyperosmotic solutions decrease food intake via a decrease in gastrointestinal motility (see Denbow, 1994).

After absorption from the gastrointestinal tract, nutrients generally travel directly to the liver. Whereas in mammals absorbed lipids are packaged into chylomicrons, enter the lymphatic system, and are transported to the subclavian vein, in birds lipids are packaged into portomicrons that enter the hepatic portal vein and travel directly to the liver. Therefore, the liver is strategically located to monitor nutrient intake and control food intake in birds.

Intrahepatic infusion of glucose, lysine, or lipids decreases food intake (Table 21.1), and these effects vary with the strain of bird. For example, intrahepatic infusion of glucose decreased food intake in Leghorns, but not broilers. Similarly, infusions of lipids decreased food intake in free-feeding Leghorns, but not broilers.

Although the liver appears able to alter food intake in response to changes in hepatic portal blood glucose concentration, there is little evidence that plasma or brain concentrations of glucose influence food intake. Savory (1987) reported no correlation between plasma glucose concentrations and food intake. Furthermore, injections of glucose, or its antimetabolites, into the lateral cerebroventricle have no effect on food intake (Denbow et al., 1982). Whereas insulin injections increase food intake in mammals, similar injections either have no effect or decrease food intake in birds (Cline and Furuse, 2012).

Sturkie's Avian Physiology.

TABLE 21.1 Effects of Compounds on Food Intake when Infused into the Hepatic Portal System[1]

Compound	Broilers	Leghorns
Glucose	→	↓
Amino acid preparations[2] FreeAmineIII®	ND	→
Lysine	ND	↓
Leucine	ND	Delayed ↓
Ammonium chloride	ND	→
Epinephrine	ND	↓
Fatty acids[3] Liposyn®	→	↓

[1]→, no effect; ↓, decrease in food intake; ND, not determined (Denbow, 1999).
[2]FreAmineIII® contains isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, valine, alanine, dl-, arginine, histidine, proline, serine, glycine, cysteine, sodium acetate, magnesium acetate, sodium chloride, potassium chloride, phosphoric acid, and potassium metabisulfite.
[3]Liposyn® is a commercial emulsified fat product.

While food intake is modified by direct injection of lipids into the liver, dietary lipids also alter food intake (Denbow, 1989). Feeding medium-chain triglycerides (glyceryl tricaprylate or glyceryl tricaprate) or corn oil containing long-chain triglycerides to Leghorns decreased food intake as soon as 30 min postfeeding. This agrees with studies showing that short- and medium-chain triacylglycerols were more effective in decreasing food intake than long-chain triacylglycerols when infused into the hepatic–portal system (see Denbow, 1994). However, medium- and long-chain triacylglycerols were equally effective in decreasing food intake when administered intragastrically. Ketone bodies, acting both peripherally and centrally, also decrease food intake in chicks (Sashihara et al., 2001).

The lipostatic theory of food intake proposed that the brain senses the state of fat depots and makes appropriate adjustments in food intake to maintain fat stores. In 1994, a protein coded by the Ob gene, named leptin, was cloned from the mouse (Zhang et al., 1994), and is believed to be part of a feedback system that indicates an animal's stores of white adipose tissue. As fat stores increase, circulating plasma leptin levels increase. This protein is lacking in ob/ob mice. Administering recombinant leptin to ob/ob mice reduces food intake, decreases body weight and lipid content, and increases thermogenesis. While many studies have shown the presence of leptin in birds, others have questioned these results (see Cerasale et al., 2011). The avian leptin gene has not been found, but its receptor has been reported to be present (Horev et al., 2000). Peripheral and central injections of leptin in rodents decrease food intake. Intracerebroventricular (ICV) injections of human leptin decreased food intake in both broiler and Leghorn chickens (Denbow et al., 2000).

Ghrelin, originally identified as a growth hormone-releasing peptide, is released from the stomach of mammals. ICV and intraperitoneal (IP) injections were shown to increase food intake in humans and rodents. In addition, its levels increase in plasma during fasting, and decrease upon re-feeding. Ghrelin is also found in the proventriculus of birds. Plasma ghrelin levels increase during fasting in Japanese quail and 6 day old layers, but not in 3 week old broilers (Richards and Proszkowiec-Weglarz, 2007; Richards and McMurtry, 2010). Ghrelin mRNA and peptide levels increase in the proventriculus during fasting and return to control levels after re-feeding. However, brain ghrelin mRNA does not change during fasting or re-feeding. While the changes in plasma ghrelin levels associated with fasting would suggest it may act as a peripheral orexigenic signal, in contrast to in rodents and humans, central administration of ghrelin decreases food intake in birds (Furuse et al., 2001). In Japanese quail, while IP injections of relatively low doses of ghrelin increase food intake, higher doses decrease food intake. Intravenous (IV) injections of ghrelin in chickens either weakly decreased food intake or had no effect.

21.3 CNS CONTROL OF FOOD INTAKE

Food intake regulation is highly conserved across animals, and thus neural and endocrine networks controlling this behavior are similarly conserved. The hypothalamus has emerged as the major site of food intake (Hussain and Bloom, 2013). The hypothalamus receives signals for the gut, pancreas, liver, and adipose tissue as well as other parts of the brain, and it integrates these inputs (Figure 21.1) (Richards and Proszkowiec-Weglarz, 2007).

As in mammals, lesioning the medial hypothalamus of avian species increases food intake, whereas lesioning the lateral hypothalamic area (LHA) decreases food intake (Kuenzel et al., 1999). While these sites were traditionally considered the satiety and feeding centers, respectively, it is currently believed that they are considered as parts of larger neural circuits involved in food intake regulation.

The neurochemical control of food intake is complex. Within the CNS, many neurochemicals have been shown to function in food intake control. As will be discussed in the "Classical Neurotransmitters" section, there are many classical neurotransmitters (Table 21.2) as well as peptides (Table 21.3) that have been shown to act in the CNS to alter food intake. In general, these compounds act similarly between mammals and avian species. However, there are some notable exceptions.

21.4 CLASSICAL NEUROTRANSMITTERS

Many classical neurotransmitters have been shown to have a role in the CNS in the control of food intake in birds, and this effect can vary with the type of bird (Table 21.2). For example, ICV injection of epinephrine (E) increased

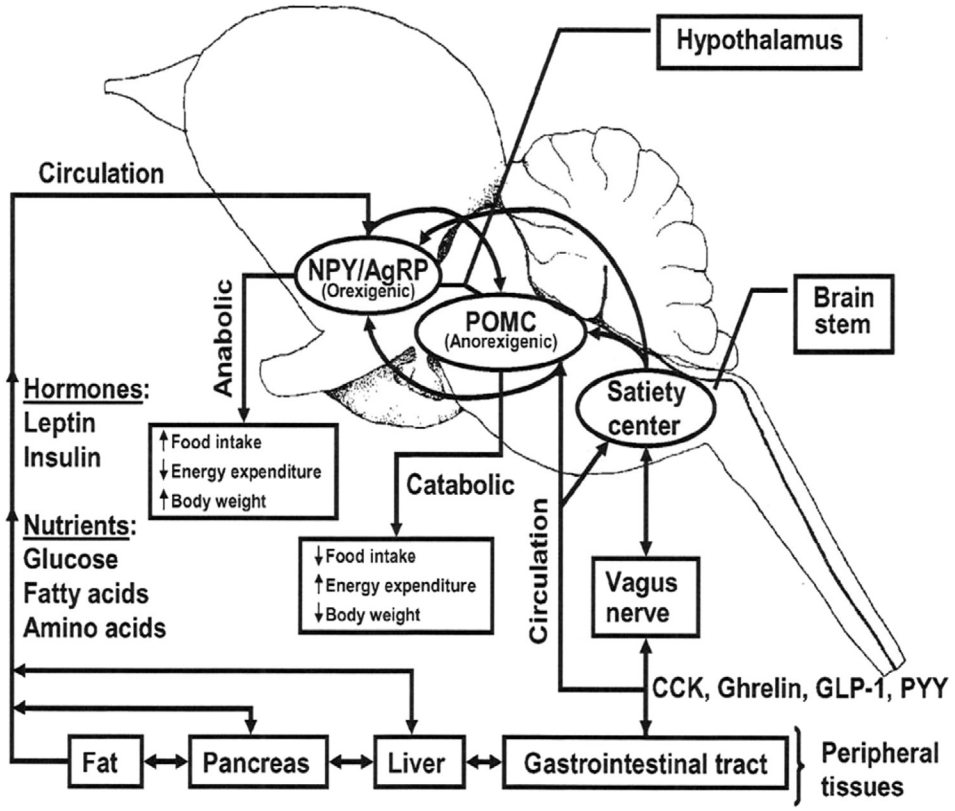

FIGURE 21.1 A proposed model describing the long-term regulation of appetite and energy balance to achieve a stable body weight in poultry that integrates peripheral tissue and central nervous system circuits regulated by hormonal, neural, neuroendocrine, and nutrient signaling mechanisms. NPY, neuropeptide Y; AgRP, agouti-related peptide; POMC, pro-opiomelanocortin; CCK, cholecystokinin; GLP-1, glucagon-like peptide-1; PYY, peptide YY.

food intake in broilers (Denbow et al., 1981), but was without effect in Leghorns (Denbow et al., 1983), and reduced food intake in turkeys (Denbow, 1983). More recently, Katayama et al. (2010) reported that high doses of norepinephrine (NE) injected ICV reduced food intake in broiler chicks, and this effect was not associated with changes in brain neuropeptide Y (NPY) or pro-opiomelanocortin (POMC) concentrations. However, Bungo et al. demonstrated a stimulatory effect of ICV NE on food intake in layer chicks. Dopamine, L-DOPA, and tyrosine have been reported to not affect feeding in layer chicks (Bungo et al., 2010). Serotonin (5-hydroxytryptamine; 5-HT) decreases food intake when injected into the brain of both Leghorns and broilers (Table 21.2). Furthermore, adding fenfluramine, a drug that increases the action of serotonin, to the diet of layers and broilers decreased food intake (Hocking and Bernard, 1993).

In mammals, NE, when injected into specific brain sites, both increases and decreases food intake depending on the site of injection. Injections into the ventromedial hypothalamus (VMH) or paraventricular nucleus (PVN) stimulate feeding, while injections into lateral sites including the perifornical region decrease feeding. In Leghorns, NE stimulated food intake when injected into the ventromedial nucleus, PVN, and medial septal sites (Denbow and Sheppard, 1993). NE inhibited food intake when injected near the lateral septal organ and the anterior portion of both the nucleus reticularis superior, pars dorsalis and the tractus occipitomesencephalicus.

Furthermore, food intake was increased in layer-type chicks by ICV injections of clonidine, an α_2-adrenergic agonist acting at presynaptic sites, and this effect was attenuated by yohimbine, an α_2-adrenergic antagonist (Tachibana et al., 2009b). Whereas ICV injections of 0.1 and 0.2 nmol of clonidine stimulated food intake in broilers (Bungo et al., 1999), 0.8 but not 0.4 nmol increased food intake in layer-type chicks. Therefore, it appears that selection for growth in broilers results in increased sensitivity to α_2-adrenergic stimulation. ICV injection of BRL37344, a β_3-adrenergic receptor agonist, suppressed food intake (Tachibana et al., 2003a).

The major inhibitory neurotransmitter in the CNS is γ-aminobutyric acid (GABA). GABA increases food intake in both broilers and turkeys (see Table 21.2). This effect appears mediated by $GABA_A$, but not $GABA_B$ (Jonaidi et al., 2002). Muscimol, a $GABA_A$ receptor agonist, was able to stimulate food intake in broilers, while baclofen, a $GABA_B$ receptors agonist, had no effect.

TABLE 21.2 Effects of Various Neurotransmitters or Their Agonists on Food Intake in Poultry when Injected Directly into the Central Nervous System[1]

Neurotransmitter	Broilers	Leghorns	Turkey

[2]From Bungo et al. (2011). AMPA and NMDA reduced feed intake in pigeons (Zeni et al., 2000).
[3]From Zendehdel et al. (2009). Glutamate also reduced feed intake in pigeons (Zeni et al., 2000).
[4]From Baghbanzadeh et al. (2010).
[5]Results for broilers are from Cline and Furuse (2012); those for Leghorns are from Meade and Denbow (2001).
[6]Results for broilers are from Zendehdel et al. (2009), those for Leghorns are from Bungo et al. (2003).

Histamine was shown to inhibit food intake when injected ICV in both broiler and Leghorn chicks (Meade and Denbow, 2001). Histamine can work at three receptor subtypes: H_1, H_2, and H_3. The H_3 receptor is an autoreceptor that inhibits the release of endogenous histamine from histaminergic neurons. The anorexigenic effect of histamine was attenuated by the H_1 receptor antagonist chlorpheniramine and the H_2 receptor antagonist cimetidine. Taati et al. (2010) showed that injection of thioperaminde, an H_3 antagonist that enhanced histamine release, decreased food intake in 3-week-old broilers. In contrast, R-α-methylhistamine, an H_3 agonist, increased food intake. The H_1 receptor antagonist chlorpheniramine attenuated the effect of thioperaminde, whereas famotidine, an H_2 receptor antagonist, had no effect except at high doses, at which it decreased food intake. Therefore, while it appears that the H_1 receptor is involved in mediating the effect of a histamine-induced decrease in food intake, the role of the H_2 receptor is still unclear.

21.5 PEPTIDES

The list of peptides known to alter food intake is large and growing (Cline and Furuse, 2012). Many of these peptides have orexigenic effects (Table 21.3), and most have anorexigenic effects (Table 21.4).

21.5.1 Neuropeptide Y

First isolated from the pig brain in 1982 (Tatemoto et al., 1982), NPY is one of the most abundantly expressed peptides in the CNS. With a highly conserved sequence of 36 amino acids, the mammalian and avian amino acid sequences differ by a single residue (Blomqvist et al., 1992; Larhammar, 1996). In both mammals and avian species, NPY is one of the most potent orexigenic regulators of food intake. NPY stimulates food intake via NPY Y_2 and Y_5 receptors, but not the Y_1 receptor. Whereas in mammals peptide YY and pancreatic polypeptide suppress appetite, in broiler and Leghorn chicks peptide YY increases food intake (Kuenzel et al., 1987; Denbow et al., 1988). Peptide YY was much more potent than NPY in stimulating food intake, which may reflect a difference in the affinities of NPY and peptide YY to these NPY receptor subtypes.

In mammals, within the hypothalamus the arcuate nucleus (ARC) is a major site for food intake regulation (Hussain and Bloom, 2013). This nucleus has a semipermeable blood–brain barrier allowing peripheral signals to reach the brain. There are first-order orexigenic neurons in the ARC containing NPY and co-expressing agouti-related peptide (AGRP), and a second population of anorexigenic neurons containing POMC–CART (cocaine- and amphetamine-regulated transcript) neurons. These neurons then communicate with second-order neurons in other nuclei expressing such peptides as orexins and melanin-concentrating hormone. Upon fasting, NPY mRNA levels increase in the ARC and this coincides with an increase in NPY peptide content and release in the PVN.

The melanocortin 4 receptor (MC4R) is associated with inhibition of food intake. Release of AGRP, an endogenous melanocortin 4 receptor antagonist, from the NPY–AGRP neurons in the ARC blocks the MC4R, causing increased food intake. In addition, α-melanocyte-stimulating hormone (α-MSH), which is transcribed from the POMC gene, is an agonist at the MC4R and causes decreased food intake.

TABLE 21.3 Peptides Administered Centrally Having an Orexigenic Effect on Food Intake in Various Avian Species

Orexigenic Peptide	Broilers	Leghorns	Other birds

[1]*Had an anorexic effect.*

Therefore, fasting increases expression of AGRP mRNA and decreases expression of POMC mRNA.

In avian species, NPY-containing neurons are located in the infundibular nucleus, homologous to the ARC in mammals (Kuenzel, 1994; Wang et al., 2001), and these neurons co-express AGRP (Boswell et al., 2002). As in mammals, NPY gene expression increases in the hypothalamus in fasted and food-restricted avian species (Phillips-Singh et al., 2003; Song et al., 2012). Therefore, as in mammals, AGRP blocks the anorexigenic melanocortin pathway, while NPY mediates the orexigenic pathway.

ICV injections of NE do not alter brain NPY or POMC mRNA expression (Katayama et al., 2010). However, the increase in food intake induced by ICV NPY is

attenuated by yohimbine, an α2-adrenergic receptor antagonist (Tachibana et al., 2009b). This suggests that NPY neurons possibly work via communication with adrenergic neurons that act at α_2-adrenergic receptors. Furthermore, a $GABA_A$ antagonist is able to attenuate the response to NPY (Jonaidi and Noori, 2012).

21.5.2 Melanocortins

Melanocortins are derived from POMC, and in mammals most are released from neurons in the ARC. While these peptides can act at five different melanocortin receptor subtypes (MC1R through MC5R) distributed throughout the

body, MC3R and MC4R are expressed in the mammalian brain. MC3R appears to regulate energy expenditure, while MC4R is involved with food intake. Agonists of the MC3R receptor decrease food intake.

ICV injection of α-melanocyte-stimulating hormone (α-MSH) significantly reduced food intake in fasted broiler chicks and attenuated NPY-induced food intake (Kawakami et al., 2000). Conversely, AGRP attenuated α-MSH-induced anorexia (Tachibana et al., 2001). CART, which is also found in the POMC neurons, also decreased food intake in broiler and layer chicks and attenuated NPY-induced feeding (Tachibana et al., 2003b).

In mammals, β-MSH binds MC4R with higher affinity than α-MSH (Harrold et al., 2003), suggesting that it may be the main endogenous melanocortin receptor agonist. However, in chickens, α-MSH binds to MC4R with greater affinity than does β-MSH (Ling et al., 2004). In broiler chicks, β-MSH decreased food and water intake while increasing plasma corticosterone concentrations (Smith et al., 2008). Gamma-MSH, a selective MC3R agonist, also reduced food intake in broiler chicks, but required a larger doses than α- or β-MSH (Smith et al., 2011). So it appears that the melanocortin system is involved in an anorexigenic effect in birds, but the role and location of the various receptors still need further elucidation.

21.5.3 Corticotrophin-Releasing Hormone

Corticotrophin-releasing hormone (CRF) acts within the brain to decrease food intake in both broilers and Leghorns (Furuse et al., 1997; Denbow et al., 1999). The ICV injection of the CRF homolog stresscopin also reduced food and water intake in broiler and White Leghorn chicks (Cline et al., 2009d). This was associated with an increased number of c-Fos immunoreactive cells in the VMH, the parvicellular and magnocellular divisions of the PVN, and the posterior hypothalamic nucleus (PHN), indicating increased neuronal activity in these areas. This anorexigenic effect was mediated via CRF receptors. Khan et al. (2008) showed that the anorexigenic affect of CRF was attenuated by blocking nitric oxide in broiler chicks.

As discussed above, the site of action of ghrelin is the CNS. In mammals, ghrelin potently stimulates food intake mainly by stimulating NPY neurons located in the ARC. In contrast, an ICV injection of ghrelin inhibits food intake in broiler chicks, an effect opposite that in mammals (see Furuse et al., 2007). In elucidating the mechanism of ghrelin in birds, Saito et al. (2005) showed that an ICV injection of ghrelin increased plasma corticosterone. Co-injection of the CRF receptor antagonist astressin attenuated the ghrelin-induced decrease in food intake and plasma corticosterone increase. Furthermore, co-injection of ghrelin with NPY inhibited the NPY-induced increase in food intake, and the ICV injection of ghrelin did not change NPY mRNA expression. In contrast to mammals, in which ghrelin induces the release of NPY from neurons in the ARC, in birds ghrelin in the CNS inhibits food intake through the release of endogenous CRF. Taati et al. (2010) demonstrated that blockade of histamine H_1 but not H_2 receptors attenuated ghrelin's anorexigenic effect. Therefore, in chicks, ghrelin, via the histaminergic system, likely causes CRF release, which is ultimately responsible for ghrelin-induced anorexia.

21.5.4 Obestatin

In addition to ghrelin, proghrelin also produces a 23 amino acid amidated peptide called obestatin, which was first isolated and purified from the rat stomach. This peptide is the endogenous ligand of the GPR39 receptor (Wolfgang et al., 2006). The role of obestatin is unclear since it has been reported to decrease food intake and body weight, but other studies failed to show an effect on food intake in rats (Seoane et al., 2006). Xu et al. (2011a) reported that ICV injection of obestatin increased food intake in a dose-dependent manner in a high-weight selected line of chickens. However, Song et al. (2013) found that IV injection of obestatin had no effect on food intake in broilers or Leghorns. Further studies are needed to elucidate the role of obestatin in food intake in birds.

21.5.5 AMP-Activated Protein Kinase

AMP-activated protein kinase (AMPK) is a heterotrimeric enzyme complex composed of one catalytic (alpha) subunit and two regulatory (beta and gamma) subunits. AMPK is activated by allosteric regulation of AMP and by phosphorylation of threonine (thr 172) on the alpha subunit by upstream kinases, including liver kinase B1 (LKB1), calcium/calmodulin-dependent protein kinase kinase (CaMKK), and TGF-beta-activated kinase-1 (TAK1). AMPK acts as an energy sensor. Glucose, leptin, and insulin inhibit hypothalamic AMPK activity and decrease food intake in mice, while ghrelin and adiponectin stimulate hypothalamic AMPK activity and increase food intake in rats (Xu et al., 2011a). ICV injection of ghrelin inhibited hypothalamic AMPK gene expression and phosphorylation of the alpha subunit of AMPK. Furthermore, ghrelin was more efficacious in decreasing food intake in low-weight selected birds than in high-weight selected birds, supporting the hypothesis that selection for lower body weight resulted in increased sensitivity to ghrelin and the AMPK system (Xu et al., 2011a).

21.5.6 Opioids

Opioids act as inhibitory neurotransmitters and are widely distributed throughout the CNS. Opioid receptors include μ, δ, or κ subtypes. The opioid antagonists naloxone and naltrexone were shown to decrease food intake in both broilers

and layers (see Denbow, 1999). Opioids appear to alter food intake in birds acting at the δ- and κ-opioid receptors (Bungo et al., 2004). Dodo et al. (2005) reported that antagonists of the μ-opioid receptor, especially the μ_1-receptor, reduced NPY-induced feeding in neonatal chicks.

Nociceptin–orphanin FQ (N/OFQ) is structurally similar to opioids, and binds to the opioid-like G protein-coupled receptor 1, or nociceptin receptor (NOP). N/OFQ shows structural similarities to the classical opioid peptides, particularly dynorphin A, but N/OFQ does not interact with the dynorphin A–κ-opioid receptor system. N/OFQ has been shown to stimulate food intake in rats (Polidori et al., 2000). Similar to other opioids, ICV injection of N/OFQ stimulated food intake and increased pecking frequency in broiler chicks (Abbasnejad et al., 2005). Similarly, ICV N/OFQ stimulated food intake in White Leghorn chicks, and this was associated with increased agouti-related peptide (AGRP) and decreased CART mRNA expression in the diencephalon (Bungo et al., 2009). N/OFQ-induced increase in food intake was blocked by α-MSH. There was no change in NPY or POMC mRNA.

21.5.7 FMRFamides

Since molluscan neuropeptide Phe–Met–Arg–Phe–NH_2 (FMRFamide) was isolated from the ganglia of the clam, similar neuropeptides containing the RFamide sequence at their C-termini (RFamide peptides) have been characterized in various invertebrates. The chicken pentapeptide Leu–Pro–Leu–Arg–Phe–NH_2 (LPLRFamide) cross-reacts with the FMRFamide antibody and was the first RFamide isolated from a vertebrate (Dockray et al., 1983).

Several RFamides have been demonstrated to function as orexigenic factors in neonatal chicks, including prolactin-releasing peptide (PrRP) and gonadotropin-inhibitory hormone (GnIH). PrRP was originally proposed to be a stimulator of prolactin release in mammals (Hinuma et al., 1998). While central administration of PrRP decreased food intake in rats (Lawrence et al., 2000, 2002; Ellacott et al., 2002), ICV injection of PrRP significantly increased food intake in layer chicks (Tachibana et al., 2004b). PrRP has a significantly weaker orexigenic effect than NPY on an equimolar basis. The orexigenic effect of NPY was further enhanced with a co-injection of PrRP.

Tsutsui et al. (2000) isolated a novel decapeptide containing the C-terminal LPLRFamide motif, SIKPSAYLPLRFamide, from the quail brain. This peptide inhibited gonadotropin-releasing factor reported in vertebrates, and it was termed GnIH. The GnIH precursor encodes one GnIH and two GnIH-related peptides (called GnIH-RP-1 and GnIH-RP-2). ICV injection of GnIH, GnIH-RP-1, and GnIH-RP-2 significantly stimulated food intake in layer chicks (Tachibana et al., 2005a). Tachibana et al. (2008) demonstrated that the effect of GnIH is likely mediated via the μ-, but not δ- or κ-, opioid receptor in broiler chicks. GnIH also did not appear to work via nitric oxide since a nitric oxide synthesis inhibitor had no effect on GnIH-induced feeding.

Ukena et al. (2010) recently demonstrated that another RFamide, 26RFa, was found in the anterior hypothalamus of Japanese quail. Its receptor, GPR103, was found in the cerebrum, diencephalon, mesencephalon, and cerebellum. Ukena et al. (2010) also demonstrated that central injection of 26RFa increased food intake of broiler but not layer-type chicks. Additionally, metastin, another RFamide first isolated from the placenta, causes increased food intake in broiler chicks, and its effects were mediated by μ-opioid receptors (Khan et al., 2009).

The RFamides, mentioned in this chapter, cause orexigenic effects in chicks when centrally administered. In contrast, there are other members of this family associated with anorexia. Chicks that received ICV LPLRFamide reduced their food intake at 30 min post injection, but this effect dissipated by 40 min post injection (Cline et al., 2009c). Since LPLRFamide-treated chicks spent more time in deep rest while other behaviors were unaffected, this may suggest that the short-term anorexigenic effect of LPLRFamide is secondary to this behavior. Further suggesting that LPLRFamide may not have a specific effect on food intake is the report from Tachibana et al. (2005b) that it had no effect on food intake in layer chicks.

Several members of the neuropeptide FF (NPFF) subfamily of the RFamide family have also been shown to cause decreased food intake in chicks (see Cline and Furuse, 2012). For example, ICV injections of NPFF caused dose-dependent reduction in food intake in broilers (Cline et al., 2007a). The effect of NPFF is mediated through the μ and κ subtypes of opioid receptors, and NPFF attenuates NPY- and β-endorphin (END)-induced food intake stimulation (Cline and Mathews, 2008).

21.5.8 Galanin

Galanin, a peptide found in both the CNS and intestine, is conserved across species. Tachibana et al. (2008) demonstrated that ICV galanin also stimulated food but not water intake of both broiler and layer-type chicks. It appears to work via μ-opioid receptors, and α_2 adrenoceptors likely mediate this response.

21.5.9 Visfatin

Visfatin, also known as pre-B cell colony-enhancing factor, is a peptide that was originally isolated from visceral fat of humans and mice, and that mimics the actions of insulin (Fukuhara et al., 2005). Visfatin is associated with metabolic syndrome in humans (Filippatos et al., 2007). The effect of visfatin on food intake was first determined

in broilers in which ICV injections nearly doubled food intake and pecking efficiency (Cline et al., 2008c). This was accompanied by an increase in the number of c-Fos immunoreactive cells in the LHA and a decrease in activity in the VMH. Brunetti et al. (2012) recently showed that in rats, visfatin injection into the ARC increased food intake and decreased CART and CRH mRNA levels, so visfatin may have a similar effect in birds and mammals.

21.5.10 Somatostatin

Somatostatin, known for the inhibition of growth hormone release, also affects food intake. While it has been shown to both increase and decrease food intake in rats depending on their feeding state, ICV injections of somatostatin increased food intake in broilers and layer-type chicks (Tachibana et al., 2009a). Its effects were mediated by μ-opioid and adrenergic α_2 receptors. By additional use of ICV injections of somatostatin analogs, it was shown that SSTR2, SSTR3, and SSTR5, but not SSTR4, receptors were associated with somatostatin-induced increased food intake (Tachibana et al., 2010).

21.5.11 Cannabinoids

The active ingredient in marijuana is Δ^9-tetrahydrocannabinol (Δ^9-THA), and it can bind to the cannabinoid receptors CB_1 and CB_2 found in the brain. The endogenous ligands for the cannabinoid receptors are 2-arachidonoylglycerol and anandamide, and endogenous antagonists include O-2050 and AM4113. The CB_1 receptor is present in the brain, as well as peripherally, in both birds and mammals, while the CB_2 receptor is found on immune and blood cells (Pagotto et al., 2006). While the effects of Δ^9-THA on food intake have been mixed, it is generally believed that it causes increased food intake and that decreased food intake is a secondary effect due to sedation (Pagotto et al., 2006). Abel et al. (1972) first showed an increase in food intake in chicks in response to Δ^9-THA. Giving an inverse agonist either via the feed or by IV injection attenuated food intake in broiler chicks (Novoseletsky et al., 2011), supporting an orexigenic role for cannabinoids in birds.

21.5.12 Glucagon-like Peptide

Glucagon-like peptide-1 (GLP1) is a member of the glucagon superfamily. Similar to results in mammals, ICV injection of GLP1 decreases food intake in broiler chicks (Bungo and Furuse, 2001). Growth hormone-releasing factor increases food intake in rats; however, it is a potent inhibitor of food intake in broiler chicks (Furuse et al., 2001). Similarly, other neuropeptides belonging to the glucagon superfamily, including vasoactive intestinal peptide (VIP) and pituitary adenylate cyclase-activating polypeptide (PACAP), reduced food intake in layer chicks (Tachibana et al., 2004a). ICV injection of PACAP and VIP increases plasma corticosterone concentrations, and these effects are attenuated by co-injection with the CRF receptor antagonist astressin, suggesting that PACAP and VIP function through activation of CRF neurons (Tachibana et al., 2004a). Similarly, glucagon (Honda et al., 2007a) and oxyntomodulin (Cline et al., 2008a) decreased food intake in chicks when injected ICV.

21.5.13 Cholecystokinin

Cholecystokinin (CCK), originally isolated from the porcine small intestine, decreases food intake when injected peripherally or centrally into mammals. CCK was also shown to decrease food intake when injected into the brain of broilers (Denbow and Myers, 1982). The structurally related peptide gastrin does not appear to decrease food intake in mammals. While the amino acid sequence of chicken CCK octapeptide (CCK8) is identical to that of mammalian species, differences in the amino acid sequence exist between chicken and mammalian gastrin. Furuse et al. (1999) demonstrated that ICV injection of chicken gastrin inhibits food intake and food passage in neonatal chicks. When further investigating the anorexigenic effects of CCK and gastrin, it was shown that the efficacy of these peptides depends on the length of their peptide sequence (Furuse et al., 2000).

21.5.14 Glucagon Superfamily

Like the glucagon superfamily, members of the calcitonin gene peptide superfamily, including calcitonin, calcitonin gene-related peptide (CGRP), and amylin, appear involved in food intake regulation. These peptides are derived via tissue-specific alternative splicing of the primary RNA transcripts of the calcitonin gene. Amylin has been shown to cause a dose-dependent decrease in food intake after ICV and IP injection in broilers (Cline et al., 2008d). This was associated with increased neuronal activity in the area postrema and the nucleus of the solitary tract. In addition, amylin caused increased alimentary canal transit time, increased plasma corticosterone concentration, and increased anxiety-related behaviors. Since amylin is co-secreted with insulin, it may be involved in terminating meals in chicks.

ICV injection of calcitonin in broiler chicks also reduced food and water intake (Layne et al., 2009). This was also associated with increased activation of the ARC, dorsomedial nucleus, and VMH. The CRF system also appears not to mediate this response. Similarly, broilers that received ICV and IP CGRP reduced both their food and water intake, but CGRP's effect on water intake appeared to be related to its effect on food intake (Cline et al., 2009a). CGRP-induced anorexia coincided with increased activation of the ARC, PVN, PHN, and VMH.

21.5.15 Insulin

Insulin decreases food intake when injected into the brain of mammals. Similarly, ICV injection of insulin decreased food intake in White Leghorn chicks (Honda et al., 2007b; Shiraishi et al., 2008a) while increasing expression of POMC, CART, and CRF, but not affecting NPY and AGRP mRNA hypothalamic expression (Honda et al., 2007b). Shiraishi et al. (2008a), however, reported a decrease in NPY expression after ICV insulin when including the brain stem. Blocking the melanocortin receptors prevented the anorexic effect of ICV insulin (Shiraishi et al., 2008a). Co-injection of β-endorphin (β-END) and insulin decreased central POMC expression more than just insulin injection, while blockade of μ-opioid receptors reduced the effect of insulin on food intake (Shiraishi et al., 2008b). Food intake is decreased in Single Comb Leghorns by chicken and pig insulin, but not by human or bovine insulin (Shiraishi et al., 2009). Kuenzel and McMurtry (1988) reported that ICV injection of insulin caused an increase in plasma insulin concentration. Insulin appears to act in the CNS to decrease food intake in chickens by both anorexigenic and orexigenic systems.

21.5.16 Bombesin

Bombesin, a tetradecapeptide originally from amphibian skin, inhibits food intake in mammalian species. Denbow (1989) reported that both ICV and IV injection of bombesin decreased food and water intake in turkeys. ICV injection of bombesin also inhibits food intake in broilers, and co-injection with NPY suppressed the orexigenic effect of NPY (Bungo et al., 2000). ICV and IP injections of bombesin analogs alytesin and litorin also decreased food intake in broiler chicks (Cline et al., 2008b, 2010a).

21.6 SELECTION FOR BODY WEIGHT ALTERS FOOD INTAKE CONTROL MECHANISMS

While broilers have been genetically selected for rapid body weight gain, Leghorns have been selected for egg production and, thus, a smaller body mass. As expected, selection for body weight alters the mechanisms controlling food intake. Several lines of evidence support this conclusion. Whereas ICV injections of NE and E increased food intake in broilers, they were without effect in Leghorns (see Denbow, 1985). While ICV injection of serotonin decreased food intake in fasted Leghorns, it had no effect in fasted broilers. So it appears that broilers are more sensitive to orexigenic compounds, whereas layer-type birds are more sensitive to anorexigenic compounds.

Much of the work exploring how selection for growth has altered the mechanisms controlling food intake has been conducted using a unique line of birds divergently selected for either low (LWS) or high (HWS) body weight at 8 weeks of age (Siegel, 1962; Rubin et al., 2010; Marquez et al., 2010). Selected for 55 generations, these lines at selection age (56 days) have a 10-fold difference in body weight (Figure 21.2) with correlated differences in food intake and body composition, and they are composed of anorexic and obese individuals.

The LWS line exhibits natural anorexia (Zelenka et al., 1988), and delayed (Dunnington and Siegel, 1996) or prevented sexual maturity (Dunnington et al., 1983, 1984). The HWS line contains compulsive eaters (Dunnington and Siegel, 1984).

Burkhart et al. (1983) reported that lesioning the VMH of low-weight-line chickens resulted in nonhyperphagic obesity, whereas similar lesions in high-weight-line chickens had no effect. These lines of birds originated from a common population selected divergently for 8 week juvenile body weight. The VMH is thought to be involved in satiety, and selection for body weight may have altered its function.

Injection of methoxamine, an α_1-adrenergic receptor agonist, stimulated food intake in the high-weight line while having no effect in the low-weight line (Denbow et al., 1986). In addition, the anorexigenic effect of 5-HT was longer lasting in the high-weight line compared to the low-weight line.

As was suggested by Bray (1991) for mammals, Denbow (1999a) suggested that differences in body weight in lines of chickens may have resulted from changes in the balance between the parasympathetic and sympathetic nervous system. Selection for increased body weight may have augmented the actions of the parasympathetic branch of the autonomic nervous system. Support for this hypothesis was provided when it was shown that LWS birds appear to have

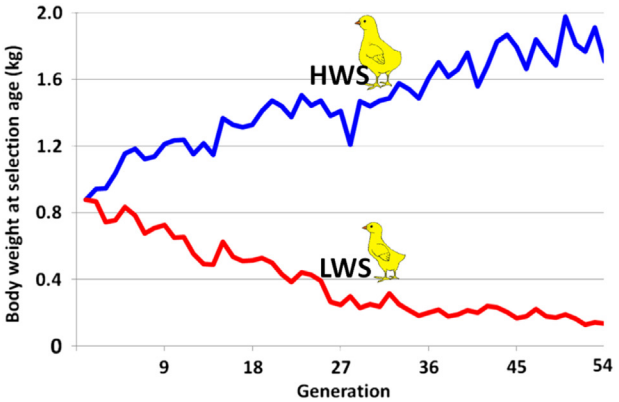

FIGURE 21.2 **Body weight at 56 days posthatch in male LWS and HWS chickens during the course of selection for low or high body weight.**

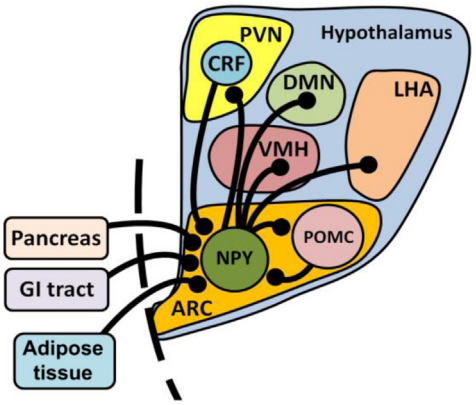

FIGURE 21.3 Based on the mammalian models, projections of NPY neurons from the ARC to other appetite-associated hypothalamic nuclei, reciprocal innervation between NPY and POMC neurons in the ARC, and reciprocal innervation between NPY and CRF in the ARC and PVN, receptively. Peripheral signals influence feed intake by affecting the ARC. *Adapted from Broberger et al. (1999); Tebbe et al. (2003); Mercer et al. (2011).*

greater sympathetic nervous system activity compared to the HWS line (Kuo et al., 2001).

For many of the anorexigenic neuropeptides, including α-MSH, CRF, insulin, amylin, and neuropeptide AF, the LWS birds respond to a lower dose than the HWS birds (Cline et al., 2010b) (Figure 21.3). For example, CRF decreases food intake in both the LWS and HWS lines, but the LWS line responded to a lower dose than did the HWS line (Cline et al., 2009b). Additionally, CRF-induced anorexia was attenuated in HWS line but not LWS line chicks by a CRF receptor antagonist. However, for neuropeptide S, calcitonin, and CGRP, the HWS respond to a lower dose than the LWS. The HWS and LWS respond similarly to ghrelin and galanin. Finally, the LWS does not respond to NPY or AGRP, while the HWS line does not reduce food intake when administered leptin.

21.7 DIFFERENCES BETWEEN BIRDS AND MAMMALS

In most cases, neurotransmitters and metabolites have similar effects in birds and mammals (Figure 21.4). However, there are several noteworthy differences. While peptide YY and pancreatic polypeptide decrease food intake in mammals, they stimulate food intake in birds. In contrast, while ghrelin is a potent orexigenic peptide in mammals, it is anorexigenic in birds. Other peptides shown to be orexigenic in mammals, including melanin-concentrating hormone, orexins (A and B), and motilin, have no effect on food intake in chickens. Finally, PrPP stimulates food intake in chickens but decreases food intake in mammals.

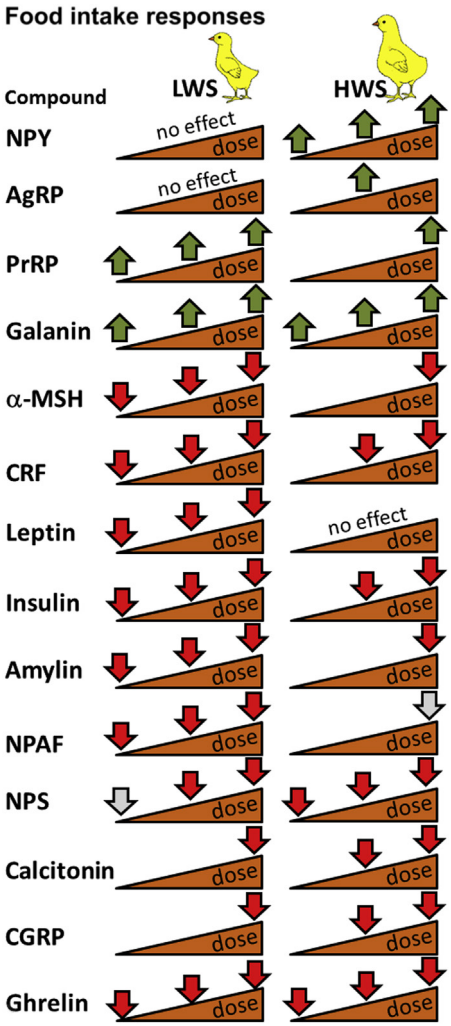

FIGURE 21.4 Summary of feed intake responses to exogenous neuropeptide injection in LWS and HWS chicks. The triangle represents an increasing dose of neuropeptide, whereas arrows indicate the relative threshold of either decreased (down red arrow) or increased (up green arrow) feed intake. Gray arrows indicate a lag in response time.

Chapter 22

Avian Endocrine System

Colin G. Scanes
Department of Biological Sciences, University of Wisconsin, Milwaukee, WI, USA

22.1 INTRODUCTION

Hormones play a critical role in controlling many aspects of the physiology of birds, including reproduction, metabolism, and growth. Hormones are produced from ductless or endocrine glands. They are then released into the bloodstream. The hormones then act on specific tissues, cells, or organs (referred to as the target organ). Each hormone acts by interacting with receptors on the surface of the cells (proteins and polypeptides) or within the cytoplasm and nucleus (steroids and thyroid hormones). Birds have a complement of endocrine organs similar to those of mammals:

- Anterior pituitary gland (discussed elsewhere in this volume in Chapter on the pituitary gland)
- Hypothalamus posterior pituitary gland complex (also discussed in Chapter on the pituitary gland)
- Gonads (discussed in Chapters on male and female reproduction)
- Pancreatic islets (discussed in Chapter on the endocrine pancreas)
- Adrenal glands (discussed in Chapter on the adrenal glands)
- Thyroid glands (discussed in Chapter on the thyroid glands)
- Parathyroid glands (discussed in Chapter on the role of hormones in the regulation of bone turnover and eggshell calcification)
- Pineal body or gland (discussed in Chapter on the pineal gland)
- Ultimobranchial bodies or glands (C cells producing calcitonin). The ultimobranchial glands are found during development in mammals, with the C cells then becoming distributed in the thyroid and parathyroid glands. (This is also discussed in Chapter on the role of hormones in the regulation of bone turnover and eggshell calcification.)
- Endocrine cells of the gut (discussed in Chapter on the gastrointestinal anatomy and physiology).

The traditional view of a distinct endocrine system, with hormones only produced by specific endocrine glands that do little else, is overly restrictive. There is production of biologically active proteins and peptides by many, if not all, tissues. Organs that were thought of as simply target organs for hormones also produce hormones such as the following:

- Adipose tissue producing adiponectin and leptin (discussed in Chapter on adipose tissue)
- Heart cells producing natriuretic peptides
- Liver producing insulin-like growth factor-1 (IGF1)
- Kidney producing renin (and hence angiotensin-I, then angiotensin-II), 1,25-dihydroxy vitamin D3, and erythropoietin (discussed in Chapters on blood and osmoregulation)

22.2 AVIAN PHYLOGENY

Caution should be expressed about extrapolating studies for poultry species such as chickens to other birds due to the multiple generations of selection, with chickens domesticated about 10,000 years ago (Sawai et al., 2010). There are differences between the present poultry and the ancestral stock. For instance, the thyroid-stimulating hormone (TSH) receptor gene exhibits the same mutation throughout multiple lines of domesticated chickens but not in jungle fowl (Rubin et al., 2010). Moreover, most of the coding sequence of SH3RF2 is deleted (Rubin et al., 2010).

Even without domestication, it is argued that neither galliform (e.g., chickens, turkeys, and quail) nor anseriform birds (ducks and geese) are necessarily good models for other avian species. Within the class Aves (birds) and Neoornithes (modern birds, including all extant species), there are two branches:

1. *Palaeognathae* (including emus, ostriches, and rhea)
2. *Neognathae*, consisting of two distinct groups:
   a. *Galloanserae*, consisting of the orders *Anseriformes* and *Galliformes*
   b. *Neoaves* (most modern species of birds) (see the Tree of Life project, http://tolweb.org; and see Hackett et al., 2008; Jetz et al., 2012; McCormack et al., 2013)

Sturkie's Avian Physiology.

The two branches, Palaeognathae and Neognathae, diverged about 140 million years ago (Sanders and Lee, 2007), while the Galloanserae and Neoaves separated about 95 million years ago (Ericson et al., 2006). Within the *Neoaves*, there are three clades:
- Water-birds
- Land-birds
- A third clade containing bustards (family: Otididae), cuckoos (family: Cuculidae), flamingos (family: Phoenicopteridae), hummingbirds (family: Trochilidae), trumpeters (family: Psophiidae), and turacos (family: Musophagidae), exhibiting marked apparent diversity

Pigeons and doves (family: *Columbidae*) form a distinct side group within the *Neoaves* (Hackett et al., 2008; McCormack et al., 2013).

22.3 PEPTIDES AND OTHER CHEMICAL MESSENGERS CONTROLLING PHYSIOLOGY

The same chemical entity may act in one or more of the following manners:

- As a *hormone* traveling from endocrine cells to target cells via the bloodstream
- As a *paracrine factor* released from one cell type to affect another cell type passing through the extracellular fluid
- As an *autocrine factor* released from one cell type to affect another cell of the same type passing through the extracellular fluid
- As an *intracrine* factor acting with a cell type to affect another cell
- As a *neurotransmitter* or *neuromodulator* released from a neuron to act with another neuron
- As a *neuropeptide* released from a neuron to act with other cell types in close proximity
- As a *neuroendocrine factor* released from neurosecretory terminals of a neuron into the blood and then acting with other cell types

Many of these chemical messengers are neuropeptides. Table 22.1 summarizes a list of neuropeptides and protein–polypeptide hormones found in avian species. This is based on the genomics of both the chicken and zebra finch (*Taeniopygia guttata*) (Delfino et al. 2010; Xie et al., 2010). Table 22.2 lists neuropeptides found in other vertebrate groups but not in birds.

Throughout vertebrate evolution, there are multiple examples of gene duplication leading to new chemical signal peptides and proteins or to new receptors. There are also cases of gene loss. For instance, prolactin-like protein (PLP) is a gene found in both fish and birds but not mammals (Wang et al., 2010). Presumably, the gene was retained in the amphibian and reptilian ancestors of birds but lost in the ancestors of mammals.

Our ability to understand the physiology of birds is being facilitated with the tremendous progress in genomics (discussed in detail in Chapter on genomics). It should be noted that there can also be polymorphisms at the gene level, splicing differences of RNA, and posttranslational differences, including proteolytic cleavage (e.g., with the translated products of the POMC and glucagon genes) and glycosylation (e.g., with luteinizing hormone (LH), follicle-stimulating hormone (FSH), and TSH).

22.4 CHEMICAL MESSENGERS FOUND IN BIRDS BUT NOT MAMMALS

There are avian neuropeptides and their respective genes that are not present in mammals. These include corticotropin-releasing factor (CRF) amide, c-type natriuretic peptide 1 precursor, renal natriuretic peptide (Delfino et al., 2010), and PLP (Wang et al., 2010).

22.5 HORMONES PRODUCED BY NONTRADITIONAL ENDOCRINE ORGANS

22.5.1 Adiponectin

A nice example of a protein produced by organs not traditionally thought of as endocrine organs is the putative hormone adiponectin. This is expressed in multiple tissues of the chicken, including the adipose tissue (highest), liver (next highest), anterior pituitary, brain, kidney, and skeletal muscle (Maddineni et al., 2005). In addition, these tissues also express the adiponectin receptors, AdipoR1 and AdipoR2, with the highest expression of AdipoR1 being in skeletal muscle, adipose tissue, and brain and with some expression in anterior pituitary gland, kidney, liver, ovary, and spleen, and with the highest expression of AdipoR2 being in adipose tissue followed by skeletal muscle and some expression also in anterior pituitary gland, brain, kidney, liver, ovary, and spleen (Ramachandran et al., 2007). It can readily be envisioned that adiponectin may act as a hormone and as a paracrine factor.

22.6 UNIQUE ASPECTS OF BIRDS

22.6.1 Song

Passerine birds have a unique ability for song. This involves complex controls from the brain. There has been rapid molecular evolution of the song-related genes in passerine birds (Warren et al., 2010).

22.6.2 Salt Glands

Salt glands allow some birds to prosper in marine environments by secreting a hypertonic solution, predominantly sodium chloride (discussed in detail in Chapter on osmoregulation). The salt glands respond to hormones. Angiotensin

TABLE 22.1 Neuropeptides and Peptide–Protein Hormone in Birds

Pre-proneuropeptide or Neuropeptide	Official Gene Symbol	Present in Chicken Genome?[1]	Present in Zebra Finch Genome?[2]	Other, Avian-Specific Notes
Adenylate cyclase activating polypeptide 1 (pituitary)	Adcyap1	√	√	Expressed (e.g., in the brain and gastrointestinal (GI) tract)
Adrenomedullin	AMD	√	√	Expressed in lungs, adrenal glands, skeletal muscle, and GI tract (Zudaire et al., 2005) Expression increased in lungs of hypotensive chicken (Gomez et al., 2007)
Arginine vasopressin	AVP	√	√	Neuropeptide in birds arginine vasotocin (AVT)
C-RF amide peptide	LOC420716/ CRF	√	√	
C-type natriuretic peptide 1	CNP 1	√	√	Expressed in the chicken—discussed in narrative
C-type natriuretic peptide 3	CNP 2	√	√	
Calcitonin-related Polypeptide alpha [also called calcitonin gene-related peptide (CGRP)] Gene encodes calcitonin also	CALCA	√	√	
Cocaine- and amphetamine-regulated transcript protein	CART	X	√	CNS effect in chickens (Tachibana et al., 2003)
Corticotropin-releasing hormone (also referred to as corticoliberin or corticotropin-releasing factor (CRF))	CRH	√	√	Expressed in hypothalamus
Cholecystokinin	CCK	√	√	
Chromogranin A (parathyroid secretory protein 1)	CHGA	√	√	
Chromogranin B	CHGB	√	√	
Chromosome 12 open reading frame 39 (spexin)	C12orf39	√	√	
Chromosome 2 open reading frame 40	C2orf40	√	√	
Endothelin 1	EDN1	√	√	Expression increased in lungs of hypotensive chicken (Gomez et al., 2007)
Endothelin 2	EDN2	√	√	
Endothelin 3	EDN3	√	√	
Follicle stimulating hormone beta subunit	FSHB	√	√	Expressed in adenohypophyseal cells
Galanin pre-propeptide	GAL	√	√	Expressed in CNS and GI tract

TABLE 22.1 Neuropeptides and Peptide–Protein Hormone in Birds—cont'd

Pre-proneuropeptide or Neuropeptide	Official Gene Symbol	Present in Chicken Genome?[1]	Present in Zebra Finch Genome?[2]	Other, Avian-Specific Notes
Gastric-inhibitory polypeptide (GIP)	GIP	√	√	Expressed in CNS and GI tract
Gastrin-releasing peptide (GRP)	GRP	√	√	Expressed in GI tract and hypothalamus
Ghrelin or obestatin pre-propeptide	GHRL	√	√	Expressed in GI tract and hypothalamus
Glucagon pro-hormone also containing glucagon-like peptide 1 (GLP1) and GLP2	GCG	√	√	Expressed in pancreas, GI tract, and hypothalamus
Glycoprotein hormone, α polypeptide	CGA	√	√	Expressed in adenohypophyseal cells
Gonadotropin-releasing hormone (GnRHI) (formerly luteinizing hormone–releasing hormone I (LHRHI))	GnRH	√	√	Expressed in hypothalamus and second gene encoding GnRHII in birds
Growth hormone	GH	√	√	Expressed in adenohypophyseal cells and CNS Duplicate GH gene on chromosome 1 on passerine birds Expression of duplicate gene not well established
Growth hormone–releasing hormone (GHRH), also called somatoliberin	GHRH	√	√	Expressed in hypothalamus
Hypocretin (orexin) neuropeptide precursor	HCRT	√	√	Expressed in CNS
Insulin	INS	√	√	Expressed in pancreas
Insulin-like 5	INSL5	X	√	
Insulin like growth factor 1	IGF1	√	√	Expressed in liver and cartilage
Insulin like growth factor 2	IGF2	√	√	
Islet amyloid polypeptide	IAPP	√	√	Functionally similar to calcitonin-related polypeptide alpha; expressed in CNS, GI tract, and pancreas (Fan et al., 1994)
Kisspeptin	KISS1	X	X	Effects of kisspeptide 10 are reported in the chicken ovary (Xiao et al., 2011).
Leptin or leptin-like	OB	√?	√	See narrative in text for details
Luteinizing hormone beta subunit	LHB	√	√	Expressed in adenohypophyseal cells

TABLE 22.1 Neuropeptides and Peptide–Protein Hormone in Birds—cont'd

Pre-proneuropeptide or Neuropeptide	Official Gene Symbol	Present in Chicken Genome?[1]	Present in Zebra Finch Genome?[2]	Other, Avian-Specific Notes
Mesotocin–neurophysin 1	MST	√	√	Equivalent to oxytocin in mammals Expressed in CNS
Motilin	MLN	√	√	Expressed in CNS and GI tract
Natriuretic peptide precursor A	NPPA	√	√	
Neuromedin B	NMB	√	√	
Neuromedin U	NMU	√	√	
Neuropeptide S	NPS	√	√	
Neuropeptide VF (gonadotropin-inhibitory hormone (GnIH))	NPVF	√	√	
Neuropeptide W	NPW	X	√	
Neuropeptide Y	NPY	√	√	
Neurotensin	NTS	√	√	Expressed in CNS and GI tract
Osteocrin	OSTN	√	√	
Pancreatic polypeptide	PPY (or PP)	√	√	Expressed in pancreas and GI tract
Parathyroid hormone	PTH	√	√	Expressed in parathyroid gland
Parathyroid hormone–like hormone (also called PTH-related peptide (PTHrP))	PTHLH	√	√	Expressed in early embryonic development skeletal tissues For expression, also see Chapter on the pituitary gland
Pituitary adenylate cyclase–activating polypeptide 1	See "adenylate cyclase–activating polypeptide"			
Platelet-derived growth factor D	PDGFD			
Platelet-derived growth factor alpha polypeptide	PDGFA			
Platelet-derived growth factor beta polypeptide	PDGFB			
Pre-pronociceptin	PNOC			
Pro-melanin-concentrating hormone (MCH)	PMCH			
Prodynorphin	PDYN			
Proenkephalin	PENK			CNS
Prokineticin 2	PROK			
Prolactin	PRL	√	√	Adenohypophyseal cells
Prolactin B (also called prolactin-like protein (PLP))	PRLB	√	√	Reported in birds and fish but not mammals

II directly decreases fluid flow from the duck salt gland (Butler, 2007). This effect is independent both of the adrenal gland and of catecholamines as angiotensin II is effective in adrenalectomized and chemically sympathectomized birds (Butler, 2007). Natriuretic peptides influence the functioning of the salt glands (Schütz and Gerstberger, 1990).

22.6.3 Unique Aspects of Metabolism

There are marked differences in circulating concentrations of glucose between wild birds and mammals, with avian concentrations double those in mammals and with physically smaller species of birds or mammals having higher circulating concentrations of glucose than larger ones (Braun and Sweazea, 2008) (discussed in detail in Chapters on carbohydrate metabolism and the pancreas). Moreover, birds do exhibit diabetes, with circulating concentrations of glucose held at a consistent level, except under one paradigm. Chickens that received passive immunization with antisera to insulin exhibit diabetic-like shifts in metabolism, with circulating concentrations of glucose of 747 mg/dL reported 5 h after antisera administration (Dupont et al., 2008; Simon et al., 2012). Interestingly, identical extremely high concentrations of glucose are observed following feeding in hummingbirds without adverse effects (Beuchat and Chong, 1998).

Birds also have high metabolic demands for both short-term flight and extended migratory flight (discussed in detail in Chapter on migration).

22.6.4 Reproduction

Birds exhibit marked differences from mammals in terms of reproduction (discussed elsewhere in this volume in Chapters on male and female reproduction). These differences include the internal testes, the production of large yolky eggs, the absence of pregnancy, the existence of only one ovary and oviduct (the Müllerian duct), and unique sexual, brooding, and parental behavior (discussed in Chapter on brooding).

TABLE 22.2 Neuropeptides Presently Not Demonstrated to Exist in Birds (Based on Delfino et al., 2010)

Apelin (APEL)	Proenkephalin-B (PDYN)
Cortistatin (CORT)[1]	Peptide YY (PYY)
Galanin-like peptide (GALP)	Putative peptide YY-2 (PYY2)
Hepcidin (HEPC)	Pro-relaxin 1 (REL1)
Insulin-like 3 (INSL3)	Pro-relaxin 2 (REL2)
Insulin-like 4 (INSL4)	Regulated endocrine-specific protein 18 (RES18)
Intermedin (ADM2)	Spexin (SPXN)
Metastasis-suppressor KiSS-1 (KISS1)[2]	Tachykinin, precursor 2 (TKN2)
Natriuretic factor B (ANFB)	Tachykinin, precursor 3 (TKN3)
Neuromedin-S (NMS)	Tachykinin, precursor 4 (TKN4)
Neuropeptide B (NPB)	Torsin family 2, member A (TOR2X)
Neuropeptide FF (NPFF)	
Neuropeptide S (NPS)	
Proprotein convertase subtilisin/kexin type 1 inhibitor (PCSK1N)	

[1]Expression of cortistatin gene reported in chicken autonomic neurons (Nishi et al., 2010).
[2]Effects of kisspeptide 10 are reported on the chicken ovary (Xiao et al., 2011).

22.6.5 Opportunities for Transgenic Poultry

Transgenic chickens have been produced that express human erythropoietin (hEPO) (Koo et al., 2010). Expression of hEPO is controlled by a tetracycline-inducible promoter (Koo et al., 2010), hence eliminating the potential of pathological effects of hEPO in the chickens had there been uncontrolled constitutive expression. Immunoreactive erythropoietin has been reported in birds (Wickramasinghe et al., 1994).

22.7 THE ENIGMA OF LEPTIN

An example of a hormone produced by adipose tissue in mammals is leptin. There is contradictory evidence for and against the existence of a chicken leptin (Taouis et al., 1998; Sharp et al., 2008; Simon et al., 2009). A leptin-like gene has been identified in the zebra finch (*T. guttata*) (leptin-like Gene ID: 101233729).

There is complete agreement in the literature that mammalian leptin exerts multiple effects in birds. The short form of the chicken leptin receptor has been characterized from the cDNA (Liu et al., 2007). The leptin receptor is present in multiple tissues, including the brain and liver in the chicken, based on expression (Liu et al., 2007) and the observed immunoreactive 180 kDa protein in multiple tissues (Ohkubo et al., 2007). The leptin receptor is expressed in the anterior pituitary gland and basal hypothalamus of the chicken (Liu and Sharp, 2007). The leptin receptor has been characterized also in the turkey (Richards and Poch, 2003) and goose (Wang et al., 2011). The leptin receptor is expressed in the brain, lung, and spleen, with some expression also in the adipose tissue, duodenum, liver, pancreas, and skeletal muscle (Richards and Poch, 2003; Wang et al., 2011). Adipose expression of the leptin receptor is increased by oleic acid *in vitro* (Wang et al., 2011). *In ovo* administration of mammalian leptin into the albumin of chick embryos was reported to result in increased posthatching growth and circulating concentrations of triiodothyrone (T_3), with greater hepatic expression of growth hormone receptor and IGF1 mRNA (Li et al., 2011). *In vitro* mammalian leptin elevates expression and activities of deiodinase in chick embryo hepatocytes (Li et al., 2011). Administration of mammalian leptin decreases food intake and fat mass in wintering white-throated sparrows (Cerasale et al., 2011). The gene for the leptin receptor has been identified in the zebra finch (*T. guttata*) (leptin receptor (LEPR) Gene ID: 100229897).

Chapter 23

Pituitary Gland

Colin G. Scanes
Department of Biological Sciences, University of Wisconsin, Milwaukee, WI, USA

23.1 INTRODUCTION

The pituitary gland (hypophysis) is intimately connected to the hypothalamus in both an anatomical and functional close relationship. The structure of the hypothalamic–hypophyseal complex is shown in Figure 23.1. The pituitary gland consists of two distinct structures:

- The anterior pituitary gland, which sits in a depression in the bone—the sella turcica
- The posterior pituitary gland, which is connected to the base of the brain by the infundibulum

The pituitary gland has a complex structure and an interesting embryonic development. Primary tissue can be classified as either adenohypophysis or neurohypophysis, each with a distinct embryonic origin. The adenohypophysis is derived from Rathke's pouch (probably ectoderm from the roof of the mouth), and the neurohypophysis is derived from the infundibulum (an outgrowth of the brain). The adenohypophysis, in mammals, goes on to form the pars distalis (anterior pituitary gland), the pars intermedia, and the pars tuberalis. However, there is not a pars intermedia in birds. The avian embryonic adenohypophysis goes on to form the pars distalis (or anterior pituitary gland) and the pars tuberalis. The neurohypophysis forms the pars nervosa (or posterior pituitary gland), the infundibular stalk, and the median eminence.

23.2 ANATOMY OF THE HYPOTHALAMIC–HYPOPHYSEAL COMPLEX

23.2.1 The Anterior Pituitary Gland or Pars Distalis

23.2.1.1 Introduction

The avian pars distalis consists of two distinct lobes: the cephalic and caudal lobes. The cephalic lobe develops from the upper and medial parts of the anterior wall of Rathke's pouch together with part of the posterior wall (Sasaki et al., 2003). The caudal lobe is derived from parts of the posterior Rathke's pouch together with the lower portion of the anterior wall of Rathke's pouch (Sasaki et al., 2003). The anterior pituitary gland is composed of secretory cells and folliculo-stellate cells together with extracellular colloid and fibrous materials (Mohanty et al., 2006).

23.2.1.2 Secretory Cells

The avian anterior pituitary gland has the full complement of secretory cells, including corticotrophs producing adrenocorticotropic hormone (ACTH), gonadotrophs producing either luteinizing hormone (LH) or follicle-stimulating hormone (FSH), lactotrophs producing prolactin, somatotrophs producing growth hormone (GH), and thyrotrophs producing thyrotropin (TSH) (Table 23.1). In addition, there are somatotolactotrophs producing both GH and prolactin (turkey: Ramesh *et al.*, 1998, 2001) and cells that co-express both the large protein, pro-opiomelanocortin (POMC), and the α subunit of LH, FSH, and TSH (chickens: Pals et al., 2006).

The pars distalis is well supplied with blood vessels, including the hypophyseal portal vessels. These latter provide a route from the neurosecretory nerve terminals in the median eminence to the anterior pituitary gland. Indeed, it is by way of the portal blood vessels that the anterior pituitary gland is controlled by *releasing hormones* (or hypothalamo-hypophysiotropic hormones) from the median eminence (Figure 23.1; also see Table 23.2).

23.2.1.3 Folliculo-Stellate Cells

The anterior pituitary gland also contains folliculo-stellate cells. These are of neuroectodermal origin, like the posterior pituitary gland. The presence of these agranular cells containing immunoreactive S-100 protein has been demonstrated in birds (Harrisson et al., 1982; Van Nassauw et al., 1987; Harrisson, 1989). Possible roles for the folliculo-stellate cells may include autocrine–paracrine

Sturkie's Avian Physiology.

regulation of hormone secretion from adjacent endocrine cells and an involvement in immune endocrine interactions. In birds, there is evidence of folliculo-stellate cells influencing thyrotrophs (Harrisson et al., 1982), with these cells expressing TSH receptor (Grommen et al., 2009), and also of their involvement in the pituitary response to an *Escherichia coli* challenge (Fernández et al., 1986). The putative influences of the folliculo-stellate cells may be mediated by gap junctions or their release of neuromodulators. The avian folliculo-stellate cells have received relatively little attention.

Follicular stellate cells are presumed to exert paracrine influences on secretory cells in the anterior pituitary gland. This may influence thyrotroph functioning in a short-loop feedback manner.

23.2.2 Pars Tuberalis

The pars tuberalis consists of adenohypophyseal cells located along the ventral surface of the median eminence. It is derived from Rathke's pouch, specifically the upper anterior portion (Sasaki et al., 2003). The pars tuberalis develops along the median eminence between days 8 and 14 of incubation in the chick embryo (Kameda et al., 2000). The pars tuberalis consists of the following cell types: (1) pars tuberalis secretory-specific cells; (2) pars distalis cell types present in the pars tuberalis, including gonadotrophs, thyrotrophs, corticotrophs, somatotrophs, and lactotrophs (Mohanty et al., 1997); (3) follicular cells (reviewed Yasuo and Korf, 2011); and (4) multiple macrophages (Sano and Murabe, 1980).

The pars tuberalis can communicate in a retrograde manner with the median eminence and in an anterograde with the pars distalis. There is high expression of the α subunit of LH, FSH, and TSH in the pars tuberalis as it develops (Kameda et al., 2000). Moreover, most cells in the pars tuberalis of the chicken co-localize LH and chromogranin A immunoreactivity (Kameda et al., 1998). There are progesterone receptors in the nuclei of cells in the pars tuberalis (Gasc and Baulieu, 1988).

23.2.3 Posterior Pituitary Gland or Pars Nervosa

The posterior pituitary gland consists of neurosecretory terminals that release either arginine vasotocin (AVT) or mesotocin (MT) (Table 23.1). These hormones are synthesized in cell bodies in nuclei in the hypothalamus and are transported to the pars nervosa through modified axons (Figure 23.1).

TABLE 23.1 Summary of the Chemistry of the Hormones of the Pituitary Gland

Pituitary Hormones	Alternate Names (IUPAC/IUB)	Chemistry
Anterior pituitary hormone		
Adrenocorticotropic hormone (ACTH)	Corticotropin	Synthesized as protein (pro-opiomelanocortin (POMC)), then proteolytically cleaved to polypeptide (ACTH)
Follicle-stimulating hormone (FSH)	Follitropin	Two glycoprotein subunits: α-subunit common to FSH, LH, and TSH β-specific subunit
Luteinizing hormone (LH)	Lutropin	Two glycoprotein subunits: α-subunit common to FSH, LH, and TSH β-specific subunit
Growth hormone (GH)	Somatotropin	Protein
Prolactin (PRL)	Lactotropin	Protein
Thyroid-stimulating hormone (TSH)	Thyrotropin	Two glycoprotein subunits: α-subunit common to FSH, LH, and TSH β specific subunit
Posterior pituitary hormone		
Arginine vasotocin (AVT)		Synthesized as protein, then proteolytically cleaved to peptide with 9 amino acid residues
Mesotocin (MT)		Synthesized as protein, then proteolytically cleaved to peptide with 9 amino acid residues

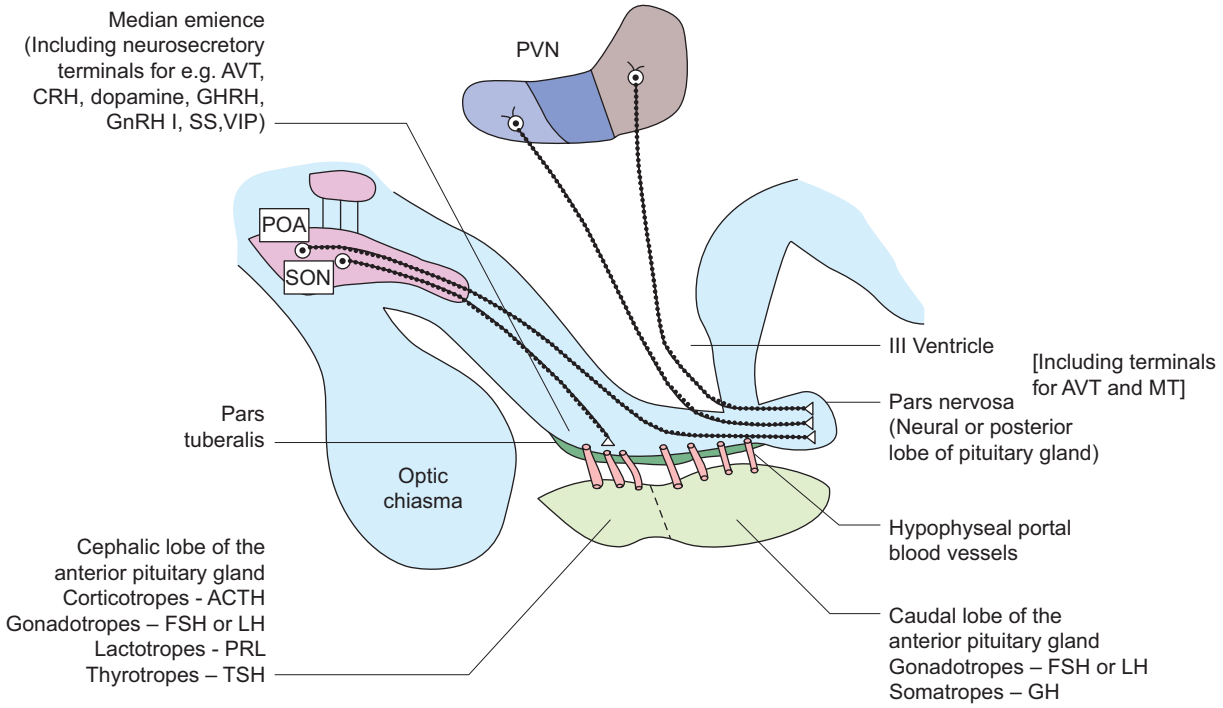

FIGURE 23.1 Schematic diagram showing structure of the avian hypothalamus and pituitary gland. Dark green: pars tuberalis; light blue: nervous tissue in the hypothalamus; light green: pars distalis or anterior pituitary gland (adenohypophyseal tissue); red: blood vessels of hypophyseal portal vessels bringing releasing hormones from the neurosecretory terminals in the median eminence to stimulate or inhibit hormone secretion from the cells of the anterior pituitary gland (neurosecretory cells have cell bodies in the nuclei in the hypothalamus and terminate either in the median eminence or the posterior pituitary gland); AVT, arginine vasotocin; MT, mesotocin, POA, pre-optic area, PVN, paraventricular nucleus; SON, supraoptic nucleus.

TABLE 23.2 Summary of Stimulatory and Inhibitory Releasing Hormones (Releasing Factors) in Birds, Including Neuropeptides Present in the Hypothalamus

Anterior Pituitary Hormones	Stimulatory Releasing Hormones	Inhibitory Releasing Hormones
Adrenocorticotropic hormone (ACTH)	Corticotropin-releasing hormone (CRH) Arginine vasotocin (AVT)	–
Follicle-stimulating hormone (FSH)	Gonadotropin-releasing hormone I? and II? (GnRH I and II)	Gonadotropin-inhibitory hormone (GnIH)
Luteinizing hormone (LH)	Gonadotropin-releasing hormone I and II (GnRH I and II)	Gonadotropin-releasing inhibitory hormone (GnIH)
Growth hormone (GH)	GH-releasing hormone (GHRH) Thyrotropin-releasing hormone (TRH) Ghrelin Pituitary adenylate cyclase–activating peptide (PACAP) Leptin? GnRH I?	Somatotostatin (SS or SRIF)
Prolactin (PRL)	Vasoactive intestinal peptide (VIP) Prolactin-releasing peptide (PrRP) AVT? TRH? Peptide histidine isoleucine (PHI)?	Dopamine?
Thyroid-stimulating hormone (TSH)	Thyrotropin-releasing hormone (TRH) CRH	SS?

23.3 GONADOTROPINS

23.3.1 Structure

Avian LH and FSH are glycoproteins with molecular weights of 30 kDa (Burke et al., 1979a). Both LH and FSH consist of two glycoprotein subunits: an α-subunit that is common to LH, FSH, and TSH and a hormone-specific β-subunit (Table 23.1). Both subunits are required for biological activity (Burke et al., 1979b). The amino acid residue sequences have been deduced from the nucleotide sequences of the cDNA for α-subunit and both LH and FSH β-subunits (α-subunit: chicken: Foster et al., 1991; domestic and Muscovy duck: Hsieh et al., 2001; LH β-subunit: chicken: Noce et al., 1989; Japanese quail: Ando and Ishii, 1994; turkey: You et al., 1995; FSH β-subunit: Japanese quail: Kikuchi et al., 1998; chicken: Shen and Yu, 2002; Japanese crested ibis: Kawasaki et al., 2003).

23.3.2 Action of Gonadotropins

For more detailed discussion of the control of female and male reproduction, see Chapter 25

23.3.2.1 Actions of LH in the Female

23.3.2.1.1 Ovulation

A major role for LH is to induce ovulation. Premature ovulation is provoked following injection of LH (Imai, 1973). Administration of LH is followed by a series of events in the most mature follicle: breakdown of the germinal vesicle, dissociation of the junctions between the granulosa projections and the oocyte surface, development of a perivitelline space, and the formation of the first and then second maturation spindle (Yoshimura et al., 1993). During follicular development, there is remodeling involving proteases such as plasminogen activator. LH decreases both secreted and cell-associated plasminogen activator in granulosa cells from the largest follicle (F1) (Tilly and Johnson, 1987, 1988a,b).

23.3.2.1.2 Steroidogenesis

In vivo, mammalian LH increases progesterone and testosterone production by the hen ovary (Shahabi et al., 1975). LH stimulates the production of progesterone and androstenedione *in vitro* by granulosa cells from the largest follicle (F1) (Tilly and Johnson, 1987, 1988a,b). LH also stimulates production of androstenedione by theca cells from the next largest yellow follicle (F2) (Tilly and Johnson, 1989) and of progesterone, dehydroepiandrosterone (DHEA), androsterone, and estradiol from theca cells from small follicles (6–8 mm) (Kowalski et al., 1991; Tilly et al., 1991a).

23.3.2.1.3 Ovarian Production of Peptide and Protein Growth Factors and Hormones

LH influences the production of growth factors and hormones within the ovary. For instance, LH reduced the expression of inhibin α-subunit in chicken granulosa cells from either F1 or F3 and F4 follicles (Davis et al., 1999). Expression of connective tissue growth factor (CTGF) is respectively decreased and increased by LH in granulosa cells from pre- and postovulatory follicles (Zhu et al., 2012).

23.3.2.1.4 Follicular Development

In embryonic development, LH increases the number of follicles together with the ratio of oocytes to oogonia while decreasing the mitosis of oogonia (González-Morán et al., 2007). Using chick embryo ovaries in culture, LH stimulates the entry of germ cells into meiosis as indicated by the increased expression of the premeiotic marker *Stra8* and meiotic marker *Scp3* (He et al., 2013).

23.3.2.2 Actions of FSH in the Female

23.3.2.2.1 Steroidogenesis

FSH influences the steroidogenesis of less mature large yolky follicles and small yellow follicles but not the large preovulatory (F1) follicles. FSH stimulates progesterone secretion by the granulosa of intermediate-stage follicles (e.g., F5, or the fifth-largest follicle) (Calvo and Bahr, 1983). In addition, FSH acutely increases progesterone, androstenedione, and estradiol production by theca cells from small follicles (6–8 and 9–12 mm) (Kowalski et al., 1991). In addition, FSH stimulates maturation of the granulosa cells of small follicles such that they attain the ability to respond to LH, FSH, or cyclic adenosine monophosphate (cAMP) with increased progesterone production (Tilly et al., 1991b). This is due, at least in part, to the induction of the P450 side-chain cleavage enzyme mRNA (Li and Johnson, 1993).

23.3.2.2.2 Proliferation and Remodeling

FSH increases proliferation of both ovarian cells in hypophysectomized chicken embryos (Sánchez-Bringas et al., 2006) and epithelial cells on the surface of the ovary in intact embryos (Méndez et al., 2003). Moreover, FSH stimulates proliferation by granulosa cells from the F1 and smaller yellow F5–F6 follicles of the chicken (McElroy et al., 2004). In embryonic development, FSH suppresses the entry of germ cells into meiosis, as indicated by the decreased expression of the premeiotic marker *Stra8* and meiotic marker *Scp3* (He et al., 2013).

FSH increases expression of occludin, an important protein in tight junctions, in granulosa cells (chicken: Schuster et al., 2004). Thus FSH facilitates the rapid development of oocytes and yolk deposition. In addition, FSH

in the presence of activin induces granulosa cell–specific differentiation markers, including zona pellucida protein C (chicken: Schierer et al., 2003).

23.3.2.2.3 Peptide and Protein Growth Factors and Hormones

FSH influences the production of growth factors and hormones within the ovary. For instance, FSH increases expression of inhibin α-subunit, together with inhibin protein levels, in granulosa cells from F1, F4–F5 follicles, small yellow follicles, and large white follicles (chicken: Davis et al., 1999, 2001). FSH depresses expression of connective tissue growth factor (CTGF) in granulosa cells from preovulatory follicles but elevates that from postovulatory follicles in the chicken (Zhu et al., 2012).

23.3.2.2.3.1 Mechanism The signal transduction mechanism for FSH involves activation of adenylate cyclase and increased production of cAMP (Calvo and Bahr, 1983; Kowalski et al., 1991).

23.3.2.3 Actions of LH in the Male

As in mammals, LH acts primarily to stimulate the Leydig cells to differentiate and produce testosterone. The administration of chicken LH to hypophysectomized Japanese quail greatly increases the number of mature Leydig cells and decreases the number of fibroblasts and transitional cell types in the interstitium (Brown et al., 1975). In Japanese quail, LH elevates plasma concentrations of testosterone (Maung and Follett, 1978) and increases testosterone synthesis *in vitro* (Maung and Follett, 1977).

23.3.2.4 Actions of FSH in the Male

The major role for FSH is stimulation of spermatogenesis. When FSH is injected into hypophysectomized quail, there are increases in testicular size (8.8-fold) and seminiferous tubule diameter (2.1-fold) with Sertoli differentiation promoted and spermatogenesis (Brown et al., 1975). FSH increases the proliferation of seminiferous tubule cells in the chick embryo (Méndez et al., 2003). FSH increases both the proliferation of chicken Sertoli cells and their secretion of inhibin *in vitro* (Guibert et al., 2011). FSH has little if any effect on testosterone production by bird testes (Maung and Follett, 1978). FSH upregulates its receptors (Tsuisui and Ishii, 1980).

23.3.2.5 Other Effects of FSH

An unexpected effect of FSH is on lipid metabolism. FSH increases adipose weight *in vivo* and influences lipid metabolism, as indicated by shifts in expression of enzymes *in vitro* (chicken: Cui et al., 2012). Evidence that the effect of FSH is specific comes from the observation that the FSH receptor (FSHR) is expressed in avian adipose tissue (chicken: Cui et al., 2012).

23.3.2.6 Chicken LH Receptor (LHR) and Signal Transduction

The chicken LHR has been characterized (Johnson et al., 1996). Expression of LHR is influenced by both peripheral and intraovarian hormones together with growth factors. Expression of LHR in granulosa cells from F1 follicles is increased by testosterone, LH, activin, and BMP6 (Johnson et al., 2006; Al-Musawi et al., 2007; Rangel et al., 2009). These effects may play a critical role in the preovulatory increase in both LH and progesterone. Activin also increases expression of LHR in granulosa cells from large (F1 and F3/F4) and small yellow follicles (Johnson et al., 2006). A soy isoflavone increases expression of LHR in chicken F1 follicles (Liu and Zhang, 2008).

The signal transduction mechanism by which LH exerts its effect on theca cells is via adenylate cyclase and cAMP (Tilly and Johnson, 1989). While in granulosa cells, LH acts by adenylate cyclase and cAMP (Johnson and Tilly, 1988) and subsequently calcium mobilization (Asem et al., 1987; Tilly and Johnson, 1988a,b).

23.3.2.7 FSHR and Signal Transduction

The cDNA for chicken FSHR has been characterized (Wakabayashi et al., 1997). Expression of the FSHR is influenced by FSH, intraovarian growth factors, and genomic variation. FSH upregulates FSHR expression by undifferentiated granulosa cells (Woods and Johnson, 2005). Activin increases expression of FSHR in granulosa cells from large (F1 and F3/F4) and small yellow follicles (Johnson et al., 2006). Bone morphogenetic protein-2 (BMP2) decreases FSHR expression by undifferentiated granulosa cells (Haugen and Johnson, 2010). Expression of FSHR in granulosa cells from large yellow follicles (F1, F2, and F3/F4) is increased by BMP6; theca cells produce BMPs, including BMP6 (Al-Musawi et al., 2007). There are polymorphisms of the FSHR gene that influence expression of FSHR (Li et al., 2011).

FSH activates the cAMP–protein kinase A, phosphatidylinositol 3-kinase–Akt (protein kinase B), and mitogen-activated protein kinase pathways in chicken Sertoli cells (Guibert et al., 2011). FSH effects on adipose tissue are mediated by peroxisome proliferator-activated receptor (PPAR) signaling (chicken: Cui et al., 2012).

23.3.3 Control of Gonadotropin Release

23.3.3.1 Introduction

Release of both LH and FSH is under predominantly stimulatory control by the hypothalamus based on de-afferentation and lesioning studies (Davies and Follett, 1980). LH is

under stimulatory control by gonadotropin-releasing hormone-1 and -2 (GnRH1 and GnRH2) (Table 23.2). It is unclear whether the release of FSH is influenced by GnRH1 or GnRH2. There is also inhibitory control for both LH and FSH by gonadotropin-inhibitory hormone (GnIH).

23.3.3.2 Gonadotropin Hormone–Releasing Hormone

23.3.3.2.1 Chemistry

There are two GnRH peptides in the avian hypothalamus, each with separate genes, respectively, for GnRH1 and -2 (Dunn et al., 1993; Ikemoto and Park, 2006):

Chicken GnRH1 (cGnRH1)
pGlu–His–Trp–Ser–Tyr–Gly–Leu–Gln–Pro–Gly–NH_2 (King and Millar, 1982)

Chicken GnRH2 (cGnRH2)
pGlu–His–Trp–Ser–His–Gly–Trp–Tyr–Pro–Gly–NH_2 (Miyamoto et al., 1984)

An identical situation exists in other birds (ostrich: Powell et al., 1987). The cDNA for starling GnRH1 has been characterized (Ubaka et al., 2009). There is a 58% homology between the precursor for GnRH1 in starlings and chickens (Ubaka et al., 2009).

Chicken GnRH2 is considerably more potent than cGnRH1 in stimulating LH release *in vitro* (chicken: Chou et al., 1985; Millar et al., 1986) and *in vivo* (chicken: Wilson et al., 1989; Proudman et al., 2006). Administration of GnRH1 or -2 either evokes less release of FSH compared to that of LH in birds (Hattori et al., 1986) or is ineffective (Scanes et al., 1977; Krishnan et al., 1993; Proudman et al., 2006). The identity of the avian releasing hormone for FSH remains unclear. The actions of cGnRH1 and -2 are mediated by cAMP and inositol phosphate (Bonney and Cunningham, 1977; Joseph et al., 2009).

23.3.3.2.2 Control of cGnRH Release

Neurosecretory terminals release cGnRH1 or -2 in response to stimuli. Neurotransmitters and neuropeptide can either stimulate or inhibit release. Examples of stimulatory control include norepinephrine via α_1-adrenergic receptors (Knight et al., 1982; Millam et al., 1984) and neuropeptide Y (Fraley and Kuenzel, 1992; Contijoch et al., 1993a). Examples of inhibitory controls include dopamine (Knight et al., 1982; Contijoch et al., 1992), β endorphin (Contijoch et al., 1993b), and GnIH (discussed in Section 23.3.3.2.3).

23.3.3.2.3 Changes in Hypothalamic GnRH Content

The variation in hypothalamic GnRH1 immunoreactivity and/or expression is consistent with GnRH1 having a role in the control of reproduction in birds. There are changes with physiological state in the hypothalamic contents of cGnRH1 in turkeys (Rozenboim et al., 1993). The GnRH1 levels are higher in laying hens compared to nonphotostimulated birds (with photostimulated birds intermediate) (Rozenboim et al., 1993). Photostimulation of turkeys results in activation (c-fos expression) of GnRH1 in the nucleus commissura pallii and dopamine neurons in the nucleus premammillaris (Thayananuphat et al., 2007). There is decreased hypothalamic expression of GnRH1 in female chickens when incubating eggs (Dunn et al., 1996) and when young male chickens receive estradiol administration (Dunn and Sharp, 1999). GnRH1 expression and the GnRH1 peptide are co-localized in neurosecretory neurons in the pre-optic region of the hypothalamus in photostimulated starlings but are not detectible in photorefractory starlings (Ubaka et al., 2009). In contrast, photostimulation of chickens on short day lengths increased secretion of LH but did not influence expression of GnRH1 (Dunn and Sharp, 1999).

Changes in GnRH2 immunoreactivity and/or expression in the hypothalamus support it in having a major role in the control of avian reproduction. The levels of GnRH2 are increased by photostimulation; they are higher in laying hens, but reduced in incubating and photorefractory turkeys (Rozenboim et al., 1993). There are more and larger GnRH2 neurons in breeding than nonbreeding zebra finches (Perfito et al., 2011). During embryonic development of the chicken, there are changes in the brain concentrations of cGnRH1 and cGnRH2, but these are not in a parallel manner (Millam et al., 1993).

GnRH immunoreactivity is found not only in hypothalamic neurons but also in mast cells in the dove medial habenular regions. The number and distribution of these mast cells depend on reproductive behavior changing immediately after courtship behavior (Silver et al., 1992; Zhung et al., 1993).

23.3.3.2.4 GnRH Receptors

There are two GnRH receptor subtypes present in birds: GnRH-R1 and GnRH-R3. Chicken GnRH2 has a higher affinity than GnRH1 for both receptor types and is more potent in stimulating inositol phosphate production (Joseph et al., 2009). There is much higher expression of cGnRH-R3 than cGnRH-R1 in the chicken pituitary gland (Joseph et al., 2009), with higher expression in sexually mature birds (McFarlane et al., 2011). Some, albeit very low, expression of cGnRH-R3 is reported in the median eminence and small intestine (Joseph et al., 2009). There is expression of cGnRH-R1 in the pituitary gland, with some expression in the median eminence, small intestine, and testes (Joseph et al., 2009).

23.3.3.3 Gonadotropin Inhibitory Hormone

23.3.3.3.1 Chemistry

A novel neuropeptide was isolated from quail brain. This 12 amino acid residue-containing peptide inhibits LH release

in quail and hence was named gonadotropin-inhibitory hormone (Tsutsui et al., 2000). The structure of GnIH and its precursor has been reported in birds (quail: Tsutsui et al., 2000; Satake et al., 2001; chicken: Ikemoto and Park, 2005; white-crowned sparrow: Osugi et al., 2004). Chicken LPLRF–NH_2 was the first RF-amide peptide found in any vertebrate (Dockray et al., 1983) and is identical to the C terminal 5-amino-acid residues of GnIH (discussed further in this chapter). The gene (neuropeptide VF precursor (NPVF) gene) also encodes GnIH-related peptide-1 (GnIH-RP1) and GnIH-RP2, each possessing an LPXRF-amide (X=L or Q) motif.

These are the structures of GnIH from three avian species:

Quail: SIKPSAYLPLRF-NH_2
Chicken: SIRPSAYLPLRF-NH_2
Sparrow: SIKPFSNLPLRF-NH_2

23.3.3.3.2 Actions of GnIH

GnIH affects gonadotrophs producing either FSH or LH, with the GnIH receptor (GnIHR) co-localizing with both LH- and FSH-expressing cells (Maddineni et al., 2008). Release and synthesis of LH are depressed by GnIH. For instance, GnIH reduces circulating concentrations of LH following castration and GnRH1 stimulation in songbirds (white-crowned sparrow: Osugi et al., 2004). In addition, GnIH reduces pituitary expression of the common α- and LH β-subunits together with circulating concentrations of LH and testosterone in Japanese quail (Ubuka et al., 2006). GnIH decreases expression of α and FSH β *in vitro* (chicken: Ciccone et al., 2004; Maddineni et al., 2008).

23.3.3.3.3 Hypothalamic GnIH

Not only does GnIH act on the pituitary but also it inhibits gonadotropin release by influencing GnRH1 and GnRH2 neurons in the hypothalamus. GnRH1- and GnRH2-containing neurons in the hypothalamus have been reported to express GnIH receptors (Ubuka et al., 2008). There is also evidence suggesting the GnIH does not always have a critical role in the control of reproduction. For instance, administration of lipopolysaccharide mimicking acute infection decreases the number of hypothalamic neurons containing immunoreactive GnRH in zebra finches, but the number expressing GnIH is unchanged (Lopes et al., 2012). Similarly, no differences in GnRH1 and GnIH neurons were seen between breeding and nonbreeding zebra finches (Perfito et al., 2011).

Hypothalamic expression of GnIH is influenced by the reproductive state being greater in incubating than in laying chickens (Ciccone et al., 2004). Moreover, there is cross-talk between the pineal gland and the hypothalamus, with melatonin increasing GnIH release from hypothalamic explants (Chowdhury et al., 2010).

23.3.3.3.4 Receptor

The GnIHR has been characterized based on cDNA (chicken: Ikemoto and Park, 2005) and has been referred to as the RF-amide-related peptide (RFRP) receptor. Estrogen combined with progesterone decrease expression of GnIHR in the anterior pituitary gland (Maddineni et al., 2008).

23.3.3.4 Other Hormones and LH Release

Prolactin can act directly on the gonadotrophs that secrete LH, with prolactin depressing LH release from turkey anterior pituitary cells *in vitro* (turkey: You et al., 1995).

23.3.3.5 Negative and Positive Feedback

Sex steroids influence gonadotropin release and synthesis in birds, via direct effect on the anterior pituitary gland or shifts in the release of releasing hormones from the hypothalamus. This is predominantly an inhibitory control. Gonadectomy leads to large increases in the circulating concentrations of both LH and FSH (e.g., Japanese quail: Davies et al., 1980). The inhibitory effect of androgens on LH secretion is mediated via androgen and estrogen receptors (quail: Davies et al., 1980) or predominantly estrogen receptors (chickens: Fennell et al., 1990).

In females, estradiol exerts a *negative feedback* effect on LH secretion. Progesterone can either stimulate or inhibit LH release depending on the state of the bird, with the preovulatory LH surge in the hen induced by progesterone. In the ovariectomized domestic hen, plasma concentrations of LH are decreased by a single injection of either progesterone or estradiol (Wilson and Sharp, 1976a,b). Progesterone has a *positive feedback* effect on LH release in intact hens or in ovariectomized hens that have been primed with progesterone and estradiol (Wilson and Sharp, 1976a,b). Progesterone receptors are present in the chicken hypothalamus, with increases in immunoreactivity following estradiol administration (Gasc and Baulieu, 1988). Estrogens also induce the presence of progesterone receptors in gonadotrophs (LH-producing cells) (Gasc and Baulieu, 1988).

23.3.3.6 Cycles

23.3.3.6.1 Seasonal Breeding

Increasing day lengths increase LH and FSH secretion in temperate-zone birds (Japanese quail: Follett and Maung, 1978; Henare et al., 2011; starlings: Dawson et al., 1985). This facilitates reproduction occurring at the most advantageous season. As little as one long day stimulates LH and FSH release (Japanese quail: Follett et al., 1977). The role of the pars tuberalis in this is discussed in Section 23.9.1.

Temperature is an additional environmental cue for time reproduction, with low temperatures slowing the photoperiodic induction of reproduction (Wingfield et al., 2003).

Increasing temperature accelerates the timing of reproduction (great tits: Schaper et al., 2012). Availability of water increases the photoperiodic response in song sparrows (Wingfield et al., 2012). The importance of supplementary environmental cues becomes progressively more important at lower latitudes (Silverin et al., 2008).

23.3.3.6.2 Ovulation Cycle

The preovulatory surge in plasma LH concentrations occurs approximately 4–6 h before ovulation (chicken: Furr et al., 1973) (Figure 23.2(A)). Preovulatory surges in LH are also reported in turkeys, but not where ovulation is arrested (Liu et al., 2001). The preovulatory LH surge is provoked by progesterone in the presence of estrogen priming (Wilson and Sharp, 1976a,b). There are increases in the expression of GnRHR in the chicken anterior pituitary gland during the ovulatory cycle (Lovell et al., 2005) (Figure 23.2(B)). Moreover, in immature hens treated with progesterone in the presence of estradiol, there are marked decreases in the expression of GnIH. There is little change in the circulatory concentrations of FSH during the ovulatory cycle of the hen (Scanes et al., 1977; Krishnan et al., 1993; Lovell et al., 2005).

23.3.4 Control of Expression of Gonadotropin Subunits

23.3.4.1 Control of Expression of the LH–FSH–TSH α-Subunit

Expression of the common LH–FSH–TSH α-subunit changes with physiology. It is not clear whether these changes are isolated to specific cell types. Starvation reduces the expression of the common α-subunit in Japanese quail (Kobayashi et al., 2002). Increasing food intake in previously feed-restricted hens is followed by increased α-subunit expression (Ciccone et al., 2007). There appears to be a negative feedback effect on expression of the α-subunit, as this is increased following ovariectomy in chickens, and this effect is reversed by estradiol replacement therapy (Terada et al., 1997). *In vivo* GnIH reduces pituitary expression of the α-subunit in Japanese quail (Ubuka et al., 2006).

23.3.4.2 Control of Expression of the LH β-Subunit

Expression of the LH β-subunit is influenced by developmental stage and by hypothalamic and ovarian hormones. It is expressed as early as day 11 of embryonic development (Grzegorzewska et al., 2009). GnRH1 increases its expression *in vitro* (turkey: You et al., 1995). Its expression is reduced by starvation (Japanese quail: Kobayashi et al., 2002), presumably due to decreased stimulation by GnRH1 and/or 2. GnIH reduces its expression of the LH β-subunit in anterior pituitary glands (Japanese quail: Ubuka et al., 2006). Expression of the LH β-subunit is also decreased, in a feedback manner, by ovarian hormones such as estradiol (Terada et al., 1997). Prolactin decreases expression of the LH β-subunit by turkey pituitary cells *in vitro* (You et al., 1995). LH β expression in hen anterior pituitary cells is elevated by prostaglandin D_2 (PGD_2) or PGJ_2, downstream metabolites of prostaglandin-D synthase via a PPAR signaling pathway (Chen et al., 2010).

23.3.4.3 Control of Expression of the FSH β-Subunit

FSH β-subunit expression changes with developmental stage by feedback from the gonadal hormones, and it seems to be affected by the hypothalamus. Chicken embryos as early as day 11 express the FSH β-subunit in their anterior pituitary glands (Grzegorzewska et al., 2009). Inhibin exerts a negative

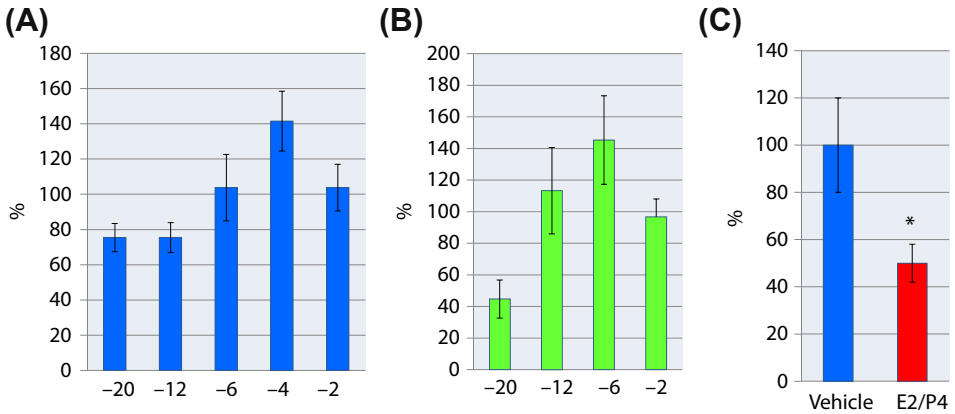

FIGURE 23.2 Changes in LH during the ovulatory cycle of the chicken. (A) Circulating concentrations of LH during the ovulatory cycle. (B) Pituitary GnRH receptor expression during the ovulatory cycle (*Data from Lovell et al. (2005)*). (C) Effect of *in vivo* treatment with estradiol (E_2) and progesterone (P_4) in immature hens on pituitary expression of GnIH receptors by chicken anterior pituitary tissue (Maddineni et al., 2008).

feedback effect on the expression of the FSH β-subunit in birds. Turkeys immunized against inhibin show increased pituitary FSH β-subunit expression and more small yellow follicles, presumably due to elevated FSH (Ahn et al., 2001).

There is stimulatory central nervous control of FSH β-subunit expression. The hypothalamic factors participating in birds have not been definitively identified. Evidence for the hypothalamic control comes from the following. Photostimulation is accompanied by increased FSH β-subunit expression (chickens: Li et al., 2009). Early puberty is induced by sulfamethazine with increased pituitary expression of the FSH β-subunit (chickens: Li et al., 2009). The expression of FSH β-subunits is reduced by starvation in Japanese quail (Kobayashi et al., 2002).

23.3.5 Pituitary Origin of Gonadotropins

Based on studies in the chicken, avian gonadotrophs seem to contain either LH or FSH (Proudman et al., 1999). The gonadotrophs containing LH are considerably more numerous than the gonadotrophs containing FSH (Proudman et al., 1999). Gonadotrophs containing either LH or FSH are found in both the cephalic and caudal lobes of the anterior pituitary gland, particularly in the periphery (Proudman et al., 1999; McFarlane et al., 2011). Most gonadotrophs producing LH also express the estrogen receptor α, while some also express the androgen receptor (Sun et al., 2012). FSH-producing gonadotrophs express betaglycan, the type 3 receptor for TGFβ and an accessory receptor for inhibin (chicken: Sweeney and Johnson, 2005).

23.3.6 Ontogeny of Gonadotropins

There is expression of the common α-subunit for LH, FSH, and TSH together with the presence of LH immunoreactivity in the basal–posterior region of Rathke's pouch on day 3.5 of development of the chick embryo prior to the formation of the pars distalis (Kameda et al., 2000). There is evidence of a role for corticosterone in the development of FSH-containing gonadotrophs. The glucocorticoid-induced leucine zipper (GILZ) is expressed in the chick embryo pituitary gland, with corticosterone increasing expression (Ellestad et al., 2009). Exogenous GILZ increases expression of the FSH β-subunit (Ellestad et al., 2009).

23.4 THYROTROPIN

23.4.1 Structure

Avian TSH is a heterodimer consisting of α- and β-subunits. Ostrich TSH has been purified and is a glycoprotein (Papkoff et al., 1982). The avian TSH β-subunit has been characterized based on the sequence of the cDNA (e.g., chicken: Gregory and Porter, 1997; Kato et al., 1998; Japanese quail: Catena et al., 2003; domestic and mule duck: Hsieh et al., 2007).

23.4.2 Actions of TSH

23.4.2.1 Role

TSH stimulates avian thyroid both to increase in size (Robinson et al., 1976) and to release thyroxine (T_4). Injection of TSH is followed by increases in the circulating concentrations of both T_3 and T_4 (chickens: MacKenzie, 1981; Williamson and Davison, 1985; doves and Japanese quail: McNichols and McNabb, 1988). It is likely that TSH does not directly increase T_3 release from the thyroid. This is supported by the extremely low level of T_3 in the avian thyroid gland (McNichols and McNabb, 1988) and the ready conversion of T_4 to T_3 (Decuypere et al., 1988; McNichols and McNabb, 1988). TSH stimulates T_4 release, which is rapidly converted peripherally to T_3.

23.4.2.2 Mechanism

TSH acts by binding to the TSH receptors (TSHRs), which are linked by G-proteins to adenylate cyclase. The TSHR has been characterized (chicken: Grommen et al., 2006). Activation of adenylate cyclase results in increased intracellular cAMP and activation of protein kinase A. TSH increases cAMP release from thyroid tissue *in vitro* (chicken: Tonoue and Kitch, 1978) and elevates the thyroid cAMP content *in vivo* (quail: McNichols and McNabb, 1988). TSH is expressed in the thyroid, as expected, along with the brain, anterior pituitary gland, retina, and pineal gland (chicken: Grommen et al., 2006). Five splice variants of TSHR are expressed in the thyroid gland (chicken: Grommen et al., 2006, 2008). Genomic sweeps indicate that the TSHR gene has been subject to genetic changes during the domestication of chickens (Rubin et al., 2010).

23.4.3 Control of Thyrotropin Release

The release of TSH from the hypothalamus is under predominantly stimulatory control with two stimulatory releasing hormones (thyrotropin-releasing hormone (TRH) and corticotropin-releasing hormone (CRH)) and also the inhibitory effects of somatostatin (SS or SRIF).

23.4.3.1 Thyrotropin-Releasing Hormone

The structure of TRH is the following:

Pyro-glutamyl-histidyl-proline (NH_2) (*Bøler et al.*, 1969)

Chicken pre-pro-TRH has been characterized, and it contains four TRH progenitor sequences (–K/RRQHPGK/RR) (Aoki et al., 2007). TRH stimulates the release of TSH (chicken: Scanes, 1974).

TRH is expressed in the chicken brain (nucleus preopticus periventricularis, nucleus preopticus medialis, regio lateralis hypothalami, paraventricular nucleus, nucleus periventricularis hypothalami, and nucleus ventromedialis

hypothalamic) (Aoki et al., 2007). The chicken TRH receptor has been characterized (Sun et al., 1998).

23.4.3.2 Somatotostatin

There is inhibitory control of TSH release. Somatostatin depresses TSH release (Geris et al., 2003a). SS acts via the following somatostatin receptors (SSTRs): SSTR2 and SSTR5 (Geris et al., 2003a; De Groef et al., 2007).

23.4.3.3 Corticotropin-Releasing Hormone

CRH stimulates TSH release in birds (Geris et al., 2003b). This is mediated via the type 2 CRH receptors (CRH-R2s), these being expressed by chicken thyrotrophs (De Groef et al., 2003b).

23.4.3.4 Negative Feedback

As in mammals, T_3 exerts a *negative feedback* effect on TSH release in birds. This is supported by the ability of goitrogens to increase thyrotroph number and pituitary TSH content (Sharp et al., 1979).

23.4.3.5 Environmental Factors and TSH Release

Cold evokes a rapid increase in TSH release in birds. There are increased circulating concentrations of T_4 with cold exposure (Japanese quail: Herbute et al., 1984). This is likely to be mediated by TRH as cold stress increases hypothalamic expression of TRH (Wang and Xu, 2008). Circulating concentrations of TSH are decreased during fasting, with thyrotropes retaining sensitivity to either TRH or CRH (chicken: Geris et al., 1999).

23.4.4 Control of TSH β-Subunit Expression (in the Pars Distalis)

Studies in mule ducks (a hybrid of male Muscovy ducks and female domestic ducks) indicate preferential transcription of the TSH β-subunit from the maternal genome (Hsieh et al., 2007).

Expression of the TSH β-subunit is increased by TRH in duck pituitary tissue *in vitro* (Hsieh et al., 2007) (Figure 23.3). Thyroid hormones inhibit expression of the TSH β-subunit. Either T_3 or T_4 suppresses expression of the TSH β-subunit in pituitary tissue *in vitro* (duck: Hsieh et al., 2007) (Figure 23.3). Similarly, expression of the TSH β-subunit by chicken pituitary cells is depressed by T_3 (Gregory and Porter, 1997). There is increased expression of the TSH β-subunit by pituitary glands in goitrogen-treated quail (Catena et al., 2003). In addition, glucocorticoids such as corticosterone depress expression of the TSH β-subunit in duck pituitary tissue *in vitro* (Hsieh et al., 2007). There is no change in the expression of the TSH β-subunit with starvation in Japanese quail (Kobayashi et al., 2002; Kobayashi and Ishii, 2002).

23.4.5 Origin of Thyrotropin

23.4.5.1 Anterior Pituitary Gland

The thyrotrophs, the cells producing TSH, are located almost entirely in the cephalic (or rostral) lobe of the avian anterior pituitary gland (Figure 23.1). This is based on immunocytochemistry with antisera against mammalian the TSH β-subunit (Sharp et al., 1979). It is not surprising, based on the stimulatory control of TSH release by TRH, that TRH binding sites have been reported for membrane preparations from cephalic lobes of chicken pituitary gland (Harvey and Baidwan, 1989). The proportion of cells of the anterior pituitary gland that are thyrotrophs ranges from 2% to 6% (adult ring doves: Reichardt, 1993). Some thyrotrophs express the androgen receptor (Sun et al., 2012). The interaction between androgens and TSH secretion is not well established.

23.4.5.2 Extrapituitary TSH

The TSH β-subunit immunoreactivity is reported in the cells lining the spinal canal, the crop, the bronchial ducts, and the linings of the pleural and pericardial cavities of the chick embryo (Murphy and Harvey, 2001).

23.4.6 Ontogeny of Thyrotropin

Both TSH (pituitary) and TRH (hypothalamus) are detectible very early in the development of the chicken embryo (TSH at day 6.5: Thommes et al., 1983; the TSH β-subunit at day 12: Ellestad et al., 2011; and TRH at day 4.5: Thommes et al., 1985). Changes in cell number and TSH–TRH content occur during development. Self-organizing maps have been constructed on the genes expressed differentially in

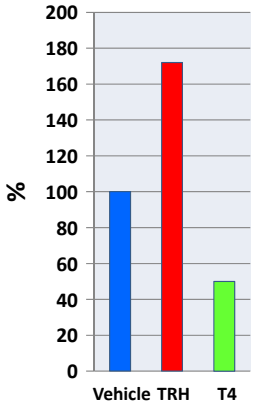

FIGURE 23.3 Effect of TRH and thyroxine (T_4) on expression of TSH β subunit by duck anterior pituitary tissue *in vitro*. *Data from Hsieh et al. (2007).*

the anterior pituitary during the development of thyrotrophs producing TSH β-subunits (Ellestad et al., 2006).

The hypothalamo–pituitary–thyroid axis appears to be functional by midembryonic development (Thommes et al., 1984). A second phase is the maturation of the axis occurs at about the time of hatching with deiodination pathways fully established (Decuypere et al., 1988; McNichols and McNabb, 1988).

23.5 GROWTH HORMONE

23.5.1 Chemistry

Chicken GH has been characterized based on cDNA (chickens: Lamb et al., 1988). An antagonist to chicken GH has been produced (Paczoska-Eliasiewicz et al., 2006).

23.5.2 Growth Hormone Variants

There are charge and size variants of avian GH. Unlike the situation with human GH, where there are multiple genes and where different splicing patterns of mRNA occur, GH variants in birds are due to posttranslation modification. There are reports of a glycosylated GH (Berghman et al., 1987), a phosphorylated GH (Arámburo et al., 1990, 1992), a cleaved 15 kDa GH (Arámburo et al., 2001), and dimeric and other oligomeric forms (Houston and Goddard, 1988) in the chicken.

Release of GH variants may be differentially controlled. There are shifts in the ratio of GH variants during growth and with GH-releasing hormone (GHRH) stimulation (Arámburo et al., 2000; Martínez-Coria et al., 2002). The ratio of glycosylated to nonglycosylated GH shifts during growth and development (chicken: Berumen et al., 2004). Glycosylated avian GH is present in the same secretory granules as nonglycosylated GH (chicken: Berumen et al., 2004).

23.5.3 Actions of Growth Hormone

Studies on the role of GH have been isolated predominantly to one domesticated species of bird—the chicken. There is a need for studies in multiple avian species.

23.5.3.1 GH and Growth

GH is likely to be required for normal posthatching growth. Hypophysectomy and the consequent lack of GH result in a decrease in the growth rate of over 50% in chickens (King and Scanes, 1986; also calculated from Kusnik et al., 2008) but either has no effect on growth rate in turkeys (Proudman and Opel, 1990a) or there is a modest depression of average daily gain (30%) (Proudman et al., 1994). The effect of pituitary ablation on growth rate is partially overcome by replacement therapy with GH in chicken (King and Scanes, 1986; Scanes et al., 1986), but no effect of GH is reported in turkeys (Proudman et al., 1994). In young intact birds, GH does not stimulate growth more than at most transitorily (chickens: Leung et al., 1986; Burke et al., 1987; Cogburn et al., 1989; turkeys: Proudman et al., 1994). Stimulation of growth in midgrowth-phase chickens is reported when GH is administered in a pulsatile manner (Vasilatos-Younken et al., 1988).

In mammals, GH exerts its effect on somatic growth by increasing production of insulin-like growth factor 1 (IGF1) by the liver. In birds, a similar situation seems to be the case. Plasma concentrations of IGF1 are reduced following hypophysectomy in young birds (chickens: Huybrechts et al., 1985; turkeys: Proudman et al., 1994) and restored somewhat by GH treatment (chickens: Scanes et al., 1986; turkeys: Proudman et al., 1994). Moreover, young female chickens that exhibited enhanced growth with pulsatile GH treatment also had elevated circulating concentrations of IGH1 (Vasilatos-Younken et al., 1988). *In vitro*, GH increases IGF1 release from chicken hepatocytes, particularly in the presence of insulin (Houston and O'Neill, 1991).

23.5.3.2 GH and Lipid Metabolism

GH exerts effects on lipid metabolism in birds. Administration of GH to chickens can influence the amount of adipose tissue, with the direction of the effect affected by the mode of administration. For instance, body fat is increased by daily injection (Cogburn et al., 1989) but decreased by pulsatile administration of GH (Vasilatos-Younken et al., 1988). GH receptors are expressed in adipose tissue (chicken: Hausman et al., 2012).

Acutely, GH influences the rate of lipolysis. GH stimulates lipolysis *in vitro* by adipose explants (chickens, turkeys, and pigeons: Harvey et al., 1977; Campbell and Scanes, 1985). This effect is blocked by a GH antagonist (chicken: Campbell et al., 1993). *In vivo*, GH increases circulating concentrations of nonesterified fatty acids (NEFAs) acutely (chickens: Hall et al., 1987; Scanes, 1992; hypophysectomized ducks: Foltzer and Mialhe, 1976) but was without an effect in intact or hypophysectomized young turkeys (Proudman et al., 1994). In addition, GH exerts an effect on avian adipose that is analogous to the insulin-like effect of GH in mammals. *In vitro*, GH reduces glucagon or cAMP-stimulated lipolysis (chicken: Campbell and Scanes, 1987).

GH inhibits lipogenesis in birds. GH suppressed insulin-stimulated synthesis of fatty acids by chick hepatocytes *in vitro* (Harvey et al., 1977). Moreover, pulsatile GH administration to young pullets *in vivo* reduced hepatic lipogenesis (Rosebrough et al., 1991).

23.5.3.3 GH and Thyroid Hormones

There are marked effects of GH on circulating concentrations of the thyroid hormone, triiodothyrone (T_3). It is not established whether GH influences thyroxine (T_4) release from the avian thyroid (chicken: MacKenzie, 1981). In young chicks, GH

increases the circulating concentration of T_3 (Kuhn et al., 1985). This is due to GH reducing both the activity of hepatic type 3 monodeiodinase (the catabolic enzyme metabolizes T_3 to T_2; Darras et al., 1992, 1993) and the expression of this deiodinase (Van der Geyten et al., 1999). This is a physiological effect of GH as type 3 monodeiodinase is elevated following hypophysectomy and partially restored to normal by GH replacement therapy (Darras et al., 1993).

23.5.3.4 GH and Immune Functioning

GH exerts a stimulatory effect on the avian immune system. For instance, GH administration increases thymus weights in hypophysectomized chicks (King and Scanes, 1986; Scanes et al., 1986) and bursal weight if T_3 is also present in hypophysectomized chicks (Scanes et al., 1986), and it influences peripheral white blood cells (Johnson et al., 1993). GH reduces apoptosis of bursal cells (Rodríguez-Méndez et al., 2010). Moreover, GH is expressed by avian immune tissues (discussed further in this chapter).

23.5.3.5 GH and Reproduction

GH administration prior to sexual maturation increases ovarian weight, increasing cell proliferation in both the stroma and small follicles and depressing apoptosis *in vivo* (chickens: Hrabia et al., 2011). However, there is no effect on reproduction in dwarf male chickens with GH receptor (GHR) deficiency (Zheng et al., 2007). In addition, GH is expressed by gonadal tissues (discussed further in this chapter).

23.5.3.6 GH and Adrenocortical Hormones

GH can influence the avian adrenal cortex. Plasma concentrations of corticosterone are increased acutely following the administration of recombinant chicken GH (Cheung et al., 1988) or chronically following the continuous infusion of native GH (Rosebrough et al., 1991). There are effects of GH on corticosteroidogenesis *in vitro* (chicken: Carsia et al., 1985c).

23.5.3.7 GHR and Signal Transduction

Chicken GHR cDNA has been sequenced (Burnside et al., 1991). As with the mammalian GHR, the chicken GHR consists of three domains: an extracellular domain, a single transmembrane domain, and an intracellular domain. There are polymorphisms in the GHR associated with growth rate and adiposity (Ouyang et al., 2008). Sex-linked dwarf chickens have mutations such that the GHR is not expressed normally (Burnside et al., 1992).

GH downregulates the GHR. Hypophysectomy increases and GH administration decreases GH binding to chicken liver membranes (Vanderpooten et al., 1991a). Both hepatic GH binding (chicken: Vanderpooten et al., 1991b) and GHR mRNA expression (Burnside and Cogburn, 1992) are low in young birds when plasma concentrations of GH are high.

Following binding to the GHR, signal transduction is via Janus kinase 2 (JAK2). In the presence of GH, JAK2 is phosphorylated in liver and skeletal muscle (chicken: Wang et al., 2005). There is an association between polymorphisms in JAK2 and growth in chickens (Liu et al., 2010).

There is a circulating binding protein for avian GH (GHBP). A transcript for the GHBP derived from the GHR gene has been identified (chicken: Lau et al., 2007). Alternatively, GHBP is viewed as generated by proteolysis of the GHR (chicken: Vleurick et al., 1999).

23.5.4 Control of GH Secretion

The release of GH from the avian pituitary gland is under hypothalamic control, with multiple stimulatory releasing hormones (including GHRH, TRH, and ghrelin) and one inhibitory releasing hormone (SS) (Tables 23.2 and 23.3).

23.5.4.1 Growth Hormone–Releasing Hormone

The structure of chicken GHRH (shown here) and its precursor has been established based on the sequence of cDNA (Wang et al., 2006, 2007).

Chicken GHRH: HADAIFTDNYRKFLGQISARKFLQTIIGKRL-RNSESSPGEGVHKLLT

Two precursors for GHRH have been identified, one also containing the sequence for PACAP (Wang et al., 2007). GHRH is expressed in avian hypothalamus and also in the small intestine, liver, kidneys, lung, ovary, anterior pituitary gland, spleen, and testes (Wang et al., 2007). There is high expression of GHRH in the pituitary gland on embryonic day 8, but subsequently this declines to a low plateau level on days 12–20 (Wang et al., 2006). GHRH increases GH release in chickens *in vivo* and *in vitro* (chicken: Scanes et al., 1984). Avian somatotrophs respond to GHRH with increased intracellular calcium (chicken: Scanes et al., 2007) (Table 23.3).

TABLE 23.3 Effects of Neuropeptides on the Intracellular Concentrations in Responsive Chicken Somatotropes

Neuropeptide	$\Delta[Ca^{2+}]_i$
GHRH	120 ± 6
TRH	222 ± 16
Ghrelin	94 ± 16
PACAP	90 ± 14

Data from Scanes et al. (2007).

23.5.4.1.1 Receptor

The structure of the chicken GHRHR has been determined (Porter et al., 2006; Toogood et al., 2006). GHRH specifically binds to the GHRHR (Wang et al., 2007). GHRHR is specifically expressed in the avian anterior pituitary gland with expression increased by GHRH and decreased by either SS or corticosterone (Porter et al., 2006). Large increases in pituitary expression of GHRHR occur between days 8 and 12 and again between days 12 and 16 in embryonic development (Wang et al., 2006).

23.5.4.2 Thyrotropin-Releasing Hormone

A physiological stimulus for GH release in birds is the tripeptide TRH (Table 23.2). Furthermore, TRH is found in the avian hypothalamus (as discussed in this chapter), with TRH receptors present in the cells of the caudal lobe of the chicken pituitary gland (Harvey and Baidwan, 1989), where GH is produced. TRH stimulates GH secretion both *in vivo* and *in vitro* (chicken: Harvey et al., 1978a; turkey: Fehrer et al., 1985). Most somatotrophs respond to TRH with increased intracellular calcium (Scanes et al., 2007) (Table 23.3). TRH is a physiological regulator of GH secretion based on the ability of antiserum to TRH to suppress circulating concentrations of GH in young chicks (Klandorf et al., 1985).

23.5.4.3 Somatostatin

The structure of avian SS_{14} is identical to that of its mammalian homolog:

H–Ala–Gly–Cys–Lys–Asn–Phe–Phe–Trp–Lys–Thr–Phe–Thr–Ser–Cys–OH (pigeon: Spiess *et al.*, 1979; chicken: Hasegawa *et al.*, 1984).

Two somatostatin precursor variants have been identified in the avian brain: pro-somatostatin (PSS1) and the related peptide pro-cortistatin (PSS2) (Trabucchi et al., 2003). The only SS influencing anterior pituitary hormone secretion is most likely to be SS1.

Somatostatin inhibits GH release in birds. Not only are there SS neurons present in the hypothalamus (duck: Blahser et al., 1978), but also SS binding has been demonstrated in the chicken anterior pituitary gland (Harvey et al., 1990). Synthetic SS depresses both the *in vivo* and *in vitro* GH response to TRH (chicken: Harvey et al., 1978a) acting via SSTR2 (Bossis and Porter, 2001; Geris et al., 2003a).

23.5.4.4 Ghrelin

23.5.4.4.1 Actions and Chemistry

Ghrelin stimulates release of GH in the chicken (Ahmed and Harvey, 2002). Only a minority of chicken somatotrophs (about one-fifth) respond to ghrelin with increased intracellular calcium (Scanes et al., 2007). Ghrelin immunoreactivity is reported in the chicken hypothalamus (Ahmed and Harvey, 2002). The structure of avian ghrelin has been established (e.g., chicken: Kaiya et al., 2002):

Chicken: GSSFLSPTYKNIQQQKDTRKPTARLH
Turkey: GSSFLSPAYKNIQQQKDTRKPTARLH
Duck: GSSFLSPEFKKIQQQNDPAKATAKIH
Goose: GSSFLSPEEKKIQQQNDPTKTTAKIH
Emu: GSSFLSPDYKKIQQRKDPRKPTTKLH

S octanyl [CH_3–$(CH2)_8$ C=O.O–] acylation site (Based on Richards et al., 2006).

23.5.4.4.2 Receptor

Ghrelin acts via the GH secretagogue receptor (GHSR). This has been characterized in birds (e.g., Japanese quail: Kitazawa et al., 2009). There are at least two forms of GHSR in the avian anterior pituitary gland: GHS-R1a and GHS-R1c. Expression of these is depressed by ghrelin, GHRH, and corticosterone (chicken: Geelissen et al., 2003).

23.5.4.4.3 Extrahypothalamic Expression of Ghrelin

In addition to the hypothalamus, there is high expression of ghrelin in the proventriculus and proventriculus–gizzard junction, together with some in the gizzard and duodenum (Shao et al., 2010).

23.5.4.5 Other Neuropeptides and Hormones

Other neuropeptides influence the release of GH. GH release is also stimulated by PACAP, another peptide from the avian GHRH gene (Peeters et al., 1998). Subpopulations of somatotrophs respond to PACAP with increased intracellular calcium (Scanes et al., 2007). The structure of chicken PACAP is as follows:

Chicken PACAP 38: HIDGIFTDSYSRYRKQQMAVKKYLAAVL-GKRYKQRVKNK (Based on Wang et al., 2007).

PACAP binds specifically to the PACAPR (Wang et al., 2007). In addition, leptin increased intracellular calcium in chicken somatotrophs (Scanes et al., 2007). PRP31 depresses circulating concentrations of GH (Tachibana et al., 2011).

Growth hormone secretion in birds is inhibited by two peripheral hormones: IGF1 and T_3 in a negative feedback manner. IGF1 inhibits GH release *in vitro* and *in vivo* (chickens: Perez et al., 1985; Buonomo et al., 1987). Elevated levels of T_3 reduce GH release (chicken *in vivo*: Scanes and Harvey, 1989; *in vitro*: Donoghue and Scanes, 1991).

23.5.4.6 Nutrition and GH Secretion

Nutritional deprivation increases the plasma concentration of GH in birds. Plasma concentrations of GH are elevated by a short period (1–2 days) of starvation (chickens: Harvey et al., 1978b; turkeys: Anthony et al., 1990). Plasma concentrations of GH are also increased by calorie–protein

deprivation in young chickens and turkeys (Engster et al., 1979). Similarly, long-term protein deficiency is accompanied by elevated plasma concentrations of GH in young chickens (Scanes et al., 1981).

23.5.5 GH Gene and Control of GH Expression

23.5.5.1 GH Gene

The structures of GH have been also reported deduced from the cDNA or genomic DNA from chicken (*Gallus gallus*) (NCBI Reference Sequence: NM_204359.2), chicken retinal GH (GenBank: AY373631.1), domestic duck (*Anas platyrhynchos*) GH (GenBank: X07079.1), domestic goose (*Anser anser*) GH (GenBank: AY149895.2), European pied flycatcher (*Ficedula hypoleuca*) (GenBank: DQ218278.1), Japanese quail (*Coturnix coturnix*) (GenBank: FJ458436.1), jungle crow (*Corvus macrorhynchos*) GH1A (GenBank: AB560855.1), ostrich (*Struthio camelus*) GH (GenBank: AB028191.1), turkey (*Meleagris gallopavo*) GH (GenBank: M33697.1), and zebra finch (*Taeniopygia guttata*) GH1 (NCBI Reference Sequence: XM_002196131.2).

In passerine birds, there is a duplicate GH gene with more rapid evolutionary changes (Yuri et al., 2008) and the structures of the second GH or GH-like proteins reported for the jungle crow (*C. macrorhynchos*) (Arai and Iigo, 2010) (GenBank: AB560856.1). Moreover, structures of GH-like proteins are reported in the zebra finch (*T. guttata*) (GH-like) (CBI Reference Sequence: XM_002187248.2). The reported structure of GH of the European pied flycatcher (*Ficedula hypoleuca*) (Buggiotti et al., 2006) appears to be more similar to GH-like or GH1B than to GH or GH1A. What are not known are the roles and control of GH-like and GH1B.

There are polymorphisms in the chicken GH gene associated with growth rate and the amount of adipose tissue (chicken: Nei et al., 2005; Zhang et al., 2007; Ouyang et al., 2008).

23.5.5.2 GH Expression

GH expression is under multiple stimulatory and inhibitory influences. For instance, GHRH increases GH mRNA *in vivo* (Vasilatos-Younken et al., 1992) and *in vitro* (Radecki et al., 1994) (Figure 23.4) via a cAMP-dependent protein kinase pathway (Kansaku et al., 1998). In addition, GH expression is increased by corticosterone in embryonic pituitary cells (Bossis and Porter, 2003; Heuck et al., 2009) and by TRH, PACAP, and ghrelin (Porter et al., 2006). In contrast, it is decreased by SRIF (Porter et al., 2006) and IGF1 (Scanes et al., 1999) (Figure 23.4). The changes in GH expression during growth are similar to those of plasma concentrations of GH (chicken: McCann-Levorse et al., 1993). The pattern of gene expression during the development of avian somatotrophs can be described by self-organizing maps (Ellestad et al., 2006).

23.5.6 Pituitary Origin of Growth Hormone

The somatotrophs are located in the caudal lobe of the anterior pituitary gland (Mikami, 1980; Reichardt et al., 1993) (Figure 23.1). During late embryological development and early posthatch life, the number of somatotrophs increases rapidly until a plateau level is achieved (dove: Reichardt et al., 1993; chicken: Malamed et al., 1997). There are ontogenic changes in the structure of the somatotroph. The number of secretory granule per unit volume of the cell increases during late embryonic development (chicken: Malamed et al., 1993), and there are also more in the adult than the young (chicken: Malamed et al., 1985, 1988). Somatotrophs are also reported in the pars tuberalis (see Section 23.2.1).

23.5.7 Extrapituitary Production of GH

In birds, GH and/or GH mRNA is present outside of the traditionally viewed site of production—the adenohypophyseal cells. GH has been found in gonads, retina, and immune tissues. An immunoreactive 17 KDa GH together with a 29 KDa GH have been reported in the testis of the adult chicken where an effect on spermatogenesis is implicated (Martínez-Moreno et al., 2011). There is also production of GH within the retina. *In vitro* chick embryo retinal ganglion cells contain immunoreactive 15 KDa GH and GHRs (reviewed Sanders et al., 2009). The GH exerts a neuroprotective role *in vitro* and *in ovo* (Sanders

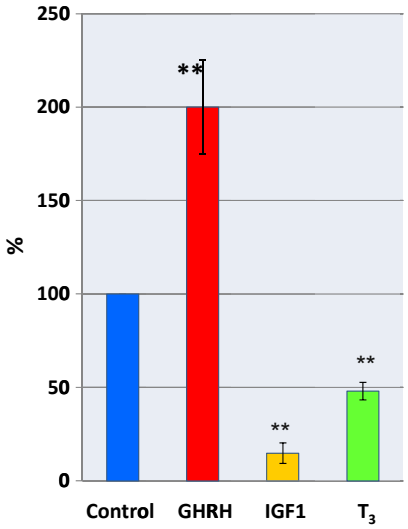

FIGURE 23.4 Effect of GHRH *in vitro*, IGF1 infusion *in vivo*, and T_3 in the diet on expression of GH in the chicken anterior pituitary gland. *Data from Radecki et al. (1994), Scanes et al. (1999).*

et al., 2010, 2011). There is evidence for GH exerting a paracrine effect on the ovary. Synthesis of progesterone by chicken granulosa cells is stimulated by GH (Ahumada-Solórzano et al., 2012). The presence of immunoreactive GH together with expression of GH have been reported in the chicken ovary, specifically the granulosa layer of the F5-2 follicles (Ahumada-Solórzano et al., 2012). Moreover, there is expression of GHR in both the F2 and F4 follicles (Ahumada-Solórzano et al., 2012). GH immunoreactivity is present in the bursa Fabricius, spleen, and thymus (chicken: Luna et al., 2005), with GH expression demonstrated in the bursa Fabricius (chicken: Luna et al., 2008). GH-containing neurons have been observed in dove and turkey brains (Ramesh et al., 2000).

23.5.8 Ontogeny of GH

23.5.8.1 Pou 1 (Pit 1)

Pou 1 (Pit 1) can transactivate a promoter for the GH gene (chicken: Murase et al., 2011). Avian Pou 1 (Pit 1) has been characterized (turkey: Wong et al., 1992; chicken: Tanaka et al., 1999) and is first expressed on embryonic day 5 (chicken: Van As et al., 2000). Two Pou 1 (Pit 1) transcripts, Pit1α and Pit1γ, are expressed in both the cephalic and caudal lobes of the chicken pituitary gland, with expression increasing in posthatching growth in a manner parallel to that of GH (chicken: Tanaka et al., 1999). Pou 1 (Pit 1) has been demonstrated to be present in somatotrophs (turkey: Weatherley et al., 2001). While no changes in Pou 1 (Pit 1)-expressing cells occur with corticosterone (chicken: Fu and Porter, 2004), TRH increases expression of Pou 1 (Pit 1) (Van As et al., 2004).

23.5.8.2 Somatotrophs and Their Differentiation

The embryonic increase in numbers of somatotrophs begins about day 14 of incubation (Porter et al., 1995). GHRH increases the number of somatotrophs (Porter et al., 1995). This increase is due to stimulatory effects of corticosterone and probably also of GHRH and thyroid hormones (Dean and Porter, 1999; Liu and Porter, 2004). The glucocorticoid induction of somatotroph differentiation involves both type 1 (mineralocorticoid) and type 2 (glucocorticoid) receptors (Bossis et al., 2004). Corticosterone induction of the GH gene is via a *cis*-acting glucocorticoid responsive element (Heuck-Knubel et al., 2012). It is likely that the corticosterone inducing differentiation of somatotrophs is of adrenal origin, but steroidogenic enzymes are expressed in the embryonic anterior pituitary gland (Zheng et al., 2008).

23.5.8.3 Secretion

A common pattern of circulating concentrations of GH has been observed in all species of birds examined. This consists of progressively rising circulating concentrations of GH in late embryonic development and early posthatch development, high plasma concentrations of GH during the period of rapid posthatching growth, and low GH concentrations in older and adult birds (Harvey et al., 1979a,b). The mechanistic basis for this ontogenic profile includes changes in GH synthesis, somatotroph numbers, and pituitary sensitivity to secretagogues. The decline in plasma concentrations of GH in the middevelopment and growth does not appear to be due to gonadal steroids as castration does not prevent the decrease (Scanes and Johnson, 1984). The ontogenic profile for GH mRNA is very similar to that of plasma concentrations of GH (McCann-Levorse et al., 1993).

23.6 PROLACTIN

23.6.1 Chemistry

Avian prolactin (PRL) has been isolated from pituitary tissue (Papkoff et al., 1982). In addition, recombinant chicken PRL has been purified following expression in *Escherichia coli* (Hanks et al., 1989a). The nucleotide sequence of avian PRL cDNA has been established, and the amino acid residue sequence deduced (chicken: Hank et al., 1989b; Watahiki et al., 1989).

23.6.2 Variants

As in mammals, posttranslationally modified variants of PRL exist in birds. In the turkey, two glycosylated PRL variants (one *O*- and one *N*-glycosylated) have been identified in addition to a nonglycosylated form (Corcoran and Proudman, 1991). These have reduced radioreceptor activity (Corcoran and Proudman, 1991). A glycosylated PRL is reported in the chicken (Berghman et al., 1992). Avian PRL can also be phosphorylated (Arámburo et al., 1992). Physiological state influences pituitary levels of PRL variants. For instance, there are shifts in the proportion of variants; between nonlaying, laying, and incubating hens (chicken: Hiyama et al., 2009); and during development (turkey: Bédécarrats et al., 1999a,b,c).

23.6.3 Actions of PRL

23.6.3.1 PRL and the Crop Sac Gland

PRL stimulates the production of "crop milk" from the crop sac gland in pigeons. There is considerable proliferation of the germinal cell layer of the crop, with expression of specific genes including keratin in nursing pigeons (Gillespie et al., 2013). Toward the end of when doves are incubating eggs, the crop increases in weight and there is a concomitant increase in the plasma concentrations of PRL (Goldsmith et al., 1981). This unique feature of

the Columbidae (pigeons and doves) has been used as the basis of a biological assay for prolactin (Nicholl, 1967). The effects of prolactin on the crop sac gland are reported to be enhanced by synlactin, a putative PRL-induced liver factor (Nicoll et al., 1985). In an analogous manner, a serum factor potentiates the effect of prolactin on Nb2 rat lymphoma cells (McNeilly and Friesen, 1985). The identity of synlactin is not established but may be IGF1 or an IGF-binding protein. PRL also directly influences behavior as discrete PRL binding sites (receptors) have been reported in dove brains (Buntin et al., 1993).

23.6.3.2 PRL and Incubation Behavior and Broodiness

In birds, incubation behavior and broodiness are controlled by PRL. Administration of PRL induces broodiness (chickens: Riddle et al., 1935; turkey: Youngren et al., 1991). Incubation behavior is completely suppressed in turkey hens actively immunized against PRL (Crióstomo et al., 1998). In turkeys, PRL acts centrally to increase nesting activity and together with sex steroids to induce incubating behavior (El Halawani et al., 1986; Youngren et al., 1991). Similarly in bantam chickens, PRL increases incubation behavior, with increased nesting behavior in previously nest-deprived birds (Sharp et al., 1988). A positive feedback loop between PRL and incubation is envisaged.

Release of PRL and hence plasma concentrations of PRL are very high when birds are incubating their eggs (chickens: Sharp et al., 1988; turkeys: El Halawani et al., 1988; Wong et al., 1991). Circulating concentrations of PRL are also elevated during incubation in wild birds, for instance in both male and female Manx shearwater (Riou et al., 2010). Furthermore, the plasma concentrations of PRL fall rapidly if incubation behavior or nesting is interrupted (El Halawani et al., 1980; Tong et al., 1997).

23.6.3.3 PRL and Reproduction

Prolactin has both stimulatory and inhibitory effects on avian reproduction (Li et al., 2011), with effects at the hypothalamic levels inducing incubation behavior (considered in this chapter); the anterior pituitary with PRL decreases expression of the LH β-subunit (turkey: You et al., 1995) and possibly gonadal levels also.

23.6.3.4 PRL and Osmoregulation

PRL may have an osmoregulatory role in avian embryos. Allantoic concentrations of both sodium and chloride are depressed by ovine or bovine PRL, while metanephric kidney Na^+–K^+–ATPase activity is increased (Doneen and Smith, 1982; Murphy et al., 1986).

23.6.3.5 PRL Receptor (PRLR)

The amino acid sequence of the avian PRLR has been established based on the nucleotide sequence of PRLR cDNA (chicken: Tanaka et al., 1992; pigeon: Chen and Horseman, 1994; goose: Xing et al., 2011). The avian receptor, like its mammalian homolog, consists of extracellular, transmembrane, and intracellular domains. However, the PRLR has a unique feature with a double-antenna structure of two putative PRL binding sites in the extracellular domain.

The PRLR is expressed in the following tissues in the turkey: brain (and hypothalamus), brood patch, crop sac, duodenum, gizzard, heart, kidney, leukocytes, liver, lung, ovary, pancreas, pectoralis muscle, pituitary gland, shell gland, and spleen (Zhou et al., 1996). Similarly, PRLR is expressed in multiple tissues in the chicken (Tanaka et al., 1992; Kang et al., 2007). In the goose, PRLR is expressed in the testes, ovary, oviduct, kidney, and small and large intestine (Xing et al., 2011).

There are marked changes in PRLR expression with physiological state: more PRLR expression in the pituitary gland and shell gland but less in the hypothalamus in photostimulated laying hens, and further increases in incubating birds (turkey: Zhou et al., 1996). There are large perihatching increases in PRLR expression in the hypothalamus, pituitary gland, liver, pancreas, kidneys, and gonads (chickens and turkeys: Bole-Feysot et al., 2007; Leclerc et al., 2007).

23.6.4 Control of PRL Release

Prolactin secretion is predominantly under stimulatory hypothalamic control, although some inhibitory influence is possible.

23.6.4.1 Vasoactive Intestinal Peptide (VIP)

VIP is the major hypothalamo-hypophysiotropic factor stimulating PRL release (Table 23.2).

23.6.4.1.1 Chemistry

The amino acid sequence of chicken VIP is as follows:

HSDAVFTDNYSRFRKQMAVKKLYNSVLT (Nilsson, 1975)

23.6.4.1.2 Activity

Prolactin release is stimulated by VIP (chickens *in vivo*: Macnamee et al., 1986; turkeys *in vivo*: Opel and Proudman, 1988; turkeys *in vitro*: Proudman and Opel, 1988). Similarly, VIP evokes a 10-fold increase in circulating concentrations of PRL in white-crowned sparrow but is not effective in another passerine bird, the Florida scrub jay (Maney et al., 1999). VIP is found in the avian hypothalamus, particularly in the median eminence (MacNamee et al., 1986).

23.6.4.1.3 Physiological Role

The physiological role of VIP in the control of both the release and expression of avian PRL is supported by studies with antisera. Immunoneutralization of VIP decreases circulating concentrations of prolactin in chicken (Sharp et al., 1989; El Halawani et al., 2000), decreases PRL expression in chicken (Avital-Cohen et al., 2011), and abolishes all prolactin-releasing activity of turkey hypothalamic extracts (El Halawani et al., 1990).

23.6.4.1.4 Hypothalamic Content

The hypothalamic VIP content varies with physiological state in a manner that is consistent with VIP being the PRL-releasing hormone. For instance, hypothalamic content of VIP is elevated in photostimulated compared to nonphotostimulated turkeys and is increased further in incubating hens (Rozenboim et al., 1993). Dopamine increases VIP expression in the infundibular nuclear complex (INF) of the hypothalamus (turkey: Bhatt et al., 2003).

23.6.4.1.5 Release and Expression

Dopamine stimulates release of VIP from the hypothalamus via D1 dopamine receptors (turkey: Youngren et al., 1996; Chaiseha et al., 1997). In addition, serotonin increases PRL secretion via hypothalamic effects on dopaminergic neurons and then release of VIP (turkey: El Halawani et al., 1995; Chaiseha et al., 2010).

23.6.4.2 Arginine Vasotocin (AVT)

AVT has some PRL-releasing activity (Table 23.2). Posterior pituitary extracts can provoke PRL release from turkey pituitary cells due to both AVT and VIP. AVT stimulates prolactin release, while antiserum to AVT partially neutralizes the PRL-releasing effects of posterior pituitary extracts (El Halawani et al., 1992).

23.6.4.3 Other Stimulatory Factors

Other peptides stimulate PRL secretion in birds. PRL release is stimulated by TRH (turkey *in vivo*: Saeed and El Halawini, 1986) and peptide histidine isoleucine (PHI) (turkey: Proudman and Opel, 1990b).

23.6.4.4 Prolactin (PRL)-Releasing Peptide (PrRP)

23.6.4.4.1 Chemistry

PrRP is an RF-amide peptide. The precursor (pre-proprolactin-releasing peptide) for avian PrRP has been characterized in the chicken from its cDNA; there are PrRPs with 20- and 31-amino-acid residues (Tachibana et al., 2011):

PrRP31: SRPFKHQIDNRSPEIDPFWYVGRGVRPIGRF-NH_2
PrRP20: SPEIDPFWYVGRGVRPIGRF-NH_2

23.6.4.4.2 Actions

Avian PrRP is thought to influence PRL secretion in birds. There is a small increase in circulating concentration of PRL after peripheral administration of an intermediate dose of PrRP31 in chickens, presumably reflecting increased prolactin release (Tachibana et al., 2011) (Table 23.2). In contrast, central administration of PrRP31 into the brain consistently depresses circulating concentrations of PRL, indicating an ultrashort feedback effect (Tachibana et al., 2011).

23.6.4.4.3 Receptors

Three receptors have been characterized that bind PrRP in birds: PrRPR1, PrRPR2, and *Carassius* RF-amide peptide (C-RFa) receptor (C-RFaR). There is moderate to high expression of PrRP, C-RFa, PrRPR1, PrRPR2, and C-RFaR in specific regions of the chicken brain, including the hypothalamus, hindbrain, and telencephalon (Wang et al., 2012). There is high pituitary expression of PrRP, C-RFa, and PrRPR1 together with modest expression of C-RFaR (Wang et al., 2012).

23.6.4.5 Dopamine

Dopamine exerts both stimulatory and inhibitory effects on avian PRL secretion. Dopamine directly inhibits VIP-stimulated PRL release from the anterior pituitary gland via D2 dopamine receptors (turkey: Youngren et al., 1998) (Table 23.2). Moreover, there are reduced numbers of dopamine receptors in the cephalic lobe of the anterior pituitary gland in broody birds (bantam chickens: MacNamee and Sharp, 1989). The stimulatory effects are at the level of the hypothalamus.

23.6.4.6 Other Inhibitory Influences

Avian lactotrophs also contain calcitonin (chicken: Maddineni et al., 2007). Based on the inverse relationship between the concentrations of PRL and calcitonin, it has been proposed that calcitonin inhibits PRL release (chicken: Maddineni et al., 2007).

23.6.5 PRL Expression

Expression of PRL is under hypothalamic control. Photostimulation of young chickens is accompanied by increased PRL expression in the anterior pituitary gland (Li et al., 2009). Moreover, PRL expression is greatly increased during incubation (turkey: Wong et al., 1991). VIP increases

expression of PRL (Kang et al., 2004), and the effect is mediated by cAMP signal transduction (Kansaku et al., 1998; Kang et al., 2002) and/or protein kinase C (Sun and El Halawani, 1995). Moreover, immunizing turkeys against VIP decreases pituitary expression of PRL (El-Halawani et al., 2000; Ahn et al., 2001).

23.6.6 Origin of PRL

The PRL-producing cells (lactotrophs) are largely restricted to the cephalic lobe of the anterior pituitary gland (Figure 23.1) (Mikami, 1980). The relative proportion of lactotrophs changes with physiological state. For instance, the proportion drops from 12% in newly hatched pigeons to less than 2% in adult pigeons (Reichardt, 1993). There are large numbers of lactotrophs in the anterior pituitary gland of incubating turkeys (Ramesh et al., 2001). A rapid decrease in the number of lactotrophs occurs if the birds are removed from their nests (Ramesh et al., 2001). The numbers of lactotrophs declines during molting (chickens: Sandhu et al., 2010).

Pituicytes containing both GH and PRL, which are somatolactotrophs, have been reported to be present in the caudal lobe both with the ventral portion of the cephalic lobe and at the cephalic–caudal junction of the anterior pituitary gland during incubation (turkeys: Ramesh et al., 1998). Somatolactotrophs rapidly disappear if the incubating birds are nest deprived (Ramesh et al., 2001). The somatolactotrophs contribute to the very high PRL secretion during incubation (Ramesh et al., 1998). There are also PRL-producing cells in the pars tuberalis (see Section 23.2.2).

23.6.7 Extrapituitary Production of Prolactin

Neurons containing immunoreactive PRL have been reported in the brain (e.g., in the hippocampus and hypothalamus; Ramesh et al., 2000). A prolactin-like protein (PLP) (also known as prolactin 22) has been characterized in the chicken and also in fish but not mammals (Wang et al., 2010). The precursor has 222 amino acids, is about 33% homologous to PRL, and can bind to the PRL receptor (Huang et al., 2009; Wang et al., 2010). It is not clear whether a different receptor exists for PLP. There is high expression of PLP in the chicken brain together with the lungs, ovary, and testes; moderate expression in the kidneys, skeletal muscle, and heart; but little expression in the pituitary gland (Wang et al., 2010).

23.6.8 Ontogeny of PRL

Corticosterone increases the number of lactotrophs in the embryonic anterior pituitary gland (Fu et al., 2004) via the zipper protein GILZ. Corticosterone increases GILZ expression in the chick embryo anterior pituitary gland (Ellestad et al., 2009). Exogenous GILZ increases expression of prolactin in the chick embryo anterior pituitary gland (Ellestad et al., 2009). The increased numbers of lactotroph occur by recruitment, with little effect of corticosterone on lactotroph proliferation (chicken: Fu and Porter, 2004).

While Pit1 can activate the promoter for prolactin, it is not present in lactotrophs (turkey: Weatherley et al., 2001). The pattern of gene expression during the development of lactotrophs has been described by self-organizing maps (Ellestad et al., 2006).

23.7 ADRENOCORTICOTROPIC HORMONE

23.7.1 Chemistry of ACTH and Other POMC-Derived Peptides

ACTH is synthesized as part of POMC (Table 23.1). This POMC also contains the sequences of β-endorphin (β-EP), which in itself is part of β-lipotropin (β-LPH), together with α- and β-melanocyte-stimulating hormone (MSH). The cDNA for chicken POMC has been characterized (Takeuchi et al., 1999). ACTH, β-EP, and β-LPH have been purified from several avian species (see Figure 23.2). Avian ACTH, like its mammalian homolog, is a simple polypeptide containing 39 amino acids (Li et al., 1978; Chang et al., 1980; Hayashi et al., 1991):

Chicken: SYSMEHFRWGKPVGRKRRPIKVYPNGVDEESAESYPMEF
Ostrich: SYSMEHFRWGKPVGRKRRPVKVYPNGVQEETSEGFPLEF

In the mammalian pars intermedia, proteolytic cleavage of POMC results in the production of α-MSH. There is not a pars intermedia in birds. Some α-MSH is found in the avian pars distalis (Hayashi et al., 1991). α-MSH may exert biological effects distinct from those evoked by ACTH. For instance, α-MSH but not ACTH stimulates sodium excretion from the nasal salt glands of ducks (Ituzziza et al., 1992). β-LPH and β-EP have been purified from ostrich and turkey adenohypophyseal tissue (Chang et al., 1980; Naude et al., 1980, 1981a,b). As in mammals, the 31 amino acid sequence of ostrich β-EP is identical to the C-terminal of ostrich β-LPH.

23.7.2 Actions of ACTH

23.7.2.1 Effects on Adrenal Cortical Cells

ACTH acts to stimulate avian adrenal cortical cells to produce corticosterone (the major glucocorticoid in birds), aldosterone (the major mineralocorticoid in birds), and deoxycorticosterone (chicken: Carsia et al., 1985a,b; ducks: Collie et al., 1992; greater rheas: Lèche et al., 2009). ACTH evokes marked changes in the morphology of avian adrenocortical cells due to changes in the cytoskeleton (Cronshaw et al., 1992).

The effect of ACTH is mediated by melanocortin receptors and cAMP (Carsia et al., 1985a). ACTH influences the expression of over 100 genes, including MC2R, cAMP response element modulator, and the steroidogenic acute regulatory protein (chicken: Bureau et al., 2009). The adrenal response to ACTH varies with physiological state (Carsia et al., 1985b). For instance, sensitivity to ACTH declines during growth.

23.7.2.2 Melanocortin Receptor (MCR)

ACTH acts by binding to MCRs. These are members of the G protein–coupled superfamily of receptors. There are five avian MCRs: MC1-R to MC5-R. These have been characterized in the chicken: MC1-R (Takeuchi et al., 1996), MC2-R (Takeuchi et al., 1998), MC3-R (Takeuchi and Takahashi, 1998a), and MC4-R and MC5-R (Takeuchi and Takahashi, 1998b).

MC2-R mediates the effects of ACTH in the adrenal and is expressed in the adrenal gland (chicken: Takeuchi et al., 1998). The expression of MC2-R is increased by ACTH (chicken: Bureau et al., 2009). There is also expression of MC3-R in avian adrenal glands (Takeuchi and Takahashi, 1998a). MC1-R, MC4-R, and MC5-R are expressed in the hypothalamus (chicken: Dridi et al., 2006), playing a role in the control of feeding.

There are differences in the specificity of the receptors to ACTH and α-MSH. ACTH is more potent than αMSH in inhibiting ligand binding to each of the MC receptor types (Ling et al., 2004). ACTH is more potent in stimulating cAMP formation with MC2-R, but α-MSH and ACTH have similar ability to stimulate cAMP formation with MC1-R, MC3-R, MC4-R, and MC5-R (Ling et al., 2004).

23.7.3 Control of ACTH Release

Stress induces the release of ACTH from the anterior pituitary gland via the releasing hormone, CRH. ACTH subsequently elevates corticosterone production.

23.7.3.1 Corticotropin-Releasing Hormone

CRH stimulates ACTH secretion (Table 23.2). The cDNA for the chicken CRH has been sequenced, and the deduced structure of chicken CRH is identical to that in mammals (Vandenborne et al., 2005a):

Chicken CRH: SEEPPISLDLTFHLLREVLEMARAEQLAQQAHSNRKLMEIIGK

Immunoreactive CRH is present in the avian hypothalamus, particularly in the median eminence (Jozsa et al., 1984). CRH stimulates ACTH release from chicken and duck pituitary cells *in vitro* (Carsia et al., 1986; Castro et al., 1986). The chicken CRH receptor has been characterized, with both CRH and urotensin-1 being effective ligands (Yu et al., 1996). The effect of CRH is mediated by CRH-R1 (De Groef et al., 2003a). A binding protein for CRH is found in brain extracts (chicken: Seasholtz et al., 2002), but its role in birds is not well established.

23.7.3.2 Other Hormones

Both AVT and MT stimulate ACTH release (Castro et al., 1986). Central administration of ghrelin increases circulating concentrations of corticosterone in young chickens (Saito et al., 2005), presumably due to elevated CRH release. There is also intrapituitary control of ACTH release with parathyroid hormone–related peptide and calcitonin enhancing ACTH release (chicken: Nakayama et al., 2011a,b,c). Corticotrophs have calcitonin receptors, with calcitonin enhancing CRH-stimulated ACTH release (chicken: Nakayama et al., 2011b,c).

23.7.3.3 Feedback

Glucocorticoids inhibit the release of ACTH via effects at both the hypothalamic and pituitary levels. This has demonstrated *in vivo* (Herold et al., 1992) and *in vitro* (Carsia et al., 1986). Corticosterone also reduces expression of CRH in the hypothalamus (chicken: Vandenborne et al., 2005b). While corticosterone does not affect CRH-R expression in the anterior pituitary gland (chicken Vandenborne et al., 2005b), paradoxically pituitary expression of VT2R, presumably in corticotrophs, is upregulated by corticosterone (Sharma et al., 2009). Protein-deprived chicks that have elevated circulating concentrations of corticosterone also have reduced circulating concentrations of ACTH (Carsia et al., 1988), presumably due to increased glucocorticoid negative feedback.

23.7.4 Control of POMC Expression

Expression of POMC mRNA in the chicken anterior pituitary gland is decreased by either water deprivation (when there is elevated AVT release) or testosterone administration (Sharma and Chaturvedi, 2011). Corticosterone administration *in vivo* does not influence expression of POMC in the anterior pituitary gland, but corticosterone is effective in reducing anterior pituitary expression of POMC *in vitro* (chicken: Vandenborne et al., 2005b; Sharma et al., 2009).

23.7.5 Origin of ACTH

POMC is expressed and processed to ACTH in corticotrophs, these being acidophilic cells in the cephalic lobe of the anterior pituitary gland (Hayashi et al., 1991; Gerets et al., 2000) (Figure 23.1). The chicken anterior pituitary gland has a high content of ACTH (1.6 μg) but low levels

of α-MSH (10 ng) (Hayashi et al., 1991), with ACTH and α-MSH coexisting in the same cells (Iturriza et al., 1980; Hayashi et al., 1991). The number of chicken anterior pituitary cells that express POMC increases when cultured in the presence of CRH (Pals et al., 2006). VT2R is found in avian corticotrophs (Jurkevich et al., 2005).

23.7.6 Extrapituitary Production

POMC is expressed in multiple organs in addition to the anterior pituitary gland. Expression of POMC has been reported in the brain, kidneys, adrenal glands, adipose tissue, gonads, and uropygial gland (chicken: Takeuchi et al., 1999). There are perikarya in the infundibular nucleus and median eminence together with fibers in the preoptic area and in the medial basal hypothalamus that contain POMC (Gerets et al., 2000). In addition, immunoreactive POMC products are present in immune tissues such as both the thymus and bursa Fabricius (Franchini et al., 1999). POMC and prohormone convertase 1 and 2 (PC1 and PC2) are expressed in feather follicles (Yoshihara et al., 2011).

The MCR is expressed in multiple tissues. There is expression of MC2-R in the spleen (Takeuchi et al., 1998). There is expression of both MC4-R and MC5-R in the brain, adrenal glands, gonads, and adipose tissues of the chicken, with expression of MC4-R also in the spleen and that of MC5-R also in the kidneys and the uropygial gland (Takeuchi and Takahashi, 1998b). The roles of these POMC products are not well established. Feather follicles also express MC1-R, which binds α-MSH or ACTH and thereby changes feather coloration (Yoshihara et al., 2011).

23.7.7 Ontogeny of ACTH

The corticotrophs are first observed on day 7 in embryonic development in the domestic fowl (Jozsa et al., 1979). Plasma concentrations of ACTH and corticosterone increase between embryonic days 11 and 17 (chicken: Jenkins et al., 2007). The rising circulating concentration of corticosterone subsequently increases both lactotroph and somatotroph cells in the anterior pituitary gland.

23.8 OTHER ANTERIOR PITUITARY PEPTIDES

In addition to the "classical" hormones of the anterior pituitary gland, other proteins are expressed. These include the following.

23.8.1 Adiponectin

The anterior pituitary expresses both adiponectin (chicken: Maddineni et al., 2005) and its receptor (AdipoR1 and AdipoR2) (chicken: Ramachandran et al., 2007). Pituitary expression of adiponectin is influenced by physiology, being increased by 48 h of feed withdrawal (Maddineni et al., 2005). There was a concomitant decrease in expression of both receptor subtypes (Ramachandran et al., 2007).

23.8.2 Calcitonin

Calcitonin is expressed in the chicken anterior pituitary gland, co-localizing with prolactin in many lactotrophs (Maddineni et al., 2007). Evidence of a physiological role for calcitonin comes from the report of an inverse relationship between pituitary expression of prolactin and calcitonin in different reproductive states (Maddineni et al., 2007). Corticotrophs have calcitonin receptors, with calcitonin enhancing CRH-stimulated ACTH release (chicken: Nakayama et al., 2011b).

23.8.3 Chromogranin A

Chromogranin A is an acidic peptide that can be secreted with protein hormones. A peptide with close (80%) homologies to mammalian chromogranin A has been purified and sequenced for ostrich adenohypophyseal tissue (Lazure et al., 1990). The function of chromogranin A or peptide fragments is not well established.

23.8.4 Glucagon Receptor

There is moderate expression of the glucagon receptor in the pituitary gland in the chicken (Wang et al., 2008). The cellular location and the function of the glucagon receptor are not yet established.

23.8.5 Ovoinhibitor

The avian egg white protein, ovoinhibitor, is co-localized in some adenohypophyseal cell types, such as somatotrophs, gonadotrophs that produce LH, and corticotrophs, but not in lactotrophs (Oubre et al., 2003).

23.8.6 Parathyroid-Related Peptide

There is parathyroid-related peptide (PTHrP) binding in the plasma membrane preparation from the anterior pituitary glands (chicken: Nakayama et al., 2011a). Administration of PTHrP into the third ventricle increases release of ACTH (Nakayama et al., 2011a). This may represent either an effect on the corticotrophs by leakage or PTHrP increasing CRH release. Evidence for a direct effect on the anterior pituitary gland comes from the reports of PTHrP expression together with the presence of a PTH-like peptide (PTH-L) in the pars distalis (Pinheiro et al., 2010).

23.8.7 Peptides

There is evidence that tetrapeptides in the anterior pituitary gland stimulate the thyroid and increase circulating thyroid hormone in hypophysectomized chickens (Kusnik et al., 2008).

23.8.8 Steroidogenic Enzymes

The embryonic anterior pituitary gland expresses steroidogenic enzymes, including P450 cholesterol side chain cleavage and 3β-hydroxysteroid dehydrogenase-1 (Zheng et al., 2008).

23.9 FUNCTIONING OF THE PARS TUBERALIS

Until relatively recently, the functioning of the avian pars tuberalis had received relatively little attention.

23.9.1 Pars Tuberalis and Photoperiodism

There is now abundant evidence that the pars tuberalis plays an important role in avian circadian rhythmicity and photoperiodism. In the Japanese quail, photoperiodic stimulation for 14 h increases expression of the TSH β-subunit in the pars tuberalis. This is followed within 4 h with elevated expression of type 2 monodeiodinase, and hence T_3, in the hypothalamus (Nakao et al., 2008). Photostimulation can be mimicked by TSH administered into the hypothalamus, indicating that TSH from the pars tuberalis is acting in a retrograde manner (Nakao et al., 2008).

23.9.2 Pineal Effects on the Pars Tuberalis

Communication with the pineal gland and the pars tuberalis is supported by the presence of melatonin-binding sites (Japanese quail: Cozzi et al., 1993) and melatonin receptor (Mel(1c)) expression in the pars tuberalis (Kameda et al., 2002). Moreover, pars tuberalis expression of the common LH–FSH–TSH glycoprotein α-subunit is increased following pinealectomy (chicken: Kameda et al., 2002). Moreover, the diurnal changes in the expression of the glycoprotein hormone α-subunit in the pars tuberalis are controlled by pineal melatonin (chicken: Arai and Kameda, 2004).

23.9.3 Circadian Rhythms and the Pars Tuberalis

There are endogenous circadian rhythms within the pars tuberalis. Circadian genes *Cry1* and *BMAL1* are expressed in the pars tuberalis of the Japanese quail (Yasuo et al., 2004; Ikegami et al., 2009).

There is communication between the pars tuberalis and both photoreceptors in other tissues. Neurons containing the photoreceptive protein opsin-5 extend to the outer region of the median eminence adjacent to the pars tuberalis (Halford et al., 2009; Nakane et al., 2010). Expression of the FSH–LH–TSH α-subunit in the pars tuberalis is decreased by continuous light regimens and increased by extended darkness irrespective of whether the birds are intact or pinealectomized (Kameda et al., 2002).

23.10 NEUROHYPOPHYSIS

23.10.1 Introduction

The anatomy of the hypothalamic neurosecretory tracts (neurons) leading to their secretory terminals in the pars nervosa is shown in Figure 23.1. The two hormones of the neurohypophysis are AVT and MT (Table 23.1). There are two genes. The first is the avian OXT encoding preprooxyphysin, the proteolytic products being MT and neurophysin-1. The second is the avian AVP gene encoding the precursor protein for AVT and neurophysin-2.

AVT and MT are produced by and secreted from predominantly separate neurosecretory neurons. The cell bodies of the AVT and MT neurons are located in both separate and overlapping areas within the hypothalamus (Goosens et al., 1977; Bons, 1980; Tennyson et al., 1985). The AVT- and MT- containing cell bodies and axons develop in the chicken embryo between days 6 and 17 (Tennyson et al., 1986).

MT and AVT are synthesized as part of the same precursor molecule as, respectively, neurophysin-1 and -2. The neurophysins act as carrier proteins in the transport of AVT and MT by axoplasmic transport. The hormones are then stored in the pars nervosa prior to release. Two avian neurophysins have been characterized and sequenced in birds (e.g., ostrich: Lazure et al., 1987, 1989; goose: Michel et al., 1990). The hormones of the avian neurohypophysis are AVT and MT (Acher et al., 1970):

AVT (8-arginine oxytocin): CyS–Tyr–Ile–Glu(NH2)–Asp(NH2)–CyS–Pro–Arg–Gly(NH2);

MT (8-isoleucine oxytocin): CyS–Tyr–Ile–Glu(NH2)–Asp(NH2)–CyS–Pro–Ile–Gly(NH2).

AVT differs from arginine vasopressin, the mammalian antidiuretic hormone, by a single amino acid residue substitution (isoleucine at position 3 for phenylalanine). MT differs from the mammalian homolog, oxytocin, by the substitution of isoleucine for leucine (position 8).

The posterior pituitary gland contains high levels of AVT and MT (chicken: 4.0 μg AVT and 0.9 μg MT) (Robinzon et al., 1988a). Low concentrations of these neuropeptides are also found throughout the brain (Robinzon et al., 1988a) and in the ovary (Saito et al., 1990). It is presumed that the major source of circulating concentrations of AVT and mesotocin is the posterior pituitary gland, although there is significant ovarian production (Saito et al., 1990).

23.10.2 Actions of AVT

The major roles of AVT are in renal functioning and reproduction.

23.10.2.1 Renal Functioning

AVT is the major antidiuretic hormone in birds (Goldstein, 2006). The absence of AVT, either following surgical removal of the pars nervosa or in AVT-deficient chicken, is accompanied by very large increases in the volume of urine produced (Shirley and Nalbandov, 1956; Dunson et al., 1972). The administration of AVT to birds has an antidiuretic effect (Ames et al., 1971). AVT exerts its principal effect on tubule function (Gerstberger et al., 1985; Stallone and Braun, 1985), with increased expression of aquaporin-2 (quail: Lau et al., 2009). Based on studies in the desert quail, AVT reduces GFR by decreasing both the number of reptilian-type nephrons filtering and the single-nephron GFR of mammalian-type nephrons (Braun and Dantzler, 1974). AVT also promotes conservation of water via a second effect on glomerular filtration together with renal vascular shifts (chickens: Stallone and Braun, 1985; gulls: Gray and Erasmus, 1988). AVT decreases urine flow rate and glomerular filtration rate in house sparrows, respectively, via V2R and VT1R (vascular, presumably renal) receptor mechanisms (house sparrow: Goecke and Goldstein, 1997). Chickens with hereditary diabetes insipidus show reduced sensitivity to AVT (Brummermann and Braun, 1995).

23.10.2.2 Cardiovascular Effects of AVT

AVT can have both vasodepressor and vasopressor activity in birds. Bolus injections of AVT to conscious adult chickens or adult or young ducks results in a marked drop in mean arterial pressure (Wilson and West, 1986; Robinzon et al., 1988b). In contrast, infusion of AVT can increase arterial blood pressure in conscious chickens (Robinzon et al., 1993). In an analogous manner, bolus injection of AVT elevates heart rate while infusion of AVT depresses cardiac frequency (Wilson and West, 1986; Robinzon et al., 1988b, 1993).

23.10.2.3 Oviposition

AVT causes oviposition, the physical process of laying eggs in birds. The hen uterus contracts in response to AVT but not to MT (Koike et al., 1988). The mechanism by which AVT provokes premature oviposition may involve AVT stimulation of local production of prostaglandins (probably E_1) by the uterus, which, in turn, causes uterine contractions (Rzasa, 1978, 1984). Circulating concentrations of AVT rise markedly at the time of oviposition (as discussed further in this chapter). There is also increased uterine sensitivity to AVT (Rzasa, 1978). A receptor for AVT, VT3R, is expressed in both the endometrium and myometrium of the chicken shell gland (Gubrij et al., 2005).

23.10.2.4 Other Roles

Neurohypophyseal peptides influence the secretion of other hormones in birds. For instance, AVT can stimulate the release of PRL (El Halawani et al., 1992) and ACTH (Castro et al., 1986).

23.10.2.5 Receptors

The receptors for AVT and MT are members of the vasotocin (VT) family of receptors within the superfamily of G protein–coupled receptors. There are four genes for the avian receptors for AVT and MT. These are the following: VT1R (expression widespread in brain), VT2R (V1b) (high expression widespread in pituitary gland), VT3R (oxytocin-like) (high expression widespread in brain), and VT4R (V1a) in birds (white-throated sparrow and zebra finch: Leung et al., 2011). The VT3R receptor has also been characterized in the chicken (Gubrij et al., 2005).

There is little expression of the VT2R (V1b) in the brain based on studies in songbirds (Leung et al., 2011). The expression of three VT receptors, VT1R, VT3R, and VT4R (V1a), has been reported in the brain of white-throated sparrows and zebra finches (Leung et al., 2011), and expression is high in regions associated with behavioral effects. The stimulatory effect of AVT on the release of avian ACTH is mediated by the VT2R, these being expressed on corticotrophs (Jurkevich et al., 2005). Surprisingly, in view of its negative feedback effect, administration of corticosterone to chickens increases both the expression of VT2R and VT2R immunoreactivity (Sharma et al., 2009). Expression of VT2R in the chicken anterior pituitary gland is increased by water deprivation or testosterone administration (Sharma and Chaturvedi, 2011). The VT3 receptor is expressed in the myometrium of the shell gland of reproductive Japanese quail (Srivastava et al., 2010).

23.10.3 Actions of MT

There is less information on the physiological role of MT in birds. While there are no changes in circulating concentrations of MT at the time of oviposition (Nouwen et al., 1984; Koike et al., 1988), MT potentiates the stimulatory effect of AVT on oviposition in laying hens by effects on AVT binding to the uterus (Takahashi and Kawashima, 2008a). Binding of mesotocin to receptors in the uterus is reported in the laying hen (Takahashi and Kawashima, 2008b). MT does not appear to influence the major cardiovascular indices of arterial blood pressure or heart rate. MT does influence blood flow to some organs (as indicated by reduced temperature of the shank and comb) (Robinzon et al., 1988b). In addition, MT infusion reduces circulating concentrations of aldosterone (Robinzon et al., 1988b).

23.10.4 Behavioral Effects of Mesotocin and AVT

Mesotocin and AVT, produced and acting within the brain, appear to influence behaviors such as bonding in birds. Administration of an oxytocin antagonist increased the latency to pair bonding and decreased pair bonding in zebra finches (Pedersen and Tomaszycki, 2012). The sociability of female zebra finches is reduced by infusions of an oxytocin antagonist into the septum (Goodson et al., 2009). There appears to be a link with flocking behavior, with a flocking- and winter-associated increase in mesotocin in the dorsal lateral septum (LS) and medial amygdala of field sparrows but not in territorial year-round song sparrows (Goodson et al., 2012). When turkey hens incubating eggs are exposed to young poults, there is c-fos mRNA expression of mesotocin-containing neurons in the nucleus paraventricularis magnocellularis (PVN) and nucleus supraopticus, pars ventralis (SOv) (Thayananuphat et al., 2011). Intracerebroventricular injection of an oxytocin agonist reduces brooding behavior when turkey hens incubating eggs are exposed to poults (Thayananuphat et al., 2011).

23.10.5 Control of AVT and MT Release

Table 23.4 summarizes the effects of factors that influence circulating concentrations of AVT. The release of AVT and MT is under independent control. For instance, heat stress increases plasma concentrations of AVT and depresses those of mesotocin (Wang et al., 1989).

23.10.5.1 Control of AVT Release Related to Renal Functioning

AVT is released when blood osmolality is high (see Table 23.4) and to prevent water loss. Frequently, conditions where blood osmolality is increased also reduce blood volume. The release of AVT is under osmotic rather than volemic control (Stallone and Braun, 1986). In the chicken, plasma concentrations of AVT are depressed by angiotensin-2, with the effects presumed to be direct on the neurohypophysis due to the presence of angiotensin receptors that, in turn, are reduced prior to oviposition (Takahashi et al., 2011).

23.10.5.2 Control of AVT Release Related to Oviposition

At the time of oviposition, circulating concentrations of AVT are greatly increased (Sturkie and Lin, 1966; Nouwen et al., 1984; Koike et al., 1988). In laying chickens, prostaglandin $F_2\alpha$ increases plasma concentrations of AVT (Shimada et al., 1987), with a decrease in prostaglandin $F_2\alpha$ receptors in the neurohypophysis (Takahashi and Kawashima, 2008c).

The pars nervosa is the most likely source of AVT at the time of oviposition, but ovarian AVT may contribute. Follicular AVT levels decline immediately prior to oviposition (Saito et al., 1990).

There are also links with the pars nervosa and the ovary–oviduct. There is estrogen binding in the membrane fraction of the chicken neurohypophysis, with decreased binding prior to oviposition (Takahashi and Kawashima, 2009). Either estrogen or progesterone can decrease prostaglandin $F_2\alpha$ receptors in the neurohypophysis (Takahashi and Kawashima, 2008c, 2009).

Not surprisingly, with the large changes in calcium fluxes during egg shell deposition, there is cross-talk between calcium control and oviposition. There are calcitonin receptors in the hen neurohypophysis and preoptic area of the hypothalamus, with changes prior to oviposition (increased affinity and decreased capacity) (Nakayama et al., 2010, 2011b,c). Estrogen decreases CT receptor binding in the hen neurohypophysis (Nakayama et al., 2011d).

23.10.6 AVT and MT Expression

MT is expressed in cell bodies in the paraventricular nucleus, specifically the parvocellular, magnocellular, and periventricular subgroups (chicken: Barth et al., 1997). Some cell bodies express both MT and AVT (Barth et al., 1997). AVT is expressed in cell bodies in the supraoptic nucleus and specifically the ventral and external subgroups (chicken: Barth et al., 1997). Expression of the AVT gene is increased both at the time of oviposition (Japanese quail: Seth et al., 2004a; chicken: Seth et al., 2004b) and with water deprivation (Japanese quail: Seth et al., 2004a). Water deprivation increases the number of neurons containing AVT immunoreactivity (Japanese quail: Seth et al., 2004a).

TABLE 23.4 Factors Influencing Circulating Concentrations of AVT in Birds

Physiological Factor	Chicken	Duck	House Sparrow (*Passer domesticus*)
Oviposition	↑↑	–	–
Water deprivation	↑	↑	↑
Angiotensin	↑	→	–
Hemorrhage	↑	↑	–
Sodium chloride loading	↑	↑	–
Anesthesia	↓	–	–

Based on Scanes (2000).

Chapter 24

Thyroids

F.M. Anne McNabb and Veerle M. Darras
Department of Biological Sciences, Virginia Tech, Blacksburg, VA, USA
Department of Biology, Katholieke Universiteit Leuven, Leuven, Belgium

24.1 ANATOMY, EMBRYOLOGY, AND HISTOLOGY OF THYROID GLANDS

Avian thyroid glands are paired, well-vascularized, oval glands located ventrolaterally to the trachea, and caudal to the junction of the subclavian and common carotid arteries (Figure 24.1). The histology and ultrastructure of avian thyroids (French and Hodges, 1977; Astier, 1980) are like those of other vertebrate classes. Avian thyroids contain follicles of epithelial cells that surround a colloid-filled lumen. The colloid contains thyroglobulin, the thyroid hormone–containing protein, which provides for large extracellular stores of hormone. Such extracellular hormone storage is unique to the thyroid and is considered an adaptation to the scarcity of the trace element iodine, a key component of thyroid hormones (for a review: see McNabb, 1992). Calcitonin cells, which are parafollicular in mammals, are lacking in the avian thyroid; they are contained in separate ultimobranchial organs (see Chapter 25 by Dacke et al.).

The thyroid gland, which arises from the ventral pharyngeal wall in vertebrates, appears very early (e.g., day 2 of the 21 day incubation in chicken embryos). This mass of epithelial cells is initially attached to the pharynx, but then detaches, and the thyroid glands assume their mature positions (by day 5). Follicle formation is initiated by midincubation and proceeds rapidly, along with functional maturation of the gland during the first half of embryonic life and establishment of hypothalamic–pituitary control in the latter half of embryonic life in precocial galliform birds. In contrast, in altricial ring doves, although some follicles appear early, little more follicular organization occurs during embryonic life, and most histological and functional development and control occur after hatch (reviews: Wentworth and Ringer, 1986; McNabb, 1992). In recent years, there have been significant advances in understanding both the intrinsic and extrinsic signals involved in the early steps of thyroid gland development. Although most of these studies have used mammalian models, investigations of a few specific aspects of this signaling in chicken embryos suggest general agreement with the more detailed information about thyroid developmental control in mammals (review: De Felice and Di Lauro, 2011). Study of the details of gene expression for most of the key components of thyroid gland function throughout embryonic life of chicken embryos has recently shown how thyroidal synthesis and release of thyroxine (tetraiodothyronine; T_4) are responsible for the increases in circulating T_4 during the latter half of incubation and during the perihatch period (Grommen et al., 2011).

24.2 THYROID HORMONES

24.2.1 Synthesis, Release, and Circulating Concentrations of Thyroid Hormones

In birds, as in other vertebrates, both T_4 and triiodothyronine (T_3) are considered thyroid hormones (Figure 24.2). Overall, investigations of avian thyroid function indicate that the mechanisms of hormone synthesis and release by avian thyroids are essentially equivalent to those in mammals (review: McNabb, 1992). Iodide is transported into the thyroid gland from the blood by a sodium-dependent iodide (Na-I) symporter, and another transporter, pendrin, is involved in transporting iodide from the follicle cells into the colloid (review on mammalian iodide transport: Bizhanova and Kopp, 2009). The effects of perchlorate on avian thyroids in several species suggest equivalency of Na-I symporter activity in birds to that in mammals and the few other vertebrates in which iodide transport has been studied (McNabb et al., 2006). The avian thyroid contains extremely high iodide concentrations and has prolonged iodide retention. Although avian thyroidal iodide can be influenced by extremes of iodide availability, circulating thyroid hormones and thyroid gland hormone content are well regulated over a wide range of iodide intakes in adult animals. Embryos and chicks also show a considerable amount of iodide regulation, although this is less than in adults (McNabb et al., 1985a,b; Stallard and McNabb, 1990).

Thyroid hormone synthesis begins with the iodination of tyrosine residues contained in thyroglobulin, the hormone storage protein of the colloid. Thyroglobulin is produced on ribosomes of the endoplasmic reticulum of follicle cells, carbohydrate components are added in the reticular lumen, further modifications and additions occur in the Golgi apparatus, and then the thyroglobulin is transported by vesicles to the apical cell border and extruded into the colloid by exocytosis. Iodination of the tyrosines in thyroglobulin requires the action of thyroid peroxidase and an oxidized form of iodide, and leads to the formation of monoiodotyrosines (MITs) and diiodotyrosines (DITs) within the thyroglobulin. These are coupled by thyroid peroxidase to yield the hormonal thyronines, T_4 (DIT + DIT) and T_3 (DIT + MIT). Hormone release from the thyroid involves endocytosis of droplets of colloid by the follicle cells, their fusion with lysosomes, digestion of thyroglobulin by lysosomal enzymes, and release of T_4 and T_3 into capillaries at the external surface of the follicle cells (review: McNabb, 1992).

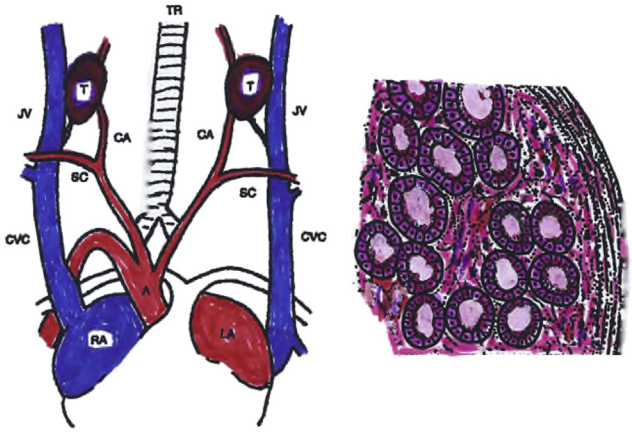

FIGURE 24.1 Avian thyroid glands. Left: ventral view of the general position of avian thyroids. In chickens, the right thyroid gland is more posterior than the left thyroid. A, aorta; CA, common carotid artery; CVC, cranial vena cava; JV, jugular vein; LA, left atrium; RA, right atrium; SC, subclavian artery; T, thyroid gland; TR, trachea. Right: diagram of part of a histological section through an avian thyroid gland, as seen with hematoxylin and eosin staining. Shown are follicles of various sizes, consisting of cuboidal cells (characteristic of a euthyroid state), surrounding a colloid-filled lumen. Part of the connective tissue capsule of the gland is shown on the right. The interstitial regions between the follicles contain blood vessels, nerves, and loose connective tissue.

In adult birds with adequate iodide intake, the thyroidal hormone content consists of primarily T_4, with lesser or undetectable amounts of T_3. When iodide is limiting, the T_3:T_4 ratio is increased and total hormone stores are decreased. Thyroid hormone secretion rates (TSRs), measured by a number of methods, are in the range of 1–3 μg T_4/100 g of body weight per day in chickens, quail, and pigeons. Cold temperatures increase the TSR, whereas iodide deficiency and aging tend to decrease the TSR (review: Wentworth and Ringer, 1986). As in other vertebrates, most control of thyroid function is by the hypothalamic–pituitary–thyroid (HPT) axis (see Section 24.3).

In embryos, the capability for hormone synthesis precedes organization of the thyroid gland into follicles. In precocial chicken embryos, thyroidal iodide concentration and some hormone production occur during the first one-fourth

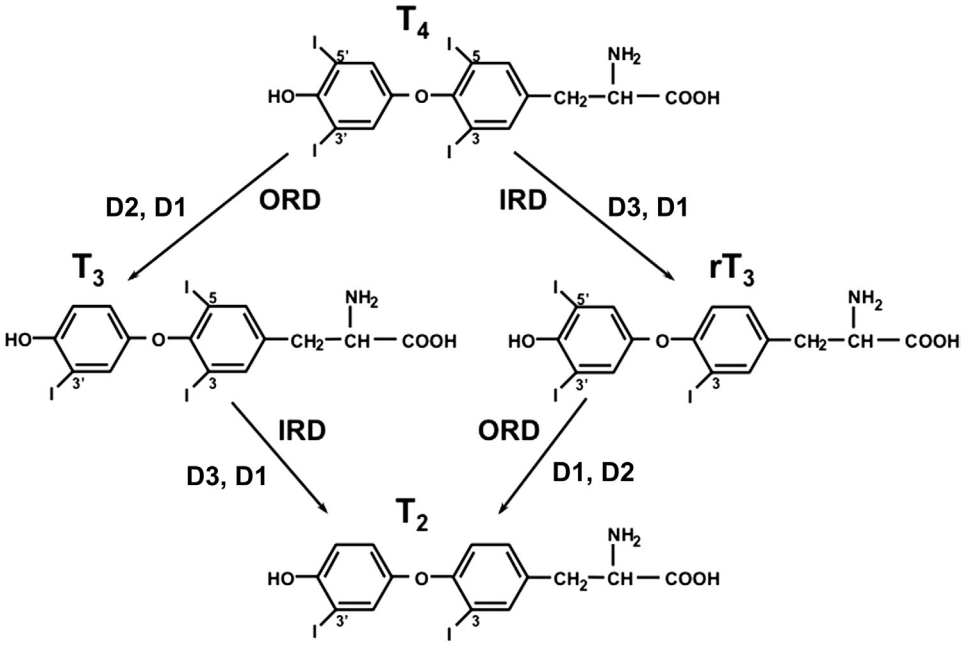

FIGURE 24.2 Thyroid hormones and their deiodination pathways leading to thyroid hormone activation and inactivation. T_4, 3,5,3′,5′-tetraiodothyronine or thyroxine; T_3, 3,5,3′-triiodothyronine; D1, type 1 deiodinase; D2, type 2 deiodinase; D3, type 3 deiodinase; IRD, inner ring deiodination; ORD, outer ring deiodination; rT_3, 3,3′,5′-triiodothyronine; T_2, 3,3′-diiodothyronine.

to one-third of incubation, but in altricial ring doves these events occur about midincubation (review: McNabb et al., 1998). Historically, circulating thyroid hormones were first measured as protein-bound iodine, then by competitive binding assay, then by radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA), and most recently by liquid chromatography and mass spectrometry. Hormone measurements by RIAs and ELISAs account for the vast majority of the data in the literature since the late 1970s.

Concentrations of T_4 exceed those of T_3 in avian plasma by several-fold, although this ratio is much lower than in the thyroid gland. Adult birds of many species have plasma or serum T_4 concentrations in the range of 5–15 ng T_4/mL (6–19 pmol/mL) and T_3 concentrations in the range of 0.5–4 ng T_3/mL (0.7–1.5 pmol/mL). In comparison with mammals, avian plasma contains less T_4 (i.e., often 10-fold less) but similar concentrations of T_3 (McNabb, 2000). Circulating concentrations of both hormones have been measured in many avian species, but generalizations about species differences should be made with care because of technique differences and the many factors that influence thyroid status (e.g., food availability, seasonality, breed, age, and time of day).

Diurnal patterns of plasma thyroid hormones are readily demonstrated in birds. Plasma T_4 rises and peaks during the dark period, and plasma T_3 rises and is highest during the light period, reflecting the timing of highest extrathyroidal conversion of T_4 to T_3 during light. Patterns of food intake are a key factor influencing peripheral T_3 production and degradation and patterns of plasma thyroid hormones. Temperature also may be important; cold temperatures increase and warm temperatures depress plasma T_3 within these diurnal patterns. In general, temperature effects on plasma T_4 are opposite to those on T_3, although the T_4 effects are more complex (reviews: Cogburn and Freeman, 1987; Decuypere and Kühn, 1988; Sharp and Klandorf, 1985).

Circulating thyroid hormones in vertebrates are transported by binding proteins that maintain extrathyroidal hormone stores and help regulate hormone availability to the tissues. However, knowledge of free hormone concentrations alone is not sufficient to understand hormone entry into different tissues under different conditions (see Section 24.2.3 on hormone transport into tissues). The major thyroid hormone–binding proteins in birds are transthyretin, which is high affinity and low capacity, and albumin, which is low affinity and high capacity. Birds lack the very-high-affinity T_4-binding protein, thyroxine-binding globulin (TBG), which is present in the blood of large mammals. Several studies in birds suggest that binding proteins modulate the picture of thyroid hormone availability, for example during development and in the diurnal cycle (review: McNabb, 2000). Transthyretin, which is produced in the choroid plexus and liver of birds, has been characterized in several avian species and compared functionally with that in other vertebrates. Avian transthyretin has higher binding affinity for T_3 than T_4, the opposite of the binding pattern in mammals (Chang et al., 1999; Schreiber, 2002).

The ontogenic pattern of plasma thyroid hormones differs in birds with precocial versus altricial development. In precocial species, in which thyroid gland function and its control mature before hatching, plasma T_4 rises several-fold during the latter half of embryonic life but plasma T_3 remains low. During the perihatch period, both hormones rise dramatically to reach some of the highest concentrations that have been measured in avian plasma. This pattern is consistent among precocial galliform birds (McNabb et al., 1998) and in precocial mallard ducks (McNabb et al., 2006). The perihatch peaks in thyroid hormones are associated with the initiation of thermoregulatory responses to cooling and pulmonary respiration that occur in precocial species during this time. After the perihatch peak, plasma thyroid hormones decrease markedly, then gradually increase during posthatch life to reach adult concentrations. In altricial species from two avian orders (columbiform ring doves, and passeriform European starlings and redwing blackbirds), plasma concentrations of T_3 and T_4 are very low during embryonic life and the perihatch period, then gradually increase during the first 2–3 weeks posthatch to approach adult levels. Endothermic responses to cooling first appear several days to a week after hatching in these altricial birds, and the young are only homeothermic by the time of fledging (reviews: McNabb and Olson, 1996; McNabb et al., 1998).

24.2.2 Mechanism of Action of Thyroid Hormones

In birds, as in other vertebrate classes, many thyroid hormone actions are mediated through nuclear thyroid hormone receptors that are members of the nuclear receptor superfamily (a large group of hormone receptors that have similar domain structures). Thyroid hormone receptors, generally referred to as T_3 receptors because of their high affinity for T_3, are responsible for the transcriptional effects of thyroid hormones (i.e., the receptors are transcription factors that act on thyroid hormone–responsive genes; Figure 24.3). Thus, with respect to transcriptional effects, T_4, the predominant hormone released from the thyroid, is considered to be mainly a prohormone. The direct responses mediated by thyroid hormones are of two types, developmental and metabolic (see Sections 24.4.1 and 24.4.2), but there also are indirect or permissive effects of thyroid hormones as well as interactive effects with other hormones.

Thyroid receptors (TRs) in vertebrates are coded for by two genes, thyroid hormone receptor-alpha (*THRA*) and -beta (*THRB*), that generate a number of receptor isoforms with high affinity for T_3 (e.g., TRα1, TRβ1, TRβ2,

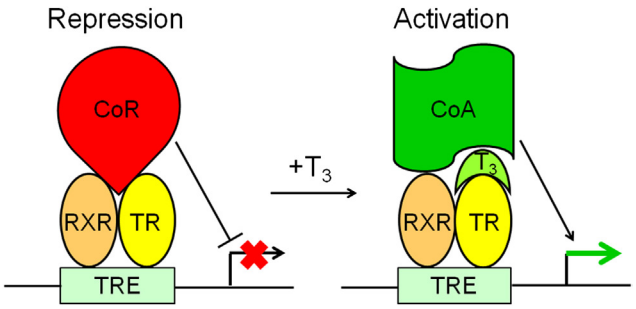

FIGURE 24.3 Thyroid hormone mechanism of action resulting in gene repression in the absence of T_3 and activation of gene transcription in the presence of T_3. CoA, co-activators; CoR, co-repressors; RXR; retinoic X receptor; TR, thyroid hormone receptor; TRE, thyroid hormone response element; T_3, 3,5,3′-triiodothyronine.

and TRβ3 in mammals, although the number and type of isoforms differ among vertebrate classes). The *THRA* gene also produces messenger RNAs (mRNAs) that can result in inhibitory effects on thyroid hormone action. In general, the TRα gene is expressed ubiquitously, although in avian brain it may vary during development. TRβ expression is restricted to fewer tissues and characteristically is regulated developmentally (reviews: mammals, Flamant et al., 2006; Cheng et al., 2010; birds, Decuypere et al., 2005; Grommen et al., 2008; Darras et al., 2011). In addition to T_3 (ligand) binding to the receptors, further regulation of transcription can result from differences in the hormone response elements located on the promoters of T_3 target genes, from differences in tissue receptor concentrations, from differences in developmental expression of receptor isoforms, and by effects of co-regulatory proteins in the nucleus. When TRs are not bound by T_3, co-regulatory proteins inhibit and repress the transcription of positively regulated thyroid-responsive genes; when TRs are bound to (i.e., occupied by) T_3, transcription is stimulated (Figure 24.3). The details of the molecular actions of thyroid hormones are best understood in mammals (review: Cheng et al., 2010). To the extent that receptor-mediated thyroid hormone actions have been investigated in birds, there is considerable similarity with mammals (Decuypere et al., 2005; Darras et al., 2011). The extent of receptor binding of T_3 (i.e., binding saturation) depends largely on deiodination reactions that supply T_3 to the circulation and play differential roles in intracellular T_3 (see Section 24.2.4) and on transport molecules that control hormone movement into specific tissues (see Section 24.2.3). In addition, other hormone degradation pathways play a role in intracellular T_3 availability.

Thyroid hormones also have effects through nongenomic actions at plasma membranes, in cytoplasm, and in mitochondria (i.e., these actions do not result from TR binding in the nucleus). These effects have only been investigated at the molecular level in mammals (Cheng et al., 2010; Scapin et al., 2010). However, one category of these nongenomic actions, thyroid hormone effects on thermogenesis, has received extensive attention at the organismal level in birds as well as mammals for decades (see Section 24.4.2).

Differences in the regulation of the different receptor isoforms in target tissues, as in mammals, have been demonstrated in birds by altering thyroid status with a goitrogen (methimazole) or by methimazole plus hormone supplementation. Hypothyroidism, sufficient to decrease growth and several developmental markers in ducklings, did not affect TRα mRNA but did result in a decrease in TRβ0 (presumed to be homologous to TRβ1) in some but not all muscles analyzed. Hyperthyroidism did not alter TRα mRNA but increased TRβ0 mRNA in cardiac, leg, and pectoralis muscles above that in euthyroid controls (Bishop et al., 2000). Developmental regulation of TR mRNA in the avian brain and pituitary has been demonstrated (review: Darras et al., 2011). TRβ2 is abundantly expressed in the pituitary, where it is thought to be important in feedback regulation (Grommen et al., 2008; and see Section 24.3).

24.2.3 Cellular Uptake of Thyroid Hormones

Since thyroid hormones are quite lipophilic, it was generally assumed that they cross the plasma membrane simply by passive diffusion. However, studies in rat hepatocytes already showed, in the late 1970s, that T_4 and T_3 enter the cell at least partly by active transport and via separate transport systems (Krenning et al., 1978, 1981). It took 30 more years before the first thyroid hormone transporter proteins were identified (Friesema et al., 2001, 2003), but we now know that several transmembrane proteins facilitate the transport of thyroid hormones in and out of cells. These proteins belong to the families of the monocarboxylate transporters (MCTs), the Na-taurocholate co-transporting polypeptides (NTCPs), the Na-independent organic anion-transporting polypeptides (OATPs), and the L-type amino acid transporters (LATs).

In humans and rodents, the transporters showing the highest specificity toward thyroid hormones are OATP1C1, which preferentially transports T_4 (and rT_3), and MCT8 and MCT10, which efficiently transport T_4 and T_3 (reviews: Friesema et al., 2005; Visser et al., 2008, 2011). So far, only one avian thyroid hormone transporter has been fully characterized, namely, chicken OATP1C1 (*SLCO1C1*). As in mammals, it is a highly specific transporter for T_4 (Nakao et al., 2006). Other transporters that are expressed in chicken are MCT8 (*SLC16A2*), MCT10 (*SLC16A10*), and LAT1 (*SLC7A5*), but they still need to be functionally characterized. These transporters are already present in the embryo, where they regulate thyroid hormone uptake in developing tissues, including brain (Geysens et al., 2012; Van Herck et al., 2012). In the adult quail hypothalamus, OATP1C1 is believed to be involved in the thyroid hormone–dependent stimulation of seasonal reproduction (Nakao et al., 2006; and see Chapter 34).

24.2.4 Thyroid Hormone Activation and Degradation

Once secreted by the thyroid gland, thyroid hormones can be metabolized in peripheral tissues by different pathways. Oxidative deamination and decarboxylation of the alanine side chain, as well as ether link cleavage, lead to irreversible degradation of the hormones. Sulfation and glucuronidation of the phenolic hydroxyl group are reversible processes that facilitate hormone solubility and subsequent excretion. The most important pathway, however, is deiodination consisting of removal of a single iodine from the phenolic outer ring (5′D or ORD) or from the tyrosyl or inner ring (5D or IRD) (Figure 24.2), processes catalyzed by enzymes called iodothyronine deiodinases. Since the avian thyroid gland secretes predominantly T_4, most of the T_3 present in the circulation and peripheral tissues is derived from extrathyroidal ORD of T_4.

The first direct proof for peripheral T_4 to T_3 conversion in birds was obtained in 1978 in Peking ducks (Astier and Newcomer, 1978). As for mammals, biochemical characterizations of deiodinating activities in birds first used liver homogenates from chickens (Borges et al., 1980; Rudas, 1986), quail (McNabb et al., 1986), and ring doves (Rieman and McNabb, 1991), and this was later extended to other tissues such as kidney, intestine, and brain. These studies suggested the presence of three types of deiodinases in birds (review: Darras et al., 2006) with activities very similar to those observed in mammalian tissues (review: Bianco et al., 2002). Cloning of the three chicken deiodinases D1 (*DIO1*), D2 (*DIO2*), and D3 (*DIO3*) finally confirmed their high homology with the mammalian homologs (Gereben et al., 1999; Van der Geyten et al., 1997). Partial information on deiodinase sequences also is available for some other avian species, including turkey, quail, tree sparrow, and zebra finch. It also is clear by now that the structures and functions of iodothyronine deiodinases have been strongly conserved throughout vertebrate evolution (reviews: Darras and Van Herck, 2012; Orozco et al., 2012).

All avian deiodinases are selenoproteins with a selenocysteine in their catalytic site. Therefore, they depend on the presence of a selenocysteine insertion sequence (SECIS) element in the 3′ untranslated region of their mRNA to allow selenocysteine incorporation (Bianco et al., 2002). The D1 enzyme is a nonselective enzyme catalyzing both ORD and IRD. In contrast, D2 only catalyzes ORD, while D3 only catalyzes IRD and is a purely inactivating enzyme (Figure 24.2). D1 is highly expressed in avian liver, kidney, and small intestine and contributes to peripheral T_3 production and rT_3 degradation. D2 is predominantly expressed in brain, where it is important in the local conversion of T_4 (that has entered the brain) to T_3. D3 is found in variable amounts in almost all chicken tissues and is believed to protect cells from overexposure to T_3 in specific situations such as early development, disease, and starvation (review: Darras et al., 2006).

Deiodinases play important roles in the pattern of circulating thyroid hormones during the perihatch period in precocial birds. D3 expression is particularly high in embryonic chicken liver. The sharp decline in hepatic D3 activity in the last days before hatching is the major factor contributing to the perihatch peak in circulating T_3 (Darras et al., 1992; Galton and Hiebert, 1987). At the level of the brain, the increase in T_3 content around hatching is facilitated by the enhanced local T_4 to T_3 conversion by D2 (Darras et al., 2009).

24.3 HYPOTHALAMIC–PITUITARY–THYROID AXIS

The avian thyroid gland is primarily under the control of the hypothalamic–pituitary axis. The avian hypothalamus produces two hormones (thyrotropin-releasing hormone (TRH) and corticotropin-releasing hormone (CRH)) that have stimulatory effects and somatostatin that has inhibitory effects on the thyrotrophs in the anterior pituitary. They produce thyroid-stimulating hormone (TSH, or thyrotropin), which is the major controller of the production and release of thyroid hormones by the thyroid gland. Thyroid hormones in turn exert a negative feedback on the pituitary and hypothalamus.

Historically, avian HPT axis control, based on investigations of chickens, appeared to be very similar to that in mammals (Decuypere and Kühn, 1988). The structure of TRH, a tripeptide, is identical in all vertebrates, and many studies have demonstrated that exogenous TRH could stimulate TSH release from the chicken pituitary. More recently, studies in birds, amphibians, reptiles, and fish have shown that CRH, rather than TRH, is often the most important hypothalamic stimulator of pituitary TSH in nonmammalian vertebrates. The most important role of TRH in influencing thyroid function in birds now appears to be through its growth hormone (GH)-releasing action, which results in circulating T_3 increases through growth hormone inhibition of T_3 degradation by type 3 deiodinase (review: De Groef et al., 2006; and see Sections 24.2.4 and 24.5).

The structure of TSH, which is a glycoprotein, differs in its β chain in different vertebrate classes, but several heterologous TSHs stimulate thyroid function in birds. The lack of antibodies specific to avian TSH meant that much of the background understanding of the development of TSH control was based on studies that used antibodies to heterologous TSHs. During development, the establishment of HPT axis control over the thyroid gland occurs about mid incubation (embryonic days 10.5–11.5) in precocial chickens. Pituitary removal by embryonic decapitation on day 9.5 does not alter plasma T_4 until day 11.5, but prevents the plasma T_4 increase that occurs after day 11.5. These

findings suggest that sufficient TSH is produced to establish HPT control of the thyroid on day 11.5 but that prior thyroid gland development must be autonomous (review: Thommes et al., 1988). Identification of the presence of TSHβ peptide and mRNA at this same stage in embryonic development has provided highly specific confirmation of these findings (Ellestad et al., 2011). Maturation of the feedback response of pituitary thyrotrophs has been confirmed by embryonic day 19 by demonstrating that goitrogen suppression of circulating T_4 stimulates increased TSHβ mRNA (Muchow et al., 2005). Likewise, T_4 feedback on somatostatin inhibition of TSH production also matures between day 19 and hatch (De Groef et al., 2007). Studies on ring doves suggest that in altricial species, pituitary control of the thyroid appears to be established after hatch. In this species, the thyroid is insensitive to exogenous TSH until the second day posthatch, and circulating thyroid hormones remain very low, then gradually increase, during the first 3 weeks posthatch. Studies of the circulating thyroid hormone patterns in other altricial species (red-winged blackbirds and starlings) show patterns consistent with this developmental pattern (review: McNabb, 2007).

The effects of environmental and external factors (e.g., temperature and food consumption) on thyroid function are mediated largely through the HPT axis. Increased thyroid gland size and changes in thyroid secretion rate provide evidence of increased pituitary TSH release during cold exposure or winter conditions, and heat exposure has the opposite effect (review: Wentworth and Ringer, 1986). The picture of temperature effects on circulating thyroid hormones is complex, because in addition to the thyroid secretion rate, deiodination and other reactions involved in hormone turnover play a role (see Section 24.2.4). For the role of thyroid hormones in stimulating thermogenesis, see Section 24.4.2. The effects of food consumption, food restriction, and starvation have received extensive study in chickens and have been important to the understanding of GH involvement in HPT axis control and the metabolic effects of differences in food consumption (see Section 24.4.2).

24.4 EFFECTS OF THYROID HORMONES

24.4.1 Thyroid Hormone Effects on Development

Thyroid hormones influence both aspects of avian development (i.e., growth and differentiation–maturation). Growth (i.e., increase in mass) involves primarily cell proliferation (hyperplasia), but also may result from increases in cell size (hypertrophy). In general, thyroid hormones appear to act permissively or indirectly, in concert with other control substances, in their stimulation of growth in birds (review: McNabb and King, 1993). The primary direct hormonal stimulation of body growth results from circulating growth factors (such as insulin-like growth factor-1 (IGF1)) that are primarily under the control of GH from the pituitary (see Chapter 22).

The need for thyroid hormones for normal growth of birds has been demonstrated by the reduced growth, associated with hypothyroidism, that results from thyroidectomy or goitrogen administration. However, within the physiological range of circulating thyroid hormone concentrations, there is little consistent evidence of thyroid hormone stimulation of general body growth. At hyperthyroid extremes, growth is depressed because of high metabolic rates and a shift toward catabolism (reviews: McNabb and King, 1993; McNabb, 2000).

Thyroid hormones are important in triggering differentiation and maturation processes in many tissues. In mammals, their roles in development have been extensively studied in the gastrointestinal tract, heart, skeletal muscle, skin, bone, and neural tissue (reviews: McNabb, 1992; Pascual and Aranda, 2013). They are known to be crucial for development of the brain, eye, and ear (reviewed, respectively, in Bernal, 2007; Forrest and Swaroop, 2012; Rusch et al., 2001).

The information available on birds suggests similar roles for thyroid hormones in the development of avian tissues. In chicken TRα is expressed in neuroectoderm from the start of development, and receptor expression increases during neurulation (Flamant and Samarut, 1998). Thyroid hormones are present in the early embryonic brain, and transporters, deiodinases, and TRs show a dynamic and region-specific expression pattern throughout embryonic development (reviews: Darras et al., 2009; Forrest et al., 1991; Van Herck et al., 2012). Thyroid hormones are necessary for the development of normal brain architecture and neuronal connections critical to the function of signaling networks, as shown, for instance, in chicken cerebellum (Bouvet et al., 1987; Verhoelst et al., 2004). They stimulate the maturation of photoreceptors in the chicken retina (Fischer et al., 2011) and probably are involved in development of the inner ear (Geysens et al., 2012). Thyroid hormones also are essential for early learning, since they determine the start of the sensitive period for filial imprinting and may prime the brain for later learning (Yamaguchi et al., 2012).

In several tissues, the stimulation of differentiation–maturation by thyroid hormones involves interaction with other hormones. In chicken embryonic gut, thyroid hormones alone can stimulate cellular differentiation and induce digestive enzymes, but combination with glucocorticoids is necessary for the maturation of intestinal glucose transport (review: McNabb et al., 2006). Skeletal muscle differentiation and growth require both GH and thyroid hormones. GH alone seems to be sufficient to increase muscle weight in hypothyroid chickens, but both hormones are needed to reverse the effect on myosin. The appearance of specific myosin isoforms critical to functional maturation

during late embryonic development is also modulated by T_3. Thyroid hormones also interact with IGF1 (e.g., in skeletal development). *In vitro* studies of pelvic cartilages from early chicken embryos have shown that thyroid hormones trigger cartilage differentiation–maturation by stimulating matrix production and ossification. In this case, T_3 stimulates chondrocyte hypertrophy but does not influence cell proliferation, which is only stimulated in the presence of IGF1 (reviews: McNabb and King, 1993; McNabb et al., 2006). *In ovo* exposure to increased levels of maternal T_4 also stimulates pelvic cartilage differentiation in Japanese quail embryos (Wilson and McNabb, 1997).

24.4.2 Thyroid Hormone Effects on Metabolism and Thermoregulation

Thyroid hormones control that part of metabolic, endothermic heat production that maintains the high and constant body temperature in homeothermic birds and mammals as well as additional adaptive changes in seasonal heat production (Danforth and Burger, 1984). The higher endothermic heat production in homeothermic birds and mammals, compared to ectothermic lower vertebrates, involves the uncoupling of aerobic metabolism from energy production as adenosine triphosphate (ATP). Historically, thyroid hormone–stimulated metabolic effects have been well documented in birds, with exogenous thyroid hormones stimulating and thyroidectomy or goitrogen administration depressing avian oxygen consumption (review: Wentworth and Ringer, 1986). Alterations in thyroid hormones also can influence the metabolic energy supply in other ways (e.g., increases in thyroid hormones facilitate liver glycogen storage, and hormone decreases lead to glycogen depletion and decreased plasma glucose).

There are fundamental differences in the regulation of endothermic heat production in mammals and birds. In mammals, brown adipose tissue (BAT), which is specialized for heat production, plays a key role in thermogenesis, but birds do not have BAT, so this thermogenesis must occur in other tissues. In all endotherms, there is uncoupling of the mitochondrial electron transport chain from ATP production, a phenomenon facilitated by anion carrier proteins in the inner mitochondrial membranes. Current evidence suggests that in mammals, uncoupling protein-1 (UCP1) is most important but that in birds the key uncoupling protein is adenine trinucleotide translocase (Walter and Seebacher, 2009), although avian uncoupling protein may play a role through interactions involving the β-adrenergic system (Joubert et al., 2010). Both T_4 and T_3 may play roles in endothermic heat production, and these responses may be nongenomic ones involving T_4 or T_3, or genomic ones resulting mainly from T_3 binding to nuclear TRs. Most of what is known about the nongenomic effects on thermogenesis is based on work in mammals, although there are a few studies in chicken embryos (review: Scapin et al., 2009).

The timing of thyroid development and HPT axis control appears to be critical to the development of thermoregulation in both precocial and altricial birds. Precocial birds, with most HPT axis maturation occurring during late embryonic life, exhibit endothermic responses to cooling during the perihatch period and gain the capability to maintain constant body temperatures (homeothermy) as chicks. Chicken embryos may exhibit some endothermic responses late in incubation. In contrast, altricial birds, with limited HPT axis maturation until several days or more posthatch, develop endothermic responses and homeothermy much more gradually in the weeks after hatch (Section 24.2.1; for a review, see McNabb et al., 1998).

Common to the perihatch period, in birds with both altricial and precocial development, are the initiation of pulmonary respiration, the maturation of those body parts involved in breaking out of the shell, yolk sac retraction, and the metabolic demands of hatching activities. Thyroid hormones are necessary for the maturation of lungs and surfactant production in the initiation of pulmonary respiration, and for a number of aspects of muscle functional maturation (i.e., genomic actions of thyroid hormones; see Sections 24.2.2 and 24.4.1). However, the circulating thyroid hormone concentrations during the perihatch period in altricial and precocial birds are very different, with only precocials showing dramatic increases in thyroid hormones at this time. This argues that the precocial peak of hormones in the circulation is primarily related to the initiation of endothermic responses to cooling (i.e., primarily nongenomic actions) that appear in the perihatch period in precocial but not in altricial species. It also suggests that the other maturational events stimulated by thyroid hormones during the perihatch period involve tissue- and organ-specific actions but do not require high circulating thyroid hormone concentrations. The exact roles of the HPT axis and its interactions with the hypothalamic–pituitary–adrenocortical axis remain to be clarified (Debonne et al., 2008; and see Sections 24.3 and 24.5).

24.4.3 Thyroid Hormone Effects on Reproduction and Maternal Influences on Developing Young

Thyroid hormones are among the factors important to avian reproductive processes, the photoperiodic initiation of reproductive cycles, and the timing of other energy-demanding processes that are timed to not compete with reproduction (e.g., molt). Egg laying is affected by thyroid status; for example, Japanese quail made hypothyroid by goitrogen administration stop laying, whereas at lower goitrogen doses, the hens may be able to maintain circulating thyroid hormones and continue to lay despite HPT axis activation. Because egg thyroid hormone content depends on circulating thyroid hormones in the hen, this indicates that hens may be able to "protect" maternal hormone supply

to eggs for developing embryos to the extent that the hens are able to maintain euthyroid status. Japanese quail hens stopped laying when treated with a methimazole dose sufficient to decrease thyroid function, so they did not produce eggs deficient in thyroid hormones (Wilson and McNabb, 1997). In contrast, in a longer term study of methimazole-induced hypothyroidism in chickens, hens continued to lay despite decreases in their own circulating hormones and produced eggs deficient in maternal hormones and containing methimazole (Van Herck et al., 2013). It is not clear whether there are species differences in the effects of hypothyroidism on laying in chickens versus quail or whether these differences result from differences in the protocols used in these studies.

Both egg iodine and maternal thyroid hormones deposited in eggs influence embryonic thyroid status (review: McNabb and Wilson, 1997) as do many other components of the egg environment (Ho et al., 2011). When egg iodine availability was restricted by extremely low iodine in the diet of Japanese quail hens, egg iodine content was decreased, but adjustments in embryonic thyroid function maintained circulating T_3 concentrations (despite marked decreases in T_4 production), resulting in hatching and early posthatch growth that did not differ from that of controls (McNabb et al., 1985a,b; Stallard and NcNabb, 1990). Further adaptive potential of the thyroid system after hatch is shown by quail chicks that adapt their thyroid function to remain euthyroid despite sustained exposure to perchlorate, a thyroid inhibitor (McNabb et al., 2004; McNabb, 2006). It should, however, be mentioned that circulating thyroid hormone levels should not be assumed to reflect intracellular hormone availability in all target tissues because differences in hormone transport and deiodination capabilities in different tissues create individual local environments with respect to thyroid hormone availability. Few studies have measured tissue hormone content. In a recent study of chicken embryos from methimazole-treated hypothyroid hens, brain hormones were regulated independently of the low circulating hormone concentrations. However, because the hens deposited methimazole in the eggs, possible tissue-specific effects of the methimazole could have added to the complexity of this picture (Van Herck et al., 2013).

Most of the laboratory studies relating to thyroid effects on egg laying, egg components, and hatching have been done on precocial galliform birds (review: Decuypere et al., 1990). However, studies of neuroendocrine control of reproduction in wild birds (reviews: Yoshimura, 2010; and see Chapter 34 in this text) and studies of wild birds exposed to thyroid-disrupting environmental chemicals indicate the need for adequate thyroid function in altricial or semi-altricial species as well (review: McNabb, 2007). For example, historical studies of herring gulls exposed to a range of environmental polychlorinated biphenyl (PCB) concentrations suggest that exposure to this group of thyroid-disrupting chemicals contributes to developmental and hatching problems (reviews: Fox, 1993; McNabb and Fox, 2003; and see Chapter 43 in this text). Lab studies of specific PCBs (Roelens et al., 2005) and of dioxin (Bruggeman et al., 2003) have shown delayed hatching associated with thyroid disruption in chicken embryos.

Thyroid hormones have long been known to be important in postnuptial molt in both wild and domestic birds, and alterations in plasma thyroid hormones occur in conjunction with natural molts (review: Kuenzel, 2003; and see Chapter 39 in this text). Inhibition of reproductive activity (including cessation of egg laying) and molt occur concurrently in seasonally reproducing wild birds, and in commercial poultry practice, thyroid hormones and/or starvation have been used to induce molt in poultry. Prolactin also plays a role in molt, as do several other hormones (review: Kuenzel, 2003). Estrogen decreases appear to be important in the initiation of molt, whereas an increase in the thyroid hormone/estrogen ratio appears to be important in new feather formation (review: Decuypere and Verheyen, 1986).

24.5 THYROID INTERACTIONS WITH OTHER HORMONES

Thyroid hormones play important roles, both direct and indirect, in development, growth, and metabolism (see Section 24.4), and in each of these functions there are interactions with a number of other hormones and hormone systems. Thyroid hormones are required for body growth, but it appears that they act in a permissive or indirect way in conjunction with GH, which influences growth factors that directly stimulate cell proliferation (see Chapter 37). Thyroid hormones modulate GH production and release by the pituitary, by direct inhibition of pituitary somatotrophs, and by negative feedback effects on TRH, which stimulates somatotrophs. However, thyroid hormones also play an important role in stimulating the development of somatotrophs, probably in conjunction with glucocorticoids (Liu and Porter, 2004). This general picture differs from how thyroid function affects the growth axis in mammals, in which T_3 stimulates GH production and release. In birds, GH in turn stimulates thyroid function by increasing circulating T_3 through its inhibitory effects on T_3 degradation by IRD, a key factor in the increases in circulating T_3 concentrations during the perihatch period (see Sections 24.2.4 and 24.4.1).

Interactions between the HPT and other hypothalamic–pituitary control axes are important in several contexts. Hypothalamic TRH exerts some of its thyroid effects through stimulation of GH release and consequent effects on deiodination, while CRH stimulates pituitary thyrotrophs to release TSH, which exerts stimulatory control over the thyroid gland (see Section 24.3). During the perihatch period, glucocorticoids rise, and this may increase

circulating T_3 levels by inhibiting T_3 degradation by type 3 deiodinase and by stimulating T_3 production by type 1 ORD (Darras et al., 1996). Thyroid hormones and glucocorticoids may both have important effects on organ differentiation in lung and gut (see Section 24.4.1). Although these hormonal interactions are conspicuous during the perihatch period, and thus have received considerable attention, they continue to be important in a variety of metabolic and developmental events at other ages. In adults, interactions with the reproductive axis are important, as thyroid hormones are necessary for the initiation and timing of reproductive cycles, and for the laying of viable eggs (see Section 24.4.3).

24.6 ENVIRONMENTAL INFLUENCES ON THYROID FUNCTION

Changes in temperature and food availability appear to be the natural environmental factors that have the greatest influence on thyroid function. As mentioned in this chapter, environmental cold can act through the HPT axis (see Section 24.3) to increase thyroid hormone release, can alter the peripheral thyroid hormone deiodination pathways (see Section 24.2.4), and can increase thyroid hormone turnover (Wentworth and Ringer, 1986). Overall, these changes provide increased thyroid hormone availability in association with the metabolic increases required for homeothermy at cold ambient temperatures. Plasma T_4 concentrations often change relatively little (i.e., proportionately less than T_3 changes) with sustained cold exposure, suggesting that the HPT axis response is less important than changes in deiodination pathways (Rudas and Pethes, 1984). In general, hot temperatures have the opposite effect (i.e., they depress thyroid function) (review: Sharp and Klandorf, 1985). However, as indicated in Section 24.4.2, the nuances of genomic and nongenomic effects on metabolism and the relative roles of T_4 and T_3 in metabolic stimulation have not been fully investigated in birds.

Like temperature change, food availability alters thyroid status. Either food restriction or starvation causes decreases in circulating T_3 concentrations, although the effects on T_4 are more variable (see review in Darras et al., 1995). There are some differences in the details of the thyroid effects and the relative causes of those effects (HPT axis role versus changes in deiodination) with starvation versus food restriction and in different vertebrate classes. In birds, both starvation and sustained partial food restriction lead to decreased circulating T_3 and increased T_4. The primary cause of the decrease in circulating T_3 is increased T_3 degradation by D3 IRD, without changes in T_4-to-T_3 conversion by D1 (Darras et al., 1995). Feeding, by increasing circulating T_3, appears to be one of the key factors that play a role in the diurnal patterns of plasma thyroid hormone concentrations (see Section 24.2.1). Likewise, it may be an important factor in some temperature-induced changes in thyroid hormone; for example, the depressed plasma T_3 concentrations in chickens exposed to 40 °C heat may result largely from the decreased food consumption at high temperatures (Williamson et al., 1985).

In addition to natural environmental events, endocrine-disrupting chemicals in the environment play a role in the thyroid function of birds exposed to such chemicals. A brief treatment of some examples is included in this chapter for the purpose of providing links to the more comprehensive coverage of endocrine disruptors in Chapter 43. Historically, large amounts of some persistent industrial chemicals, such as PCBs, that appeared to be thyroid disruptors were released into major bodies of water such as the Great Lakes. Major monitoring efforts in the Great Lakes, since the late 1960s when PCBs were last released, have provided circumstantial evidence that total PCB exposure in herring gulls, which are fish eating and experience bioaccumulation of such chemicals, results in population declines and thyroid disruption (Fox, 1993). Studies of thyroid function in gull embryos collected in 1998–2000 suggest that embryonic thyroid disruption, from the persistent environmental PCBs, continued at the most contaminated sites compared to the reference sites (McNabb and Fox, 2003). More recent studies have explored how commonly used PCB mixtures, such as Aroclor 1254, affect thyroid function through altering a key enzyme system (uridine diphosphate-glucuronosyltransferase (UDP-GT)) that increases T_4 clearance (Webb and McNabb, 2008) and how specific PCB isomers, such as the dioxin-like PCB77, induce changes in deiodinase patterns, resulting in decreases in plasma thyroid hormone concentrations (Beck et al., 2006). Thyroid hormone binding by transthyretin also is affected by PCBs (see reviews in Ishihara et al., 2003; Scanes and McNabb, 2003). Thus, PCBs affect thyroid function through a number of mechanisms, and understanding of their effects is further complicated by the large number of congeners and mixtures present in the environment.

Perchlorate compounds, which have been used as experimental goitrogens, also are environmental contaminants in many regions, so they affect thyroid function in animals exposed through drinking water or food sources. The primary effect of perchlorate ion is to competitively inhibit iodide uptake by the Na-I symporter in the thyroid, creating iodine deficiency and the consequent effects on thyroid function. There also is building evidence that perchlorate has additional effects within the thyroid and on HPT axis function. Most of what is known about perchlorate effects in birds comes from laboratory studies that include environmentally relevant perchlorate exposures (review: McNabb et al., 2006). Perchlorate-exposed quail hens transfer perchlorate to their eggs, where embryos may become hypothyroid and exhibit thyroid hypertrophy, decreased thyroidal hormone content, decreased body growth, delayed hatching, increased mortality, and some associated alterations

in thyroid-responsive gene expression (Chen et al., 2008). Similar effects were observed in quail chicks exposed to perchlorate in drinking water (Chen et al., 2009). In both cases, the deiodinase responses appeared to "protect" T_3 supply to the brain but not the liver under hypothyroid conditions.

Other categories of environmental thyroid-disrupting chemicals that have received attention in recent years are those used as flame retardants (polybrominated diphenyl ethers (PBDEs)), those employed as nonstick coatings for cookware (perfluoroalkyl compounds (PFCs)), and bisphenol A, which is used in plastics and food can liners. These materials are widespread, persistent contaminants that are present in wild birds and have been shown to alter thyroid function. Flame retardants have been found in avian populations worldwide and have been shown to alter thyroid function in domestic galliform birds, model passerine species, and wild-caught kestrels and bald eagles (respectively, chickens: Farhat et al., 2013; zebra finches: Eng et al., 2013; kestrels: Fernie et al., 2005; eagles: Cesh et al., 2010). PFCs also have been shown to alter thyroid function in birds (Vongphachan et al., 2011; Cassone et al., 2012). Bisphenol A, which can act as a thyroid hormone analog for binding to TR (Zoeller, 2005), alters thyroid function in a number of animal species but does not appear to have been investigated in birds except with respect to reproductive disruption.

24.7 CONCLUSIONS AND SUMMARY

This chapter reviewed the development of the anatomy and function of the thyroid gland and the establishment of its control by the hypothalamic–pituitary–thyroid axis, with emphasis on differences in the timing of these events in precocial and altricial modes of avian development. The binding of thyroid hormones to proteins in the circulation, their transport in and out of cells via plasma membrane transport proteins, and deiodination by enzymes that activate and inactivate thyroid hormone are explained in the context of their functions in controlling intra-organ events. The mechanisms of thyroid hormone genomic actions, mediated primarily by nuclear receptors, as well as nongenomic actions are described in the context of their developmental and metabolic effects. Interactions of thyroid hormones with other hormones systems and environmental influences on thyroid function, including those by environmental contaminants, are discussed.

ABBREVIATIONS

$1,25(OH)_2D_3$ or $25(OH)D_3$ Metabolites of vitamin D
Ca or Ca^{++} Calcium or ionic calcium
CA Carbonic anhydrase
cAMP Cyclic adenosine monophosphate
CGRP Calcitonin gene-related peptide
CT Calcitonin
DBP Vitamin D binding proteins
ESG Eggshell gland
OPG Osteoprotegerin
PGs Prostaglandins
PGE_2 Prostaglandin isoform E_2
Pi Inorganic phosphate
PKA, PKC Protein kinase A or C
PTGs Parathyroid glands
PTH Parathyroid hormone
PTHrP Parathyroid hormone-related peptide
PLP Parathyroid-like peptide
PTX Parathyroidectomized
RANK Receptor-activated nuclear factor κ-B
RANKL RANK ligand

25.1 INTRODUCTION

Calcium (Ca) is one of the most efficiently regulated plasma constituents in birds. Classical Ca regulating hormones, all recognized in birds, include parathyroid hormone (PTH), calcitonin (CT), and 1,25-dihydroxy vitamin D_3 ($1,25(OH)_2D_3$), although their actions and/or sensitivities can be quite different from those in mammals (Dacke, 1979) and it is clear that avian skeletal metabolism acts at an amplified rate compared with that in mammals (Gay, 1988). Other putative Ca and bone-regulating factors including prostaglandins (PGs) (Dacke, 1989), calcitonin gene-related peptides (CGRPs) (Dacke et al., 1993a), amylin (Guzel et al., 2009), and intracellular factors including the receptor-activated nuclear factor κ-B (RANK), RANK ligand (RANKL) and osteoprotegerin (OPG) system, also affect avian Ca metabolism in ways that are profoundly different from those in mammals. This may be partly related to enhanced requirements for Ca during eggshell formation when a dramatic change takes place in the bone biology of the hen at the onset of sexual maturity (Dacke, 2000; Whitehead, 2004).

More recent reviews of avian Ca and bone metabolism include those by Gay (1996), Sugiyama and Kusuhara (2001), Whitehead (2004), Stamford (2006), Bar (2008), de Matos (2008), and Kim et al. (2012). Avian Ca metabolism shares many features with other vertebrate classes, but is also typified by several characteristics related to the ability of birds to lay large megalecithal eggs with well-developed calcified eggshells (Romanoff and Romanoff, 1963). Other Archosaurian species, extant crocodilia and at least some extinct dinosaurs, the closest relatives of modern birds, also lay or laid eggs with calcified shells (Dacke, 1979; Schweitzer et al., 2005, 2007). The amount of Ca in each egg typically represents about 10% of the total body Ca stores in the bird (Kenny, 1986), an enormous amount. The Ca metabolism of an egg-laying hen in domesticated species

*The author has retired, and is no longer connected with the University of Portsmouth.

Sturkie's Avian Physiology.

such as chickens and Japanese quail on a daily basis compares with that of human females in 18 months of combined pregnancy and lactation. In order to provide a source of Ca for eggshell calcification to supplement the supply provided directly from the diet, egg-laying hens and some extinct therapod dinosaurs possess a highly labile reservoir in the form of medullary bone, developing within long bones of hens in response to gonadal steroids. It is the most overtly estrogen-sensitive form of vertebrate bone (Simkiss, 1967; Kusuhara and Schraer, 1982; Dacke et al., 1993b; Imamura et al., 2006; Hiyama et al., 2009).

A second feature influencing the evolution of avian Ca metabolism is the ability to fly. This probably led to development of light but robust skeletons in which long bones tend to be more hollowed out than in other vertebrates. Similar lightweight structures are found in fossilized bones of flying pterosaurs (Wellnhoser, 1991). This hollowing implies a high degree of remodeling during the growth phase of the skeleton, which probably influenced the evolution of certain hormonal activities and sensitivities in birds.

Mammals given either acute hyper- or hypocalcemic challenges respond within a few hours, whereas one-week-old chickens correct such challenges within minutes, recovery from the hypocalcemia being dependent upon the presence of PTH (Koch et al., 1984). An intravenous dose of ^{45}Ca in a week-old chick rapidly clears from the plasma pool, and by 15 min approximately 40% of the original dose is located within the skeleton (Shaw et al., 1989). By calculating the unidirectional plasma–bone clearance constant ($K_{pb}{}^{45}Ca$) and hence net Ca^{++} influx, and by estimating the total rate of Ca accretion into the skeleton, we find that total skeletal outflux of Ca^{++} is approximately 80% of influx, and that the plasma pool of Ca^{++} clears into the skeleton every few minutes. Typically, net Ca accumulation into the chick femur is about 0.28 µmol/min/g wet weight, although this will vary according to prevailing rates of dietary Ca absorption and other factors. Clearly any factor that modifies either rapid influx or outflux of Ca^{++} in this system will profoundly affect minute-to-minute plasma Ca modulation in the rapidly growing animal. Bronner and Stein (1992) calculated, using data from Shaw et al. (1989), that the t ½ for ^{45}Ca uptake by the chick femur is less than 10 min, compared with around 30 min in rabbit, dog, and rat.

The discovery of Ca- and bone-related disorders that affect both production and welfare has stimulated interest in the bone biology of the laying hen. Caged layer paralysis, identified soon after the introduction of battery cages (Couch, 1955), is associated with weakened skeletons characterized by osteoporosis (Stamford, 2006).

Avian osteoporosis is defined as a decrease in the amount of fully mineralized structural bone, leading to increased fragility and susceptibility to fracture (Whitehead and Fleming, 2000). Incidence and severity of avian osteoporosis are closely associated with egg-producing ability. High egg-producing hens are very susceptible to osteoporosis (Fleming et al., 2006); lines of egg-laying hens selected by their bone strength resistance to osteoporosis produce eggs with lower shell quality. The onset of osteoporosis is related to estrogen activity, which stimulates medullary bone formation for eggshell formation, and concomitantly starts to decrease the volume of cancellous bone and the thickness of cortical bone, finally contributing to weakened skeleton strength (Fleming et al., 1998; Turner et al., 1993; Wilson and Thorp, 1998). This osteoporosis is prevented by the antiestrogen tamoxifen, but egg laying also stops (Wilson and Thorp, 1998). There is a dramatic decrease in circulating estrogen in 70 week old hens compared with those in peak production (up to 29 week) with parallel changes in estrogen receptor-α populations in both kidney and duodenum. This results in decreasing $1,25(OH)_2D_3$ production and intestinal Ca absorption (Beck and Hansen, 2004; Hansen et al., 2003).

Much of this review is based around the physiology of Ca regulation in chickens, reflecting the abundant literature on this species, but other avian species are referred to where appropriate.

25.2 EVOLUTIONARY ASPECTS OF EGGLAY AND MEDULLARY BONE

25.2.1 Egglay and Evolution of Calcium Reservoirs

Reptiles and birds lay cleidoic eggs, which differ from those of lower vertebrates in that no primitive larval stage is produced at hatching. Instead, the hatchling is morphologically similar to the adult and has an ossified skeleton. This is true for Archosaurian (crocodilian, dinosaurian, and avian) eggs. This requires a supply of Ca provided by the egg yolk. Reptilian eggs tend to have leathery shells, although turtle shells are thick and impregnated with deposits of calcium carbonate ($CaCO_3$). Apart from its protective function, the avian and presumably other archosaurian eggshells are a major source of Ca for skeletal calcification (Johnston and Comar, 1955; Simkiss, 1967; Tuan and Ono, 1986; Dacke, 1979). It has been suggested that slow-developing (precocial) avian species such as the Japanese quail (*Coturnix japonica*) move more Ca from the eggshell and therefore have more ossified skeletons compared with fast-developing (altricial) species such as the starling (*Sturnus vulgaris*) (Blom and Lilja, 2004; Karlsson and Lilja, 2008).

The large throughput of Ca in these species means that the reproducing female requires a highly labile Ca reservoir in addition to the more stable cortical bone. These range from the turtle plastron (Dacke, 1979) to the heavily calcified scutes (scales) in crocodilia (Elsey et al., unpublished data), while in some archosaurians the unique presence of medullary bone within the cavities of long bones has evolved (Schweitzer et al., 2005).

25.2.2 Evolution of Medullary Bone

Medullary bone is described as a secondary bone tissue that develops within marrow cavities of long bones in reproducing female birds, provides Ca for the eggshell, and has no biomechanical function. Avian medullary bone is a very brittle and fragile type of bone; the spicules of the medullary bone are easily separated from the originating layer. It was hitherto considered to be a unique avian phenomenon (Bloom et al., 1941; Simkiss, 1967; Dacke, 1979). Anecdotal suggestions that this bone could be found in crocodilians (Whitehead, 2004) are now largely discounted following a comprehensive study in reproducing alligators where no evidence of medullary bone was found during the reproductive cycle (Schweitzer et al., 2007).

A groundbreaking paper (Schweitzer et al., 2005) provided unambiguous evidence for the presence of endosteally derived bone tissues lining the interior marrow cavities of portions of a fossilized therapod dinosaur (*Tyrannosaurus rex*) hindlimb specimen, and hypothesized that these tissues are homologous to avian medullary bone. In the same paper, they showed similarities of *T. rex* medullary bone to that in ratites, the most primitive extant birds. Because medullary bone was hitherto considered unique to female birds, its discovery in dinosaurs solidified the link between dinosaurs and birds, and suggests similar reproductive strategies within this archosaur clade. Subsequently, Lee and Werning (2008) found medullary bone in another saurischian dinosaur, *Allosaurus*, and the ornithischian dinosaur *Tenontosaurus*.

25.2.3 Bone Formation and Resorption during the Egg-Laying Cycle

Medullary bone is a labile source of Ca for eggshell formation. It lines the endosteal surface of structural bone and also occurs as spicules within the marrow cavity (Simkiss, 1967; Dacke, 1979; Sugiyama and Kusuhara, 2001). It has little inherent strength but can contribute to fracture resistance.

There are bone-forming osteoblasts, bone-resorbing osteoclasts on medullary bone surfaces, as well as osteocytes embedded in the matrix (Gay, 1988; Gay et al., 2000; Gay and Weber, 2000; Miller, 1992; Turner et al., 1994). The space between the spicules is filled with hematopoietic cells, erythrocytes, and marrow stromal cells (Bloom et al., 1941; Simkiss, 1967).

Osteoclasts resorb both medullary and structural bone so that during the period while hens remain in reproductive condition, there is a progressive loss of skeletal structural bone, which is characteristic of osteoporosis. Increasing fragility makes the bones more susceptible to fractures. The dynamics of bone loss can be affected by a number of nutritional, environmental, and genetic factors (Whitehead, 2004). About 30% of battery hens experience fractures, either during the production period or during depopulation (Gregory and Wilkins, 1989).

Similar to cortical bone, medullary bone matrix consists mainly of inorganic and organic phases. The organic matrix is divided into collagenous and noncollagenous proteins. There is a much greater amount of protein in medullary bone than in the cortical bone. The principle component of the protein is type I collagen, the content of which is one-half or one-quarter of that in cortical bone, and spicule density and direction are coarse and irregular (Ascenzi et al., 1963; Bonucci and Gherardi, 1975; Hiyama et al., 1998; Knott and Bailey, 1998). Most of the noncollagenous protein consists of proteoglycans, and medullary bone contains 2–3 times as much proteoglycan as in cortical bone (Candlish and Holt, 1971). Keratan sulfate is the major proteoglycan in medullary bone (Candlish and Holt, 1971; Hunter and Schraer, 1981), which is also co-localized with the calcified matrix, suggesting close involvement in the regulation of medullary bone calcification (Yamamoto et al., 2001, 2005). Interestingly, tartrate-resistant acid phosphatase (TRAP), a bone-degrading enzyme, accumulates in the medullary bone matrix during bone formation (Yamamoto and Nagai, 1994). Most of the inorganic phase of medullary bone is hydroxyapatite, similar to cortical and trabecular bones. However, it also contains significant amounts of $CaCO_3$ (calcite) (Lorcher and Newesely, 1969; Pellegrino and Biltz, 1970), which may be closely correlated with rapid formation and resorption.

Calcification of medullary bone initially occurs in matrix vesicles found between the collagen fibrils of the osteoid tissue, and spreads into the surrounding interfibrillar matrix (Bonucci and Gherardi, 1975). However, Ca and apatite contents are similar to those in cortical bone (Ascenzi et al., 1963). The characteristics of medullary bone matrix are clear, but their detailed functions are not fully understood. Thus, the matrix of medullary bone is substantially different from that of cortical bone. This is probably an important factor in rapid bone turnover during eggshell formation.

In nonseasonal layers such as domestic hens, medullary bone formation begins 12–14 days preceding the first ovulation, whereas seasonal layers such as pigeons develop medullary bone before the first ovulation, and it disappears after the last egg in the clutch has been laid (Bloom et al., 1941; Miller, 1992; Turner et al., 1994). Simultaneously, the ovarian interstitial cells together with the growing ovarian follicles secrete increasing amounts of estrogen during the onset of sexual development. The final rapid growth of the follicles occurs within a 7 to 11 day period prior to ovulation, during which time estrogen secretion by the thecal cells reaches a peak (Phillips et al., 1985; Johnson, 2000). Thus medullary bone formation in the female birds coincides with the initiation of ovarian follicle maturation and estrogen secretion. The cycle of medullary bone formation and resorption during the egg-laying cycle is shown in Figure 25.1.

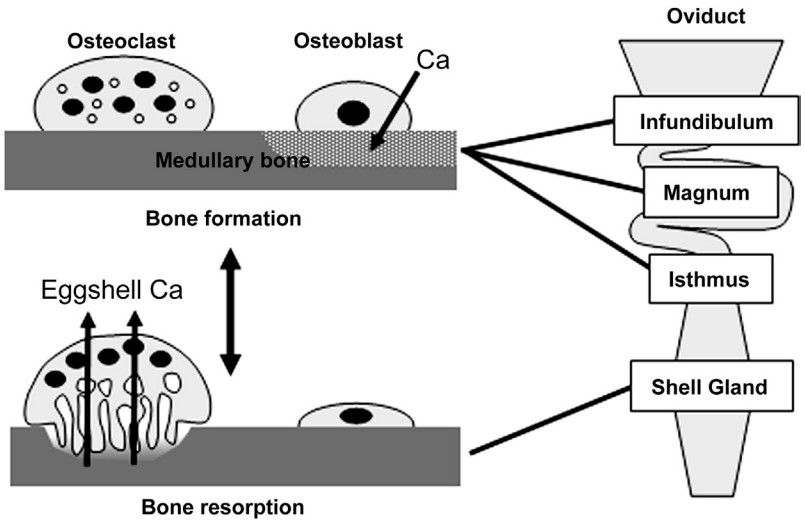

FIGURE 25.1 Medullary bone formation and resorption during the egg-laying cycle. *Modified after Sugiyama and Kusuhara (2001).*

The important role of gonadal hormones in regulating medullary bone formation has been recognized for many years, this process requiring the combined influence of estrogen and androgen (Bloom et al., 1942). Adult male pigeons, quails, ducks, and chickens form medullary bone if estrogen is administered to them, as will immature female birds if both hormones are provided. Medullary bone will not form if only one of these hormones is present (Ascenzi et al., 1963; Bloom et al., 1942; Miller and Bowman, 1981). Injection of estrogen into male quails promotes proliferation of the endosteal bone lining cells and then differentiation into osteoblasts (Kusuhara and Schraer, 1982). In addition, estrogen receptors are present in medullary bone osteogenic cells, including osteoblasts, preosteoblasts, lining cells, and marrow stromal cells, of egg-laying and estrogen-treated chickens or quails (Ohashi and Kusuhara, 1993; Ohashi et al., 1991; Turner et al., 1993). This suggests that new medullary bone at the onset of egg laying is formed by osteoblasts differentiated from endosteal bone-lining cells, and later the osteoblasts involved in the cyclic bone formation during the egg-laying cycle are supplied from bone marrow stromal cells (Sugiyama and Kusuhara, 2001). The structure of medullary bone is shown in Figure 25.2.

It was demonstrated, using reverse transcriptase polymerase chain reaction (RT-PCR) and *in situ* hybridization, that estrogen receptor-α, a typical receptor, is highly expressed in hen medullary bone osteoblasts (Imamura et al., 2006; Hiyama et al., 2009), while the estrogen receptor antagonists tamoxifen and trioxifene (LY133314) inhibit medullary bone formation in estrogen-treated male birds (Williams et al., 1991). Estrogen is synthesized by conversion of testosterone to estradiol by the action of aromatase in follicles, and letrozole, an aromatase inhibitor, inhibits medullary bone formation in prelay pullets (Deng et al., 2010). If the hen goes out of reproductive condition, estrogen levels fall, osteoblasts resume structural bone formation, and skeletal regeneration occurs.

Periods of medullary bone formation and resorption relate to the position of an egg in the oviduct during the egg-laying cycle. Following ovulation, the ovum enters the infundibulum, staying for 15–20 min before passing to the magnum, where it remains for 3–3.5 h during which time albumen is secreted. Thereafter, both inner and outer shell membranes are formed in the isthmus, taking 1.25–2 h, and the outer membranes are deposited with $CaCO_3$ in the shell gland forming the eggshell, over a period of 18 h. The calcified egg then passes to the vagina and is expelled within a few minutes. In domestic hens, the egg-laying cycle takes about 24 h, and osteoblasts and osteoclasts periodically modify their morphology and functions during such a cycle (Figure 25.1).

While an egg is in the magnum, cuboidal osteoblasts actively form medullary bone (matrix formation and calcification). When the egg enters the shell gland, spindle-shaped osteoblasts no longer form bone (Bloom et al., 1942; Ohashi et al., 1990a). Nevertheless, van de Velde et al. (1985) and Wilson and Duff (1990) reported little significant change in medullary bone volume, regardless of the degree of mineralization during the egg-laying cycle, suggesting that osteoblasts form the nonmineralized bone matrix (osteoid) and later mineralize the bone. It is known that the medullary bone formation in domestic hens is regulated by estrogen fluctuations during the egg-laying cycle, plasma estrogen concentration being highest immediately before oviposition and very low in the latter period of eggshell formation (Shahabi et al., 1975; Shodono et al., 1975). Treatment of egg-laying hens with the estrogen receptor modulator tamoxifen inhibits osteoblastic bone formation during the inactive period of shell formation (Ohashi et al., 1990a).

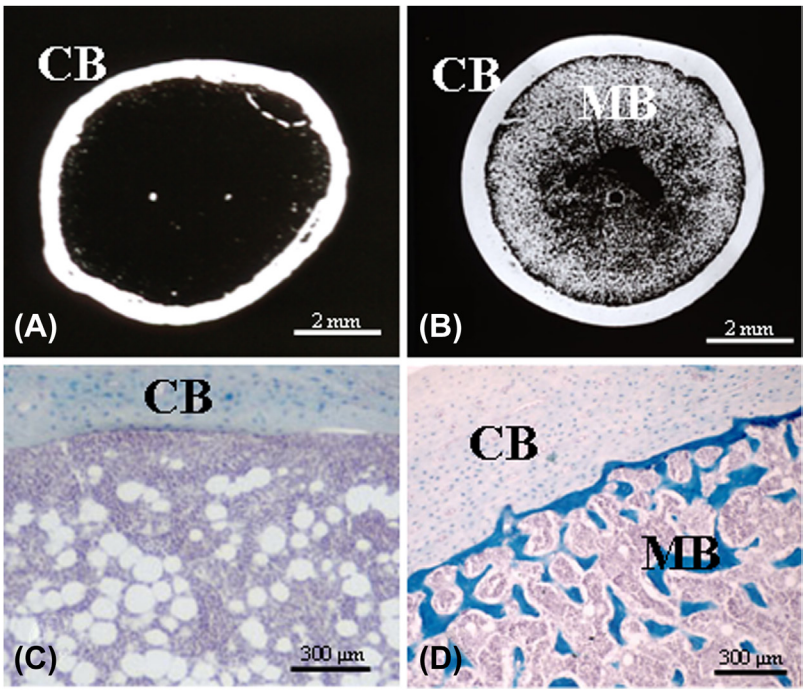

FIGURE 25.2 Micrographs (A and B) and light microscopy (C and D) of cross-sections of femurs from male chickens (A and C) and egg-laying hens (B and D). CB, Cortical bone; MB, medullary bone. Reticular medullary bone is developed within the marrow cavities of long bones in the egg-laying hen. The calcified density of the medullary bone is lower than that of the cortical bone. Medullary bone is intensely stained with alcian blue staining, suggesting that it has an abundance of acid mucopolysaccharide Medullary bone is not present in the male chicken.

Medullary bone osteoclasts alternatively cease and accelerate resorption during the egg-laying cycle, thus moderating supplies of Ca for eggshell formation. While osteoclast populations do not change during the egg-laying cycle in chickens and quails, their morphology and ultrastructure dramatically modify, concomitant with Ca requirements (Miller, 1977, 1981; Sugiyama and Kusuhara, 1993, 1994b; van de Velde et al., 1984b). Thus, when an egg is in the infundibulum, isthmus, or magnum, osteoclasts lose their ruffled borders (bone resorption sites) and cease to resorb bone. However, when an egg is calcifying in the shell gland, osteoclasts develop ruffled borders and resorb the bone for eggshell formation.

In general, the modification of osteoclast activities is regulated by both PTH and CT. PTH is secreted by parathyroid glands in the response to low plasma Ca^{++} levels. CT blocks osteoclastic resorption of medullary bone when an egg is in the magnum of the oviduct, and PTH stimulates osteoclastic bone resorption for eggshell formation during the period when an egg is in the shell gland. Injection of PTH into hens when an eggshell is not being calcified causes osteoclast ruffled border development, thus increasing the plasma Ca levels (Miller, 1978; Kusuhara, 1982). PTH, in chicken medullary bone organ culture systems, stimulates the development of ruffled borders and the acid phosphatase activity of osteoclasts, while CT inhibits them (Sugiyama et al., 1993; Sugiyama and Kusuhara, 1994a, 1996a, 1996b).

25.2.4 Specific Calcium Metabolism for Eggshell Formation

In laying hens, approximately 2.4 g Ca is required over 18 h to produce a shelled egg of 60 g. Only 60–75% of eggshell Ca can be provided directly by feed, the remainder coming from body stores (Whitehead, 2004). A hen produces up to one egg per day for a 52 week period. Eggshell formation requires large amounts of the ionic precursors for $CaCO_3$ deposition. Both ionic species ($Ca^{++}$and HCO_3^-) are supplied by the blood via transepithelial transport through the shell gland mucosa. This is one of the most rapid of biomineralization processes. The process by which Ca is secreted by the oviduct into the eggshell has attracted considerable attention because of its commercial implications (Whitehead, 2004).

Avian eggshells consist largely of $CaCO_3$. Carbonate ions are formed from metabolic CO_2 (i.e., $CO_2 + H_2O \leftrightarrow H^+ + HCO_3^-$) catalyzed by carbonic anhydrase (CA), an enzyme family consisting of at least 14 different isozymes (reviewed in Chegwidden and Carter, 2000). Disruption of this process results in profound effects on eggshell thickness and quality (Berg et al., 2004). CA is localized in epithelial columnar cells and the tubular gland cells of the eggshell gland (ESG) (Gay et al., 1974; Arai et al., 1996). Ca^{++}-ATPase, however, is distributed in the cytoplasm of the tubular glands (Yamamoto et al., 1985; Arai et al., 1996). These results suggest that HCO_3^- and Ca^{++} are supplied independently from different parts of the shell gland.

$CaCO_3$ secretion by the ESG is a thermodynamically active process (Schraer and Schraer, 1965). The egg-laying quail oviduct contains a Ca^{++}–Mg^{++}-activated ATPase within the microsomal fraction of the ESG mucosa. The activity of this enzyme is between one and a half and three times greater than that in precalcifying or immature birds (Pike and Alvarado, 1975). The role of uterine (i.e., ESG) ion transporters for mineralization precursors of the avian eggshell, according to Jonchere et al. (2012), is summarized in Figure 25.3.

25.3 CHEMISTRY AND SECRETION OF CALCIUM-REGULATING HORMONES

25.3.1 Parathyroid Hormone and Related Peptides

25.3.1.1 The Parathyroid Glands

Two to four parathyroid glands (PTGs) are present in birds; two pairs in chickens slightly caudal to the thyroid and one pair in Japanese quail are less closely associated with the thyroids than the four or more found in mammals (Dacke, 1979; Clark and Sasayama, 1981; Kenny, 1986). PTGs derived from the third and fourth branchial pouches in the embryo are encapsulated by connective tissue and composed mainly of chief cells, a situation similar to that in rats (Roth and Schiller, 1976). Oxyphil cells, present in mammalian PTGs, are absent in birds. The low granular content of the avian chief cell is consistent with a low level of PTH secretion (Kenny, 1986).

The importance of PTH in maintaining avian Ca levels has been recognized for years. Parathyroidectomy (PTX) in birds leads to hypocalcemia, tetany, and death depending on factors such as dietary Ca intake, the presence of accessory parathyroid tissue, and reproductive status (Kenny, 1986). PTH injections into Japanese quail or chickens increase plasma Ca levels (Kenny and Dacke, 1974). The hypercalcemic effects of PTH are greater in egg-laying hens than in cockerels, due to either Ca^{++} binding by yolk proteins in the plasma or additional PTH receptors present in medullary bone and oviduct (Dacke, 1979). Immature birds show rapid and sensitive responses to intravenous PTH, this being formerly used as a bioassay (Dacke and Kenny, 1973; Parsons et al., 1973). Primary targets for PTH in birds are bone and kidney. The major physiological stimulus for PTH secretion from the chief cells is a fall in plasma Ca^{++} concentration, while increasing plasma Ca^{++} suppresses it (Brown, 1991).

25.3.1.2 Chemistry of Parathyroid Hormone and Related Peptides

Mammalian PTH is an 84 amino acid polypeptide, while chicken PTH is 88 amino acids (Khosla et al., 1988; Limm et al., 1991). However, only the first 32–34 amino acids from the N terminus are necessary for biological activity (Tregear et al., 1973). The nucleotide sequence of chicken pre-pro-PTH mRNA was determined from a 2.3-kilobase fragment of complementary PTH DNA cloned in *Escherichia coli*. The mRNA (2.3 kilobases) for chicken hormone precursor was approximately three times the size of that for mammalian pre-pro-PTH. The amino acid sequence deduced from the DNA showed that chicken pre-pro-PTH mRNA encoded a 119 amino acid precursor peptide and an 88 amino acid hormone which is four residues longer than all known mammalian homologs and includes gene deletions and insertions. There is significant homology of sequence in the biologically active 1–34 region with mammalian hormones, but much less in the middle and carboxyl terminal regions (Russell and Sherwood, 1989).

PTH and PTH-related peptide (PTHrP) belong to a family of endocrine factors sharing a highly conserved N-terminal region (amino acids 1–34) and play key roles in Ca homeostasis, bone formation, and skeletal development. Recently, a third PTH-like peptide (PTH-L) was identified in teleost fish, amphibians (*Xenopus*), and birds (chicken), raising questions about the evolution of these proteins (Guerreiro et al., 2007; Pinheiro et al., 2010). The function of PTHrP in nonmammalian vertebrates is poorly documented. Amphibians and birds occupy phylogenetic positions, the former at the transition from aquatic to terrestrial life and the latter at the transition to homeothermy. The PTH-L gene is present throughout vertebrates with the exception of placental mammals. Gene structure of PTH and PTH-L seems to be conserved in vertebrates, while PTHrP gene structure is divergent and has acquired new exons and alternative promoters. Splice variants of PTHrP and PTH-L are common in *Xenopus* and chicken and transcripts of the former have a widespread tissue distribution, although PTH-L is more restricted. PTH is widely expressed in fish tissue, but from *Xenopus* to mammals it becomes largely restricted to the PTG. The N-terminal (1–34) regions of PTH, PTHrP, and PTH-L in *Xenopus* and chicken share high sequence conservation and the capacity to modify Ca fluxes across epithelia, suggesting a conserved role in Ca metabolism possibly via similar receptors (Guerreiro et al., 2007).

In teleosts, five genes encode PTHrP (2), PTH (2), and PTH-L (1); in tetrapods, including birds, there are three (PTHrP, PTH, and PTH-L); while placental mammals lack PTH-L. It is hypothesized that genes of the PTH family appeared at approximately the same time during the vertebrate radiation and evolved via gene duplication and deletion events. PTH, which has a paracrine distribution in lower vertebrates, became the product of a specific endocrine tissue, the PTG first evolving in amphibians. The PTHrP and PTH-L gene organization diverged and retained its widespread tissue distribution complex in vertebrates, which is congruent with its paracrine nature (Pinheiro et al., 2010).

At the time of writing, there appear to be few reports of calcemic or other actions of the third member of the PTH-peptide family, PTH-L, in either birds or mammals. Guerreiro et al. (2007) suggest that PTH-L is the ancestral from which PTH and PTHrP have evolved, while Pinheiro et al. (2012) suggest that PTH-L can influence Ca fluxes across membranes in *Xenopus* and chickens as well as in fish.

25.3.1.3 Parathyroid Hormone Release

Similar to mammals, a Ca^{++}-sensing receptor is found in the avian PTG. The Ca-receptor (CaR) gene is expressed by PTG chief cells, which also store and secrete PTH. Increases in plasma Ca^{++} increase expression of the CaR gene. Low plasma Ca^{++}, before or after eggshell formation, is associated with decreased CaR gene expression in the PTG. The level of CaR gene expression is inversely correlated with PTH content of the PTG. Thus, in contrast to mammals, CaR gene expression in the PTG of the chicken is inversely associated with changes in plasma Ca^{++} (Yarden et al., 2000).

25.3.1.4 Circulating Parathyroid Hormone

Relatively few reports exist of circulating PTH levels in birds, reflecting the fact that they are normally low relative to those in mammals and that pure avian PTH was hitherto unavailable for antibody production. Van de Velde et al. (1984a) measured plasma PTH-like bioactivity during the egg-laying cycle of the chicken by cytochemical bioassay. This is elevated during eggshell calcification, after which it falls to a low level but is slightly raised again 2 h after ovulation. Singh et al. (1986) similarly measured levels of "PTH" during the egg cycle of chickens using *in vitro* bioassay. PTH was higher in hens fed Ca-deficient diets compared with those on a high Ca diet. The levels were highest during shell calcification, then shortly after ovulation, in both groups of hens; furthermore, they showed an inverse relationship with plasma ionized Ca levels (see Dacke, 2000), suggesting that changes in bioactive PTH play an important role in the Ca metabolism of the chicken under physiological Ca stress. At least part of the PTH-like activity measured in these studies was probably PTHrP, but at the time of writing there are no reports distinguishing between the two peptides to ascertain their respective roles in the avian egg cycle or in avian Ca metabolism in general.

25.3.2 Calcitonin and Related Peptides

CT contains 32 amino acids and a seven-membered N-terminal ring, all of which are necessary for biological activity. Variations in amino acid sequence of CT from different species give rise to differences in bioactivity, with CTs of fish origin being particularly potent (Dacke, 1979). Structures of different CTs, including that from chicken, are reviewed by Zaidi et al. (1990a), who also give detailed consideration to their structure–activity relationships.

CT secretion is regulated primarily by rising plasma Ca levels leading to an increased secretion from ultimobranchial glands (Dacke, 1979). In egg-laying quails, plasma CT concentrations are at their highest after oviposition and fall as eggshell calcification proceeds, rising at the end of calcification (Dacke, 2000; Dacke et al., 1972).

Eliam-Cisse et al. (1993) studied influences of Ca and vitamin D deficient diet on CT gene expression in the CT-secreting ultimobranchial cells of the developing chicken. They exhibited a striking reduction of CT biosynthesis by decreasing the number of secretory cells and not by triggering modifications of the biosynthetic activity of the ultimobranchial endocrine cells.

25.3.2.1 Circulating Calcitonin Levels

High levels of circulating bioreactive CT are present in submammalian species, including birds (Dacke, 1979). They are higher in adult males than in egg-laying females except for a brief period immediately before commence of lay. In quail hens, they are at their highest shortly after ovulation and fall as eggshell calcification proceeds, rising at the end of this period. In this species at least, gonadal steroids, especially androgens, appear to have a major influence on circulating CT levels (see Taylor and Dacke, 1984; Kenny, 1986). In chickens, plasma CT levels positively correlated with dietary Ca intake and thus to circulating Ca levels (Taylor and Dacke, 1984), while in chick embryos they are very low until just prior to hatching (Abbas et al., 1985).

Figure 25.4 shows the relationships between PTH, CT, $1,25(OH)_2D_3$, estrogen, and Ca levels during the hen's egglay cycle.

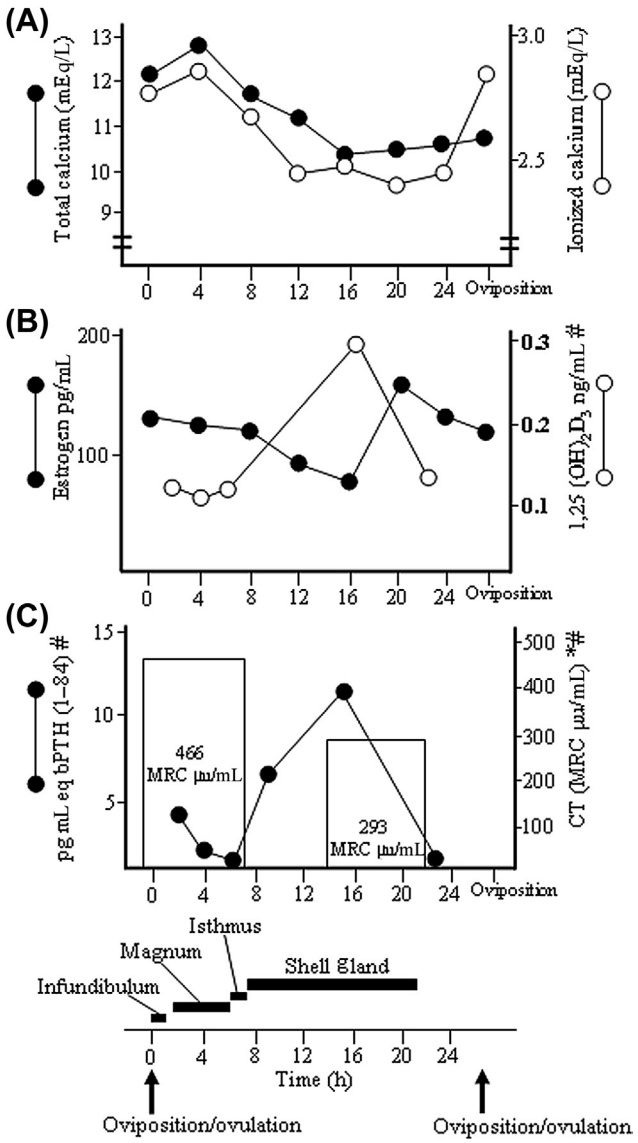

FIGURE 25.4 Concentrations of plasma calcium and hormone levels in the domestic hen during the egg-laying cycle. (A) Plasma total Ca and Ca^{++} (Parsons and Combs, 1981); (B) estrogen (Shodono et al., 1975) and 1,25 $(OH)_2D_3$ (Abe et al., 1979); and (C) PTH (van de Velde 1984b) and CT (Dacke et al., 1972). *: Data from egg-laying quails; the others are from egg-laying chickens. #: Data after ovulation; the others are after oviposition. 1 mEq/L = 0.5 $mmol^{-1}$. 25.3.3 The Vitamin D System

Hou (1931) first reported the importance of the preen gland in vitamin D metabolism and the prevention of rickets in growing chickens.

Vitamin D_3 regulation in birds was reviewed by Taylor and Dacke (1984), Norman (1987), Hurwitz (1989a), Nys (1993), and Bar (2008). It is well established that chickens metabolize vitamin D_3 to $25(OH)D_3$ and $1,25(OH)_2D_3$ in their liver and kidneys, respectively (Holick, 1989). Birds, unlike mammals, discriminate between vitamin D_2 and D_3, and chickens are unable to utilize vitamin D_2 as efficiently as D_3 (Taylor and Dacke, 1984). This appears to be due to the fact that in birds, plasma vitamin D–binding protein has relatively low affinity for vitamin D_2, which is thus more rapidly broken down (Holick, 1989). The avian kidney, as in other vertebrates, synthesizes and secretes $1,25(OH)_2D_3$. Numerous factors stimulate production

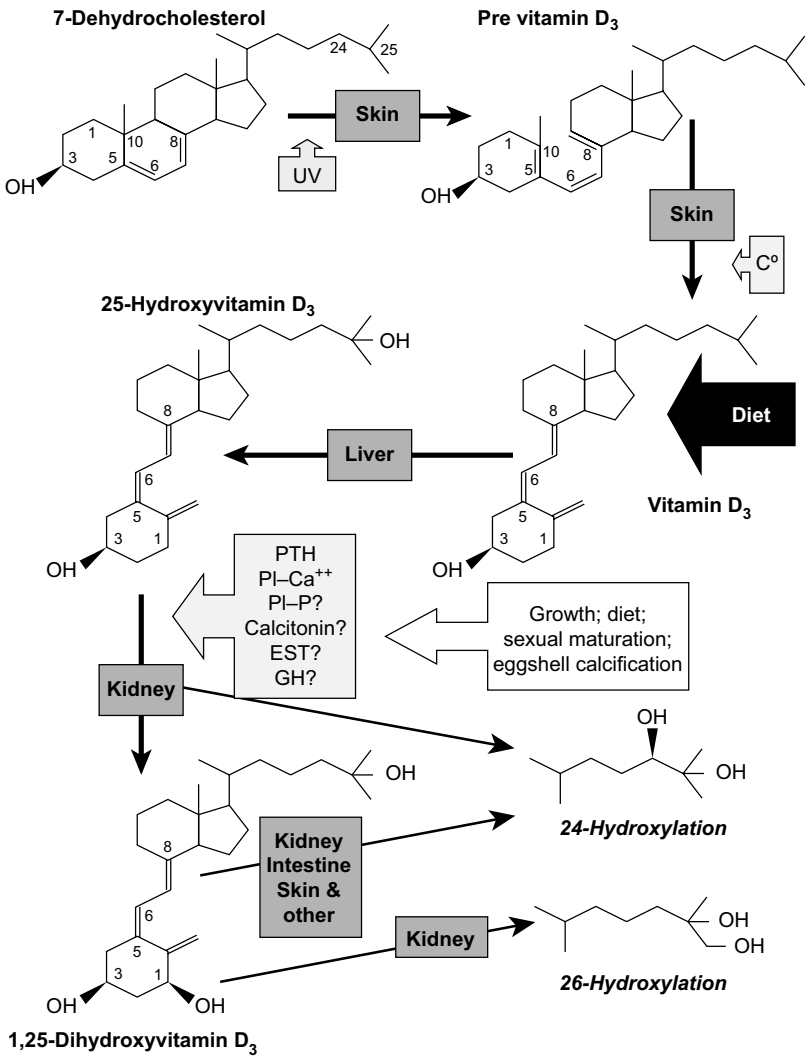

FIGURE 25.5 Vitamin D metabolism and regulation in the laying bird. EST: estrogens; GH: growth hormone; Pl–Ca^{++}: plasma Ca^{++}; Pl–P: plasma phosphate. *Originally from Bar (2008).*

of $1,25(OH)_2D_3$, including PTH, $1,25(OH)_2D_3$ itself, and prolactin (Kenny, 1981; Henry and Norman, 1984). There are contradictory reports as to whether CT influences $1,25(OH)_2D_3$ production by avian kidney, but Kenny (1986) concluded that CT is not a major regulator of vitamin D_3 in birds. The metabolism of vitamin D to its active forms in birds is summarized in Figure 25.5. Egg yolk is a rich source of vitamin D, of which 90% is in the form of vitamin D_3 and 5% in the form of $25(OH)D_3$. This vitamin D is probably derived from the hen rather than the embryo (Fraser and Emtage, 1976).

The extra demands on Ca homeostasis, especially in domestic birds characterized by their long clutch lengths, stimulate vitamin D metabolism and expression. Vitamin D metabolism is also influenced by other processes associated with increased demands for Ca, including growth and bone formation. A series of intestinal, renal, or bone proteins are consequently expressed in the target organs via mechanisms involving a vitamin D receptor. Some of these proteins (CA, calbindin, and Ca-ATPase) are found in the ESG and are believed to be involved in Ca transport as they are in the intestine or kidney. These processes are reviewed by Bar (2008).

Bar et al. (1999) investigated relationships between age, eggshell thickness, and vitamin D metabolism and its expression in laying hens. Hens forming thin shells synthesize less $1,25(OH)_2D_3$ and less duodenal and eggshell gland (ESG) calbindin than normal laying hens. Hens forming thin shells had lower intestinal and ESG calbindin and its mRNA. Reducing ESG Ca^{++} transport by the CA inhibitor acetazolamide, but not by dietary Ca restriction, reduced ESG calbindin and its mRNA. It was suggested that the mechanism responsible for Ca^{++} transport to the eggshell consists of a vitamin D-dependent absorption of Ca^{++} and a multifactor-dependent transfer of

Ca^{++} to the shell. Both steps are most likely calbindin mediated; however, the induction of calbindin gene expression in the ESG is predominantly Ca^{++} dependent, and the apparent defect in vitamin D metabolism or its expression seen in older hens is typical of, or even exclusive to, thin-shell-forming hens.

25.3.3.1 Circulating Levels of Vitamin D Metabolites

Vitamin D_3 and its metabolites are transported in association with vitamin D binding–protein (DBP), with plasma albumins, and in some avian species with α- and β-globulins as well. The DBP exists as two 4S forms that differ in the number of neuraminic acid residues present. DBP probably has a single binding site for all vitamin D metabolites, and its affinities for 25- and $24,25(OH)_2D_3$ are similar, whereas $1,25(OH)_2D_3$ has a 10-fold lower affinity. The plasma concentration of DBP is more than twice as high in laying hens than in immature birds or adult males (reviewed by Taylor and Dacke, 1984; Hurwitz, 1989a).

Levels of circulating vitamin D_3 metabolites in Japanese quail and egg-laying chickens have been determined. Increased intestinal Ca absorption occurring after sexual maturity and during eggshell formation is related to renal 25-hydroxycholecalciferol-1-hydroxylase activity (Kenny, 1976), which in turn enhances circulating $1,25(OH)_2D_3$ levels (Castillo et al., 1979) and the accumulation of this metabolite in the intestinal mucosa (Bar et al., 1978). Increases in $25(OH)D_3$-1-hydroxylase activity are induced by injecting estrogen into immature birds (Baksi and Kenny, 1977; Sedrani et al., 1981). Abe et al. (1979) reported that plasma concentrations of $25(OH)D_3$ and $1,25(OH)_2D_3$ but not $24,25(OH)_2D_3$ in egg-laying hens fluctuate during the eggshell calcification cycle. Nys et al. (1986) confirmed these results and also demonstrated that hens laying soft-shelled eggs do not show these fluctuations. Circulating levels of $1,25(OH)_2D_3$ increase in hens during the prelaying period and again at the onset of egg production (Nys, 1993). Bar and Hurwitz (1979) demonstrated that the stimulatory effect of estrogen on renal $25(OH)D_3$-hydroxylase in Ca-deficient birds is eliminated, suggesting that increased $1,25(OH)_2D_3$ production results from Ca deficiency induced by estrogens.

Plasma $1,25(OH)_2D_3$ concentrations fluctuate during the egg-laying cycle of domestic hens, reaching a peak during eggshell formation (Abdulrahim et al., 1979; Castillo et al., 1979). $1,25(OH)_2D_3$ is necessary for osteoblastic bone calcification, and osteoblasts possess its receptors (Boivin et al., 1987; Hurwitz, 1992). Studies on the effects of $1,25(OH)_2D_3$ deficiency on hen Ca metabolism suggest that feeding vitamin D deficient diets results in increased osteoid (Takahashi et al., 1983; Wilson and Duff, 1991). Therefore, $1,25(OH)_2D_3$ is important for the calcification of medullary bone during the egg-laying cycle.

25.4 ACTIONS OF PARATHYROID HORMONE, CALCITONIN, AND VITAMIN D ON TARGET ORGANS

25.4.1 Actions on Skeleton (Bone and Cartilage)

25.4.1.1 Actions of PTH

PTH has multiple catabolic and anabolic effects on the skeleton. The slow hypercalcemic response in mammals involves recruitment and activation of osteoclasts mediated via receptors located in osteoblasts (Hurwitz, 1989b). Birds are exquisitely sensitive to PTH, with hypercalcemic responses occurring in egg-laying hens as early as 8 min after administration (Candlish and Taylor, 1970), too brief a time for significant osteoclastic resorption (Hurwitz, 1989a) and unlikely to be due to intestinal or renal transport mechanisms. Using acute ^{45}Ca labelling, Kenny and Dacke (1974) demonstrated that the initial (0–30 min) response to PTH involved inhibition of plasma Ca^{++} clearance. Using a method of temporal microwave fixation of injected radioisotopes in skeletal and other tissues, it was demonstrated that decreased plasma ^{45}Ca clearance in chicks is accounted for by an inhibition of net Ca uptake into the skeleton (Shaw and Dacke, 1985; Shaw et al., 1989). These dose-dependent responses were elicited using the active bPTH(1–34) fragment, but could also be seen following intravenous injection of a stable PGE_2 analog, 16,16-dimethyl PGE_2. They are rapid and most apparent in the femur and, to some extent, calvaria (Dacke and Shaw, 1987). Phosphodiesterase inhibitors, caffeine or 3-isobutyl-1-methylxanthine, mimic effects of PTH on skeletal ^{45}Ca uptake in chicks, indicating a role for cAMP in this response (Shaw and Dacke, 1989).

PTH receptors are located on osteoblast surfaces but have been considered absent in osteoclasts (Hurwitz, 1989b), although this is disputed (Pandala and Gay, 1990; Teti et al., 1991; May et al., 1993). Considerable evidence exists to suggest that PTH can induce rapid changes in Ca transfer by osteoblasts and osteocytes. Thus, PTH-stimulated increases in Ca uptake by these cells have been observed, while others have reported either no response in intracellular Ca^{++} concentration or a net Ca efflux from bone cells, at least in embryonic chick bone *in vitro* (Hurwitz, 1989b; Malgaroli et al., 1989). At least two types of voltage-controlled ionic channels were described using patch clamp techniques in cultured embryonic chick osteoblasts (Ypey et al., 1988), which predicted a role for these channels in the response to PTH.

PTH also affects cell spread area in avian osteoclasts (Miller, 1977, 1978) in studies that used electron microscopy to determine responses of medullary bone osteoclasts in egg-laying Japanese quail *in vivo* during the inactive phase of their eggshell calcification cycle. PTH induced the

osteoclasts to form ruffled borders bounded by filamentous-rich clear zones within 20 min of hormone treatment, these changes being characteristic of "active" bone-resorbing cells found during shell calcification. Similarly, Sugiyama and Kusuhara (1994a, 1996a) demonstrated that PTH induces ruffled border formation in osteoclasts located within hen medullary bone maintained in culture. Zambonin-Zallone et al. (1982) adopted a procedure whereby domestic hens are prefed a Ca-deficient diet in order to increase cell yield, and then a prolonged isolation technique is used consisting of unit sedimentation and filtration. Osteoclasts from tibiae of Ca-deficient chicks *in situ* were shown to increase their cell spread area by 40% within 2–4 min of PTH challenge (Pandala and Gay, 1990). Whether this response represents direct or indirect effects of the hormone on these cells, it is remarkably fast compared with classical responses to PTH (Dacke, 1979; Hurwitz, 1989a). Bronner (1996) speculated that an important mechanism underlying minute-to-minute regulation of blood Ca levels in both birds and mammals is the ability of bone-lining cells, osteoclasts and osteoblasts, to alter their size and shape and migrate to and from areas of the bone surface where high- or low-affinity binding sites for Ca^{++} are located; this is an interesting hypothesis that remains to be tested experimentally.

Biochemical mechanisms underlying avian osteoclast function are similar to those of mammalian osteoclasts, although in some respects they are functionally distinct from the latter variety (Gay, 1988). Thus the ruffled border contains a proton pump-ATPase and an Na^+, K^+-ATPase. It also contains carbonic anhydrase, which is closely associated with the cytoplasmic side of the membrane. Ca^{++}-ATPase is present on the plasma membrane of the marrow side of osteoclasts but absent in the ruffled borders; its role is presumably to direct the outward flow of transmembrane Ca^{++} flux. May et al. (1993) demonstrated a direct effect of PTH resulting in increased acid production by chick osteoclasts, the mechanism involving activation of adenylate cyclase via a G_s-type protein. Stimulation of acidification by PTH and cAMP is blocked by estradiol. Estradiol was inhibitory to the same extent as CT; these effects were not additive. Estradiol-17β in micromolar, but not in nanomolar, amounts blocked proton pumping in isolated plasma membrane vesicles (Gay et al., 1993). The actions of PTH and other calciotrophic factors on bone cell function are summarized in Figure 25.6.

25.4.1.2 Action of PTH on Cartilage

Both PTH and PTHrP enhance cAMP and inhibit collagen synthesis in avian epiphysial cartilage cells, an effect that is blockadeable by the PTH antagonist PTH (3–34) (Pines et al., 1990). Two reports show that PTH and PTHrP can modulate growth of avian tibial and sternal cartilage via chondrocytic maturation and proliferation. Regulation of phenotype in chick tibial growth plate chondrocytes by PTHrP is facilitated via signaling through three pathways: protein kinase A (PKA), protein kinase C (PKC), and inositol-1,4,5-trisphosphate-induced Ca^{++} transients

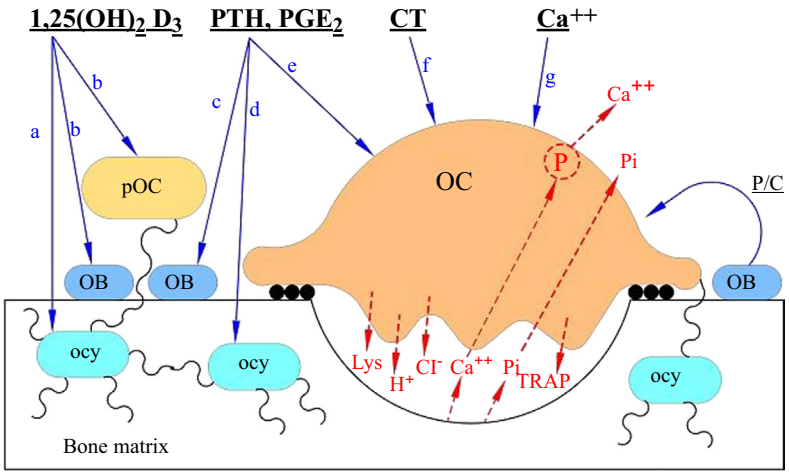

FIGURE 25.6 Summary diagram showing key features of avian osteoclast regulation and activities during remodeling of the skeleton. Osteoblasts control osteoclasts during the early phases of bone growth through interaction of RANKL and RANK (not shown, see text). RANK-expressing osteocytes become the command cells during bone remodeling, as recent *in vivo* studies show. Vitamin D and PTH often work synergistically and can be either anabolic or catabolic. PGE2 effects on osteoclasts are powerful but are likely to be indirect. Cells: pOC, pre-osteoclast; OC, osteoclast; OB, osteoblast; ocy, osteocyte; P, Ca-ATPase pump. Secretions through the ruffled border into the resorption lacuna include the following: Lys, lysosomal contents; TRAP, tartrate-resistant acid phosphatase; and various ions. OC effectors include $1,25(OH)_2D_3$, PTH, CT, Ca^{++}, and paracrine and cytocrine factors (P/C). Podosomes (●) contain αvβ3 integrin, which binds to osteopontin, secreted by osteoclasts onto the sealing zone. Solid lines: controlling factors; dashed lines: secretions and ion fluxes. (a) Nakashima et al. (2011); (b) Norman and Hurwitz (1993); (c) Hurwitz (1989b) and Dacke (1989); (d) Bonewald (2011); (e) Dacke (1989), Pandala and Gay (1990), Teti et al. (1991), and May et al. (1993); (f) Eliam et al. (1988), Pandala and Gay (1990), Hall et al. (1994), and Sugiyama and Kusuhara (1996b); and (g) see section 25.4.1.4.

(Zuscik et al., 2002). PTH (10^{-7}–10^{-15} M) decreased terminal chondrogenesis in the avian sterna. During the first half of an 8 day culture, 100 nM PTH (1–34) significantly increased sternal length and downregulated the deposition of type X collagen and its mRNA expression. There was less type II and X collagen in PTH-treated sterna with concomitant decreases in mRNA production, suggesting that proliferation is the major contributor to cartilage growth in the presence of PTH and PTH-related peptide receptor activation. These experiments demonstrated that PTH increased cartilage growth by upregulating cell proliferation and the expression and secretion of extracellular matrix components (Harrington et al., 2007).

25.4.1.3 Actions of Calcitonin

Despite the discovery of CT more than five decades ago, its role in bone and Ca metabolism remains an enigma. Only in mammalian species has CT been shown to regulate plasma Ca levels, the basis of its hypocalcemic action lying in an ability to inhibit osteoclastic bone resorption (Copp and Kline, 1989). Plasma Ca levels in submammalian vertebrates are refractory to dosage with CT (Dacke, 1979). Whether or not this is due to the high circulating levels of biologically active hormone causing receptor downregulation is not clear. Initial studies in avian osteoclasts showed no postreceptor responses to CT (Miyaura et al., 1981; Ito et al., 1985; Nicholson et al., 1986; Dempster et al., 1987); however, cAMP responses were demonstrated in osteoclasts from chicks maintained on low-Ca or rachitogenic diets (Eliam et al., 1988; Rifkin et al., 1988). Moreover, osteoclasts from Ca-deficient chicks respond to CT *in vitro* within 4 min by a 58% reduction in cell spread area (Pandala and Gay, 1990) and also by an inhibition of their bone-resorptive activity (de Vernejoul et al., 1988). Hall et al. (1994) reported specific surface binding and rapid clearance (within 10 min) of CT applied to isolated chick osteoclasts. CT also causes the disappearance of ruffled borders in cultured medullary bone osteoclasts (Sugiyama et al., 1993; Sugiyama and Kusuhara, 1996a), these findings being consistent with the idea that CT receptors in chicks are downregulated under normal physiological conditions. Ancill et al. (1991) found that dosing heavily (22 h) fasted chicks with salmon CT *in vivo* caused a rapid (10 min) but variable inhibition of net ^{45}Ca uptake into the skeleton. This effect is similar to that of PTH and PGE_2, but its physiological significance is obscure.

Salmon CT acutely increased embryonic chick calvarial cell proliferation *in vitro*, [^{3}H]-thymidine incorporation into DNA, [^{3}H]-proline incorporation into bone matrix collagen, and [^{3}H]-hydroxyproline in intact calvaria and tibiae (Farley et al., 1988). The increased [^{3}H]-hydroxyproline incorporation was associated with proportional increases in bone alkaline phosphatase activity. [^{3}H]-proline incorporation in embryonic chick calvariae also increased during 3 days of limited exposure (i.e., 4 h/day) to CT. These actions of CT also occur in cultures of neonatal mouse calvaria.

Zambonin-Zallone et al. (1982) isolated chicken medullary bone osteoclasts that lacked CT receptors and showed no increase in cAMP levels in response to CT. Similar results were reported by Ito et al. (1985) and Nicholson et al. (1986, 1987). However, isolated osteoclasts from chicks fed low-Ca diets do possess CT receptors; hence, osteoclastic bone resorption is inhibited by the CT treatment (Rifkin et al., 1988; Eliam et al., 1988). In these reports, interestingly, plasma Ca levels influence the induction of CT receptors in osteoclasts, suggesting that CT receptors in chicken osteoclasts are remarkably downregulated with high plasma Ca levels. Furthermore, Gay (1988) and Gay and Weber (2000) reported that isolated chick osteoclasts possess CT-binding sites that mediate the signal without the increase of cAMP levels, and CT inhibits the osteoclastic bone resorption within a few minutes. PTH-binding sites were also detected in chick and hen medullary bone osteoclasts (Teti et al., 1991; Agarwala and Gay, 1992), and the PTH induction of the osteoclastic bone resorption is directly mediated by PTH receptors on osteoclasts, contrary to the mammalian observations where PTH indirectly stimulates the osteoclastic bone resorption via PTH receptors on osteogenic cells (May et al., 1993). Estrogen receptors are detected in isolated medullary bone osteoclasts (Oursler et al., 1993), and receptor occupancy inhibits the lysosome-related genes and adhesion activity of the medullary bone osteoclasts (Oursler et al., 1993; Sugiyama et al., 1999). However, estrogen receptors were not detected in these osteoclasts by histochemical techniques (Ohashi et al., 1990a, 1990b; Imamura et al., 2006), Brubaker and Gay (1999) suggested that bone resorption of chick osteoclasts is directly inhibited by a membrane-mediated nongenomic action of estrogen.

Yasuoka et al. (2001) studied developmental changes of PTH, PTHrP, and CT receptor binding properties in chicken calvaria and kidneys. The equilibrium dissociation constant (Kd) and the maximum binding capacity (Bmax) of receptors for PTH, PTHrP, and CT in the membrane fraction of calvariae and kidney were examined from one day after the hatch up to 24 weeks of age using radioligand binding assays. Kd values of the PTH and PTHrP receptor in both tissues were decreased at 10 and 24 weeks in female birds, whereas values were increased at 24 weeks in males. Bmax values of the PTH and PTHrP receptor in both tissues decreased at 10 weeks and returned to baseline at 24 weeks in females but then increased at 24 weeks in males. The Kd and Bmax values of CT receptors in both tissues were constant during these periods in both sexes. This suggested that binding properties of PTH–PTHrP receptors but not CT receptors may be influenced by gonadal hormones relating to sexual maturation.

25.4.1.4 Role of Extracellular Calcium

Freshly isolated quail medullary bone osteoclasts, unlike those from neonatal rats, do not respond to elevated extracellular Ca $[Ca^{++}]_e$ by a rise in intracellular Ca $[Ca^{++}]_i$ (Bascal et al., 1992). Unlike rat cells, cultured chicken osteoclasts are sensitive to changes in membrane voltage and to dihydropyridine-type Ca^{++} channel blockers (Miyauchi et al., 1990). When medullary bone osteoclasts are cultured away from bone substrata for several days, they recover an ability to respond to elevated $[Ca^{++}]_e$, but neither the fresh nor cultured cells exhibit any response to CT in terms of raised $[Ca^{++}]_i$ (Arkle et al., 1994). Freshly isolated quail medullary osteoclasts are also refractory to $[Ca^{++}]_e$ in terms of cell spread area; however, unlike neonatal rat cells, they respond to ionomycin (a Ca^{++} ionophore) with modest reductions in cell spread area. This suggests that the quail cells retain intracellular mechanisms necessary for elaboration of the aforementioned responses, but lack receptor mechanisms for detecting changes in $[Ca^{++}]_e$. When medullary bone osteoclasts are cultured for several days, the stimulus causes a reduction in cell spread area similar to that in fresh rat cells (Bascal et al., 1994). These results indicate that putative Ca^{++} "receptors" on freshly isolated quail medullary bone osteoclasts are normally downregulated but that this disappears upon culturing the cells for several days. This suggests that during the eggshell calcification cycle, when resorption of medullary bone prevails and raised local Ca^{++} levels are generated by intense osteoclastic activity, osteoclasts become insensitive to inhibitory factors such as elevated $[Ca^{++}]_e$ (Figure 25.6).

Ca-sensing receptors (i.e., CaRs) are present in many cell types. In skeletal tissues, CaRs are present in osteoblasts, osteocytes, and chondrocytes (Rodriguez et al., 2005). Discovering the signaling pathways utilized by CaRs has been fraught with difficulty. This is perhaps not surprising since Ca ions are utilized by cells in a plethora of ways, including maintaining membrane potential and serving as an intracellular signal. Ca^{++} moves across the plasma membrane through a variety of channels, including stretch-activated channels. Ca^{++}-ATPase pumps are also employed. There is general agreement that raised extracellular Ca^{++} stimulates proliferation of osteoblasts and inhibits osteoclastogenesis (Theman and Collins, 2009). While the precise roles of CaR in bone cells are unknown, one possibility worthy of investigation is that early-stage osteoblasts may be able to follow a Ca^{++} gradient and migrate to sites of bone resorption. Also, inhibition of osteoclasts by elevated local $[Ca^{++}]$ closes a negative feedback loop.

25.4.1.5 Actions of Vitamin D

Feeding laying hens vitamin D deficient diets results in medullary bone resorption, while in nonlaying birds osteodystrophy results (Wilson and Duff, 1991). The vitamin D metabolite, $1,25(OH)_2D_3$, appears to facilitate bone formation by inducing biosynthesis of osteocalcin (bone γ-carboxy-glutamic acid protein). The biological function of this noncollagenous vitamin D binding protein in skeletal mineralization is obscure, although it appears to be a specific product of osteoblasts during bone formation. This small MW bone protein has been purified and sequenced for several species, including chicken. Its precise function is unknown, but it binds Ca^{++} and shows affinity for hydroxyapatite, suggesting an involvement in mineral dynamics (Hauschka et al., 1989). Osteocalcin is released into the circulation, where it provides a convenient index of bone turnover, reflecting new osteoblast formation rather than release of matrix protein during bone resorption (Nys, 1993). Osteocalcin synthesis is stimulated by binding $1,25(OH)_2D_3$ to promoter elements and enhancing osteocalcin gene transcription. However, unlike intestinal calbindin, substantial osteocalcin synthesis occurs in vitamin D-deficient chicks (Lian et al., 1982).

Approximately 30–40% of eggshell Ca derives from medullary bone, the remainder being provided directly by dietary sources (Simkiss, 1967; Dacke, 1979; Hurwitz, 1989a). Formation of medullary bone matrix is induced by gonadal steroids regardless of vitamin D status, although it only becomes fully mineralized when both vitamin D_3 and the steroids are present (Takahashi et al., 1983). Nys (1993) reports that changes in blood osteocalcin levels parallel those of $1,25(OH)_2D_3$ in laying hens so that concentrations of blood osteocalcin rise in hens fed a low-Ca diet and decrease in hens laying thin-shelled eggs. It is possible that increased osteocalcin levels in response to estrogen are a reflection of increased vitamin D receptor expression by osteoblasts (Liel et al., 1992). However, osteoclasts from medullary bone as well as from rat bone appear to be devoid of $1,25(OH)_2D_3$ receptors, and the effects of the metabolite are considered to be mediated via the osteoblasts (Merke et al., 1986). Harrison and Clark (1986) cultured medullary bone obtained from egg-laying hens and demonstrated that these cultures could respond to $1,25(OH)_2D_3$ by a dose-dependent inhibition of $[^3H]$-proline uptake.

The vitamin D receptor (VDR) shares a conserved structural and functional organization with other nuclear receptor (NR) superfamily members. For many NRs, N-terminal variant isoforms that display distinct cell-, stage- and promoter-specific actions have been identified. The novel VDR isoform VDRB1, with a 50 amino acid N-terminal extension, is produced from low-abundance transcripts that contain exon 1d of the human VDR locus. There is evidence for the conservation of this exon in other mammalian and avian species. The transactivation differences between VDRB1 and the original VDR provide insights into mechanisms that may contribute to

functional differences and potentially distinct physiological roles for these two VDR isoforms (Gardiner et al., 2004). A detailed review of the molecular mechanisms of vitamin D actions in mammals is provided by Haussler et al. (2013).

25.4.1.6 The RANK–RANKL–OPG System

Elucidation of how bone cells interact through the RANK–RANKL–OPG system is currently a very exciting area of skeletal research. A review by Nakashima and colleagues (2012) provides an historical and up-to-date account of the discoveries so far. This system is essential for osteoclast differentiation and activation. RANK is a transmembrane receptor found on osteoclasts and osteoclast progenitor cells. RANKL, the ligand for RANK, occurs in both soluble and membrane-bound forms and is expressed in a number of cell types, including osteoblasts and osteocytes. Osteoprotegerin (OPG), so named because of its protective role for bone, is a soluble decoy receptor that binds to RANKL and thereby blocks the signaling pathways that lead to osteoclast formation and activation. The RANKL–OPG ratio is useful for estimating the extent of osteoclastogenesis. Genes for all three proteins are known, making it possible to overexpress or ablate expression in specific cell types both *in vitro* and *in vivo*. Much information comes from gene manipulation in mice, but a number of studies with avian systems reveal the necessity of RANK, RANKL, and OPG in birds as well. The expression of the components of this system is regulated by a number of osteotropic hormones.

OPG was the first of the triad to be discovered by two independent groups (Simonet et al., 1997; Yasuda et al., 1998a) using a variety of molecular approaches described in a review by Khosla (2001). OPG is widespread in occurrence, being expressed in lung, heart, kidney, liver, stomach, intestine, brain, spinal cord, mesenchymal cells in bone marrow, osteoblasts, and osteocytes. Identification of OPG quickly led to the realization that OPG likely bound to an unidentified component that stimulated osteoclastogenesis. This unidentified component turned out to be the elusive osteoclast-differentiating factor (ODF). Using expression cloning with OPG as a probe, ODF was found to be identical to RANKL (Lacey et al., 1998; Yasuda et al., 1998b). These two groups of investigators developed the concept and proved that direct contact between RANKL-expressing osteoblasts and RANK-possessing osteoclasts, and their progenitors, is essential for osteoclastogenesis during bone development and growth to proceed. This was an important, major advance in understanding osteoclastogenesis.

RANKL, the second member of the triad to be discovered in bone, occurs in a number of cell types, including osteoblasts, osteocytes, bone marrow stromal cells, and several lymphoid cells. Since 1998, a vast literature has emerged that shows how RANKL expressed by osteoblasts controls osteoclasts, as a review by Suda et al. (2012) describes. Meanwhile, osteocytes have been found to express RANKL in great abundance, at a level several-fold higher than in osteoblasts, and to control RANK-expressing osteoclasts during bone remodeling (Bonewald, 2011; Xiong et al., 2011; Nakashima et al., 2012). This conclusion is based on gene deletion studies. In both osteoblasts and osteocytes, RANKL synthesis is increased by $1,25(OH)_2D_3$, PTH, PGE_2, glucocorticoids, and a number of proresorptive cytokines (e.g., interleukins) and is downregulated by estrogen (Khosla, 2001; Nakashima et al., 2012).

RANK, the third triad member, is the receptor for RANKL and is found on osteoclasts and their progenitor cells. RANK–RANKL interaction is essential for the development of osteoclasts from progenitor cells to fully functional, multinucleate resorptive cells. M-CSF (macrophage colony-stimulating factor) is also required. Both RANK and its ligand, RANKL, had been identified previously (and named) by immunologists, so the search for RANK in osteoclasts fell readily into place (Hsu et al., 1999). Many of the molecular details of the signaling pathway that follow RANK–RANKL interaction are coming to light through use of the tools of gene expression in mice, as described in recent reviews (Ross, 2008; Nakashima et al., 2012; Bonewald et al., 2013).

While elucidation of the RANK–RANKL–OPG story has been carried out largely in mice, studies with avian skeletal cells make it clear that avian osteoblasts, osteocytes, and chondrocytes control avian osteoclasts through RANK–RANKL interaction. Human recombinant (hr) RANKL has been shown to stimulate the resorptive activity of osteoclasts isolated from embryonic chick tibia (Boissy et al., 2001) and from bone marrow of Muscovy ducks (Gu et al., 2009). A model for examining podosome development utilized the transition of avian monocytes to osteoclasts by treating monocyte cultures with hrRANKL (Pfaff and Jurdic, 2001). Primary sternal chondrocytes isolated from chickens were found to express cell surface RANKL and stimulate osteoclast formation and resorptive activity at the eroding face of the growth plate (Masuyama et al., 2006). Chicken RANKL has been shown to induce osteoclast formation from chicken bone marrow and to activate primary chicken osteoclasts (Wang et al., 2008). Bone morphogenetic protein-2 (BMP2) induced RANKL in chicken and mouse chondrocytes and stimulated osteoclastic resorption (Usui et al., 2008). Embryonic chick calvaria are widely used as a source of osteocytes for RANK–RANKL investigations. These studies indicate that there is considerable conservation of RANKL and its receptor, RANK, among avian and mammalian species. OPG has been similarly conserved. Chicken OPG has been shown to inhibit Ca^{++} release, to reduce the amount of TRAP expressed, and to increase apoptosis of chick embryo-derived osteoclasts (Hou et al., 2011) and of primary chicken osteoclasts

(Wang et al., 2008). The signaling pathways of the controlling factors of osteoclastic bone resorption (RANKL, vitamin D, PTH, etc.) have been and are being studied in great detail in mammalian systems; it is likely that these pathways will be similar or the same in avian species, given the close parallels found so far.

With the advent of techniques to isolate highly pure, viable osteocytes, it has become apparent that RANKL is expressed by osteocytes in great abundance and that direct contact of osteocyte processes with osteoclasts has profound effects on osteoclast function. How do matrix-embedded osteocytes gain control of surface-bound osteoclasts and their progenitors in bone marrow? Anatomically, osteocyte processes have been shown to reach through and beyond the osteoblast layer of chick calvarial bone surfaces (Kamioka et al., 2001), and the processes can be as long as 1 mm, a length ~100 times the diameter of an osteocyte (Sugawara et al., 2005). This makes it possible for osteocytes to physically connect with osteoclasts and cells in the bone marrow compartment. Additionally, the soluble form of RANKL has a molecular mass of ~31 kDa (Lacey et al., 1998), small enough to diffuse through canaliculi and have effects quite distant from sites of synthesis. Osteocytes also secrete the small, diffusible OPG.

As the osteocyte transforms from an osteoblast on a bone surface, it must change shape, develop long processes (about 50 per cell), secrete unmineralized matrix (osteoid), regulate the mineralization of osteoid, and develop and maintain contact with other bone cells (i.e., osteoblasts, bone-lining cells, osteoclasts, and each other). The molecular composition of the osteocyte changes profoundly during this transition (Bonewald, 2011). Osteocytes, rather than being simple, passive cells that serve only to maintain bone, are substantially different from osteoblasts and are, in fact, the regulators of bone remodeling. An entire issue of the journal *Bone*, edited by Bonewald et al. (2013), provides considerable information on osteocytes as a network of communicating cells that respond to hormones, vitamins, cytokines, and mechanical forces. The roles of RANK, RANKL, and OPG in medullary bone, the formation of which requires estrogen, await investigation. Are medullary bone osteoclasts regulated by osteoblasts or by osteocyte processes reaching into the bone marrow compartment? Or will a different mechanism be found that controls the daily demands supplying Ca^{++} eggshell formation?

25.4.2 Renal Actions

PTX leads to increased urinary Ca excretion and decreased inorganic phosphate (Pi) excretion in starlings (Clark and Wideman, 1977) and Japanese quail (Clark and Sasayama 1981). Mechanisms of renal Ca and Pi regulation were reviewed by Laverty and Clark (1989). In immature males and egg-laying females, intravenous injections of PTH transiently reduce plasma Ca and Pi levels, followed by an increase peaking 20–30 min after the injection. In contrast, adult cockerels seldom show any variation in plasma Ca or Pi levels. In all birds, PTH increased the glomerular filtration rate, the urine flow rate, and Pi and Ca clearance. Infusion of CT decreases plasma Ca only in PTX chickens, but in all birds it increased GFR, urine volume, and Ca excretion, and in PTG-intact birds renal Pi clearance also increased.

Clark (1991) measured serum and renal clearance of Pi and Ca and compared these in vitamin D–deficient and vitamin D–replete chickens. She observed that most renal functions studied after Ca loading, PTH administration, or PTX are unaltered by vitamin D deficiency in the chicken. The major significant finding was that vitamin D-deficient chickens do not excrete increased amounts of Pi in response to PTH stimulus.

Renal Ca and Pi homeostasis in birds, as in mammals, depends on a balanced release of PTH and CT. However, in the chicken, response times are faster, thus minimizing fluctuations in plasma Ca and Pi levels. This rapid homeostatic response is less effective when Ca demands are high in growing or laying birds (Sommerville and Fox, 1987).

Goldstein et al. (1999) studied second messenger production in avian medullary nephron segments in response to peptide hormones. Activity of adenylyl cyclase in the thin descending limb was stimulated approximately twofold by PTH but not by other hormones tested: arginine vasotocin (AVT), glucagon, atrial natriuretic peptide (ANP), or isoproterenol, each at 10^{-6} M. Activities in the thick ascending limb were stimulated two- to threefold by both AVT and PTH. These data support a tubular action of AVT and PTH in the avian renal medulla.

Dudas et al. (2002) studied transepithelial Pi transport regulation by PTH in chicken proximal tubule epithelium. The effect of PTH and activation of PKC and PKA on transepithelial Pi transport was examined in monolayers of chick proximal tubule cells (PTCs) in primary culture. Acute exposure of the PTCs to PTH (10^{-9} M, basolateral side) significantly decreased the net reabsorption of Pi by approximately 66%. There was no effect after the addition of PTH to the luminal side. PTH inhibition was blocked by either Bisindolylmaleimide I (a highly selective PKC inhibitor) or H-89 (a potent inhibitor of PKA). Tissue electrophysiology remained stable after all treatments. PTH treatment decreased immunoreactivity of the luminal Na^+–Pi cotransporter NaPi-IIa. These data indicate that PTH inhibition of Pi reabsorption in this *in vitro* system is mediated by PKC and PKA.

Electrophysiological responses to PTH were studied by Laverty et al. (2003) in primary cell confluent monolayer cultures of chick proximal tubules. These exhibited vectorial transport, including glucose-stimulated current. Under short-circuit conditions, PTH induced dose-positive current

(short-circuit current (I(sc))) responses, with a 2 min peak response over baseline followed by slow decay. Responses were dose dependent, and half-maximal at 5×10^{-9} M. They were nearly abolished by apical addition of EIPA, an inhibitor of Na^+–H^+ exchangers, and partially blocked by Cl^- channel blockers. Bilateral reduction of Cl^- in the buffer from 137 to 2.6 mM abolished the response. The authors concluded that in the chick proximal tubule, PTH activates both a Na^+–H^+ exchanger and a Cl^- channel that may be functionally linked. Yasuoka et al. (2001) documented developmental changes of PTH, PTHrP, and CT receptor binding in chicken kidneys (and calvaria).

Bouizar et al. (1989) studied distributions of renal CT-binding sites in vertebrates. No renal ^{125}I-sCT binding sites were detected in fish, amphibians, or reptiles. In rat, chicken, and quail binding, CT binding sites observed in the medulla and in the cortex. The pattern followed the distribution of the glomeruli and/or the collecting tubules, suggesting that CT renal receptors appeared late in evolution and regulation of renal function by CT is effective in only birds and mammals. As mentioned in this chapter, CT has effects on renal Ca and Pi excretion, being most pronounced in PTX chickens.

25.4.3 Actions on Intestine and Oviduct

Ogawa et al. (2000) and Ieda et al. (2000) described PTH receptor binding in the endometrium of the shell gland (uterus) of the oviduct of, respectively, the guinea fowl and domestic hens during an oviposition cycle. Receptor binding in the membrane fraction was analyzed by the use of [^{125}I] PTH-related peptide (PTHrP) binding assays. Specificity, reversibility, and saturation of binding were demonstrated, while in both studies, Scatchard plots revealed a single class of binding sites. The equilibrium dissociation constant (Kd) was 0.50–1.15 nM in laying birds and 1.07–1.16 nM in nonlaying birds. Maximum binding capacity (Bmax) per milligram of membrane protein was 65.2–110.9 fmol in laying birds and 105.8–120.6 fmol in nonlaying birds. Both Kd and Bmax values changed within the above range during an oviposition cycle in laying birds, showing a decrease during the period of eggshell formation. No change was found in nonlaying birds. These results collectively suggest that PTH and PTHrP act on the endometrium of the ESG during eggshell calcification (discussed further in this chapter).

Intestinal absorption of Ca is regulated by $1,25(OH)_2D_3$ by inducing RNA transcription and synthesis of proteins such as calbindin D28k. The physiological function of calbindin D_{28k} is not well established, but its concentration in the intestine is reflected by the ability to absorb Ca. Three forms of calbindin D28k with varying size have been identified in the chicken intestine, with the smallest being most abundant (Nys, 1993). In vitamin D deficient chicks, intestinal calbindin mRNA is barely detectable but increases dramatically following $1,25(OH)_2D_3$ injection (Mayel-Afshar et al., 1988). The onset of ovulation in hens is associated with increased intestinal Ca absorption and elevated concentrations of calbindin D28k (Nys, 1993) coinciding with increased plasma $1,25(OH)_2D_3$ concentrations (Castillo et al., 1979; Nys et al., 1992). A similar or identical protein is present in the ESG (Fullmer et al., 1976). The uterus of the laying hen contains receptors for $1,25(OH)_2D_3$, although a large part of the calbindin appears to be independent of this metabolite (Coty, 1981). Uterine calbindin and its mRNA concentration increase in immature pullets treated with estrogen and are higher in hens laying thin-shelled eggs (Navickis et al., 1979). However, the effect of the sex steroid on uterine calbindin appears to be an indirect one, probably related to the general development and maturation of the oviduct (Nys, 1993). Although concentrations of uterine calbindin and its mRNA rise during formation of the first and subsequent eggs in chickens and quail, they are not directly related to the activity of $1,25(OH)_2D_3$ (Bar et al., 1992; Nys, 1993). The function of uterine calbindin is not precisely established, but its presence is indicated wherever there is a physiological requirement for Ca translocation across the uterine wall (Hurwitz, 1989a).

Sugiyama et al. (2007) investigated the expression and localization of calbindin D28k in all intestinal segments of laying hens. Western blotting analysis showed that the entire intestine expressed CaBP-D28k to the following degree: duodenum>jejunum>cecum>ileum>colon; while immunohistochemistry showed strong CaBP-D28k localization in enterocytes along the villus tip-crypt axis in the duodenum and in villus tips in the cecum and colon. The jejunum and ileum had moderate localization with respect to the number of immunoreactive cells and staining intensity. This suggests that laying hens actively absorb Ca in both the large and small intestines.

Ogawa et al. (2003), using radioligand binding assays of membrane fractions of the endometrium, identified CT receptors in the shell gland of the guinea fowl and changes in binding properties during an oviposition cycle. The equilibrium Kd obtained by Scatchard analyses was 0.50–1.25 nM in laying birds and 1.12–1.19 nM in nonlaying birds, while the Bmax per milligram of protein was 33.1–107.5 fmol in laying birds and 101.4–114.9 fmol in nonlaying birds. Both Kd and Bmax values changed during eggshell formation in laying birds, suggesting that CT receptor binding may be related to eggshell formation.

Krzysik-Walker et al. (2007) studied CT expression in the chicken ovary and identified influences of follicular maturation and ovarian steroids. CT has been linked to reproduction specifically as a marker for embryo implantation in the mammalian uterus. Although CT expression is documented in several tissues, there are no previous reports of CT production by the ovary of any vertebrate

species. Using RT-PCR, they detected CT mRNA and the CT receptor (CTR) mRNA in the granulosa and thecal layers of preovulatory and prehierarchical follicles. Both CT and CT mRNA were localized in granulosa and thecal cells. Using quantitative PCR analysis, the F1 follicle granulosa layer was found to contain significantly greater CT mRNA and CTR mRNA levels compared with those of any other preovulatory or prehierarchical follicles. Progesterone treatment of sexually immature chickens resulted in a significantly greater abundance of ovarian CT mRNA, whereas estradiol or prostaglandin combined with estradiol treatment significantly reduced ovarian CT mRNA. These results suggested that follicular maturation and gonadal steroids influence CT and CTR gene expression in the chicken ovary.

25.4.4 Actions on Smooth Muscle

PTH has potent hypotensive activity in several vertebrate classes, including birds. In the domestic hen, a PTH bolus reduces bone blood flow before 3 min, which is associated with transient hypocalcemia, followed by hyperemia within 30 min associated with an increased venous–arterial Ca gradient and hypercalcemia (Boelkins et al., 1976).

More recently, dose-dependent relaxant effects of PTH and PTHrP were demonstrated on oviduct motility in bird and mouse oviductal tissues *in vitro* (Francis et al., 2003). Effects of N-terminal PTH and PTHrP on the spontaneous *in vitro* contractility of oviductal smooth muscle using tissues from egg-laying Japanese quail (10–15 h post ovulation) and 4–9 days pregnant mouse uterus were investigated. Myometrial tissues from both species contracted vigorously for several hours when incubated in organ baths in De Jalon's solution. Contractions were enhanced in high (1.2–2.5 mM) compared with low (0.1–0.5 mM) Ca-containing media. Bovine PTH (1–34 amide) (bPTH (1–34)), human PTH (1–34) (hPTHrP (1–34) amide), and hPTHrP (1–40) caused similar concentration-related inhibition of contractions in media containing 1.2 mM Ca over dose ranges of 10^{-9}–10^{-7} M, whereas C-terminal hPTHrP (107–139) was devoid of activity. Responses to bPTH (1–34) were inhibited by both nonselective and selective neuronal nitric oxide synthase (NOS) inhibitors, which were more effective in inhibiting bPTH (1–34)-induced relaxation in the absence of L-arginine compared with in the presence of 1 mM L-arginine (an NOS substrate) in the incubation media. This suggests that relaxant responses to N-terminal PTH and PTHrP peptides are well conserved in oviductal and uterine tissues from avian and mammalian species. The results also suggest that NO may be responsible for mediating relaxant activities of these peptides in a variety of uterine tissues.

25.5 PARATHYROID HORMONE RELATED PEPTIDES

PTHrP is found in the circulation of certain patients with malignancy-associated hypercalcemia and also as the predominant peptide in fetal mammals. PTH and PTHrP genes are located on different chromosomes but share common organizational features, and the peptides show much structural homology, suggesting a common ancestral gene. PTHrP exists in three known forms, ranging in size from 139 to 173 amino acids, as the result of alternative gene splicing. It has a wide spectrum of actions in mammals, many in common with PTH, ranging from stimulation of osteoclastic bone resorption to enhancement of placental mineral transport (Mallette, 1991). PTHrP is expressed in a variety of tissues in chick embryos, this molecule having a highly conservative structural homology with the human sequence, the first 21 residues being identical (Schermer et al., 1991). It is also expressed in the isthmus and shell gland of the hen's oviduct, where it has a potential role as a local modulator of vascular smooth muscle tension and shell gland motility during the egg-laying cycle (Thiede et al., 1991). They followed the expression of PTHrP in the shell gland at different times in the laying cycle and found levels of PTHrP to transiently increase as the egg moves through the oviduct, gradually returning to basal levels during the calcification period. PTHrP mRNA and immunoreactive PTHrP were localized to the shell gland serosal and smooth muscle layer, suggesting that the peptide may modulate vascular smooth muscle activity. In support of this hypothesis, synthetic chicken PTHrP (1–34) NH_2 was found to relax the resting tension of isolated shell gland blood vessels in a dose-dependent manner (Thiede et al., 1991). Together, these data indicate that expression of the PTHrP gene in the avian oviduct is both temporally and spatially regulated during the egg-laying cycle and that PTHrP functions as an autocrine–paracrine modulator of shell gland smooth muscle activity. The vasorelaxant properties of N-terminal fragments of PTHrP support a role for this molecule in the temporal increase in blood flow to the shell gland during egg calcification.

PTHrP (1–34) was tested in the chick hypercalcemic assay and showed only slight PTH agonist activity with respect to either plasma Ca levels or ^{45}Ca clearance. In femur, the peptide caused a substantial decrease in ^{45}Ca uptake, while in calvarium the opposite effect apparently occurred (Dacke et al., 1993a). Fenton et al. (1994) studied carboxyl-terminal peptides from PTHrP for their effect on bone resorption by embryonic chick osteoclasts. Basal bone resorption was directly inhibited by chicken and human PTHrP (107–139) and by the pentapeptide PTHrP (107–111). The number of resorption pits and total area resorbed per bone slice were reduced by PTHrP (107–139), while resorption stimulated by hPTH (1–34) in co-cultured chicken osteoclasts and osteoblasts was also inhibited by

cPTHrP (107–139). These results suggest that c-terminal PTHrP may be a paracrine regulator of bone cell activity.

Schermer et al. (1994) studied functional properties of synthetic chicken PTHrP fragments in chicken renal plasma membrane, 19-day chick embryonic bone cells, canine renal plasma membranes, and rat osteosarcoma cells (UMR-106-H5). The biologic activities of human PTHrP (1–34) and bovine PTH (1–34) are remarkably similar despite marked sequence divergence in their primary binding domain, residues 25–34. In both avian and mammalian systems, the binding affinity of [36Tyr]cPTHrP(1–36)NH_2 is half that of hPTHrP(1–34)NH_2. Potencies of [36Tyr]cPTHrP(1–36)NH_2 and hPTHrP(1–34)NH_2 for activation of adenylate cyclase were similar in canine renal membranes and chick bone cells. In UMR-106 cells and chicken renal membranes, the potency of [36Tyr]cPTHrP(1–36)NH_2 for activation of adenylate cyclase was half that of [36Tyr]hPTHrP(1–36)NH_2. Binding of ^{125}I-[36Tyr]cPTHrP(1–36)NH_2 to chick bone cells and chicken renal membranes was completely displaced by bPTH(1–34) and hPTHrP(1–34)NH_2, suggesting no evidence for a distinct chicken PTHrP N-terminal receptor.

Medill et al. (2001) studied PTHrP expression in the epiphyseal growth plate of chick bones and concluded that most of the PTHrP present originates in the growth plate itself. Furthermore, the presence of large amounts of PTHrP protein in the hypertrophic zone supports the concept that PTHrP has other paracrine functions in addition to regulating chondrocyte differentiation.

25.6 CALCITONIN GENE-RELATED PEPTIDE AND AMYLIN

CGRP is a 37 amino acid neuropeptide derived from the same gene as CT, both belonging to the amylin superfamily (Rosenfield et al., 1983). Unlike CT, which is expressed mainly within the avian ultimobranchial body, CGRP is found within the central and peripheral nervous system, including the chicken retina (Kiyama et al., 1985), carotid body (Kameda, 1989), spinal cord motor neurons of developing embryos and posthatch chicks (Villar et al., 1988), and bone neurones (Bjurholm et al., 1985), where its distribution corresponds with that of substance P (Mallette, 1991). It is also expressed within the dense distributions of peptidergic neurones found within the chick ultimobranchial gland (Kameda, 1991). CGRP molecules from human, rat, cow, salmon, and chicken have been sequenced; the structure is well conserved with around 90% structural homology between chicken and human CGRPs, compared with only 50% between respective CT molecules (Zaidi et al., 1990a). CGRP presence in bone neurones, coupled with the interaction of this peptide with osteoclastic CT receptors (Goltzman and Mitchell, 1985; Zaidi et al., 1987), suggests a paracrine role, modulating bone turnover and hence Ca homeostasis. A further member of the CT–CGRP family, amylin, a peptide from pancreatic islet cells, is the most potent non-CT peptide thus far discovered, at least in mammalian assay systems (Zaidi et al., 1990a). CGRP has several putative physiological functions. It is a potent vasodilator and is implicated in central and peripheral neurotransmission and modulation (Zaidi et al., 1990a). Its role in bone and Ca metabolism is also recognized. CGRP shares the acute hypocalcemic effects of CT, albeit at around 1000-fold less potency in rodents, in inhibiting bone resorption, stimulating cAMP production in mouse calvaria, and inhibiting neonatal rat osteoclastic spreading (Zaidi et al., 1990a). In the rabbit, *in vivo* CGRP causes transient hypocalcemia followed by a more sustained hypercalcemia (Tippins et al., 1984), and the same paper reported *in vivo* hypercalcemic effects of the peptide in chicks. These findings in chicks were repeated and extended (Bevis et al., 1990; Ancill et al., 1991). Bevis et al. (1990) gave details of comparative dose response curves for CGRP and PTH in chicks, the two peptides being approximately equipotent on a molar basis. In Ancill et al. (1991), we investigated the effects of the peptide on a simultaneously injected ^{45}Ca label in the plasma. Intravenous injection of rat CGRP gave a rapid hypercalcemic response that was sustained for at least 1 h. This was most evident in nonfasted chicks, while fasted chicks gave a hypophosphatemic response and increased plasma ^{45}Ca clearance. The effect of CGRP on ^{45}Ca uptake into the chick skeleton was subsequently investigated (Ancill et al., 1991). Both rat and chicken CGRP sequences caused transient (10 min) increases in ^{45}Ca uptake into a variety of bone types, these responses being well developed in fasted chicks but absent in fed ones; the greatest were in calvariae and vertebrae. Furthermore, with low doses of CGRP, reversal of the response was noticed in the calvaria but not in other bone types, while in fed animals this was the only response seen, again in the calvaria. These findings indicate that CGRP may have a variety of effects on bone and Ca metabolism in the chick that involve acute effects on net movement of Ca into and out of the skeleton. However, while consistent with changes in plasma ^{45}Ca clearance, they seem too transient to account for them and would not account for the hypercalcemic responses found, although some alternative target site such as the kidney (Zaidi et al., 1990b) may be responsible for these.

Mixed bone cell cultures obtained by sequential collagenase-trypsin digestion of neonate chick and rodent calvariae respond to CGRP with increases in cAMP formation (Michelangeli et al., 1989). This effect was not the result of an action as a weak CT agonist, since in most instances no CT effect was observed. They concluded that chick, rat, and mouse bones contain osteoblast-rich populations that respond specifically to CGRP by a rise in cAMP.

Another member of the CT family, amylin, is co-secreted with insulin from the pancreatic beta cells and can act as an osteoblast mitogen and as an inhibitor of bone resorption in mice and humans. No effect of amylin on Ca metabolism was found in chicks *in vivo* (Dacke et al., 1993a). However, Guzel et al. (2009) studied effects of amylin on bone development and egg production in hens. Hens injected subcutaneously with amylin at a 75 μg/kg dose every other day and along with control hens were slaughtered at 14, 16, 18, and 20 week of age, and serum and bone parameters were compared. In amylin-treated hens, bone Ca levels increased, whereas serum Ca decreased versus controls. Amylin also increased the cortical width of tibiotarsae in hens. Eggshell thickness was thicker in the treated groups than in controls. These results suggest that amylin may stimulate the bone and eggshell quality by increasing Ca uptake from the bloodstream and may influence the sustainability of yield in hens.

25.7 PROSTAGLANDINS AND OTHER FACTORS

Prostaglandins (PGs) are lipids that act in an autocrine–paracrine manner and mainly utilize G protein–coupled receptors that span the plasma membrane for signaling. PGs are synthesized by most cell types in the body by the action of the inducible enzyme cyclooxygenase-2 (COX2). COX2 is induced by many systemic and local factors, including cytokines (IL1, IL6, and TNFα), growth factors (TGFα, TGFβ, fibroblast growth factor-2 (FGF2), and BMP2), systemic hormones (PTH, 1,25 $(OH)_2D_3$), calcium, fluid shear and mechanical loading (Pilbeam et al., 2008). PGs are not stored but are synthesized locally as needed. They are rapidly metabolized by passage through the lungs. PGs can have both anabolic and catabolic effects. Reviews of the roles of PGs and other eicosanoids in Ca metabolism in vertebrates (including avians) include Dacke (1989) and Pilbeam et al. (2008). PG effects on mammalian bone cells are similar to those of PTH in that they stimulate cAMP production, cause transient increases in Ca^{++} influx, stimulate carbonic anhydrase synthesis, release lysosomal enzymes, and may inhibit collagen synthesis. They also elicit morphological responses in osteoclasts and osteoblasts similar to those with other osteolytic agents (Dacke, 1989). It was demonstrated that a stable methylated PGE_2 analog, 16,16-dimethyl PGE_2, is hypercalcemic when injected into chicks, the response being more profound than that in mammals (Kirby and Dacke, 1983), while indomethacin, a drug that interferes with PG synthesis, produces hypocalcemia in egg-laying chickens (Hammond and Ringer, 1978) and quail (Dacke and Kenny, 1982). In chickens, this is accompanied by a considerable delay in oviposition and thicker eggshells. PGE_2 and other eicosanoids are powerful stimulators of bone resorption (Dacke, 1989). The effects of CT, PTH, and PGE_2 on cAMP production were studied in osteoclast-rich cultures derived from avian medullary bone and the long bones of newborn rats. PGE_2 increased cAMP production in both types of osteoclasts, suggesting essentially similar mechanisms (Nicholson et al., 1986; Arnett and Dempster, 1987). In addition to PTH, CGRP, and possibly CT, PGs can acutely influence Ca exchange between avian blood and bone compartments. We previously published a simple model (Shaw et al., 1989) in which the rapid effects of PTH and PGE_2 on skeletal ^{45}Ca uptake could be explained in terms of cAMP-mediated inhibitions of outwardly directed Ca^{++} pumps located in the membranes of bone-lining cells. Such a model has its disadvantages; for example, it would be metabolically wasteful since the intracellular free Ca level would have to remain undisturbed in the face of a high rate of bidirectional transcellular Ca^{++} flux. Because of the transient nature of PGs, *in vitro* studies require careful interpretation since PGs added to cultured cells will be present over much longer periods of time than in the *in vivo* situation. However, clear-cut results from *in vivo* studies are also difficult to obtain due to the presence of several types of cells in a given locale. Adding to the complexity is that regulation by PGs occurs at multiple levels and utilizes multiple receptors. PGE_2 is the most widely utilized prostaglandin in bone. It is synthesized by all bone cell types and by hematopoietic cells. How PGE_2 is released from cells is largely unknown, with the exception that avian osteocytes have been shown to release PGE_2 through hemi-channels (Cherian et al., 2005). There are four known PGE_2 receptors in bone. In osteoblasts, PGE_2 signals through the cAMP–PKA pathway. There is evidence for a strong direct effect of PGE_2 on osteoclast activity with signaling through cAMP–PKA (Dacke, 1989; Mano et al., 2000; Okamoto et al., 2004). In addition, indirect regulation of osteoclasts can occur by increased expression of RANKL–OPG in osteoblasts and osteocytes that have been stimulated by PGE_2.

Osteopontin (OPN) is a noncollagenous protein found in many tissues, and it has a number of functions. In bone, it is secreted into matrix by osteoblasts, where it appears to have a number of roles. For example, it appears ahead of the mineralization front (Roach, 1994) and may be involved in mineralization as well as in hemopoietic stem cell regulation (Haylock and Nilsson, 2006). OPN is secreted by osteoclasts and has been postulated to be an autocrine factor that stimulates osteoclast motility (Chelliah and Hruska, 2003). It binds to αvβ3 integrin found in podosomes of osteoclasts and thereby forms a seal around the resorption pit (Pfaff and Jurdic, 2001). OPN is speculated to mediate disuse-induced osteoclastic resorption. In a study by Gross et al. (2005), OPN was found to be upregulated in immobilized long bones of turkeys.

BMPs are expressed by a number of cells, including mesenchymal cells, chondrocytes, osteoblasts, preosteoclasts,

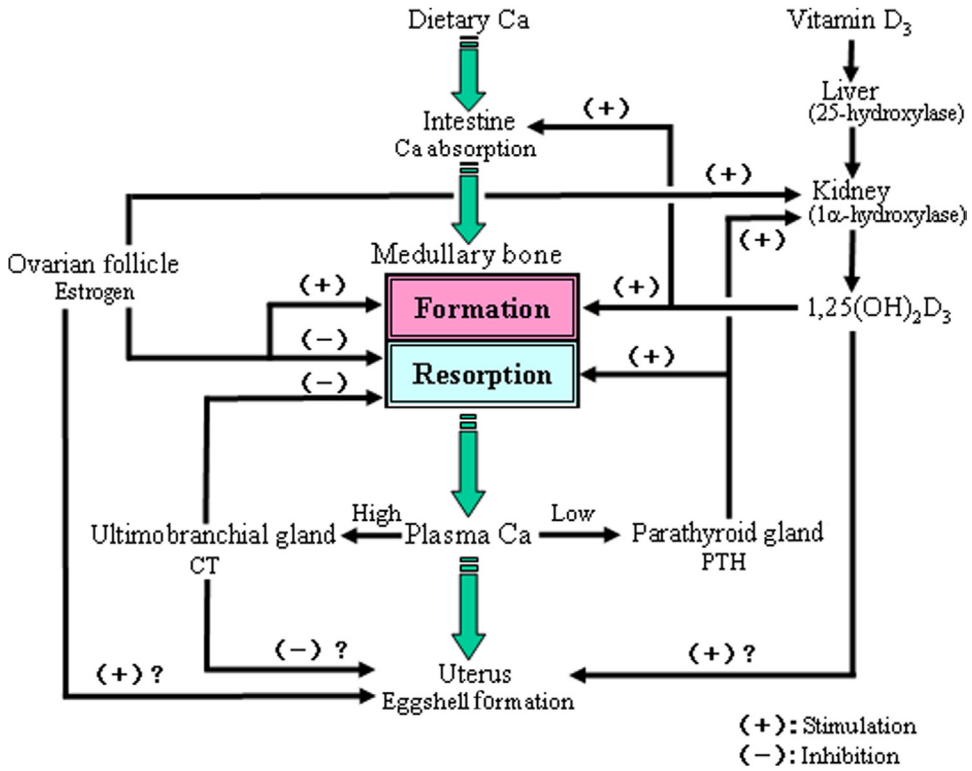

FIGURE 25.7 Summary of Ca metabolism in egg-laying birds. Transfer of Ca between diet, plasma, and medullary bone and across the oviduct may be influenced by a variety of recognized and putative hormonal factors (see text). *Modified after Sugiyama and Kusuhara (2001).*

osteoclasts, and endothelial cells. BMPs are produced locally, signaling through transmembrane receptors. The signal is relayed by Smads (Sma- and Mad-related proteins) in the cytoplasm and, upon binding to Smad4, enters the nucleus to stimulate cell proliferation. BMPs can have both anabolic and catabolic effects, depending on cross-communication among other signaling pathways and various other factors. The osteogenic function of BMPs, notably BMP2 and BMP7, has been studied extensively, as a review by Kaymia and Mishina (2011) describes. BMP2 has been shown to stimulate osteoclastic resorption through binding to BMP receptors on preosteoclasts and osteoclasts (Kaneko et al., 2000; Itoh et al., 2001) as well as hypertrophic chondrocytes in chicks and mice (Usui et al., 2008). Signaling in these latter cases is through the RANK–RANKL pathway.

25.8 CONCLUSIONS

Figure 25.7 summarizes our present understanding of the regulation of avian Ca and bone metabolism.

Within the last two decades, it has become apparent that a variety of nonclassical factors can influence bone and Ca metabolism in birds as well as in mammals. Avian responses are often more explicit than equivalent ones in mammals, for example the hypercalcemic responses to PGs. Other factors such as PTHrP and CGRP are represented in birds, while novel factors such as the RANK–RANKL–OPG system are also now recognized in birds and the next few years can be expected to provide fertile ground for new research on their role in bone and Ca metabolism in general, to which avian models are likely to make an important contribution. The interactions of these novel agents with more classical hormones in avian bone remain to be elucidated. Their interactions with gonadal steroids in forming and maintaining avian medullary bone may prove a particularly rewarding area for future studies. Medullary bone represents the most overtly estrogen sensitive of all vertebrate bone types. It forms in male birds dosed with estrogens within a matter of days, and this process can be blocked by the simultaneous administration of anti-estrogenic compounds such as tamoxifen (Ohashi et al., 1987; Williams et al., 1999). Upon cessation of estrogen treatment, medullary bone resorbs just as rapidly. Medullary bone represents an excellent rapidly responding model for studies of the effects of anti-osteoporotic drugs such as bisphosphonates. Preliminary studies indicate that the bisphosphonate alendronate can protect structural bone and inhibit medullary bone formation if given to hens before the commencement of egglay. When given during egglay, the drug reduces medullary bone volume and, at higher doses, eggshell quality (Thorp et al., 1993). It is anticipated that this model will become exploited to a much greater extent than hitherto.

Chapter 26

Adrenals

Rocco V. Carsia
Department of Cell Biology, Rowan University School of Osteopathic Medicine, Stratford, NJ, USA

26.1 ANATOMY

26.1.1 Gross Anatomy, Blood Supply, and Innervation

The paired adrenal glands are located anterior and medial to the cephalic lobes of the kidneys (Figure 26.1). Although their intraclass shape is highly variable, they are generally flat and lie close together and are closely applied to the dorsal aorta and posterior (caudal) vena cava. The gland is enclosed in a highly vascularized but extremely friable connective tissue capsule (Assenmacher, 1973; Holmes and Phillips, 1976; Chester Jones and Phillips, 1986). In the domestic chicken (*Gallus gallus domesticus*), the glands differ in shape and dimensions with the left gland being consistently heavier (Kober et al., 2012). The glands receive direct arterial blood supply from the cranial renal arteries and occasionally from the aorta. Each gland is drained by a single adrenal vein that enters the posterior (caudal) vena cava or its caudal bifurcation. In the chicken, each gland also receives one or two lymphatic vessels.

Each gland generally has two postganglionic sympathetic ganglia (cranial and caudal) embedded within the pericapsular sheath or more deeply within the outer gland substance (e.g., see Figure 26.2(A)). In the duck (*Anas platyrhynchos*), these ganglia are composed of 30–60 cell bodies (Squillacioti et al., 2008). The caudal ganglion mainly supplies surrounding organs, including the gonads. Smaller clusters of ganglion cells are found within the gland (e.g., see Figure 26.2(D)). Preganglionic sympathetic fibers in thoracic and synsacral splanchnic nerves converge on the ganglia. The preponderance of the fibers (cholinergic) course through the ganglia without synapsing and penetrate the gland substance to innervate clusters of adrenal chromaffin cells consisting of 12 or more chromaffin cells. Indeed, gland denervation leads to atrophy of the chromaffin tissue (Holmes and Phillips, 1976). In addition, postganglionic sympathetic fibers emanating from the ganglia mainly innervate the adrenal blood vessel (vasomotor), and the adrenergic type innervates the chromaffin cells. Current thinking is that the outer cranial ganglion and intraglandular ganglion cells form the adrenal intrinsic innervation; however, studies supporting this postulate are limited to chromaffin cells. In any study, endings on adrenocortical cells are rarely observed. Overall, these studies indicate that the postganglionic adrenergic innervation is, in part, involved in the regulation of catecholamine synthesis and secretion, although a nonneurogenic mechanism may operate as well in some species (Ghosh et al., 2001). Finally, there is an extrinsic innervation of additional postganglionic sympathetic fibers and possibly preganglionic parasympathetic fibers from the vagus nerve, but the extent of this innervation and its function are poorly understood. Evidence indicates that the vagus innervation affects the structural and functional integrity of both adrenocortical and chromaffin tissues (Ghosh et al., 2001).

26.1.2 Microanatomy

26.1.2.1 The Chromaffin Tissue

The adrenal gland of birds consists of an intermingling of steroid-secreting cells (adrenocortical cells) and chromaffin (adrenomedullary) cells (Figures 26.2 and 26.3). The adrenocortical cells are arranged in parallel cords of columnar cells (Figures 26.2 and 26.3) and are described later in this chapter. The chromaffin cells are larger, polygonal cells arranged in nests or clusters surrounded by a thin basal lamina. A single nerve bundle innervates the cluster such that one neuronal terminal synapses with up to three chromaffin cells of the same type (i.e., norepinephrine (NE) or epinephrine (E) chromaffin cells) (Unsicker, 1973). The consensus of studies suggests that the ratio of adrenocortical to chromaffin cells is about 1.5:1 (Holmes and Phillips, 1976). Indeed, a similar ratio has been demonstrated in dispersed chicken adrenal cells (Carsia et al., 1985a). However, there is a tendency for this ratio to increase in the peripheral region of the gland and to decrease approaching more central regions of the gland (Kober et al., 2010). Indeed, in the chicken, there is a subcapsular layer of essentially pure chromaffin cells (Kober et al., 2012).

Sturkie's Avian Physiology.

Nagele, PhD, New Jersey Institute for Successful Aging and Department of Cell Biology, Rowan University School of Osteopathic Medicine.*

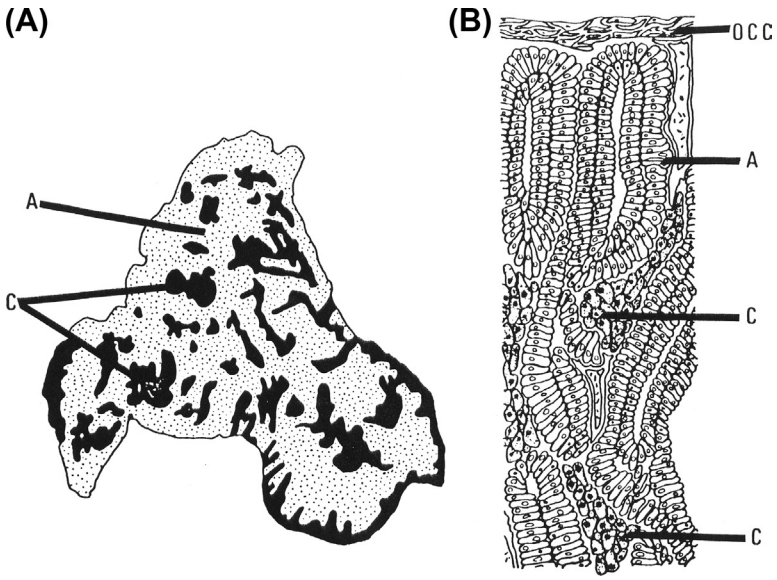

FIGURE 26.3 Microanatomy of a typical avian adrenal gland (Florida quail, *Colinus virginiatus floridanus*). (A) Distribution of chromaffin (C) and adrenocortical (A) tissue. (B) Structure of the looped cords of adrenocortical cells with intermingled chromaffin cell islets. The outer connective tissue (OCC; adrenal capsule) is also indicated. *Taken from Chester Jones and Phillips (1986).*

The ratio of E- to NE-secreting chromaffin cells varies with species. There is some suggestion that the ratio is smaller (i.e., a greater proportion of NE cells) in orders with more primitive ancestry and greater in more recently evolved birds (Ghosh et al., 2001; Kober et al., 2010). In the domestic chicken, 70% of the chromaffin cells are E-secreting cells (Ohmori, 1998). Complicating this picture is that this ratio also varies with age within the same species. Also variable are the sizes of the secretory vesicles within chromaffin cells. In galliform and anseriform species, NE vesicles tend to be larger than E vesicles. Across avian species, vesicles can range from 80 to 500 nM (Ghosh et al., 2001). In general, in NE cells, the granules are compact, electron opaque, and eccentrically placed, not completely filling the vesicles, whereas in E cells, the granules are more rarefied, are less electron opaque, and fill the vesicles (Holmes et al., 1991).

The avian adrenal gland is endowed with an intrinsic innervation. A proposed scheme based on comparative work on the chromaffin and neural components of the intrinsic adrenal regulation is shown in Figure 26.4.

The preponderance of ganglion cells are catecholaminergic; however, there appears to be noncatecholaminergic cells as well. Ganglion cells and the chromaffin cells elaborate a number of biogenic amines and neuropeptides (García-Arrarás et al., 1992; Wolfensberger et al., 1995; Ehrhart-Borstein et al., 1998; Ohmori, 1998; De Falco et al., 2008; Squillacioti et al., 2008), and avian adrenal tissues exhibit a robust expression of cognate receptors. The ganglion cells and the chromaffin cells are primarily innervated by preganglionic sympathetic fibers containing acetylcholine and neuronal nitric oxide synthase (nNOS) (Squillacioti et al., 2008). Nitric oxide appears to be mainly inhibitory on corticosteroid secretion, but the presence of nNOS in multiple postganglionic cell types, chromaffin cells, and subpopulations of ganglion cells, and within pre- and postganglionic terminals, indicates its importance. For example, it appears to be important in maintaining the normal ratio of adrenocortical tissue to chromaffin tissue (Chaturvedi and Kumar, 2007).

Another prominent peptide is vasoactive intestinal peptide (VIP) and a related peptide, pituitary adenylyl cyclase-activating peptide (PACAP). VIP is mainly present in intrinsic and extrinsic postganglionic sympathetic terminals. In addition, VIP and PACAP are synthesized in the chromaffin cells. Furthermore, receptors for these peptides exist on both adrenocortical cells and chromaffin cells, providing a robust synaptic and paracrine interaction. VIP and PACAP directly stimulate corticosteroid release from adrenocortical cells. However, VIP and PACAP also stimulate catecholamine secretion, and this, in turn, can activate β-adrenergic receptors on adrenocortical cells (Mazzocchi et al., 1997b). Here again is another example of direct synaptic and paracrine interactions controlling corticosteroid secretion and also epinephrine secretion since corticosterone stimulates epinephrine synthesis.

Concerning adrenocortical function, the avian adrenal chromaffin cells have an intrinsic corticotropin-releasing hormone (CRH)–melanocortin system and the requisite cognate receptors (Takeuchi and Takahashi, 1998, 1999; Takeuchi et al., 1998, 1999, 2000; De Groef et al., 2004; Mirabella et al., 2004). Intraadrenal ACTH can activate melanocortin-2 (ACTH) receptors on adrenocortical cells. Chromaffin cells also synthesize atrial natriuretic peptide

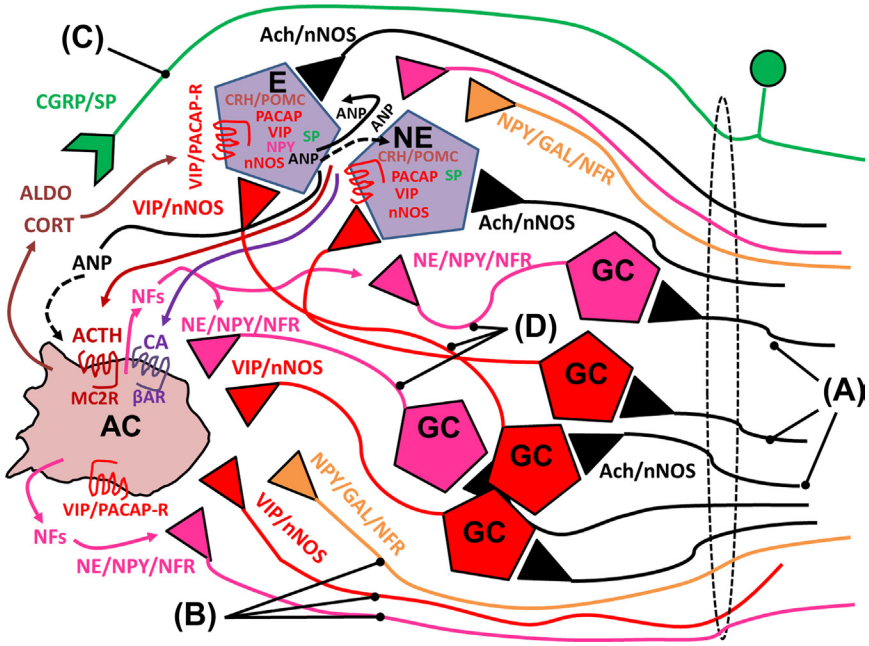

FIGURE 26.4 A proposed model for the intraadrenal neuroendocrine regulation based on comparative studies of reptiles, birds, and mammals. The neural regulation has both extrinsic and intrinsic components of the sympathetic nervous system. Its axonic terminals are represented by *black and colored triangles*. The extrinsic innervation is composed of (A) preganglionic sympathetic efferent axons containing acetylcholine (Ach) and neuronal nitric oxide synthetase (nNOS) (*black*); (B) postganglionic sympathetic efferent axons containing vasoactive intestinal peptide (VIP) and nNOS (*red*), neuropeptide tyrosine (NPY) and galanine (GAL) (*orange*), or NPY and norepinephrine (NE) (*pink*); and (C) sympathetic afferent (sensory) peripheral processes (dendrites) containing substance P (SP) and calcitonin gene-related peptide (CGRP) (*green*). *Dotted oval* represents the splanchnic nerve bundle that contains these extrinsic fibers. The intrinsic innervation (D) is composed of the postganglionic sympathetic ganglion cells (GCs; *smaller colored pentagons*) of the cranial and caudal ganglia and the scattered ganglion cells throughout the gland. A GC contains VIP and nNOS (*red*) or NPY and NE (*pink*). There is evidence that in some species, GCs also have phenylethanolamine *N*-methyltransferase for the synthesis of epinephrine, but it is not clear if this enzyme is active or if epinephrine is released from axonic terminals. Postganglionic axons containing NPY probably also express neurotrophic factor receptors (NFRs) for axonal growth. Growth of NPY axons is stimulated by neurotrophic factors (NFs) released by adrenocortical cells. This neurotrophic loop probably remodels the adrenocortical tissue during life-history cycle or stage transitions and periods of prolonged stress. The intrinsic endocrine component consists of the chromaffin cells (*larger purple pentagons*) and the adrenocortical cells (ACs). The chromaffin cells are also modifications of postganglionic sympathetic neurons and are of two functional types: epinephrine-secreting cells (E) and NE-secreting cells. These cells also have the enzymatic machinery for an intrinsic corticotropin-releasing hormone (CRH)–adrenocorticotropin (ACTH) system in that they contain and process pro-opiomelanocortin (POMC). They also contain many neurotransmitters: pituitary adenylyl cyclase-activating peptide (PACAP), VIP, SP, and the nitric oxide–producing enzyme, nNOS. In addition, the E cells contain atrial natriuretic peptide (ANP). The intraadrenal ACTH interacts with melanocortin 2 (ACTH) receptors (MC2R) on adrenocortical cells to stimulate corticosteroid (corticosterone (CORT) and aldosterone (ALDO)) synthesis and secretion (*brown arrows*). The intraadrenal CORT, in turn, stimulates E production. Whereas the intraadrenal ANP dampens corticosteroid production in adrenocortical cells and inhibits NE cell function (*dotted black arrows*), it may stimulate the conversion of NE cells to E cells (*solid black curved arrow*). Both adrenocortical and chromaffin cells have VIP–PACAP receptors (VIP–PACAP-R). In general, activation of these receptors stimulates corticosteroid and catecholamine production. Furthermore, intraadrenal catecholamines interact with β-adrenergic receptors (βARs) on adrenocortical cells to augment corticosteroid production. SP from sensory endings stimulates adrenocortical cells to produce corticosterone and aldosterone. In addition, it stimulates the release of catecholamines. CGRP and GAL also appear to be stimulatory for adrenocortical cells. In this scheme, the parasympathetic components are omitted because of the absence of definitive work. See the text for additional details. *Scheme drawn by R. V. Carsia.*

(ANP) (Wolfensberger et al., 1995). Intraadrenal ANP not only dampens corticosteroid secretion but also influences the chromaffin cell composition by inhibiting norepinephrine cells and stimulating the conversion of norepinephrine cells to epinephrine cells.

Another ubiquitous peptide is neuropeptide tyrosine (NPY). It is present in many extrinsic postganglionic terminals and in subpopulations of ganglion cells. It is also synthesized in chromaffin cells, predominantly the epinephrine cells (Squillacioti et al., 2008). Its widespread, intraadrenal distribution is matched by the number of receptor subtypes expressed in the avian adrenal gland (Bromée et al., 2006). In many cells and in axonic terminals, NPY is accompanied by galanine. NPY has the broad effect of stimulating catecholamine secretion and, indirectly, corticosteroid secretion through β-adrenergic receptor stimulation by catecholamines. However, its main effect may be to regulate the adrenocortical cell composition, that is, the rudimentary zonation, to meet physiological needs (see Tran et al., 2010). In this scenario, physiological demands or stressors stimulate the release of neurotrophic factors from adrenocortical cells, which, in turn, activate cognate receptors on

postganglionic sympathetic NPY terminals to stimulate axonal growth. The enhanced innervation induces hyperplasia of the appropriate adrenocortical cell subpopulation to address the physiological demand or stressor. When the stressor subsides, the axons regress and the zonation gradually returns to the prestressor state.

In addition to the pre- and postganglionic sympathetic efferent components, there are extrinsic afferent components, the cell bodies of which reside in the dorsal root ganglia (Figure 26.4). The peripheral processes or dendrites of type B sensory neurons release substance P and calcitonin gene-related peptide (CGRP). Substance P is also present in the chromaffin and ganglion cells. Substance P stimulates adrenocortical cells to produce corticosterone and aldosterone. In addition, it stimulates the release of catecholamines. CGRP also appears to be stimulatory for adrenocortical cells. However, in studies with the rat adrenal gland, it does not appear to function in the reorganization of the adrenocortical cell subtypes with various physiological demands and stressors (see Tran et al., 2010).

Thus, as in mammals, in addition to the direct intraadrenal innervation, there is supporting evidence for a rich environment of autocrine, juxtacrine, and paracrine interactions among chromaffin and adrenocortical cells. These interactions are further complicated when one considers the intraglandular cytokines, growth factors, and endothelial-derived substances. The impact of this extrinsic and intraadrenal regulation is poorly understood, but it may support an intrinsic clock for corticosteroid secretion rhythmicity and adrenocortical sensitivity to ACTH (Dickmeis, 2009). In short, the immunocytochemical and molecular biological observations on this regulation far exceed frank *in vivo* and *in vitro* studies in determining its importance in avian adrenal function over life history cycle and life history stage.[1] Although the emerging story of the avian intraadrenal regulation may describe additional levels of control of adrenocortical and chromaffin secretion, the "traditional" concepts of the regulation of avian adrenal function (i.e. the splanchnic innervation and the hypothalamus–pituitary–adrenal (HPA) axis) remain valid.

26.1.2.2 The Adrenocortical Tissue

The adrenocortical cells are arranged in cords that radiate from the deep part of the gland, branching and anastomosing freely (Figures 26.2 and 26.3(B)). At the periphery, the cords form tighter loops of cells that in some species resemble the glomerular structure seen in mammals (Figure 26.2). The cords consist of a double row of adrenocortical cells oriented with their columnar axes perpendicular to the cord (Holmes and Phillips, 1976). This pattern is highly variable among species, and there appears to be no phylogenetic trend (Bhattacharyya et al., 1972).

The preponderance of histological, ultrastructural, and functional evidence indicates that birds have a modest segregation of adrenocortical cell subpopulations that resembles the zonation of the mammalian adrenal cortex (Bhattacharyya et al., 1972; Pierce et al., 1978; Holmes and Cronshaw, 1984, 1993). Histological preparations reveal at least two different zones of cells: a subcapsular zone (SZ) and an inner zone (IZ). More recently, based on studies of the chicken adrenal gland and the amount of intermingling of adrenocortical and chromaffin tissues (Kober et al., 2012), a three-zone nomenclature is proposed: a subcapsular zone of essential pure, small chromaffin cells immediately deep to the capsule; a peripheral zone consisting of mainly adrenocortical cells with scattered, small islets of chromaffin cells; and a central zone in which the two tissues are evenly intermingled. However, this alternative zonal description is not apparent in other species, nor is there functional evidence to support it. Thus, for consistency in further discussions in this chapter, we shall adhere to the SZ–IZ pattern exemplified in the duck (*A. platyrhynchos*) adrenal gland.

Adrenocortical cells of the subcapsular zone are large, often binucleated, and replete with lipid droplets. Like most steroid-secreting cells, they have the troika of organelles: stores of lipid, mainly in lipid droplets; varying amounts of smooth endoplasmic reticulum; and mitochondria. The mitochondria bear regularly arranged tubular cristae (incorrectly described as platelike), similar to mammalian zona glomerulosa cells. Functionally, the tissue secretes predominantly aldosterone in response to ACTH and exclusively aldosterone in response to angiotensin II, and it is insensitive to adrenocorticotropin (ACTH) withdrawal (adenohypophysectomy) (Klingbeil, 1985; Pierce et al., 1978; Holmes and Cronshaw, 1984, 1993).

Adrenocortical cells of the IZ are smaller, are more elongated or columnar, contain fewer lipid droplets, have more abundant smooth endoplasmic reticulum, and have mitochondria bearing tubulovesicular cristae, similar to mammalian zona fasciculata cells. Functionally, the tissue secretes predominantly corticosterone in response to ACTH, is refractory to angiotensin II, and undergoes atrophy with ACTH withdrawal (adenohypophysectomy), with some cells converting to the SZ type (Klingbeil, 1985; Pierce et al., 1978; Holmes and Cronshaw, 1984, 1993).

Additional evidence for a segregation or zonation of avian adrenocortical tissue comes from work with dispersed adrenocortical cells from the domestic turkey (*Meleagris gallopavo*) subjected to dietary Na^+ restriction and in which functionally distinct cell subpopulations were segregated

[1] Life-history cycle and life-history stage are sometimes used interchangeably in the literature. Here we define life-history cycle as the avian developmental and maturational transitions: the embryonic period, hatch, posthatch (postnatal), and sexual maturation. We define life-history stage as the predicable periods or phases of sexually mature birds that are coordinated with habitat, such as the seasonal, prelaying, breeding, late-breeding, and molting periods.

based on density (Kocsis et al., 1995a). A population of high-density cells, the proportion of which was enhanced by the Na^+ restriction, had functional and ultrastructural features similar to those of mammalian zona glomerulosa cells (Figure 26.5). In addition, these cells have a disproportionately enhanced aldosterone response to angiotensin II and K^+ (Kocsis et al., 1995a).

Unfortunately, much of what is known about the functional zonation of the avian adrenal gland comes from work on a limited number of precocial species (see Holmes and Cronshaw, 1993) using tissue slices from the SCZ and IZ or dispersed adrenocortical cells. Clearly, similar work needs to be expanded to semiprecocial and altricial species. In addition, these *in vitro* studies, although facile and informative, have the inherent problem of organ disruption and at best are a declension of the *in vivo* situation. Tissue slices are conceivably better than dispersed cells. For example, whereas PACAP (Figure 26.4) induces release of corticosterone and aldosterone from chicken adrenal quarters, it has no effect on dispersed chicken adrenal cells (Mazzocchi et al., 1997a), presumably because its effect in this species is indirect through the release of catecholamines from nearby chromaffin cell islets. Nevertheless, it can be generally concluded that extrapolation of findings from any *in vitro* study to the *in vivo* condition must be viewed with caution (see Vinson et al., 1985).

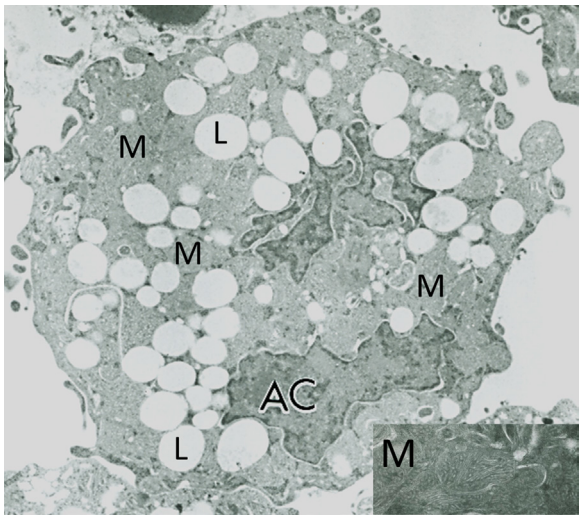

FIGURE 26.5 Section through a high-density adrenocortical cell (AC) of the growing (6 weeks old) domestic turkey (*Meleagris gallopavo*) subjected to dietary Na^+ restriction (0.04%) for 8 days (×8700). Inset: higher magnification of a section through a mitochondrion (×41,700). Features are similar to subcapsular zonal cells of the duck (*Anas platyrhynchos*) (Pierce et al., 1978). Note the numerous lipid droplets (L) and mitochondria (M) and scant endoplasmic reticulum. Inset: mitochondria have regularly arranged tubular cristae. These cells have a disproportionately enhanced aldosterone response to angiotensin II and K^+ compared with other density-separated subpopulations (Kocsis et al., 1995a). *Electron micrographs courtesy of Jean Gibney, Department of Neuroscience and Cell Biology, Rutgers University–Robert Wood Johnson Medical School.*

26.2 ADRENOCORTICAL HORMONES

26.2.1 Corticosteroid Secretory Products

The glucocorticoid corticosterone is the principal corticosteroid released by the avian adrenal gland. The principle mineralocorticoid, aldosterone, is produced in considerably less quantity in the posthatch bird. *In vitro* studies with anseriform and galliform adrenal tissue and dispersed adrenal cells indicate that the ratio of aldosterone to corticosterone production rates is about 1:19. However, based on studies in which both corticosteroids were measured, the average ratio of the baseline circulating concentrations of aldosterone to corticosterone is about 1:175 (Table 26.1). Younger birds tend to have higher circulating concentrations of each compared to those of adults. This ratio discrepancy is probably due to varying sample stress and corticosteroid half-life in the avian circulation. In a very limited number of earlier studies, the average half-lives of corticosterone and aldosterone in the circulation are similar, about 15 and 13 min, respectively. However, more recent work shows these half-lives to be considerably less, perhaps 8–9 min.

The avian adrenal gland secretes additional steroids that presumably have important ontogenetic function and play a role in life history cycle transitions (Landys et al., 2006; Wada, 2008; Wingfield, 2013). Cortisol is a significant secretory product during the embryonic and early posthatch periods, and then declines thereafter. Indeed, earlier work with chick embryos reports equivalent concentrations of

TABLE 26.1 Baseline Peripheral Plasma Concentrations of Corticosterone and Aldosterone in Some Galliform and Anseriform Birds in Which both Corticosteroids were Measured in the Same Samples by Radioimmunoassay (Averages from 26 Studies)

Bird Order	Life-History Cycle	Corticosterone (ng/ml)	Aldosterone (pg/ml)
Galliform birds[1]	Hatch	11	33
	Immature	11	46
	Adult	2	19
Anseriform birds[2]	Hatch	16	345
	Immature	8	308
	Adult	18	60

[1]Values derived from studies using the domestic chicken (Gallus gallus domesticus), the domestic turkey (Meleagris gallopavo), and the Japanese quail (Coturnix japonica).
[2]Values derived from studies using the wild mallard duck and the Pekin duck (Anas platyrhynchos) and the Muscovy duck (Cairina moschata).

adrenal corticosteroids (progesterone, corticosterone, cortisol, and cortisone) in the circulation that reach a peak near hatch and then decline after hatching (Kalliecharan and Hall, 1974). Presumably, cortisol has a role in the development and maturation of several organ systems (see Carsia et al., 1987a). During posthatch life, circulating cortisol may serve as a depot for modulation of the active hormone at the tissue level. For example, in some psittacine species, circulating cortisol is insensitive to exogenous ACTH (Lothrop et al., 1985; Walsh et al., 1985). Thus, the availability and action of cortisol may be less dependent on the HPA axis and is more dependent on regulation at the tissue level (as discussed further in this chapter).

The efficacy of corticosterone and cortisol during development and during posthatch and adult life history cycle and stage transitions is influenced by a number of factors. For example, there appear to be isoforms of corticosteroid-binding globulin that preferentially bind cortisol and, thus, influence its half-life for delivery to sensitive tissues (Schmidt et al., 2008, 2010), and there appear to be isoforms of glucocorticoid receptors (GRs) in various target tissues that selectively bind cortisol (Schmidt et al., 2010). In addition, there is interplay between systemic delivery of corticosteroids to target tissues and the intrinsic local production within tissues (Schmidt and Soma, 2008; Schmidt et al., 2008). For example, corticosterone may be synthesized or regenerated in the brain (Newman et al., 2008), and locally may mediate the acute effect of stress on brain aromatase activity in a sex-dependent manner (Dickens et al., 2011a). The picture is further complicated by the local expression of 11β- and 20-hydroxysteroid dehydrogenases that can degrade and regenerate active glucocorticoids within cells. Overall, despite its relatively low circulating concentration relative to corticosterone, cortisol produced locally throughout the posthatch life of birds (e.g., within immune tissues and possibly the brain) suggests it has unique and important functions in both an organ-specific and age-specific manner.

In addition to cortisol, the adrenal is an important source of sex steroids (Tanabe et al., 1986; Ottinger et al., 2001) during the embryonic and perinatal periods, and it complements the gonads for establishing adequate levels of androgens and estradiol. This "adrenal–gonadal unit" is thought to be important for the sexual differentiation of the hypothalamus.

Here again, as seen with cortisol, the adrenal continues to complement the gonads in the regulation of circulating sex steroids through maturity and during life history stage transitions (e.g., breeding and nonbreeding periods) (Bhujle and Nadkarni, 1976; Soma and Wingfield, 2001). Furthermore, a similar theme between systemic and locally produced sex steroids is evident, and its expression is dependent on life history cycle, life history stage, and species-specific adaptations (Schmidt et al., 2008). A growing body of evidence supports the notion that the adrenal gland assists the gonads in establishing the balance between systemic delivery of sex steroids to the brain and their local production within the brain. This dynamic balance between systemic and locally produced sex steroids establishes important central nervous signals that support breeding, territorial, and courtship behaviors (Soma and Wingfield, 2001; Schmidt et al., 2008; Pintér et al., 2011).

26.2.2 Other Secretory Products

The chicken adrenocortical tissue is a major source of inhibin during embryonic development (Rombauts et al., 1994; Decuypere et al., 1997). Dexamethasone depresses inhibin release *in ovo*, whereas ACTH elicits a rise in inhibin release that parallels corticosterone release in primary cultures of embryonic chick adrenal cells. Furthermore, the adrenal gland continues to be a complementary extragonadal source of inhibin in the adult (see Vanmontfort et al. (1997), Bruggeman et al. (2003)), and molecular studies suggest activin as well (Chen and Johnson, 1996). The roles of locally produced activin and inhibin in adrenal gland function *per se* remain to be investigated. Their release from cultured adrenal cells are directly inhibited by dexamethasone (Vanmontfort et al., 1997). Based on comparative studies, the adrenal activin–inhibin system may have a negative autocrine–paracrine effect on intraglandular steroid synthesis (Vänttinen et al., 2003).

26.2.3 Synthesis and Intraadrenal Degradation of Corticosteroids

The framework for avian adrenocortical steroidogenesis is composed of the organelles, mitochondria, smooth endoplasmic reticulum and lipid droplets, and cytoskeleton (reviewed in Feuilloley and Vaudry (1996)) (Figure 26.5). Under the action of ACTH, the cytoskeleton and a variety of molecular motors and shuttles bring about a clustered organelle deployment, primarily the tethering of the smooth endoplasmic reticulum to mitochondria, for steroidogenesis (Poderoso et al., 2013; Sewer and Li, 2013). In addition, corticosteroidogenesis involves intracellular depots of cholesterol in both membranes and lipid droplets. Cholesterol stores for steroidogenesis are apparently initially derived from plasma lipoproteins (Hertelendy et al., 1992; Latour et al., 1995). Avian adrenocortical cells are laden with cholesterol–ester-rich lipid droplets (Holmes and Cronshaw, 1980; Carsia et al., 1985a; Holmes et al., 1991), and thus, not surprisingly, their intrinsic ability to synthesize cholesterol is normally low (Lehoux et al., 1977). Cholesterol is accessed from esterified stores through the action of hormone-sensitive lipase. Once free, cholesterol is intracellularly transported by steroidogenic acute regulatory (StAR)-related lipid transfer domain (StarD) proteins.

StarD proteins are responsible for loading free cholesterol to the outer mitochondrial membrane. StAR is a hormone-sensitive protein that delivers the free cholesterol from the outer mitochondrial membrane to the inner mitochondrial membrane, where it can access the cholesterol side-chain cleavage enzyme, P450scc, and be converted to pregnenolone (Miller and Auchus, 2011). In response to ACTH, StAR is acutely synthesized as a 37 kDa protein that has a mitochondrial localization sequence, and then is cleaved into its active, 30 kDa fragment upon mitochondrial entry. StAR is recycled such that each molecule moves hundreds of molecules of cholesterol before being degraded. Not surprisingly, StAR is highly conserved in vertebrate steroidogenic tissue (Bauer et al., 2000). StAR activity requires the peripheral benzodiazepine receptor (PBR), also known as translocator protein (TSPO). PBR may have additional significance in birds in that certain associated proteins may underlie changes in adrenocortical sensitivity to ACTH (Bureau et al., 2009).

The synthetic pathways of the major steroids secreted by the avian adrenal gland during the life cycle are shown in Figure 26.6. The pattern of enzymes carrying out these synthetic steps is highly conserved among the vertebrates and homologous to that characterized in the mammal (Miller and Auchus, 2011). Although there are substantial differences in the primary structure of steroidogenic enzymes studied thus far between mammalian and avian species, conserved domains of enzymatically active sites are apparent (see Nomura et al. (1999)). This conservation has aided in assessing the expression of steroidogenic enzymes in developing and adult birds (e.g., Nomura et al. (1999), Freking et al. (2000), Kanda et al. (2000), Kamata et al. (2004)).

Although steroidogenic enzymes in homogenates can be bidirectional, they are almost uniformly unidirectional in intact cells and *in vivo,* and accumulation of products does not drive flux back to the immediate precursor. In this steroidogenic scheme, mitochondrial cytochrome P450SCC (or CYP11A1) (Nomura et al., 1997) mediates 20α-/22-hydroxylation and scission of the C20-22 carbon bond, producing pregnenolone and isocaproaldelhyde, a set of reactions traditionally called "20, 22-desmolase". Pregnenolone is converted to progesterone by 3βHSD2 (HSD3B2) (Nakabayashi et al., 1995), a non-P450 microsomal–mitochondrial dehydrogenase–isomerase complex that mediates 3β-hydroxysteroid dehydrogenase and isomerase (Δ^5 double bond to Δ^4 double bond) activities. Microsomal P450c21 (CYP21A2) then mediates 21-hydroxylation steps converting progesterone to 11-deoxycorticosterone. Corticosterone is the predominant corticosteroid product of the avian adrenal gland, although 11-deoxycorticosterone is also a significant secretory product. Corticosterone is formed from 11-deoxycorticosterone by an 11β-hydroxylation via a mitochondrial enzyme, P450c11β. To date, this enzyme has not been cloned from reptiles and birds.

Aldosterone is largely formed from 11-deoxycorticosterone and not from corticosterone because corticosterone is a poor substrate. Thus, 11-deoxycorticosterone undergoes an 11β-hydroxylation, converting it to enzyme-bound corticosterone that serves as an intermediate. This is followed by an 18-hydroxylation and lastly an 18-methyl oxidase step, producing the potent mineralocorticoid aldosterone. In birds, it is not clear whether the same enzyme catalyzes the conversion of 11-deoxycorticosterone to aldosterone (CYP11B0), as it does in amphibians (Nonaka et al., 1995) and cattle (Morohashi et al., 1987), or whether in addition to P450c11β (CYP11B1), a separate enzyme, as in humans (CYP11B2 (P450c11AS), or aldosterone synthase) (Mornet et al., 1989), or two additional enzymes, as in rats (CYP11B2 and CYP11B3) (Mellon et al., 1995), catalyze the final steps to aldosterone. In addition, gene array analysis of chicken adrenals from birds stimulated with ACTH does not reveal a differential expression of these key enzymes (Bureau et al., 2009). However, if perhaps it is just one enzyme, there must be additional controls for the predominant or exclusive secretion of aldosterone: first, SCZ slices from the duck adrenal gland secrete predominantly aldosterone in response to ACTH and exclusively aldosterone in response to angiotensin II, whereas the IZ tissue secretes predominantly corticosterone in response to ACTH and is refractory to angiotensin II (Klingbeil, 1985; Pierce et al., 1978; Holmes and Cronshaw, 1984, 1993); and, second, dietary Na^+ restriction in the domestic turkey induces a subpopulation of adrenocortical cells that have a disproportionately enhanced aldosterone response to angiotensin II and K^+ (Kocsis et al., 1995a).

Other enzymatic activities are also apparent mainly during the embryonic and neonatal periods and at modest levels in the adult. Formation of cortisol is predominantly via 17α-hydroxylation of progesterone by a microsomal P450c17 (CYP17A1) (Ono et al., 1988) to form 17α-hydroxyprogesterone, then a 21-hydroxylation by microsomal P450c21 (CYP21A1) to form 11-deoxycortisol, and finally an 11β-hydroxylation step by a mitochondrial P450c11β to form cortisol. A minor pathway is pregnenolone to 17α-hydroxypregnenolone via P450c17, and then to 17α-hydroxyprogesterone via 3βHSD2. There is some evidence that 11β-hydroxyprogesterone serves as a precursor for corticosterone (via a 21-hydroxylation step) and cortisol (via 17α- and 21-hydroxylation steps), although these pathways appear to be of little significance.

The pathway for adrenal sex steroids uses a microsomal P450c17 (CYP17A1) (Ono et al., 1988), which has both 17α-hydroxylase and 17,20-lyase activities, and efficiently converts pregnenolone to 17α-hydroxypregnenolone and then to dehydroepiandrosterone (DHEA). In addition, the 3β-hydroxyl group of DHEA can be sulfated by an adrenal sulfotransferase. As mentioned in this chapter, DHEA and DHEA-sulfate are in the avian circulation

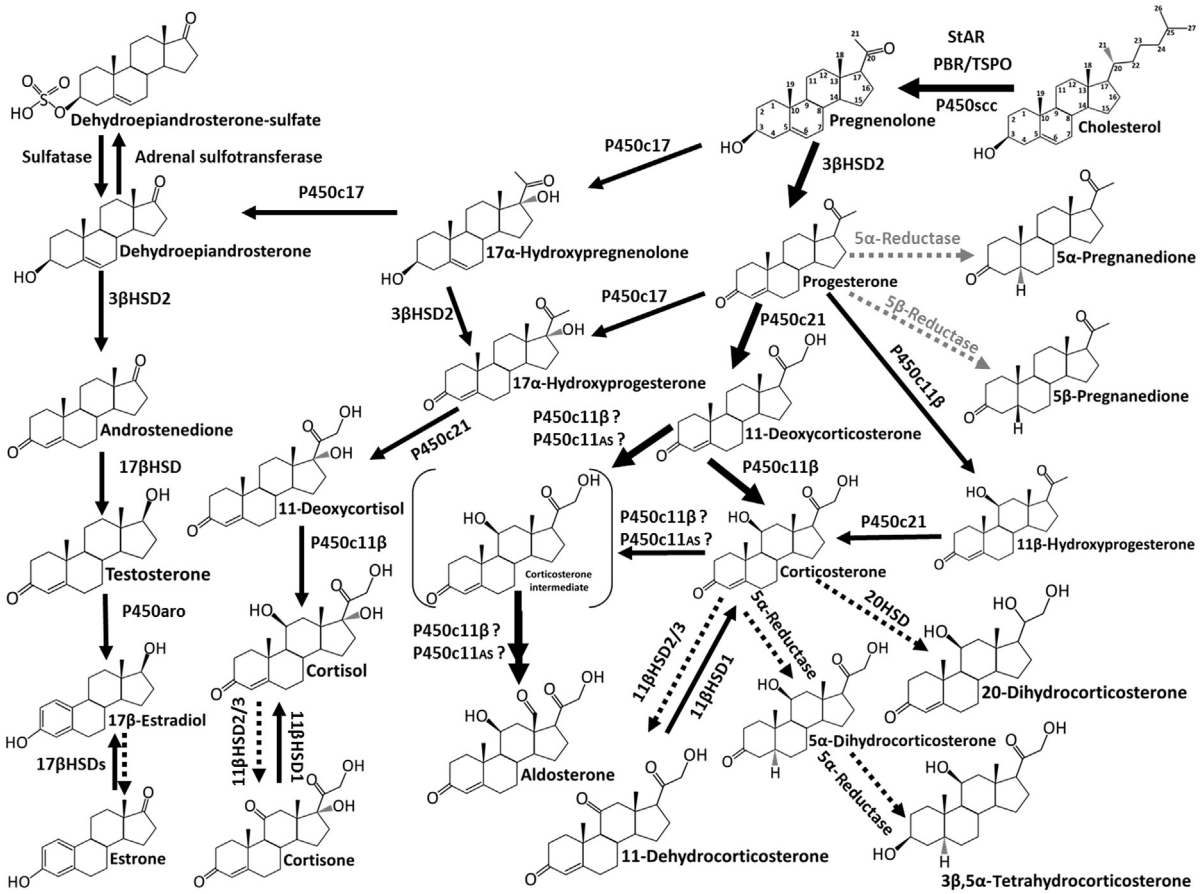

FIGURE 26.6 Steroidogenesis in the avian adrenal gland. *Thick arrows* indicate the predominant pathway of posthatch (postnatal) birds leading to corticosterone and aldosterone. *Thin arrows* indicate additional pathways that are more prominent in the embryonic and early-posthatch (postnatal) periods, and during life-history stage transitions; these are the pathways to cortisol and to the sex steroids. *Dotted arrows* indicate steroid-inactivating or degrading pathways. Dotted *gray arrows* indicated degradative pathways of progesterone during the embryonic period. Solid black and gray bonds on steroids represent key alpha (down) and beta (up) positions; however, not all hydrogen bond positions are shown. StAR, steroidogenic acute regulatory protein; PBR–TSPO, peripheral benzodiazepine receptor–translocator protein; P450scc, mitochondrial cytochrome P450 cholesterol side-chain cleavage enzyme; 3βHSD2, microsomal–mitochondrial 3B-hydroxysteroid dehydrogenase–Δ5→Δ4 isomerase, type 2; P450c21, microsomal cytochrome P450 21-hydroxylase; P450C11β, mitochondrial cytochrome P450 11β-hydroxylase; P450C11AS?, mitochondrial aldosterone synthase (it is not clear if the avian adrenal gland has just one enzyme, P450C11β, that catalyzes the 11β-hydroxylation of 11-deoxycorticosterone to corticosterone and of 11-deoxycortisol to cortisol and also, under certain conditions, catalyzes (1) the 11β-hydroxylation of 11-deoxycorticosterone to a corticosterone intermediate, then (2) an 18-hydroxylation step taking the corticosterone intermediate to an 18-hydroxycorticosterone intermediate, and then (3) an 18-methyl oxidase step (which is the key function of aldosterone synthase) to aldosterone. *Double superimposed arrows* indicates steps 2 and 3.); P450c17, microsomal cytochrome P450 17α-hydroxylase/17,20-lyase; 17βHSD, microsomal 17-ketosteroid reductase; P450aro, microsomal cytochrome P450 aromatase; 17βHSDs, not fully characterized adrenal microsomal enzymes in birds; 11βHSD2/3, microsomal 11β-hydroxysteroid dehydrogenase, types 2 and 3; 11βHSD1, 11β-hydroxysteroid dehydrogenase type 1 (this is largely microsomal, although there is evidence for a significant cytosolic type-1-like enzyme); 20HSD, microsomal 20-hydroxysteroid dehydrogenase. See text for additional details. *Pathway drawn by R. V. Carsia.*

(Soma and Wingfield, 2001) and in the adrenal gland. Although P450c17 can also convert small amounts of progesterone to 17α-hydroxyprogesterone and then to androstenedione, it does so poorly.

Adrenal androstendione can be converted to testosterone by a17βHSD (Nomura et al., 1999), a microsomal, non-P450 enzyme. Indeed, androgens are detected in the avian adrenal gland (Ottinger et al., 2001; Soma and Wingfield, 2001). Furthermore, there is evidence that testosterone is aromatized to estradiol by a microsomal aromatase, P450aro (CYP19A1) (Shen et al., 1994), in that estradiol has been detected in the embryonic adrenal gland (Tanabe et al., 1979, 1986; Ottinger et al., 2001), and that it persists into the posthatch period (Ottinger et al., 2001). But this sex steroid pattern may not be uniform among the avian species. For example, in the developing zebra finch, the adrenal expresses P450scc and 3βHSD2 but not P450c17 and P450aro, and the converse is true in the gonadal tissue (Freking et al., 2000). However, in the adult zebra finch, P450c17 activity is only detected in the male adrenal gland, and this level of activity is about 1/10th to 1/100th that of the ovary and testis (Schlinger et al., 1999). Thus, in some

species, there may be an "adrenal–gonadal unit" in which the adrenals contribute precursors for gonadal steroidogenesis. This may have significance in influencing primary sex bias in offspring. In the domestic hen, raising plasma testosterone at the critical period of meiotic segregation produces a significant bias toward male embryos (Pinson et al., 2011).

Degradation pathways exist in the avian adrenal gland during development, in the posthatch period, and in the adult. Metabolites of progesterone, corticosterone, cortisol, estradiol, and testosterone have been detected. Thus, the adrenal gland has the sets of enzymes to carry out both degradative and regenerative reactions. For example, during the embryonic period, progesterone can undergo a 5β- and, to a lesser extent, a 5α-reduction to 5β- and 5α-pregnanedione (5β- and 5α-pregnan-3,20-dione) (Gonzalez et al., 1983).

In the adult gland, a more prominent enzyme is 5α-reductase (Miller and Auchus, 2011; Langlois et al., 2010). The activity of this enzyme has been shown to degrade corticosterone to 5α-dihydrocorticosterone (5α-pregnan-11β,21-diol-3,20-dione) and 5α-tetrahydrocorticosterone (5α-pregnan-3α,11β,21-triol-20-one) (Carsia et al., 1984). In dispersed chicken adrenocortical cells stimulated with ACTH, 5α-reductase activity is acutely enhanced by exogenous corticosteroids, and is part of a short-looped negative feedback on the avian adrenocortical cell (Carsia et al., 1984, 1987b). The importance of this negative feedback is demonstrated by the fact that may be overridden with certain stressors, such as protein restriction stress, resulting in enhanced corticosterone secretion (McIlroy et al., 1999). It is also acutely inhibited by prolactin (Carsia et al., 1984, 1987b). This acute action of prolactin is Ca^{2+} dependent and occurs with a half-effective concentration (EC_{50}) of 55 ng/ml, a concentration that is well within the physiological range of circulating prolactin. Furthermore, this *in vitro* effect of prolactin on the avian adrenocortical cells to facilitate corticosterone secretion by limiting its degradation may have broader physiological significance. Corticosteroid production by dispersed chicken adrenocortical cells increases abruptly at hatch and is maximal at one day posthatch (Carsia et al., 1987a). Similarly, prolactin and the expression of its receptor increase abruptly approaching the perihatch period (Leclerc et al., 2007), and in the adult adrenal gland, the receptor is expressed at a level as high as the gonad (Ohkubo et al., 1998). In addition, some studies suggest that prolactin levels can promote corticosterone secretion (Koch et al., 2004; Miller et al., 2009), and injections into chick embryos dramatically raise plasma corticosterone within 2 h (Kühn et al., 1996). Furthermore, the plasma levels of the two hormones appear linked with migratory condition (Holberton et al., 2008). Finally, depending on species and life history stage context, corticosterone response and prolactin response to certain stressors may be complementary (Árnason et al., 1986; Angelier and Chastel, 2009); however, the consistency of this relationship is controversial (Angelier et al., 2012).

The adrenal glands of birds, like that of mammals (Cole, 1995), probably have 11β-hydroxysteroid dehydrogenase activities that metabolize (11βHSD2) and regenerate (11βHSD1) corticosterone and cortisol and 17βHSD activity to degrade estradiol to estrone (see Figure 26.6). Although *in vitro* studies support the presence of these metabolites in homogenates of avian adrenal glands (DERoos, 1961; Tanabe et al., 1986), the regulation of these pathways awaits future studies.

26.2.4 Transport of Corticosteroids

In birds, most circulating corticosterone and cortisol are transported bound in dynamic equilibrium to plasma proteins. More than 90% of circulating corticosteroids are bound to the α-2 globulin, corticosteroid-binding globulin (CBG) (that has a high affinity and low binding capacity for corticosteroids). Minor amounts are bound to low-affinity, high-capacity, nonspecific binding proteins (mostly albumin) (Wingfield et al., 1984). Complementing a previous study (Malisch and Breuner, 2010), a random survey containing more recent studies from different species suggests a fairly wide range of affinities (K_d), 1.2–8.3 nM, and capacities, 38–225 nM, for corticosterone (white-crowned sparrow, *Zonotrichia leucophrys gambelii* (Lynn et al., 2003; Charlier et al., 2009); barn owl, *Tyto alba* (Almasi et al., 2009); zebra finch, *Taeniopygia guttata* (Schmidt et al., 2010); Japanese quail, *Coturnix japonica* (Malisch et al., 2010); American kestrel, *Falco sparverius* (Whitman et al., 2011); house sparrow, *Passer domesticus*; northern mockingbird, *Mimus polyglottos*; curved-bill thrasher, *Toxostoma curvirostre*; Albert's towhee, *Pipilo alberti*; and canyon towhee, *Pipilo fuscus* (Fokidis et al., 2009)). In chickens, corticosterone binds to CBG with an average K_d of about 2 nM and a capacity of about 50 nM (Fässler et al., 1986). In some species, cortisol binds to avian CBG with a similar affinity and capacity (Schmidt et al., 2010); however, in many species, it binds with affinities similar to those of the sex steroids (see Malisch and Breuner (2010)). CBG also binds progesterone with high affinity, and testosterone and dihydrotestosterone with a lower affinity, but within the physiological range of these sex steroids. Binding of estrogen is negligible.

A number of factors affect the circulating concentration of CBG, and these responses vary with species and life history stage (Malisch and Breuner, 2010). Various perturbations or stressors have been shown to increase plasma CBG capacity (Malisch and Breuner, 2010), such as poor environmental conditions (Almasi et al., 2009), territorial intrusion (Charlier et al., 2009), and the composite stress of urbanization (Fokidis et al., 2009). However, decreases in CBG capacity are seen with fasting stress (Lynn et al., 2003),

handling stress (Malisch et al., 2010), and neonatal handling (Whitman et al., 2011). In addition, changes in CBG capacity in response to stress can be acute (within 30 min) (Breuner et al., 2006; Charlier et al., 2009; Malisch et al., 2010). Thus, as in rats (Qian et al., 2011), the CBG response in birds to stressors can be rapid, but its direction is context and species specific. Furthermore, CBG capacity is influenced by ontogenic processes, hormonal manipulations, and other physiological states (see Landys et al. (2006), Wingfield (2013)).

The binding of corticosteroids to CBG and other plasma proteins influences the bioavailability of the corticosteroid for target cells, but this can be altered by changes in competing binding steroids, such as progesterone (Malisch and Breuner, 2010). It is thought that only unbound glucocorticoids enter cells (Breuner et al., 2003; Landys et al., 2006; Malisch and Breuner, 2010). However, there may be differential tissue attraction or targeting of CBG-bound glucocorticoids that may finely regulate their local concentrations and hence their bioavailability and action. In addition, there appear to be isoforms of CBG that preferentially bind cortisol and, thus, influence its half-life for delivery to sensitive tissues (Schmidt et al., 2008, 2010). Furthermore, it is possible that the CBG–glucocorticoid complex may initiate unique cellular processes mediated through unexplored receptors (Hryb et al. (1986), Hammond (1990), Maitra et al. (1993)). Thus, the interaction between glucocorticoids, their cognate binding proteins, and their target tissues is complex, and the precise role played by CBGs in mediating the actions of glucocorticoids awaits further investigation.

26.2.5 Circulating Concentrations of Corticosterone and Aldosterone

Investigations in which the circulating concentrations of corticosterone and aldosterone were measured in the same study are restricted to galliform (chicken, turkey, and Japanese quail) and anseriform (duck) species. The circulating concentration of corticosterone in unstressed birds is in the nanogrampermililiter (ng/mL) range, whereas that for aldosterone is in the picogram-permililiter (pg/mL) range (Table 26.1). There is a tendency for the circulating values to fall from hatch to maturity. Part of this is explained by the decrease in relative adrenal weight with age (Holmes and Phillips, 1976; Carsia and Weber, 1986). However, it also may be due to the decrease in adrenal sensitivity and maximal steroidogenic capacity with posthatch age (Carsia et al., 1985c, 1987a; Carsia and Weber, 1986).

In recent years, carefully controlled studies have demonstrated a good correlation between plasma corticosterone and the concentration of corticosterone in feathers (Koren et al., 2011; Crossin et al., 2013). This relatively noninvasive approach may be useful in predicting survival and reproductive success in various avian species. A more detailed discussion of the use and value of feather corticosterone can be found in the next chapter.

26.2.6 Secretion, Clearance, and Metabolism of Corticosterone and Aldosterone

Not surprisingly, corticosteroid concentrations that are initially high in the adrenal gland and adrenal venous effluent (in micrograms per milliliter), and then are secreted at about a microgram per minute per kilogram (Assenmacher, 1973), are then rapidly diluted in the circulation and distributed to the extracellular fluid.

Circulating concentrations of corticosteroids are maintained by the dynamic balance between metabolic clearance and adrenal secretion. Transmembrane passage of corticosteroids is rapid for all cells (~10^{-4} cm/s) (Giorgi and Stein, 1981), thus facilitating rapid clearance and metabolism in competent cells such as the kidney and liver. Indeed, in a very limited number of studies, the average half-lives of corticosterone and aldosterone in the circulation are similar, about 15 and 13 min, respectively. These averages, however, do not reflect the species differences in half-lives. For example, in the duck, the half-lives for corticosterone and aldosterone are considerably less—about 8 and 6 min, respectively—and are increased by adenohypophysectomy threefold to eightfold, indicating a dramatic decrease in the metabolic clearance rate (Holmes et al., 1972, 1974). Indeed, these altered circulatory parameters and the altered profile of metabolites in cloacal fluid in response to adenohypophysectomy are restored to normal with corticosterone replacement (Holmes and Slikker, 1976).

The metabolic clearance rate for corticosterone varies with physiological status; it is decreased with age (Holmes and Kelly, 1976) and by thyroidectomy (Kovács and Péczely, 1983). In addition, it appears to be influenced by nutritional status. For example, in chickens subjected to dietary protein restriction, it is increased 85%, which translates to a fourfold increase in secretion rate (Carsia et al., 1988a). Clearance from the circulation is facilitated by intracellular binding and sequestration and ultimately metabolism, primarily by the liver. The metabolizing enzymes include hepatic 5α-reductase, which converts corticosterone and aldosterone to inactive metabolites. The activity of this 5α-reductase appears to be augmented by acute stress (Daniel and Assenmacher, 1971). The metabolites in urine exist as several polar and nonpolar forms, including intact corticosteroids, some free and some conjugated to sulfate and glucuronide (Helton and Holmes, 1973; Holmes et al., 1974; Holmes and Slikker, 1976; Rettenbacher et al., 2004).

Glucocorticoids are the end product signals of a system largely concerned with regulating energy flow—a system of which the HPA axis is a component. By contrast, mineralocorticoids are the end product signals of a system largely concerned with maintaining salt and water balance—a system

of which the renin–angiotensin–aldosterone system is a component. These steroid hormones work on specific effector tissues of each system. However, glucocorticoids are also essential to permit the full expression of almost all metabolic processes.

The effector molecules in the effector tissues are the glucocorticoid and mineralocorticoid receptors (MRs), which are ligand-inducible transcription factors. However, the MR binds corticosterone with an affinity that is more than 30 times that of the GR. Since the circulating concentration of corticosterone is about 20–300 times that of aldosterone, almost all of the MRs are fully occupied by corticosterone. Thus, in order for aldosterone to represent the system regulating salt and water balance, corticosterone (and cortisol) in the effector tissues needs to be either sequestered from the MR or rapidly degraded so that its intracellular concentrations exposed to the MR are extremely low.

The main enzymes that carry out the local degradation of corticosterone and cortisol are 11β-hydroxysteroid dehydrogenase 2 (11βHSD2) and 20-hydroxysteroid dehydrogenase (20HSD) (Figure 26.7). 11βHSD2 catalyzes the oxidation of corticosterone and cortisol to the inactive metabolites, 11-dehydrocorticosterone and cortisone, respectively, and 20HSD converts corticosterone to 20-dihydrocorticosterone (see Figure 26.7). 11βHSD2 and 20HSD are found in the chicken intestine, liver and kidney, testis, oviduct, and brain (Vylitová et al., 1998; Ahmed et al., 2013). There also appears to be a second corticosterone (cortisol)-degrading enzyme, 11βHSD3, expressed in the chicken colon and, to a greater extent, in the kidney (Katz et al., 2008). These enzymes are obviously expressed in other avian groups. A recent study shows robust expression of 11βHSD2 and 20HSD in the zebra finch brain and several peripheral tissues analyzed, and, to a lesser extent, in the gonads, moreso in the ovary than in the testis (Katz et al., 2010).

Also expressed in chickens is the enzyme catalyzing the reverse reactions (reductive), 11βHSD1, regenerating corticosterone (and cortisol). There is also evidence for a significant cytosolic form of an 11βHSD1-like enzyme (Katz et al., 2007). Thus, a balance in inactivation and reactivation of glucocorticoids provides a prereceptor modulation of corticosteroid signals in avian effector tissues (Kučka et al., 2006).

Corticosterone, along with sex steroids, does accumulate in the egg (Hahn, 2011) and in a species-specific manner (Quillfeldt et al., 2011), although the role of follicle HSDs in this process is unclear. It is suggested that the bulk of corticosterone that accumulates in the egg is derived from the adrenal glands and is delivered to the egg from the circulation (Hahn, 2011). Indeed, elevating circulating corticosterone concentrations within the physiological range in the barn owl (*T. alba*) result in the deposition of corticosterone in the egg (Almasi et al., 2012). In addition, restraint stress in the Japanese quail (*C. japonica*) increases corticosterone and decreases testosterone in the egg, thereby possibly serving as a signal about adverse environmental conditions from

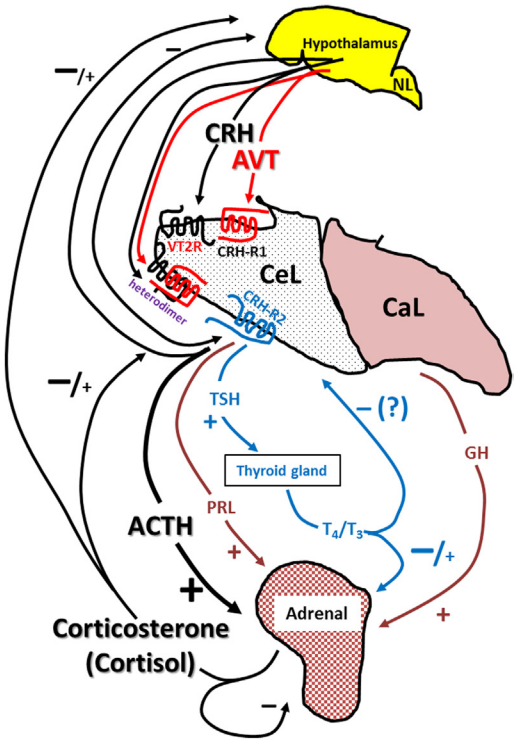

FIGURE 26.7 The hypothalamus–pituitary–adrenal (HPA) axis in birds. The hypothalamus is depicted in a sagittal view and with yellow fill. NL is the neural lobe. The pars distalis of the pituitary gland is depicted in a sagittal view with a dot pattern and light brown fill. CeL is the cephalic lobe of the pars distalis, and CaL is the caudal lobe of the pars distalis. The adrenal gland is in a brown pattern to depict the intermingling of chromaffin and adrenocortical tissues. Cartoons of structures are not drawn to actual relative size, with the pituitary disproportionately enlarged. Negative (–) and positive characters (+) and their relative sizes when paired indicate the general consensus of the effect of a particular hormone. CRH, corticotropin-releasing hormone; AVT, arginine vasotocin; CRH-R1, corticotropin-releasing hormone receptor type 1; CRH-R2, corticotropin-releasing hormone receptor type 2; VT2R, vasotocin receptor type 2; ACTH, adrenocorticotropic hormone (corticotropin); TSH, thyroid-stimulating hormone (thyrotropin); PRL, prolactin; GH, growth hormone; T4, thyroid hormone 3,5,3′,5′-tetraiodothyronine; T3, thyroid hormone 3,5,3′-triiodothyronine. CRH and AVT (and sometimes mesotocin) interact with their respective receptors, CRH-R1 and VT2R, to stimulate the release of ACTH in a synergistic manner. ACTH most likely exerts a negative short-loop feedback on CRH release. Part of the synergism of CRH-R1 and VT2R is due to their separate signaling pathways, and it is suggested that part is also due to their receptors undergoing heterodimerization. CRH also interacts with CRH-R2 to stimulate the release of TSH. TSH acts on the thyrocytes of the thyroid gland to release T4 and T3. ACTH stimulates the secretion of glucocorticoids from adrenocortical cells of the adrenal gland. Its action is assisted by the action of PRL, which is also released from the CeL, and GH, which is secreted from the CaL. Sufficient evidence indicates that in addition to ACTH, PRL and probably GH are released during stress. Glucocorticoids exert a negative long-loop feedback on both the pituitary gland and the hypothalamus to curtail ACTH release. However, some brain CRH neurons and pituitary VT2Rs are upregulated by glucocorticoids. Further illustrating the complexity of HPA axis regulation is the role of thyroid hormones. Thyroid hormones appear to decrease VT2R expression and also inhibit the expression of prohormone convertase 1, an enzyme that processes POMC to produce ACTH and other melanocortins. In addition, most studies suggest that thyroid hormones have a negative impact on corticosteroid secretion. Intraadrenal and circulating glucocorticoids also exert a negative short-loop feedback on the adrenocortical cells to reduce the release glucocorticoids. See text for details of additional modulators of the HPA axis. *Cartoon drawn by R. V. Carsia.*

the mother to progeny (Okuliarová et al., 2010). However, it is unclear whether egg corticosterone has a direct effect on embryonic and posthatch development or an indirect effect on egg quality and subsequent progeny development (Henriksen et al., 2013). Perhaps the influence of egg corticosterone on lowering egg androgen may be more significant. For example, in domestic chicks, yolk androgen, in particular androstenedione, which is deposited into egg yolk in substantially higher concentrations than testosterone, is linked with sex-dependent alterations in growth and behavior (Benowitz-Fredericks and Hodge, 2013).

26.2.7 General Regulation of Adrenocortical Function

26.2.7.1 Adrenocorticotropin

The most efficacious stimulator of avian corticosteroid secretion is ACTH, a 39aminoacid peptide derived from pro-opiomelanocortin (POMC) (Takeuchi et al., 1999). Numerous studies *in vivo* and *in vitro* with isolated adrenocortical cells (Carsia, 1990) from several species demonstrate a dose-dependent and rapid (less than 5 min) corticosteroid response to ACTH. Not surprisingly, this rapid response needs to be considered when assessing corticosterone rhythms in birds (Breuner et al., 1999; Romero and Reed, 2005; de Jong et al., 2001).

Of the avian species studied, there are differences between the primary sequences of ACTH in that the chicken ACTH sequence has greater identity with an amphibian ACTH (*Xenopus laevis*) than with that of another galliform (turkey, *M. gallopavo*) and that of a ratite (ostrich, *Struthio camelus*) (Hayashi et al., 1991). Interestingly, despite this difference in primary sequences, both chicken and turkey adrenocortical cells exhibit similar steroidogenic responses to mammalian and avian ACTH peptides (Carsia et al., 1985a, 1988a; Kocsis and Carsia, 1989; Carsia, 1990).

Studies with isolated chicken adrenocortical cells suggest that ACTH operates through specific receptors that are present at a concentration of about 2000–3000 sites per cell (Carsia and Weber, 1988). In birds, ACTH-induced corticosteroid production operates through a G protein–coupled receptor (GPCR), the melanocortin-2 receptor (MC2R) (Takeuchi et al., 1998; Boswell and Takeuchi, 2005), which is activated exclusively by ACTH (Veo et al., 2011). In addition, ACTH is a potent stimulator of the other four avian melanocortin receptor subtypes (Ling et al., 2004). Yet, despite the high identity of the avian MC2R with mammalian orthologs, there are comparative differences in ACTH receptor signaling. For example, unlike rat adrenocortical cells, chicken adrenocortical cells fail to distinguish between mammalian αACTH-(1–24) and its 9-tryptophan-(*O*-nitrophenylsulfenyl) derivative (Carsia et al., 1985a). However, like rat adrenocortical cells, human ACTH-(7–38) is a complete antagonist of ACTH in chicken adrenocortical cells (Carsia and Weber, 1988).

Comparative molecular studies (Veo et al., 2011) and numerous *in vitro* studies with isolated adrenocortical cells from diverse avian species confirm that dissemination of the ACTH signal in avian adrenocortical cells is largely through the cyclic adenosine monophosphate (cAMP)-dependent pathway involving a stimulatory guanine nucleotide binding protein, adenylyl cyclase, cAMP, and cAMP-dependent protein kinase (see Carsia (1990), McIlroy et al. (1999)). In addition, physiological concentrations of Ca^{2+} (Kocsis et al., 1994a) and a background level of calmodulin activity (Kocsis et al., 1995b) appear to be critical for optimal cellular response to ACTH.

Cell surface expression and function of the MC2R require melanocortin receptor accessory proteins (MRAPs) (Hinkle and Sebag, 2009; Webb and Clark, 2010; Cooray and Clark, 2011; Liang et al., 2011; Veo et al., 2011; Cerdá-Reverter et al., 2013). MRAPs are small linear proteins (~14 kDa) of about 100–170 amino acids, having a single hydrophobic transmembrane domain. Cytoplasmic MRAPs form antiparallel homodimers that interact with the MC2R and probably assist folding of the MC2R into a functional conformation for ACTH binding and signal transduction. Formation of the heterotrimeric complex is essential for trafficking to the cell surface. MRAP1 facilitates full receptor function, that is, high-affinity ACTH binding and optimal signal transduction (cAMP production). By contrast, MRAP2 competes with MRAP1, and although it still assists with trafficking of MC2R to the cell surface, it serves as an endogenous inhibitor of MC2R activation by ACTH. MRAPs, StAR, and CYP11A are key steroidogenic proteins comprising the rapid transcriptional response to ACTH (Liu et al., 2013). Future investigations of the avian MRAPs may be important in understanding the changes in adrenal sensitivity and response to ACTH during development, life history cycle and stage transitions, and stress (Lattin et al., 2011a). Furthermore, MRAP2 proteins appear to regulate energy expenditure and energy intake in vertebrates by influencing melanocortin receptors in various brain regions both postnatally and during the transition from embryonic to postnatal life (Asai et al. (2013), Sebag et al. (2013)). Thus, these accessory proteins and their cognate receptors may play similar roles in regulating food intake and energy expenditure in birds.

26.2.7.2 Angiotensins

There is now a strong body of evidence supporting the role of angiotensins in the regulation of avian adrenocortical function (reviewed in Holmes and Cronshaw (1993)). *In vivo* studies and *in vitro* work with adrenal tissue and cells suggest that angiotensins, notably angiotensin II, play a direct role in adrenocortical regulation. This topic is discussed in detail under the "Regulation of Aldosterone Secretion" section.

26.2.7.3 Other Putative Regulators

Studies indicate that avian adrenocortical function is modulated by secretory products of the immune system and other endocrine organs. Interpretations of results derived from these studies should be viewed with caution since they are restricted to anseriform and galliform species and in many instances are based on *in vitro* systems that have not been substantiated *in vivo*. Nevertheless, these studies deserve attention. Such peripheral agents may directly stimulate or inhibit adrenocortical function or may act as positive or negative modulators of tropic-hormone-induced responses.

26.2.7.3.1 Stimulators and Positive Modulators

26.2.7.3.1.1 Prolactin and Growth Hormone The pituitary secretory products, prolactin and growth hormone, appear to have a positive influence on avian adrenocortical function (Figure 26.7). The effect of prolactin has been mentioned here. The actions of growth hormone are less clear. Nevertheless, the importance of growth hormone in avian adrenocortical maintenance is indicated by its hyperstimulation of cellular steroidogenic capacity after hypophysectomy in the absence of ACTH and other hormonal replacement (Carsia et al., 1985c). Additionally, like prolactin, growth hormone is increased with various stressors. Furthermore, growth hormone assists in the overall maintenance of the avian adrenal gland (Harvey et al., 1995).

26.2.7.3.1.2 Calciotropic Hormones In chicken adrenocortical cell preparations, chicken parathyroid hormone (PTH) is a potent stimulator of cAMP, corticosterone secretion, and especially aldosterone secretion (Rosenberg et al., 1987, 1988a,b, 1989a). It is important to point out that the latter studies used purified extracts derived from chicken parathyroid glands. By contrast, a more recent study with recombinant chicken PTH did not demonstrate this novel steroidogenic action (Lim et al., 1991). Nevertheless, avian forms of the PTH and parathyroid hormone-related peptide (PTH–PTHrP) receptor have been characterized (Pinheiro et al., 2012) and are expressed in many tissues. In addition, a PTH–PTHrP receptor in chicken adrenocortical cells, which is absent in chromaffin cells, has been demonstrated. Furthermore, PTHrP enhances ACTH-induced corticosterone production by these dispersed cells (Kawashima et al., 2005).

This corticosteroidogenic effect is not limited to PTH–PTHrP peptides. A similar potentiation of ACTH action is seen with chicken calcitonin, and here again, it appears to act through specific receptors on avian adrenocortical cells and not chromaffin cells (Nakagawa-Mizuyachi et al., 2009). Thus, calciotropic hormones appear to influence the action of ACTH on avian adrenocortical cells.

26.2.7.3.1.3 Humoral Immune System There is evidence suggesting that the humoral immune system may exert trophic and tropic influences on the avian adrenal gland. Although a large part of the ACTH is from the pituitary, it appears that significant quantities of ACTH are released from activated lymphocytes. For example, an antigen challenge or CRH induces the release of ACTH from chicken lymphocytes that is sufficient to elicit a corticosterone response from co-incubated chicken adrenocortical cells (Hendricks et al., 1991, 1995a), and this direct effect of CRH on chicken leukocyte ACTH release is inhibited by corticosterone (Hendricks et al., 1995b). In addition, the bursa of Fabricius may elaborate substances necessary for adequate corticosteroidogenic capacity during development and maturation (Pedernera et al., 1980) and for normal corticosterone response of adrenocortical cells to ACTH (El-Far et al., 1994). However, a bursal suppressive factor has received more attention (*vide infra*).

26.2.7.3.2 Inhibitors and Negative Modulators

26.2.7.3.2.1 Humoral Immune System A bidirectional link between the immune system and the adrenal gland, similar to that which exists in mammals (Besedovsky and del Rey, 1996), is present in birds. There is evidence that the immune system elaborates adrenal suppressor substances. Highly purified extracts of prepubescent chicken bursae suppress inducible steroid synthesis from chicken granulosa and adrenocortical cells and from mammalian adrenocortical cells. The active principle has been termed bursal antisteroidogenic peptide (BASP) (Byrd et al., 1994). BASP appears to be a late-pathway inhibitor in that although it stimulates cAMP production, it inhibits cAMP analog-stimulated steroidogenesis. This peptide awaits full characterization, but recent work suggests that BASP is an ovoinhibitor or is a variant of an ovoinhibitor (Moore et al., 2004).

26.2.7.3.2.2 Thyroid Hormones Evidence indicates that the thyroid hormone, 3,5,3′-triiodothyronine (T_3), is an important modulator of avian adrenocortical function (Figure 26.7). In many cases, there is an inverse relationship between circulating T_3 concentrations and adrenocortical function (Carsia and Weber, 1986; Carsia et al., 1988a). For example, thyroidectomy in chickens results in a marked enhancement in adrenocortical function, and the enhanced function is normalized with T_3 replacement. At least part of this effect of T_3 appears to be direct at the adrenocortical cell level (Carsia et al., 1997). Furthermore, in hypophysectomized cockerels, T_3 replacement alone reduces cellular corticosterone production even more than that due to hypophysectomy in the absence of hormonal replacement (Carsia et al., 1985c). Also, there is some suggestion that thyroid hormones negatively modulate POMC processing in that work with the rat demonstrates that T_3 suppresses

pituitary prohormone convertase-1 expression (Li et al., 2001). It should be pointed out, however, that other studies show that thyroid hormones stimulate avian adrenocortical activity (see Sharma and Chaturvedi (2009)), and therefore the thyroid hormones may fall into the biphasic category of avian adrenocortical regulation (*vide infra*).

26.2.7.3.2.3 Androgens The effect of androgens on adrenocortical secretion appears to be variable depending on the species and type of endocrine manipulation. Exogenous testosterone in wild species seems to enhance circulating corticosterone, suggesting an increase in adrenocortical function (Ketterson et al., 1991; Schoech et al., 1999). Early work suggests that testosterone suppresses adrenocortical function in orchiectomized chickens (Nagra et al., 1965). Nevertheless, more recent work with orchiectomized cockerels suggests that although androgen (testosterone and 5α-dihydrotesterone) replacement suppresses adrenocortical cell response to ACTH, it maintains relative adrenal weight (Carsia et al., 1987c). Interestingly, orchiectomy is required to demonstrate the effects of androgens on adrenocortical function and domestic fowl (Nagra et al., 1965; Carsia et al., 1987c). Thus, it is quite possible that the testis elaborates both inhibitory and trophic substances that influence avian adrenocortical function.

In this connection, there are reported sex differences in adrenocortical activity, and some of these are correlated to sexual maturity (see Madison et al. (2008)). In addition, sex-dependent alterations in adrenocortical cellular sensitivity and maximal corticosterone response to ACTH have been reported (Carsia et al., 1987a, 1988b; Kocsis and Carsia, 1989). Sex differences are also apparent at more proximal steps of the HPA axis, such as the axis response to corticotropin-releasing hormone and arginine vasotocin (Madison et al., 2008). However, the fact that these alterations at the cellular level are apparent during the embryonic and early posthatch periods and prior to sexual maturity (Carsia et al., 1987a; Kocsis and Carsia, 1989) argues that they are in part sex linked and independent of the higher levels of sex steroids accompanying sexual maturity.

26.2.7.3.3 Biphasic Modulators

26.2.7.3.3.1 Thyroid Hormones Whereas the use of isolated adrenocortical cells has a caveat when extrapolating findings to *in vivo* physiology, it is amenable to gaining insights into the fine regulation of adrenal steroidogenic function that would be difficult or impossible to obtain from *in vivo* studies. An example is the understanding that a hormone may elicit biphasic influences on steroidogenic function. Thyroid hormones may fall into this category since T_3 suppresses corticosteroidogenic capacity but preserves cellular sensitivity to ACTH in the hypophysectomized chicken (Carsia et al., 1985c). However, in the thyroidectomized chicken, T_3 replacement influences cellular steroidogenic capacity but does not alter cellular sensitivity to ACTH (Carsia et al., 1997). Thus, the prevailing overall hormonal status in which T_3 acts will influence its effect on adrenocortical function. Indeed, as mentioned here, there are studies showing that thyroid hormones stimulate adrenal activity (Sharma and Chaturvedi, 2009).

26.2.7.3.3.2 Prostaglandins Prostaglandins also seem to fall into this category. Prostaglandins appear to be potent and efficacious stimulators of avian adrenocortical function. In the Japanese quail (*C. japonica*), prostaglandin E_2 is more than six times greater than immobilization stress in raising circulating corticosterone. In addition, it synergizes with immobilization stress to rapidly increase plasma corticosterone (Satterlee et al., 1989). A large part of the effect of prostaglandins appears to be due to their interaction with prevailing concentrations of ACTH. In both chicken and turkey adrenocortical cells, prostaglandins exert a biphasic influence on corticosterone production, depending on their concentration. At low concentrations (10^{-8}–10^{-5} M), they synergize with submaximal concentrations of ACTH, whereas at high concentrations (10^{-5}–10^{-3} M), they are inhibitory. The most potent and efficacious prostaglandin for stimulation is prostaglandin E_2, whereas prostaglandin A_2 is the most potent for inhibition. Prostaglandins have a similar but considerably weaker biphasic influence on basal corticosterone secretion (Kocsis et al., 1999).

26.2.8 Regulation of Aldosterone Secretion

26.2.8.1 Role of Angiotensin II (Ang II)

As in other vertebrates (Wilson, 1984; Holmes and Cronshaw, 1993; Kempf and Corvol, 2001; Nishimura, 2001), the avian kidney contains juxtaglomerular cells capable of producing renin. Renin cleaves fowl angiotensinogen ([Asp^1, Val^5, Ser^9] tetradecapeptide renin substrate) to form the decapeptide angiotensin I ([Asp^1, Val^5, Ser^9] Ang I). The Ang II octapeptide produced from this decapeptide ([Val^5] Ang II; $M_r = 1031.53$) is that of most vertebrates, including ovine and bovine species, whereas other mammalian species produce [Ile^5] Ang II. In several species studied thus far (Japanese quail, duck, and turkey), plasma Ang II concentrations range from 30 to 70 pg/ml (i.e., from 2.9×10^{-11} to 6.8×10^{-11} M) but can increase to 100–400 pg/ml (from 9.7×10^{-11}–3.9×10^{-10} M) with perturbations to electrolyte and hemodynamic balance and with adaptation to saltwater (see Kocsis et al. (1995a)).

Earlier *in vivo* studies demonstrated a direct regulation of aldosterone production by Ang II. An intraperitoneal injection of Ang II into Japanese quail (Kobayashi and Takei, 1982) and infusions of Ang II into ducks (Gray et al., 1989) increase circulating aldosterone, with the latter study showing a dose-dependent aldosterone response exclusive of alterations in circulating corticosterone. In addition, an

exclusive, dose-dependent aldosterone response to Ang II has been demonstrated with duck adrenal tissue, specifically from the subcapsular region (Klingbeil, 1985; Holmes and Cronshaw, 1993). This is also true for isolated turkey adrenocortical cells (Kocsis et al., 1994b, 1995a), largely because Ang II does not stimulate cholesterol side chain cleavage in these cells (Kocsis et al., 1995a). Presumably, the prevailing basal level of precursors within the cells is sufficient to support aldosterone synthesis. However, the distinction of functional zones exhibited by the duck adrenal gland may be less apparent or absent in other species. For example, in studies with isolated adrenocortical cells from normal turkeys, there are few functional differences between density-separated subpopulations. However, after dietary Na^+ restriction, one subpopulation, which comprises about 5% of the total adrenocortical cell population, exhibits disproportionately greater aldosterone responses to Ang II and potassium (K^+) but not to ACTH (Kocsis et al., 1995a). It may be that in other avian species, perturbations in electrolyte and hemodynamic homeostasis or other stressors are required to induce zona glomerulosa–like function in a subpopulation of adrenal steroidogenic cells. Furthermore, conceivably other cell subpopulations with distinct function may be induced by different stressors. Indeed, this is the case in the domestic turkey subjected to protein restriction (Carsia and McIlroy, 1998; Carsia and Weber, 2000) and in which Ang II may play a specific role. In this stress model, Ang II may induce cell death in some cell subpopulations, permitting other subpopulations with different steroidogenic function to predominate.

Finally, although it is fairly clear what the releasing factors for aldosterone are in birds with decreased plasma Na^+ and no salt glands, that is, gallinaceous birds, it is not clear what the aldosterone-releasing factors are in birds with salt glands and excessive Na^+ intake or when birds with salt glands undergo dehydration. It does not appear to be Ang II or changes in plasma K^+. Furthermore, the interaction of hormones regulating aldosterone secretion has not been studied in birds that live exclusively in marine and desert environments (see Hughes (2003)).

26.2.8.2 Mechanism of Ang II Action in Avian Adrenocortical Cells

Studies with duck adrenal membrane preparations (Gray et al., 1989) and isolated turkey (Kocsis et al., 1994a,b, 1995a,b,c; Carsia and McIlroy, 1998) and chicken (Holmes and Cronshaw, 1993) adrenocortical cells indicate that the avian adrenal gland possesses high-affinity Ang II receptors, having a K_d of 0.9–2 nM and a concentration of about 30,000–150,000 sites per cell. It should be pointed out that chickens are odd in that mature birds exhibit a complete aldosterone tachyphylaxis to Ang II both *in vivo* and *in vitro,* even though their adrenocortical cells express high-affinity Ang II receptors (Holmes and Cronshaw, 1993). In addition, the receptor concentration may vary among cell subpopulations, as demonstrated in the turkey adrenal gland, and the receptor concentration among cell subpopulations may be differentially modulated by physiological stressors, such as dietary Na+ restriction (Kocsis et al., 1995a).

Turkey (Murphy et al., 1993) and chicken (Kempf and Corvol, 2001) Ang II receptors have also been cloned. They are both 359-amino-acid proteins (sharing 99.7% identity) and exhibit a 75% sequence identity with the mammalian type 1 receptor, although there are frank differences in the pharmacological and physicochemical properties between mammalian and avian forms. Both avian forms have been shown to couple to the phosphoinositide–lipid–protein kinase C pathway (Murphy et al., 1993; Kempf and Corvol, 2001). However, differences in tissue expression exist between turkeys and chickens. For example, the cloned turkey receptor is exclusively expressed in the adrenal gland (Carsia et al., 1993), whereas the chicken receptor has a broader tissue expression (Kempf and Corvol, 2001). In support of ligand binding isotherms with turkey adrenal cells, the galliform adrenal Ang II receptor is not expressed in adrenal chromaffin cells (Kocsis et al., 1995b; Kempf and Corvol, 2001) but is expressed in the postganglionic catecholaminergic cells of the ganglia adjacent to the gland (Kempf and Corvol, 2001; Nishimura, 2001). Furthermore, it is expressed in chicken vascular endothelial cells but not in vascular smooth muscle cells (Kempf and Corvol, 2001; Nishimura, 2001). These observations support the model to explain the biphasic action of Ang II on chicken vascular tonus (Nishimura, 2001): the rapid vasorelaxation after infusion is due to the response of vascular smooth muscle cells to cyclic guanosine monophosphate (cGMP) subsequent to nitric oxide generation by Ang II–stimulated endothelial cells; the later response of α-adrenergic-dependent vasoconstriction is due to the more delayed catecholamine release from Ang II–stimulated postganglionic neuronal endings.

In turkey adrenocortical cells, Ang II induces a rapid and sustained increase in cytosolic Ca^{2+} (Kocsis et al., 1994b, 1995b). However, demonstrating a link between increases in cytosolic Ca^{2+} and aldosterone production has been difficult. Avian corticosteroidogenesis is fairly refractory to agonists and antagonists of the Ca^{2+}–phosphoinositide–lipid–protein kinase C pathway (Rosenberg et al., 1988b; Kocsis et al., 1995b). However, extracellular Ca^{2+} is required for optimal Ang II–induced aldosterone secretion (Kocsis et al., 1994a), and calmodulin activity appears to be essential for aldosterone synthesis in turkey adrenocortical cells (Kocsis et al., 1995b). Even more puzzling is the action of K^+. Extracellular K^+ does nothing to aldosterone secretion in chicken adrenocortical cells (Rosenberg et al., 1988b). By contrast, it is an absolute requirement for Ang II–induced aldosterone production by turkey adrenocortical

cells (Kocsis et al., 1994a, 1995b), having a maximal effect at a physiological concentration (about 5 mM; Rosenberg and Hurwitz, 1987). Here again, this effect of K^+ in turkey adrenocortical cells is not linked to changes in cytosolic Ca^{2+} (Kocsis et al., 1995b). In addition, in turkey adrenocortical cells, Ang II–induced increases in cytosolic Ca^{2+} and aldosterone production appear to be dissociated (Kocsis et al., 1995b). Thus, in agreement with other studies of nonmammalian vertebrates, there appear to be unidentified Ang II receptors awaiting molecular characterization (Kempf and Corvol, 2001; Nishimura, 2001).

26.2.8.3 Action of ACTH on Aldosterone Secretion

Whereas there is an ample number of studies demonstrating the selective action of Ang II on avian aldosterone secretion, the action of ACTH is less specific, stimulating both aldosterone and corticosterone secretion. Overall, most studies *in vivo* and *in vitro* indicate that ACTH is a competent stimulator of aldosterone secretion. Indeed, although less potent, ACTH is 2- to 10-fold more efficacious than Ang II in stimulating aldosterone secretion in studies with avian adrenal tissue and avian adrenocortical cell preparations. These observations raise further questions concerning the importance of Ang II. However, the specificity and importance of Ang II reside not in its ability to greatly stimulate aldosterone secretion, but in its ability to link perturbations in electrolyte and hemodynamic balance to aldosterone secretion—a role not readily fulfilled by ACTH. Furthermore, with turkey adrenocortical cells, threshold and suboptimal concentrations of ACTH greatly augment the efficacy of Ang II in stimulating aldosterone secretion (Kocsis et al., 1994a). Thus, against an ACTH background *in vivo,* Ang II probably stimulates aldosterone secretion to a magnitude that exceeds what is revealed when tested alone *in vitro.*

26.2.8.4 Action of Atrial Natriuretic Peptide (ANP) on Aldosterone Secretion

In general, there are few studies on the regulation of aldosterone secretion in avian species, but even less is known about interacting factors in its regulation. Somatostatin has been shown to inhibit Ang II–stimulated, but not ACTH-stimulated, aldosterone production by turkey adrenocortical cells (Mazzocchi et al., 1997c). However, more attention has been paid to the role of ANP in avian aldosterone secretion.

Avian ANP was originally demonstrated as a diuretic agent in extracts from chicken hearts (Gregg and Wideman, 1986). It is a 29-amino-acid peptide (M_r=3158.45) that has significant structural homology to mammalian ANPs (Miyata et al., 1988). Avian ANP is stored and released from both atrial and ventricular cardiocytes (Toshimori et al., 1990), but it is also produced by adrenal chromaffin cells (Wolfensberger et al., 1995). In ducks and chickens, the plasma concentration of ANP is about 70–80 pg/ml ($\sim 2.5 \times 10^{-11}$ M) and is inversely related to changes in blood volume in response to hemodynamic and electrolyte perturbations (Gray et al., 1991a; Gray, 1993). ANP receptors are found in both renal and adrenal tissue of the duck (Gray et al., 1991b). In adrenocortical cells, it is present at a concentration of ~90,000 sites per cell (Kocsis et al., 1995c). The receptors have an apparent K_d of 1–3 nM (Gray et al., 1991b; Kocsis et al., 1995c). In the duck, infusions of avian ANP inhibit plasma aldosterone responses to Ang II without affecting circulating corticosterone (Gray et al., 1991b). In addition, in chicken adrenocortical cells, ANP is a potent ($EC_{50} \sim 1$ nM) and efficacious inhibitor (>90%) of maximal ACTH- and PTH-induced aldosterone secretion without affecting corticosterone secretion (Rosenberg et al., 1988b, 1989b). ANP appears to act at several intracellular loci (Rosenberg et al., 1989b), and cGMP appears to be its second messenger (Rosenberg et al., 1988b, 1989b). Interestingly, in turkey adrenocortical cells, ANPs are as efficacious as Ang II in stimulating aldosterone production and actually augment maximal aldosterone production induced by Ang II, K^+ and ACTH (Kocsis et al., 1995c). Obviously, further work with diverse avian species is required to resolve this inconsistency and to understand the physiological relevance of ANP.

26.2.9 Overview of the HPA Axis

The HPA axis (Figure 26.7) is composed of hypothalamic neurons that contain the releasing hormones CRH, arginine vasotocin (AVT), and mesotocin (MT); the corticotropes of the cephalic lobe of the pituitary gland, which contain enzymes that synthesize and process (prohormone convertases) POMC to produce ACTH (corticotropin); and the steroid-secreting cells of the adrenal gland, which express MC2R, which exclusively binds ACTH.

It is well established that glucocorticoids exert a negative feedback on both the hypothalamus and pituitary gland to decrease CRH and POMC in a classical negative feedback (Denver, 2009). However, this negative feedback is finely modulated by changes in the pituitary AVT receptor (vide infra). Furthermore, ACTH itself appears to exerts a short-loop feedback on the hypothalamic CRH neurons (Jankowski et al., 2009), and, as mentioned in this chapter, glucocorticoids induced a short-loop feedback on the adrenocortical cell, probably by reducing MC2R expression and signal transduction (McIlroy et al., 1999).

The components of the HPA axis interact to produce corticosterone rhythms that are thought to regulate homeostatic mechanisms (Breuner et al., 1999; de Jong et al., 2001). However, the different components can have a level of independent but complex regulation suited for life

history stage and its interaction with season, suited for a changing and unpredictable environment (Romero et al., 1998; Romero and Rich, 2007; Cyr and Romero, 2009; Lattin et al., 2011a), or as a result of genetic selection (Carsia and Weber, 1986; Carsia et al., 1988b; Hazard et al., 2007). In addition, the HPA axis operates within a larger regulatory system for energy flow and partitioning, especially for the central nervous system.

CRH and AVT are the main stimulators of ACTH secretion from corticotropes, the ACTH-secreting cells of the cephalic lobe (Berghman et al., 1998). CRH is a 41-amino-acid peptide that binds to the type 1 CRH receptor (CRH-R1) on corticotropes and activates adenylyl cyclase to elevate intracellular cAMP, resulting in the release of ACTH (Carsia et al., 1986; Kuenzel et al., 2013). It also binds to the type 2 CRH receptor (CRH-R2) on thyrotropes and stimulates the secretion of thyroid-stimulating hormone (thyrotropin) (TSH) (De Groef et al., 2005, 2006). This is not surprising since thyroid hormones regulate intermediary metabolism, and the HPA and hypothalamic–pituitary–thyroid (HPT) axes interact tightly to regulate certain developmental processes and hatching in birds. Furthermore, the hypothalamus–pituitary–gonadal axis may interact with the HPA axis as well since there are sex differences in the plasma corticosterone response to CRH in AVT (Madison et al., 2008) and in AVT release and hypothalamic AVT receptor expression in response to osmotic stress (Chaturvedi et al., 2000). Finally, there are periodic resurgences of interest in a possible interaction between the pineal gland and the HPA axis, since both melatonin and glucocorticoids exhibit circadian rhythms (see Barriga et al. (2002)). However, a definitive link remains elusive.

AVT is a nonapeptide that binds to the type 2 VT receptor (VT2R) (and the type 4 VT receptor) on corticotropes. VTRs activate phospholipase C, leading to the generation of inositol-1,4,5-triphosphate and diacylglycerol and mobilization of intracellular Ca^{2+} (see Kuenzel et al. (2013)). There is evidence that a low thyroid hormone status (Sharma and Chaturvedi, 2009) and high circulating corticosterone (Sharma et al., 2009a) increase VT2R expression and that chemical adrenalectomy decreases it (Sharma et al., 2009a), but POMC expression is unaltered. The effect of glucocorticoids on VT2R expression may be the basis for the observed glucocorticoid programming of the HPA axis for enhanced stress response in zebra finches (Spencer et al., 2009). Also, here again, these studies show the intersection of both the HPA and HPT axes. Furthermore, AVT may recruit the HPA axis in response to osmotic stress (Sharma et al., 2009b). Thus, the intersection of CRH and AVT in regulating stress response in a number of avian species is clearly indicated. It should be pointed out, however, that these molecular studies using semiquantitative methods to measure messenger RNA levels are complex and are better understood when coupled with adrenal function studies. It is not unusual for receptor and POMC expression to be at variance with the adrenocortical response because of the less understood posttranscriptional regulation (Sharma et al., 2009b).

Because CRH and AVT operate through different signal transduction cascades, their combined action leads to synergistic release of ACTH (Mikhailova et al., 2007). In addition, there is evidence that this synergistic effect is also due to heterodimerization of CRH-R1 and VT2R (Mikhailova et al., 2007; Cornett et al., 2013).

Taken collectively, studies indicate that there are multiple pathways to elicit ACTH release from the cephalic lobe for normal rhythms of corticosteroid secretion and for greater corticosteroid responses to address a variety of environmental and homeostatic stressors. The adrenal gland, in turn, has intrinsic mechanisms to permit the episodic release of corticosteroids of varying magnitude in response to varying ACTH levels. This involves not only the rapid transcriptional regulation of such important proteins (MC2R, MRAP, StAR, and CYP11A) but also the rapid induction of inactivation pathways (Liu et al., 2013). Finally, the resultant circadian and ultradian rhythms of free glucocorticoids are highly synchronized between the circulation, the subcutaneous tissue, and the brain (Qian et al., 2012). This underscores the precision of how glucocorticoids are distributed to different body compartments for target tissue-specific functions.

26.2.10 Adrenocortical Function in Development, Maturation, and Senescence

The domestic fowl (*G. gallus domesticus*) is the most studied model to describe the development of the avian adrenal gland. Thus, the pattern of development of this precocial species described herewith may be somewhat different from those of semiprecocial, semialtricial, and altricial species.

The chick adrenal begins as an adrenogenital primordium that is apparent at about 3 days of development. Development of steroidogenic cells requires the nuclear receptor, steroidogenic factor-1 (SF1, or NR5A1), which is expressed in the adrenogenital primordium (Smith et al., 1999). SF1 promotes cell growth, limits cell death (apoptosis), and regulates the expression of genes involved in steroidogenesis, the MC2R, and StAR. However, work with knockout mice suggests that additional transcription factors are necessary for adrenocortical cell differentiation from steroidogenic progenitor cells and for the final cytoarchitecture of gland (Pihlajoki et al., 2013). At this time, the expression of key steroidogenic enzymes is detected in the chick embryo (Nomura et al., 1999) and in the developing zebra finch adrenal gland (Freking et al., 2000). However, *in situ* hybridization detects these key enzymes at about 5 days of development (Kanda et al., 2000), and this is in agreement with a more recent gene expression study (Kamata et al., 2004). Also, at about 5 days of development, the segregation

of the adrenogenital primordium into the adrenal gland and the gonad is apparent (Smith et al., 1999) as well as the histological identification of steroid-secreting cells arranged in cords (Chimenti and Accordi, 2008). From days 7 to 15 of development, chromaffin cells penetrate gland, and complete morphogenesis of the adrenal gland is complete by day 15.

It is thought that the adrenal gland is capable of steroidogenic function as early as day 5 of development, well before morphogenesis is complete. Embryonic circulating corticosterone levels slowly rise to day 15, but are independent of pituitary ACTH, even though immunoreactive ACTH is present in corticotropes at day 7 and embryonic adrenocortical cells can respond to ACTH. However, negative feedback is probably established by day 11. After day 15 and until hatch, the gland is under ACTH control, and CRH neurons become detectable in the hypothalamus a day earlier (see Jenkins and Porter (2004), De Groef et al. (2008), Ellestad et al. (2011)). So, there is general agreement that the adrenal gland of precocial species is under the control of pituitary ACTH at day 15 of development. From that day to hatch, circulating corticosteroids reach their peak. This rise is matched by an abrupt increase in maximal cellular corticosteroid response and maximal cellular sensitivity to ACTH (Carsia et al., 1987a). However, 1–2 days posthatch, chicks have a stress hyporesponsive period (see Wada (2008)). This is due to a proximal HPA axial block since adrenocortical cells are fully responsive to ACTH (Carsia et al., 1987a). Interestingly, there is evidence for an age-dependent window for "imprinting" the avian adrenal gland for a long-term, enhanced setpoint of response to ACTH (Avrutina et al., 1985). In chickens, this appears to be about 2–4 weeks posthatch. For example, subjecting cockerels to transient protein restriction over this period induces long-term potentiation of adrenocortical cell function (Weber et al., 1990).

In altricial birds, the time frame for HPA axis development is shifted later in the posthatch period. It is hypothesized that the peak corticosteroid response to a fully developed axis occurs at fledging (Wada, 2008). Here again, birds of an earlier age can respond to an ACTH challenge, indicating that the reduced corticosteroid response prior to fledging is proximal to the adrenal gland. It is thought that in altricial species, this uncoupling of the hypothalamus–pituitary unit from the adrenal prevents increases in circulating corticosteroids in response to stress, which could have an adverse effect on growth and immune function. In addition, the body condition of nestlings, such as fat stores, impact the HPA axis response to stress and circulating CBG, which modulates the target tissue effects of the prevailing circulating levels of corticosterone (Müller et al., 2010).

Overall, a limited number of studies indicate a gradual decline in adrenocortical function with age (Schmeling and Nockels, 1978; Avrutina et al., 1985; Davis and Siopes, 1987) and during senescence. In chickens, this decline, in part, may be due to a decrease in adrenocortical cell sensitivity and response to ACTH (Carsia et al., 1985b, 1987a). However, there is some suggestion from work with wild house sparrows (*P. domesticus*) that there is an increase in glucocorticoids that heralds death in birds susceptible to the stresses accompanying the winter season (Koren et al., 2011).

26.3 PHYSIOLOGY OF ADRENOCORTICAL HORMONES

Corticosteroids are the end products of the integration of environmental stimuli that impinges on the HPA axis. They are the transducers of these environmental cues and therefore regulate physiological and behavior processes appropriate to the environmental situation. The action of corticosteroids in birds is highly complex, and sometimes quixotic and paradoxical, depending on species, gender, life history stage, habitat, and a changing environment within a particular habitat. This corticosteroid hormonal pleiotropy is largely due to the expression and interaction of their cognate receptors and the intracellular coactivators and transcription factors. Many studies are associative, linking endogenous or exogenous glucocorticoids to an effect in birds. Given the fact that the MR, GR, and mGR have decreasing affinities to glucocorticoids (~0.2 nM (~69 pg/ml), ~6 nM (~2 ng/ml), and ~20 nM (~6.9 ng/ml), respectively), it is presumed that the effective concentration or dose of free glucocorticoid operates through the corresponding receptor. These studies are relatively underpowered to determine a causal association. Other studies use available mammalian receptor antagonists; however, complete antagonists are lacking. Finally, little is known about the repertoire of intracellular coactivators and other transcription factors that mediate the activated forms of the corticosteroid receptors. Nevertheless, an overview of the corticosteroid receptors and the complex functions that they are thought to regulate are discussed in the remainder of this section.

26.3.1 Corticosteroid Receptors and Their Action in Target Cells

The structure of avian forms of the GR (Kwok et al., 2007) and MR (Proszkowiec-Weglarz and Porter, 2010) has been determined. In traditional ligand-binding and competitive-binding studies, these manifest as the low-affinity site and high-affinity site for corticosterone binding. Both share high homology with mammalian corticosteroid receptors and, for the most part, function as homodimers after corticosteroid binding. However, as seen in mammalian studies, they probably can function as activated monomers in some instances (see Adams et al. (2003)).

Localization of the unstimulated GR and MR is mainly to the cytoplasm, and there is active translocation to the nucleus with corticosteroid treatment (Proszkowiec-Weglarz and Porter, 2010). Transfection of receptors shows that aldosterone is 2–3 times more effective than corticosterone for receptor activation. Interestingly, like aldosterone, the glucocorticoid corticosterone is 10 times more effective in activating the MR than the GR (Proszkowiec-Weglarz and Porter, 2010). However, the mammalian GR antagonist, onapristone, only partially blocked the corticosterone-activated chicken GR, and the mammalian MR antagonist, spironolactone, was a very weak antagonist of the activated chicken MR and actually had agonistic activity. Thus, the mammalian corticosteroid receptor antagonists (Figure 26.8) do not always work with the same fidelity in avian studies. This functional observation in transfection studies supports and explains the receptor-binding affinities observed in ligand-binding and competitive-binding studies, with cytosol and membrane preparations from the tissues of diverse avian species.

Like mammalian GRs, the chicken GR has a putative palmitoylation site (cysteine 660) providing the opportunity for membrane localization. However, like mammalian MRs, the chicken MR has an isoleucine in this site (isoleucine 773), although it is recognized that other portions of the hormone-binding domains of each are sufficient for membrane localization (Grossmann et al., 2008; Samarasinghe et al., 2011). Roughly 5–10% of classical corticosteroid receptors are associated with the plasma membrane. Localization to the plasma membrane involves association with caveolae, specialized plasma membrane invaginations within sphingolipid-rich lipid raft domains. Within the caveolae, the corticosteroid receptors are associated with caveolin-1 protein and other scaffolding proteins. Caveolae are important "signalsomes" in which activated steroid receptors are brought into close contact with various tyrosine kinases, other adaptor proteins, and also GPCRs. It is thought the membrane localization orientates the ligand-binding domain to face the extracellular environment where free corticosteroids can bind. Like the membrane-associated estrogen receptor, it is also thought that homodimerization occurs after binding of corticosteroids to membrane-associated corticosteroid receptors. In general, membrane localization most often leads to extracellular signal-regulated kinases (ERKs) for relatively rapid cellular responses. This type of signaling contrasts with the relatively slower, classical genomic signaling. Because the ERKs phosphorylate proteins that play a role in genomic signaling, it is thought that plasma membrane signaling modulates corticosteroid nuclear signaling—an "outside–inside" regulation of steroid hormonal action (Hammes and Levin, 2011; Hammes and Mendelson, 2012). In birds, this regulation may permit the uncoupling of receptor occupancy from transcriptional processes controlling protein and glucose metabolism in a tissue-specific manner (Orchinik, 1998). It should be pointed out that there is also support for nonclassical membrane receptors for corticosteroids, that is, heptahelical-GPCRs, especially for aldosterone (Wendler et al., 2012), although this novel mode of corticosteroid signaling awaits validation and characterization.

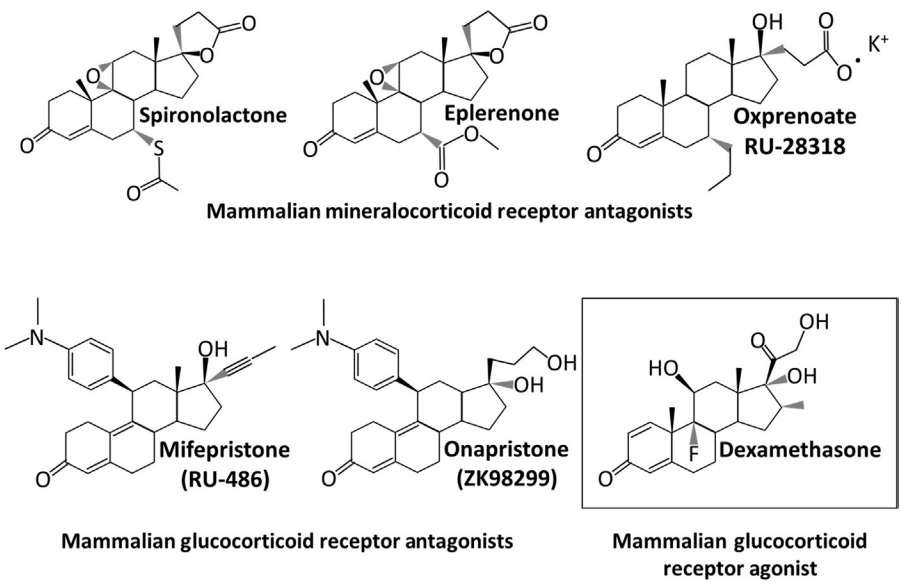

FIGURE 26.8 Chemical structure of mammalian mineralocorticoid and glucocorticoid receptor antagonists, and the potent glucocorticoid receptor agonist, dexamethasone. The use of these compounds in avian corticosteroid receptor studies has yielded mixed results, since they sometimes are only partially active or have agonist or antagonist activity opposite their usually complete action in mammalian receptor studies. *Molecules drawn by R. V. Carsia.*

Corticosteroid nuclear signaling involves the activation of monomeric receptors bound to heat shock protein 90 (HSP90). After binding, there is a conformational change freed by the release of HSP90. The receptor undergoes homodimerization and recruits a coactivator complex that contains histone acetyltransferase activity. This favors an opening of the chromatin structure and the recruitment of proteins for transcriptional activation. The complement of genes transcribed is tissue specific. Activated GRs can also interact directly with transcription factors instead of a particular DNA response element. Thus, the effect of corticosterone-activated GR on the immune system is in part by direct interaction with transcription factor nuclear factor κB. This leads to repression of transcription of genes encoding cytokines and cyclooxygenase-2 and, thus, a reduction in inflammatory response.

Corticosteroid receptors have been described through standard ligand- and competitive-binding studies on cytosolic and nuclear preparations of many tissues from diverse species, such as the house sparrow (*P. domesticus*) (Breuner and Orchinik, 2001, 2009; Lattin et al., 2011b) and the zebra finch (*T. guttata*) (Schmidt et al., 2010). The binding sites are sufficiently different from mammalian types in that known mammalian MR antagonists fail to displace corticosterone from the high-affinity site (MR), and, similarly, the mammalian GR antagonist mifepristone (RU-486) is a variable and often weak antagonist of the low-affinity site (GR). The affinities of these mineralocorticoid and GRs for corticosterone are fairly consistent: K_d*s* of about 0.2 nM and 6 nM, respectively, with a membrane-binding site of about 14–30 nM. Since the affinity of avian CBG is about 2 nM, the high-affinity site (MR) can easily draw corticosterone from CBG compared to the low-affinity site (GR). Thus, corticosterone most likely activates the avian MR and only in certain tissues with high 11βHSD2 and 20HSD activity is aldosterone selectively more active. Interestingly, cytosolic and membrane-associated corticosteroid receptors differentially bind corticosterone and cortisol in a tissue-specific manner (Schmidt et al., 2010). This differential binding of glucocorticoids is most likely due to posttranslational modification of the GR and MR. It is plausible that the membrane and cytosolic GR and MR and related isomorphs from posttranslational modifications and perhaps even novel corticosteroid receptors interact to provide a complex regulation of effector tissues.

The cloned avian GR and MR also serve as molecular tools to assess receptor expression in the avian brain (Hodgson et al., 2007; Dickens et al., 2009, 2011b; Banerjee et al., 2012). For example, various stressors such as maternal care deprivation (Banerjee et al., 2012); chronic, combined stress protocols (Dickens et al., 2009); and genetic selection for heightened stress response (Hodgson et al., 2007) all show differential changes in MR and GR expression in various regions of the brain, whereas translocation stress (Dickens et al., 2011b) is not associated with changes in expression. However, studies of corticosteroid receptor expression based on messenger RNA should be viewed with caution because of poor correlation with actual acceptor protein (i.e., corticosteroid receptor) levels in neuronal tissue (Medina et al., 2013).

26.3.2 Corticosteroids and Intermediary Metabolism

Since the HPA axis is within a larger system that regulates energy flow and partitioning, the overall action of glucocorticoids is to maintain adequate circulating concentrations of glucose. Studies in birds indicate that glucocorticoids exert profound effects on protein, carbohydrate, and lipid metabolism for this purpose (see Landys et al. (2006), Scanes (2009)). As a result, there is a tendency for prolonged elevated glucocorticoids to decrease body mass, but this is not a consistent effect among wild and domestic species because the increase in fat depots sometimes compensates for protein loss. However, baseline glucocorticoids are permissive for processes that maintain adequate food intake and optimal body mass. Similarly, some studies indicate that high glucocorticoids increase food intake and, in defense of protein partitioning, stimulate a preference for diets with higher protein value and negatively impact feed efficiency. Indeed, glucocorticoids operating through an interaction between the MR and GR seem to influence food choice. Furthermore, blocking GR activation (e.g., RU-486) suppresses the compensatory increase in food intake during periods of high energy demand, but not other types of feeding behavior during periods of low energy demand. Moreover, the variations in expression of brain corticosteroid receptors may underlie the changes in feeding behavior in different life history stages, as for example migration (discussed further in this chapter). Glucocorticoids also appear to work on the alimentary system by increasing transit time and the uptake of glucose, calcium, and phosphate. Further complicating the picture is that high glucocorticoids may differentially increase oxidative stress in tissues, impacting the interpretations of changes in key metabolic indicators (Costantini et al., 2008).

Since most studies use some form of glucocorticoid depot or glucocorticoid feeding regimen, the normal rhythms of glucocorticoids and, in turn, the complementary rhythms of delivery to target tissues, as well as the normal responses of interacting endocrines to those rhythms, are largely disrupted. Thus, it is not clear whether the responses in birds to exogenous glucocorticoids are physiological or pharmacological. Nevertheless, some conclusions as to their action can be drawn from the large number of studies conducted in diverse avian species.

26.3.2.1 Protein Metabolism

The action of glucocorticoids largely results in protein catabolism (see Landys et al. (2006), Scanes (2009)). The amino acids enter the citric acid cycle as an energy source and also shunt to hepatic, renal, and possibly intestinal sites (Watford, 2005) for gluconeogenesis to maintain adequate glucose levels. In domestic fowl, the important enzyme for gluconeogenesis is cytosolic phosphoenolpyruvate carboxykinase. In young chickens, the activity of this enzyme is localized in both the kidney and liver, whereas in the adult, it is predominantly in the kidney.

Frank changes in circulating glucose are not always apparent because of facilitated entry into cells through the action of insulin. Indeed, in domestic fowl, corticosterone induces hyperinsulinemia. However, a number of molecular markers also indicate insulin resistance in the liver and muscle and an increase in muscle glycogen (Lin et al., 2007). This paradox may be due to species, dose of exogenous glucocorticoid, and route of delivery and duration of treatment.

Since one of the largest sources of protein is muscle, it is not surprising that there is muscle breakdown. Strong indicators of generalized protein catabolism and more specific muscle protein breakdown are increases in circulating uric acid and the concentration of 3-methyhistidine in muscle, respectively. In domestic fowl, both sarcoplasmic and myofibrillar protein breakdown is apparent, and protein synthesis is depressed (Dong et al., 2007). However, in wild species, there is evidence for a differential effect in which sarcoplasmic reticular proteins are preferentially degraded, whereas myofibrillar proteins are initially spared, presumably to preserve flight muscle. The effect of glucocorticoids on protein metabolism is clearly concentration dependent, suggesting that these steroid hormones finely modulate protein metabolism.

26.3.2.2 Lipid Metabolism

Exogenous glucocorticoids, at concentrations reflecting ranges just exceeding circulating baseline levels and probably into stress levels, do have an impact on lipid metabolism (see Landys et al. (2006), Scanes (2009)). Again, as with protein catabolism, lipid stores are accessed to preserve circulating glucose and to provide an alternate energy source. Evidence suggests that the action of glucocorticoids on lipid metabolism is mediated through the low-affinity GR in that some actions are blocked by RU-486. Indeed, thus far, only the low-affinity, GR-type receptor is detected in avian adipose tissue (Lattin et al., 2011b).

Glucocorticoids restrict glucose utilization in many tissues, including adipose tissue. This drives some lipolysis but mostly depresses free fatty acid re-esterification, some of which is used as an energy source via the citric acid cycle within adipose tissue and some of which is released into the circulation. In addition, glucocorticoids regulate amino acid availability and utilization within adipose tissue to provide enzyme intermediates within the citric acid cycle.

In birds with positive energy balance, glucocorticoids also stimulate lipogenesis and fat deposition in the liver, and increase abdominal fat pad size. This lipogenic effect may be driven largely by insulin. In adequately fed, growing poultry, all glucocorticoid-driven effects on lipid metabolism are seen: an increase in adiposity and hepatic lipogenesis, an increase in circulating free fatty acids, and a decrease in glucose utilization.

In mammals, leptin is the circulating hormone derived from the adipose secretome that integrates the HPA axis, feeding behavior, and fat stores (e.g., see Glasgow et al. (1998)). Many wild avian species have extreme seasonal and life history stage–specific differences in appetite and fat accumulation. Some undergo fat depot changes that comprise up to 30% of their body mass. Yet, a factor like leptin of the avian adipose secretome remains elusive, and it is suggested that the cloned avian (chicken) leptin receptor is an orphan receptor (see Hen et al. (2008), Kordonowy et al. (2010), Pitel et al. (2010), Yosefi et al. (2010), Gogga et al. (2013)).

26.3.3 Corticosteroids and Electrolyte Balance

Birds regulate both plasma electrolytes and plasma volume within fairly narrow limits. Corticosteroids are critical for maintaining electrolyte and water balance. Most of the action of corticosteroids is mediated by the high-affinity MR. Thus, prevailing glucocorticoids are sufficient to maintain this balance. However, specific detection systems of perturbations in this balance activate the MRs in the main target tissues—the kidney, intestine, and hindgut—by deploying the potent mineralocorticoid aldosterone. Since some extreme perturbations also call in the HPA axis, it is especially important that glucocorticoid-inactivating enzymes (11βHSD2 and 20HSD) are upregulated and/or activated in these target tissues to permit aldosterone action (see Hughes (2003), Landys et al. (2006), Laverty et al. (2006)). This is especially important in birds with life history stages between freshwater and marine habitats, or between water-replete environments and arid environments.

Interestingly, the mechanism of aldosterone action on these target tissues is similar between birds without and with salt glands. Birds without salt glands cannot tolerate high Na^+ intake, but they do respond to low Na^+ intake. In this situation, there is an expected increase in circulating aldosterone in order to maintain adequate plasma Na^+ concentrations. Aldosterone acts on the kidney to reabsorb Na^+ from the glomerular filtrate. In addition, it increases the Na^+ channels and their activity in the colon and coprodeum to reabsorb lost Na^+ from the ureteral fluid. Furthermore, it induces ureteral fluid reflux from the coprodeum to more

orad (proximal) segments for additional cycles of Na^+ reabsorption.

In estuarian and marine birds with salt glands, aldosterone levels are maintained and elevated with high Na^+ intake through an unknown mechanism. The actions of aldosterone are for the most part the same as in birds without salt glands. Birds with salt glands tend to have larger kidneys and greater rates of glomerular filtration compared to birds without salt glands. Thus, there is an increase in Na^+ and water reabsorption at the kidney and hindgut with refluxing to augment reabsorption. However, in birds with salt glands, the resultant excess circulating Na^+ is secreted from the salt glands, which are stimulated by high plasma osmolality and high extracellular fluid volume but are not under the control of aldosterone. In this way, water is added to the extracellular fluid without the high concentrations of Na^+, thus maintaining a plasma volume and osmolality compatible with life.

26.3.4 Corticosteroids and Immune Function

Some aspects of the immune system influences on avian adrenocortical function have been mentioned in previous sections of this chapter. The focus here is on the action of corticosteroids on immune tissues. The obvious importance of corticosteroids in immune regulation is evinced by a growing body of literature indicating that the immune tissues of birds have an intrinsic system for either the local production of corticosteroids (Lechner et al., 2001) and/or the enzymes capable of reactivating circulating corticosteroid metabolites (Schmidt et al., 2008). Furthermore, it appears that avian immune tissues possess both MRs and GRs, with the suggestion that the MRs are activated preferentially by corticosterone (and aldosterone?) and the GRs by cortisol (Schmidt et al., 2010; Lattin et al., 2011b).

In general, birds have a different repertoire of immune organs, immune cells, and elaborated signaling molecules and immune-regulating genes compared to those of mammals. For example, birds lack lymph nodes for antigen presentation and rely predominantly on tissue dendritic cells. Nevertheless, the observed effects of glucocorticoids on the avian immune system appear consistent with those seen in the mammalian immune system, that is, the effects are largely immunosuppressive (see Mumma et al. (2006), Kaiser et al. (2009), Shini et al. (2010)). Exogenous corticosterone reduces the relative weight of the spleen and the bursa of Fabricius. As mentioned here, an antigen challenge or CRH induces the release of ACTH from chicken lymphocytes that is sufficient to elicit a corticosterone response from co-incubated chicken adrenocortical cells (Hendricks et al., 1991, 1995a), and this direct effect of CRH on chicken leukocytes is inhibited by corticosterone (Hendricks et al., 1995b). Conversely, immune stimulation upregulates high-affinity ACTH and GRs in lymphocytes (Mumma et al., 2006). However, there is evidence showing an initial phase of stimulating antibody response and a general positive influence on the adaptive immune response. Exogenous corticosterone stimulates heterophils and reduces leukocytes, thereby increasing the heterophil–leukocyte ratio. This response is different than that stimulated by lipopolysaccharide treatment, suggesting that different cytokines are stimulated by corticosterone. Indeed, corticosterone treatment initially upregulates the expression of proinflammatory chemokines. However, prolonged corticosterone treatment, thought to mimic prolonged stress, downregulates proinflammatory cytokines and chemokines (Shini et al., 2010). Thus, corticosterone may finely modulate immune response, and its group of corticosteroid receptors may serve as an important avian immune rheostat to ensure optimal immune response in birds.

26.3.5 Corticosteroids and Behavior

Behavior strategies used by birds, especially breeding behavior, are energy costly. Glucocorticoids and other hormones function to partition energy flow in order to balance breeding-related activity and self-maintenance and survival-oriented activities (Landys et al., 2006; Cornelius et al., 2013a,b; Wingfield, 2013). This balance is strongly influenced by the investment in breeding for the perpetuation of the species (Cornelius et al., 2013b). Those species with a high investment in a breeding cycle because of limited opportunities for breeding or because of short life spans employ mechanisms to dampen the HPA axis, allowing for just basic maintenance levels of corticosterone for permissive functions that support other hormones involved in energy partitioning. For those species with greater life spans that permit numerous opportunities for breeding, greater emphasis is on maintaining an active HPA axis in order to exploit those opportunities. Since many activities are associated with preparation for breeding, migration, territorial behavior, nest building, and so on, it is not surprising that glucocorticoids regulate these activities.

In general, glucocorticoids affect activity patterns, cognitive and learning processes, reproductive parameters such as courtship, copulation, and parental behavior such as interaction with offspring and procurement of food for offspring (Mostl and Palme, 2002; Rubolini et al., 2005). Since glucocorticoids regulate a number of locomotory patterns of birds, it is not surprising that locomotory activity and circulating glucocorticoid levels are tightly linked (Landys et al., 2006). The effect of glucocorticoids is rapid, is concentration dependent, and is not blocked by the GR antagonist RU-486. This suggests that the receptor mode employed to regulate locomotory activity is nongenomic and perhaps even of the nonclassical membrane type.

Glucocorticoids are essential for processes related to migration. They regulate the replenishment of energy stores

at stopover points and at final breeding grounds by increasing brain neurotransmitters controlling the increase in food intake, by decreasing thermogenesis, and by promoting fat deposition (Cornelius et al., 2013a). They also regulate the transition from migration to breeding in that high circulating levels inhibit the progression into breeding if environmental conditions are not conducive for nesting.

Of recent interest and of great importance is the role of glucocorticoids in the behavioral responses of birds to anthropogenic stressors and the worldwide encroachment of urbanization (Bonier, 2012; Wingfield, 2013). Evidence indicates that these persistent abiotic stressors can shape endocrine traits, including glucocorticoid responses. As mentioned here, glucocorticoids can be deleterious to survival or to species propagation by disrupting breeding. The emerging picture is that due to the variations in HPA axis plasticity among avian species, urban stressors may differentiate species into urban avoiders, urban adaptors, and urban exploiters (Bonier, 2012).

26.4 ADRENAL CHROMAFFIN TISSUE HORMONES

26.4.1 Catecholamine Synthesis and Secretion

Catecholamines are widely synthesized throughout the postganglionic sympathetic nervous system, which includes the adrenal chromaffin tissue. The biosynthetic pathway for the adrenal catecholamines (Ghosh et al., 2001; Mahata et al., 2002; Trifaró, 2002) is outlined in Figure 26.9. The rate-limiting step in catecholamine biosynthesis is tyrosine hydroxylase. Catecholamines exert a negative feedback on tyrosine hydroxylase. Acetycholine released from preganglionic sympathetic (splanchnic) nerve terminals interacts with both nicotinic and muscarinic receptors to stimulate phosphorylation of tyrosine hydroxylase, for rapid catecholamine synthesis and release, and it upregulates tyrosine hydroxylase synthesis with more long-term stimulation. Phosphorylation of tyrosine hydroxylase lowers its K_m for the cofactor tetrahydrobiopterin. VIP and PACAP also stimulate the phosphorylation of tyrosine hydroxylase.

Tyrosine hydroxylase catalyzes the conversion of tyrosine to dihyrophenylalanine (L-DOPA). Dihydrophenylalanine is converted to dopamine by aromatic L-amino acid decarboxylase (DOPA decarboxylase). Dopamine either is secreted or undergoes further conversion to norepinephrine (NE) by dopamine β-hydroxylase with ascorbic acid as a cofactor.

The final step to epinephrine (E) is carried out by phenylethanolamine *N*-methyltransferase (PNMT) in which the *S*-methyl group of *S*-adenosyl methionine is transferred to the primary nitrogen group of NE. All of these enzymes have some requirement for innervation and are affected by numerous intraadrenal peptides. However, PNMT is strictly GR dependent.

The release of catecholamines into the circulation occurs by the well-studied stimulus secretion coupling mechanism. In this mechanism, preganglionic nerve impulses release acetylcholine, which in turn activates its cognate receptors to depolarize the chromaffin cells. This results in an influx in Ca^{2+}, which induces exocytosis of the secretory granules. In addition to catecholamines, there are a number of neuropeptides that are co-released (see Section 26.1.2.1). Furthermore, chromagranins and secretogranins are also released. The peptides derived from chromagranins in particular have autocrine and paracrine effects on catecholamine release (Trifaró, 2002).

There is no preferential release of E or NE from isolated chicken chromaffin cells in response to acetylcholine analogs (Knight and Baker, 1986). *In vivo,* however, the secretion of E and NE from the avian adrenal gland is thought to be finely regulated by a number of neural-derived and blood-borne factors and hormones resulting in the differential release of catecholamines (Ghosh et al., 2001). Yet, it is not known precisely how the differential adrenal secretion of E and NE occurs in response to disparate physiological conditions and stressors. What is fairly clear is that the adrenal gland is nearly the sole contributor to circulating E and most of the NE in response to acute stressors (Butler and Wilson, 1985; Lacombe and Jones, 1990).

26.4.2 Circulating Catecholamines and Stress Response

Studies on the circulating concentrations of catecholamines in avian species have yielded disparate and conflicting values. The most recent and consistent values are obtained from studies with the domestic chicken (*G. gallus domesticus*) and Muscovy duck (*Cairina moschata*) using high-pressure liquid chromatography with electrochemical detection. The plasma concentrations of NE and E in growing and mature chickens average 0.52 and 0.96 ng/ml, respectively, whereas those of the duck average 0.45 and 2.10 ng/ml, respectively. Thus, the circulating concentrations of NE tend to be greater than those of E. Dopamine also exists at variable but comparable concentrations (Butler and Wilson, 1985; Cheng et al., 2001; Pohle and Cheng, 2009). In the chicken, NE, but not E, shows a diurnal rhythm (de Jong et al., 2001). Catecholamines are degraded mainly in the liver by catecholamine-*O*-methyltransferase and monoamine oxidase, and the inactive products are removed by the kidney. Monoamine oxidases are also present in the adrenal gland and thus can modulate intraadrenal levels of catecholamines (Ghosh et al., 2001).

Adrenal catecholamines are part of the first wave of the acute stress response (i.e., the "fight-or-flight response"). The epinephrine response to stress stimulates immediate

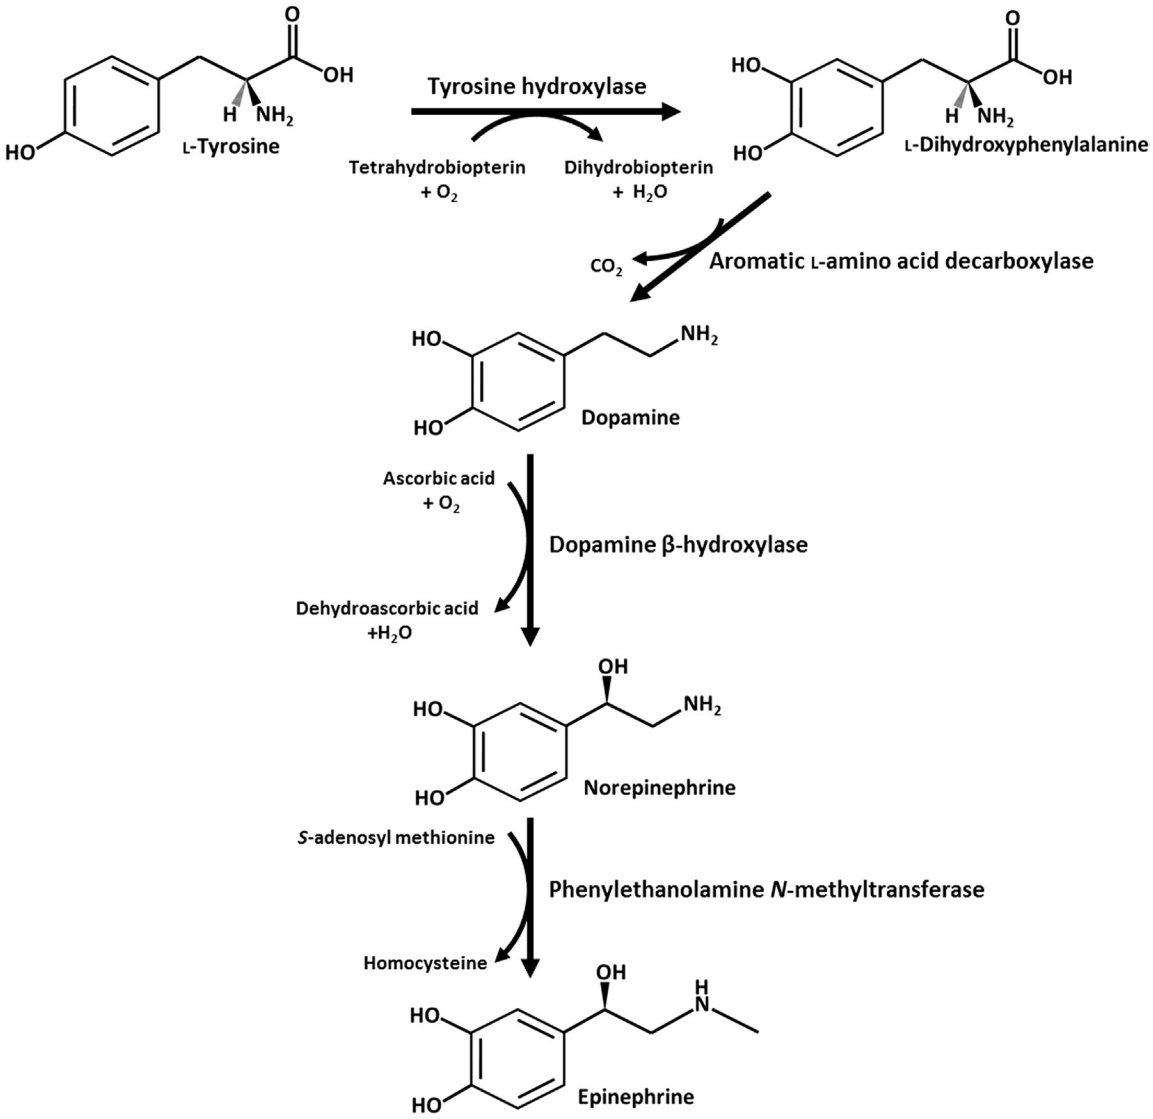

FIGURE 26.9 Biosynthesis of norepinephrine and epinephrine. Solid black and gray bonds on molecules represent key alpha (down) and beta (up) positions; however, not all hydrogen bond positions are shown. See text for additional details. *Pathway drawn by R. V. Carsia.*

hepatic glycogenolysis to provide glucose for critical tissues during energetic stress. In addition, catecholamines appear to interact with glucagon to regulate thermogenesis in cold stress (Abdelmelek et al., 2001; Filali-Zegzouti et al., 2005) Furthermore, catecholamines enhance the activity of the HPA axis at all levels ultimately driving more glucocorticoid release. In turn, the action of catecholamines is dependent on glucocorticoids (Sapolsky et al., 2000; Cyr and Romero, 2009). Glucocorticoids enhance cardiovascular sensitivity to catecholamines. The effect of glucocorticoids occurs at multiple levels of catecholamine action. They inhibit re-uptake of catecholamines by sympathetic terminals, reduce catecholamine-degrading enzymes, catechol-*O*-methyltransferase and monoamine oxidase, and increase the binding parameters and transmembranous signaling of β-adrenergic receptors. Indeed, a large part of the modulation of catecholamine action occurs through the regulation of adrenergic receptor function.

26.4.3 Some Physiological Actions of Norepinephrine and Epinephrine

Catecholamines have diverse effects on immune cells. For example, continuous infusion of physiological concentrations of NE and E enhance chicken leukocyte migration and differentially affect the phytohemagglutinin wattle response (McCorkle and Taylor, 1993). In addition, NE and E, *in vivo* and *in vitro,* have contrasting effects on immunoglobulin plaque-forming cells from splenic lymphocytes, and these contrasting effects are probably mediated by

α- and β-adrenergic receptors (Denno et al., 1994). Catecholamines also differentially affect macrophage effector functions, *in vitro* (Ali et al., 1994).

The metabolic effects of catecholamines are widespread in that they interact with other regulating hormones such as insulin, prolactin, thyroid hormones, growth hormone, and glucagon. Catecholamines influence carbohydrate and lipid metabolism (also see Chapter X). E stimulates glycogenolysis in chicken hepatocytes via β-adrenergic receptor activation and cAMP production, which, in turn, activates glycogen phosphorylase. Thus, the effect of catecholamines leads to a rapid increase in blood glucose levels (Thurston et al., 1993). Catecholamines (NE and presumably E) also stimulate gluconeogenesis via α-adrenergic receptor activation of intracellular calcium mobilization (Cramb et al., 1982). It is probable that the effects of E on glycogenolysis, gluconeogenesis, and also lipogenesis (discussed further in this section) are physiological roles for adrenal E, as these metabolic parameters are influenced by concentrations of E that are found in the circulation of a stressed bird.

In chickens, during periods of behavioral inactivity, there is a positive relationship between circulating catecholamines and free fatty acids. Thus, catecholamines, at least in the liver, may be physiological regulators of lipid metabolism. The synthesis of fatty acid (lipogenesis) by liver tissue and cells is inhibited by E and, to a lesser extent, by NE. This effect is mediated via both α- and β-adrenergic receptors and, at least partially, by cAMP acting as the intracellular messenger (Campbell and Scanes, 1985). Lipolysis in fat cells is stimulated by E in several species of birds and appears to be mediated via β-adrenergic receptors and cAMP (Campbell and Scanes, 1985).

26.4.4 Changes in Development, Maturation, and Senescence

Experiments with precocial species indicate that the adrenal chromaffin cells are derived from caudal thoracic (the region of somites 18–24) populations of neural crest cells (sympathoadrenal progenitor cells) (see Shtukmaster et al. (2013)). Recent evidence indicates that the adrenal chromaffin cells and postganglionic sympathetic neurons are derived from a common precursor cell population. In the chick embryo at about day 2, this population delaminates from the neural tube and migrates ventrally to the area of the dorsal aorta. Under the induction of bone morphogenic proteins elaborated from the aorta, the cells acquire catecholaminergic features, such as the expression of tyrosine hydroxylase. Cells that reach the region of the adrenal gland at around embryonic day 6 gradually lose neuronal features such as the expression of neurofilament proteins and gain chromaffin cell features. This transformation from neuronal type to chromaffin type does not require the GR or even adrenocortical tissue (Gut et al., 2005; Huber, 2006). However, the differentiation to E cells and the expression of PNMT is absolutely GR dependent and is apparent in chromaffin cells at day 5, although E cell differentiation does not require penetration into the developing adrenocortical tissue (Chimenti and Accordi, 2008). Indeed, chromaffin cell migration and penetration into the developing adrenocortical tissue do not occur until around day 8 or 9 and are not complete until day 15. In the chick, in addition to catecholamines, a variety of peptides are elaborated by the adrenal chromaffin cells postnatally. Some of these peptides were described in this chapter.

E is detected in the chick embryonic circulation somewhere between embryonic days 10 and 13 (see von Blumröder and Tönhardt (2002)). The importance of the adrenal gland in providing catecholamines for embryonic homeostasis is unclear since catecholamines can come from both adrenal and neuronal sources. However, a consistent observation is that circulating levels of NE predominate over those of dopamine and E. In the chick embryo, plasma catecholamines increase approaching hatch (von Blumröder and Tönhardt, 2002). NE appears to be an important catecholamine that supports the embryo for pipping and hatching, and the metabolic changes associate with the perihatch transition.

There appears to be an extreme range of variation in the adrenal NE and E content of birds of different phylogenetic groups (see Ghosh et al. (2001)). Although there has been recent interest in birds as comparative models to study the mechanisms of aging (Holmes et al., 2001; Holmes and Ottinger, 2005; Ricklefs, 2010), there is little information concerning the endocrine changes associated with aging. The chromaffin catecholamine content and content response to endocrine alterations appear to vary among different species with age. However, a consistent emerging picture that is shared with the limited number of vertebrate species studied thus far is that chromaffin activity increases with age in disparate avian species (Ghosh et al., 2001). Since there is a suggestion that glucocorticoids increase with age-related failure in adaptation to environmental and seasonal stressors (Koren et al., 2011), presumably similar changes occur with adrenal catecholamines. Clearly, more definitive studies are needed to understand the specific age-related changes in adrenocortical and adrenal chromaffin function in birds.

ACKNOWLEDGMENTS

The author thanks Walter L. Miller, MD, for helpful discussions on adrenal steroidogenic enzymes and Stephen R. Hammes, MD, PhD, for clarification on the types of glucocorticoid receptors. The author is especially indebted to Colin G. Scanes, PhD, ScD, for his invitation to write this chapter and for his invaluable guidance throughout its development.

27.1 INTRODUCTION

The endocrine pancreas of the chicken (and of birds in general) displays several peculiarities (Hazelwood, 2000; Simon, 1989). Before discussing the current knowledge, we will recall the basics from these previous reviews. Most of these are certainly connected and interacting.

- Birds have high plasma uric acid and glucose levels, despite normal plasma insulin levels (see Simon et al., 2011, for chicken). Such high plasma glucose levels (2–2.15 g/L in the fasting state) would be harmful for humans.
- In chickens and ducks, high doses of exogenous insulin are required to induce hypoglycemia, and huge doses are not lethal. The chicken features high blood glucose and low insulin sensitivity and, as will become apparent in this chapter, the weak insulin release elicited by glucose in the isolated chicken pancreas is characteristic of type 2 diabetes in humans.
- Experimental diabetes models are not available for chickens. Pancreatectomies are rarely complete; plasma glucose regulation is, however, impaired during re-feeding. Diabetogenic drugs (alloxan or streptozotocin) are inefficient, even when glycemia is decreased before streptozotocin injection. Some isolated cases of diabetes have been described in pet birds, although not cited here.
- Glucagon exerts a potent hyperglycemic effect; it is the lipolytic hormone in birds. The glucagon-induced cyclic adenosine monophosphate (cAMP) increase is comparatively small but long-lived; the feedback decrease of cAMP by fatty acids appears inefficient in chicken adipocytes. Insulin lacks an antilipolytic effect in chicken adipocytes. Several peptides have been shown to have an antilipolytic effect *in vitro*: APP (avian pancreatic polypeptide), somatostatin, gastrin, and GLI (gut glucagon-like immunoactivity); however, their function in chicken physiology has not been fully quantified *in vivo*.
- Chicken insulin is "hyperactive", whereas duck insulin is "hypoactive". Chicken insulin has accordingly been suggested as more potent at inducing hypoglycemia in chickens than sheep or bovine insulin (in Hazelwood, 2000). The extent of the difference may have been overestimated: at high concentrations, a similar nadir (maximal hypoglycemic effect) should be achieved irrespective of insulin type (this is the case for insulin binding and phosphorylation of artificial substrate in solubilized chicken liver or brain insulin receptors).
- The importance of the insulin–glucagon ratio in the control of metabolism has been demonstrated in chickens and ducks. *In vivo*, this ratio is governed by opposite insulin–glucagon variations in response to nutritional status (fed versus fasting). Glucagon–insulin interactions are, however, more complex. Insulin immuno-neutralization in fed chickens (i.e., a nutritional status for high insulin demand, a protocol previously developed in ducks; Mirsky et al., 1964 in Dupont et al., 2008) evokes a rapid (less than 30 min) and large rise in plasma glucose levels. Surprisingly, injection of a glucagon antagonist (des-His^{1} [Glu^{9}] glucagon) has no effect on plasma glucose levels in fed chickens (Dupont et al., 2008); a hypoglycemic effect might be expected. This strongly suggests that in normally fed chickens, the control of plasma glucose level relies more on insulin than on glucagon (in Dupont et al., 2008, 2012). The presence of glucagon is, however, essential: in the pathological model of "hypoglycemia-spiking mortality syndrome", where pancreatic glucagon content is extensively depleted following a virus infection, chickens do not eat and ultimately die from starvation in a profound hypoglycemic status (Davis and Vasilatos-Younken, 1995). To inhibit pancreatic glucagon release, glucose requires the presence of insulin (Dupont et al., 2008), which confirms previous results obtained in ducks and later on in mammals (see Miahle's group references in Simon, 1989).

Sturkie's Avian Physiology.

- Chicken (and bird) metabolism is also peculiar in several ways (as discussed throughout this book). In short, gluconeogenesis is active in liver and kidneys but appears able to be regulated only in kidneys. Liver is the organ for *de novo* lipogenesis.
- Insulin exerts pleiotropic effects in chickens during embryonic and posthatch development. The major typical effects on carbohydrate, lipid, and protein metabolism have been demonstrated. Insulin stimulates glucose and amino acid transport in various cells. The insulin effect on glucose transport is, however, limited in muscle and still doubtful in chicken adipocytes. Insulin stimulation of amino acid transport requires protein synthesis. Insulin greatly stimulates liver lipogenesis and expression of lipogenic enzymes. In contrast, insulin stimulation of lipogenesis remains marginal, at best, in chicken adipocytes (lipogenesis is also intrinsically low in human adipocytes). Glucagon counteracts insulin stimulation of lipogenesis in chicken liver.
- Finally, birds have a high body temperature (about 42 °C in chickens) and a high metabolic rate and anabolism. They are able to adapt to long catabolic states and to survive long periods without food.

This chapter offers a synthetic view of current knowledge, focusing on major aspects of glucagon and insulin control for the sake of brevity. References have been kept as few as possible; early major original contributions (including ours) for chickens and birds are acknowledged and listed only by the first author's name and date, but not referenced, when quoted in recent publications. For evident reasons, knowledge of the role of the endocrine pancreas is far more advanced in mammals; on several occasions, it was necessary to refer to it. Again, to save space, these data are listed in the text by the first author's name and date. Readers will need to connect to PubMed to have access to full references.

27.2 PANCREAS EMBRYOGENESIS AND DEVELOPMENT

27.2.1 Morphology of Avian Pancreas (Figure 27.1)

In most birds, the pancreas is situated in the duodenal loop and consists of three lobes: the dorsal, ventral, and splenic lobes. The splenic lobe is contiguous with the rest of the pancreas, but in some birds it can be completely separated. A fourth lobe, sometimes confusingly called the "third lobe", is a part of the ventral lobe and is distinguishable in galliform birds (which include chickens and quail).

27.2.2 Distribution of Avian Pancreatic Endocrine Cells between the Different Pancreatic Lobes

The endocrine pancreas contains clusters of cells called the islets of Langerhans, which are distributed throughout

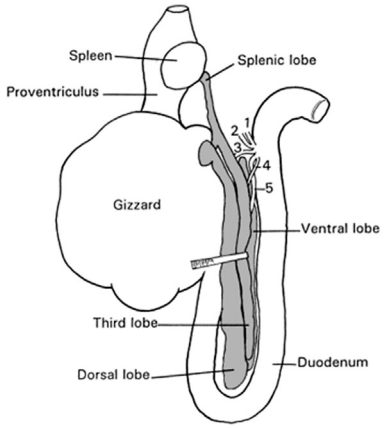

FIGURE 27.1 Morphology of the avian pancreas. The anatomical relationship in the chicken of the four lobes of the pancreas (shaded) and neighboring organs (blood supply and liver not shown) viewed from the dorsal aspect. (1) cystic duct; (2) hepatic duct; (3) dorsal pancreatic duct; (4) duct of the third lobe; and (5) ventral pancreatic duct. *After Mikami, S.I., Ono, K., 1962. Glucagon deficiency induced by extirpation of alpha islets of the fowl pancreas. Endocrinology 71, 464–473; The Endocrine Society.*

the exocrine parenchyma. These represent only 1–2% of the whole gland. In contrast to mammals, in which only one type of islets occurs, three types of islets are found in birds: the light, the dark, and the mixed islets. They differ in shape, size, and staining characteristics. The light islets (or B-islets) remain clear after classical staining procedures (Heidenhain's iron hematoxylin); they are essentially composed of β- and δ-cells secreting insulin and somatostatin, respectively, and occasionally very few α-cells secreting glucagon. The dark islets (or A-islets) are composed essentially of α- and δ-cells secreting glucagon and somatostatin, respectively. They are larger in size than the B-islets. The mixed islets are composed of numerous β-cells and a few α- and δ-cells. Some wild bird species have mixed islets (randomly distributed) rather than light and dark islets (Steiner et al., 2010). A fourth type of endocrine cell is found in the pancreas: the F-cells. These cells synthesize and release APP; they occur as single cells or in groups disseminated in the exocrine parenchyma, mainly in the dorsal and ventral lobes. Some F-cells can be found within the islets. Isolated δ-cells (as numerous as F-cells) are also found as dispersed extra-insular endocrine elements. The splenic lobe and, to a lesser extent, the third lobe (when present) notably contain more islet tissue per unit volume than do the dorsal and ventral lobes (Rideau, 1988).

The feature unique to the avian pancreas is the predominance of the glucagon-producing cells over the insulin-producing cells in the ratio of approximately 2:1 (see Andrew, 1984 in Manakova and Titlbach, 2007). In addition, somatostatin-producing δ-cells are also more numerous in the avian pancreas than in that of mammals (Rideau, 1988). The existence, distribution, and relative frequency of various (neuro-)endocrine cells (biotin, serotonin, neuropeptide

Y (NPY), and chromogranin) have been demonstrated in the pancreas of avian species (Ku et al., 2000; Lucini et al., 2000).

The islet tissue is richly vascularized, irrigated by the pancreaticoduodenal artery and drained by the pancreaticoduodenal vein. Innervation of the pancreatic islets of birds is not as apparent as it is in mammals. Electron microscopic studies have clearly shown that the main endocrine cellular types of the pancreas of the domestic fowl are associated with nerve terminals. The nerve supply to the islets is, however, less abundant than that to the acinar cells; it is also less marked to the A-islets than to the B-islets. In contrast, δ-cells are richly and directly innervated in chickens (Rideau, 1988).

27.2.3 Development of Avian Pancreas

The pancreas is of endodermal origin; it is formed from the embryonic foregut. In birds it arises from three buds: a dorsal bud and right and left ventro-lateral buds (Rawdon, 1998) that appear at the stage of 22–31 somites (ss) (56–67 h) and begin to fuse at day 7 of embryonic development (Hamburger and Hamilton stage 30 (HH30)) (Matsuura et al., 2009).

The determination of endoderm to form dorsal and ventral bud derivatives occurs before formation of the buds. In mammals, the signaling pathways underlying the pancreatic development process include the Hedgehog system, the homeobox gene Pdx1, and Notch signaling. The vast majority of neurogenin-3 (ngn3)-expressing cells are committed to the endocrine lineage (Rosenberg et al., 2010). Two transcription factors, Pax4 and Arx, have competing roles in the commitment of the first of the ngn3-positive cells to generate either the α/pancreatic polypeptide (PP)-cell lineage or the β/δ-cell lineage. Subsequently, within cells that are committed to the β/δ-cell lineage, the persistence of pax4 expression seems to select for the β-cell lineage, whereas suppression of pax4 expression selects for the δ-cell lineage (Gittes, 2009).

Early *in vitro* studies by Rawdon using the dorsal pancreatic bud of 5 day chick embryo established that pancreatic mesenchyme may play an instructive role with respect to the early development of the chick pancreas. Results also suggested that the notochord plays an early role in induction of the pancreas, although experimental evidence was lacking (Rawdon, 1998). Studies of the past decade confirmed and extended Rawdon's observations (Rawdon, 1998). Prepancreatic endoderm first receives pancreas-inducing signals from the underlying somatic mesoderm, inducing Pdx1 expression as early as 4 ss (i.e., in 1.5 day old embryos) (Katsumoto et al., 2009). The regulation of pancreatic endocrine development by Notch is also found in chicken: inhibition of Notch signaling results in increased endocrine differentiation, whereas activation of the Notch1 receptor blocks endocrine development and maintains the proliferation of pancreatic progenitor cells in the embryonic chicken pancreas (Ahnfelt-Ronne et al., 2007). Neurogenin 3, which is transiently expressed in pancreatic endocrine progenitors, is responsible for the activation of a transcription factor cascade that ultimately leads to the maturation of endocrine cells in chicken endoderm (Rosenberg et al., 2010). The origin of the ventral pancreatic precursor cells has been studied less extensively; they are located at sites in which Pdx1 expression is detected by *in situ* hybridization (Matsuura et al., 2009).

Organization, volume, and ratio among the different endocrine cell types vary throughout embryonic development and postnatal life. The dorsal bud is the major source of insulin, glucagon, and somatostatin cells, whereas the ventral buds generate PP cells (Rawdon, 1998). In the dorsal bud, glucagon immunoreactive cells appear first at 2.25–2.5 days of incubation, then insulin cells at 3–5 days and somatostatin cells at 3.25 days (Manakova and Titlbach, 2007). PP cells appear only later, at 7 days in the splenic lobe (Cowap, 1985). In contrast to the dorsal bud, insulin cells have not been identified in prospective ventral bud derivatives until 13 days of incubation (Manakova and Titlbach, 2007). Development of exocrine tissue is delayed in comparison to that of endocrine tissue (Manakova and Titlbach, 2007).

27.3 INSULIN AND GLUCAGON PEPTIDES

27.3.1 Insulin and Pre-pro-insulin, Pro-insulin, and C-Peptides

The chicken insulin gene was cloned and sequenced as early as 1980 (Perler et al. in Simon et al., 2004); it is localized on GGA5 and exhibits the "ancestral" structure containing two introns: intron-1 interrupts the 5′ untranslated region, and intron-2 (about 3.5 kb, versus 141–786 bp in other animal species; Steiner et al, 1985 in Simon et al., 2004) interrupts the coding sequence. It encodes a pre-prohormone (i.e., pre-proinsulin) that contains the signal peptide (rich in hydrophobic residues), the insulin B-chain, the connecting peptide (C-peptide), and the insulin A-chain. To date, there is no evidence for the existence of a second insulin gene in birds (in Simon et al., 2004).

Insulin has been purified and sequenced in chickens, turkeys, ostriches, geese, and Pekin and Muscovy ducks (in Chevalier et al., 1996). The insulin gene has been cloned and sequenced in other bird species, including hummingbird and 28 other species (Fan et al., 1993 in Simon et al., 2004). From deduced amino acid sequences, bird insulins appear highly conserved. As compared to human insulin, minor neutral changes on the B-chain concern few residues at both ends: B1, B2, B3, B20, B27, or B30 (out of 30 positions). On the A-chain, changes concern positions A8–10 (out of 21 positions). In our study (Simon et al., 2004), some uncertainty remains for the last six amino acids of

the A-chain because the reverse primer was targeting the corresponding codons and the stop codon. Changes on the A-chain (at A8–10 positions) between bird and human insulins are not neutral. This region is the most variable and is considered as the most immunogenic part. Accordingly, most antibodies prepared against mammalian insulins do not cross-react with chicken or duck insulin.

At the A8 position, a histidine residue is found in most bird species, as opposed to a glutamic acid residue in six species of the Anseriform order and a threonine in human insulin. The A8 position is now thought to be involved in the insulin-binding site to the insulin receptor (site 1; Sajid et al., 2009); the synthesis of human insulin analogs wearing different residues at the A8 position confirmed an early hypothesis, namely, the presence of histidine at A8 confers the properties of chicken insulin to such analogs (high binding affinity and low dissociation rate; see Weiss et al., 2001, 2002; Wan et al., 2004 and references quoted in Chevalier et al., 1996). Chicken insulin is the only natural super analog thus far described (at least twice as potent as human or pig insulin in bioassays or binding assays in many species; see Kemmler et al., 1978; Schauder and Buck, 1969; Simon et al., 1974, 1977 in Chevalier et al., 1996).

A8 glutamic acid, as found in the Anseriform order, increases the thermodynamic stability of the molecule, which should make "duck-type" insulins even more potent than "chicken-type" insulins (Weiss, 2001). In fact, the presence of negatively charged residues such as glutamic or aspartic acid at this position decreases the affinity of analogs for the receptor (Weiss, 2001). Duck insulin accordingly exhibits low affinity in rat liver membranes (Chevalier et al., 1996) and low bioactivity in rat fat cells (Moody, personal communication). The fact that chicken or Pekin and Muscovy duck insulin receptors (IRs) do not discriminate so extensively, compared to potencies observed with rat IR, may be specific to bird IRs (see Section 27.5.2). So, thus far, only two types of insulin have been found in 30 bird species: the hyperactive "chicken-type" insulin and the hypoactive "duck-type" insulin. From alignments of nonmammalian insulins (see references in Simon et al., 2004), A8 histidine was present early in the ancestor insulin molecule and disappeared in mammals (which possibly decreases the risk of hypoglycemic events and tumorigenicity). The appearance of A8 glutamic acid in anseriform birds and some snakes may have occurred independently in these species.

As in other species, bird C-peptides have been much less conserved; 14 changes out of 28 amino acid residues are found in 29 bird species (Simon et al., 2004). In other animal species, C-peptides are longer (31–38 amino acids; see Gross et al., 1989; Wahren et al., 2000 in Simon et al., 2004). Whether the shortness of bird C-peptide modifies the rate and yield of insulin synthesis is unknown. C-peptide is linked to B- and A-insulin chains through two dibasic residues at both ends (RR or KR, as in other species). In mammals, proteolytic cleavage and removal of these two pairs are performed by specific endopeptidases: PC3/PC1 and PC2 prohormone convertases and carboxypeptidase E. Such endoproteases have been detected in chicken embryos using heterologous antibodies (see Hernandez-Sanchez et al., 2002; Teshigawara et al., 2001 in Simon et al., 2004). Though predicted to be 28 residues long in all bird species, purified duck (*Anas platyrhyncos*) C-peptide is only 26 amino acids long (Marksen and Sundby, 1973 in Simon et al., 2004). Such extensive cleavages are also suggested in all the birds studied (with a possible exception in *Passer* in Simon et al., 2004). In mammalian species, at least two acidic amino acids surrounding a hydrophobic residue are present at the NH2-terminal end of C-peptide (e.g., EAED, EVE, and EAE); such a structure has been found to be critical for a normal rate of conversion of proinsulin to insulin. A very similar structure is observed in bird species studied (DVE, DIE, or DAE; Simon et al., 2004). C-peptide has long been considered as devoid of physiological functions on its own (other than structuring the precursor during insulin biosynthesis). C-peptide is now considered to control e-NOS, Na^+, K^+-ATPase, alpha-enolase, and several transcription factors (Wahren et al., 2012; Ishii et al., 2012). The central segment (ELGGGPGAG) or the COOH-terminal pentapeptide fragment (EGSLQ) of human C-peptide mimics the action of the entire peptide in several assays. The central part is very different in bird species, and C-terminal fragments are acidic (QEEYE, HEEYQ, QEEFE, or PEEYE). The C-peptide may therefore have acquired specific biological functions only in mammals, unless the still putative receptor co-evolved in bird species.

The length of available pre-proinsulin gene reading frames is similar in all bird species (187 nucleotides at the 5′ end and 134 nucleotides at the 3′ end; Simon et al., 2004). In contrast, the size of the PCR products varies greatly (from 2.7 kb in Passeriformes (*Passer*, *Turdus*, and *Pica*) to about 4.5 kb in Paleognathae species (*Struthio*, *Rea*, and *Dromiceius*)). Phylogenetic analyses supported the monophyletic origin of birds and identified the Paleognathae group as an isolated group at 100%, strongly suggesting this group is basal. After the branching of Paleognathae, a gallo-anserae was identified (at 63%), whereas all other Neognathae clustered at 99%. If we accept that Paleognathae, rather than Passeriformes, are basal to Neornithes, intron-2 must have evolved from a very long ancient form (likely close to that found in present day Paleognathae species) toward the shorter form found in Passeriformes.

In humans, some insulin gene polymorphisms are associated with diabetes. Some polymorphisms have been described in chicken (Bennett et al., 2006; Qiu et al., 2006) and in duck (one paper in Chinese: Kong et al., 2008) insulin genes. In the chicken, polymorphisms (mostly single nucleotide polymorphisms), thus far identified, are located in 5′- and 3′-UTR or intron. In these pioneer studies, significant

associations were found between body weight at hatching, 28 days, and 55 weeks and small intestine length (but not with abdominal fat weight) at 13 weeks of age. Further studies conducted at other ages and involving other physiological parameters may reveal other associations.

27.3.2 Glucagon and Glucagon-like Peptides

27.3.2.1 Glucagon Structure and Physiological Effects

Glucagon (a member of the vasoactive intestinal polypeptide (VIP)–secretin family of peptide hormones) is a 29 amino acid peptide that is very similar across species. In mammals, glucagon is encoded by a single proglucagon gene, and there is a single mRNA that generates a single protein precursor that contains glucagon and two structurally related peptides at its carboxyl terminus: glucagon-like peptide 1 (GLP-1) and glucagon-like peptide 2 (GLP-2). The posttranslational proteolytic processing of this unique precursor is tissue specific. In the pancreas, glucagon is one of the major peptides released by the α cells of A-islets in response to low glucose levels, whereas GLP-1 and GLP-2, but not glucagon, are produced in intestinal L cells and the central nervous system.

Chicken glucagon is also a 29 amino acid peptide that is derived from a single proglucagon gene, which expresses multiple mRNA transcripts with different coding potentials (Richards and McMurtry, 2008). In the case of the domestic fowl, the pre-proglucagon precursor is 151 amino residues long. Chicken glucagon differs from rat and human glucagon by only one amino acid (ser versus asn at position 28) and from duck glucagon by two amino acids (ser versus asn at position 28 and thr versus ser at position 16). In contrast to mammals, the chicken proglucagon gene expresses two classes of proglucagon mRNA transcripts (PGA and PGB): class A mRNA (PGA) codes for glucagon and GLP-1 and resembles lower vertebrate transcripts such as those found in fish, while class B mRNA (PGB) codes for glucagon, GLP-1, and GLP-2 and is more like mammalian transcripts. Pancreas and proventriculus displayed the highest expression levels of class A and class B mRNA. Two prohormone convertases (PCs: PC2 and PC1/3) cleave the precursor into active peptides: PC2 mRNA is predominantly expressed in the pancreas and proventriculus, whereas PC1/3 mRNA is more highly expressed in the duodenum and brain. Fasting and re-feeding have no effects on proglucagon mRNA expression in various chicken tissues: pancreas, proventriculus, duodenum, or whole brain. This indicates that transcriptional regulation does not account for acute changes in plasma glucagon resulting from short-term changes in energy status in birds (Richards and McMurtry, 2008, 2009). The proglucagon gene is also expressed in various neurons of the avian retina (Fischer et al., 2006) and in chicken adipose tissue (Cogburn, personal communication), whereas, in contrast to in other tissues, PGB mRNA levels appear insulin dependent (Ji et al., 2012).

In birds, glucagon has several physiological roles and peculiarities that already have been described in Hazelwood, 2000, 5th Edition. Plasma glucagon levels are much higher in birds than in mammals. Chicken, ostrich, and pigeon glucagons were initially found to be less potent than mammalian glucagon, but this was not confirmed in a subsequent study (see the following: McCumbee and Hazelwood, 1978; Ferreira et al., 1991; Tung et al., 1977; Huang et al., 1987 in Simon, 1995). In turkeys, pig and chicken glucagon were found to be equally effective in promoting hyperglycemia, an increase in plasma nonesterified free fatty acid levels, and a decline in circulating levels of T_3 and T_4 (McMurtry et al., 1996). Long-term injection of glucagon has been shown to induce uncoupling protein (UCP) expression in the skeletal muscle of ducks, consistent with the thermogenic action of this hormone in birds (Raimbault et al., 2001). Glucagon is also important in the chicken eye for regulating ocular growth (Vessey et al., 2005). Honda et al. found that central, but not peripheral, administration of glucagon suppressed food intake and induced hyperglycemia in chickens and that these effects were mediated by the downstream actions of corticotrophin-releasing factor (CRF; Honda et al., 2007 in Honda et al., 2012). Thus, glucagon may serve as a neurotransmitter in the avian central nervous system, as has been suggested for mammals (Mayo et al., 2003).

27.3.2.2 GLP-1

GLP-1 slows down nutrient assimilation by inhibiting gastric emptying and acid secretion. Central but not peripheral administration of GLP-1 inhibits food intake and crop emptying in chickens and shifts fuel utilization from carbohydrates to lipids without affecting overall energy expenditure (Tachibana et al., 2007). The hypothalamus is involved in the anorexic effect of GLP-1 in chicks (Tachibana et al., 2004 in Tachibana et al., 2007). Moreover, the anorexigenic effect of central GLP-1 administration is mediated by the GLP-1 receptor because co-administration of a specific GLP-1 receptor antagonist (exendin 5–39) or N-terminal fragments attenuates the anorexia, while injection of the antagonist alone increases food intake in layer-type but not broiler chicks (Furuse et al., 1998). These results indicate the potential for variable responses in food intake to endogenous GLP-1 among different strains of poultry. Expression of the GLP-1 receptor mRNA in chicken pancreas is consistent with a possible incretin role for GLP-1 in birds (although it is not yet demonstrated in chicken).

27.3.2.3 GLP-2

In mammals, GLP-2 plays a role in intestinal growth and nutrient absorption by maintaining the integrity of mucosal epithelial cells. Secreted by enteroendocrine L-cells in

response to the presence of nutrients, GLP-2 promotes crypt cell proliferation and suppresses apoptosis in mucosal epithelial cells. Elevated expression of GLP-2 receptor mRNA in chicken duodenum is consistent with the proposed role for GLP-2 in intestinal growth and function. Shousha et al. reported no effect of intracerebroventricular or intraperitoneal administration of GLP-2 on food intake, body temperature, or locomotor activity in Japanese quail (Shousha et al., 2007). However, these studies involved the use of rat GLP-2, which shares only 52% amino acid identity with chicken GLP-2 and may lack activity in avian species.

27.4 INSULIN AND GLUCAGON RELEASE

27.4.1 Pancreatic Hormone Levels During Development and After Hatching

Circulating concentrations of insulin and glucagon rise during development of the chicken embryo. In Cobb 500 chick embryos and hatched chicks, plasma insulin increased from 10 days of embryonic life (E10) (30 pg/mL), reaching 1000 pg/mL at 17 days after hatching (Lu et al., 2007). Plasma insulin concentrations, at 3–4 ng/mL in fed growing ducks and chickens, are similar to those of mammals (Simon et al., 2011). They are low at one day post hatch and increase with age up to 28 days, with higher insulin sensitivity in one-day-old chicks than in 21 day old broiler chickens, as observed in the latest strain of broiler chickens (Shiraishi et al., 2011b) and in previous reports on egg-laying or meat-type chickens. Plasma insulin concentration decreased by 45–50% after 6 h of fasting in 19 to 47 day old male and female modern meat-type chickens (Christensen et al., 2013). A low plasma glucagon concentration (59 pg/mL) was found in embryos at E10, remaining low until E17 and then increasing approximately threefold by the time of hatching (Lu et al., 2007). Values between 152 pg/mL and 450 pg/mL were measured in fed and 6 h fasted modern meat-type chickens, respectively (Christensen et al., 2013). It should be noted that in some of these experiments, the feeding pattern of chickens was not always synchronized with light–dark cycles.

27.4.2 Insulin Release

Whereas in mammals glucose is the primary physiological regulator of insulin secretion, the insulinotropic effect of glucose is less obvious in birds *in vivo* and *in vitro*. *In vivo*, raising blood glucose levels in ducks and chicken only transiently increases insulin levels (Rideau, 1988). The high basal plasma glucose concentrations found in chickens may themselves contribute to the relative insensitivity of the chicken β-cell to glucose: impairment of glucose-induced insulin release has been reported in hyperglycemic mammalian models. The mechanisms are, however, presently unknown in chickens. Somatostatin, which is present at high concentration in the chicken pancreas (Weir, 1976 in Rideau, 1988), may also exert inhibitory paracrine effects on the β-cell and partly explain the insensitivity of the β-cell to fuel nutrients. However, somatostatin immunoneutralization in isolated-perfused chicken pancreas has only transitory effects on insulin release at high glucose concentration (42 mM) and no effect at low levels (14 mM) (Honey, 1981 in Rideau, 1988). *In vitro* studies provided further insight into the mechanisms responsible for the relative glucose insensitivity of chicken β-cell. Using isolated and perfused duodenum-pancreas from adult hens (King et al., 1976 in Rideau, 1988, 1998) first showed that the pancreatic β-cell is relatively insensitive to glucose as very high and nonphysiological glucose concentrations (30–40 mM) are required to induce a modest insulin release. This insensitivity was confirmed and extended to other fuel nutrients, which are potent insulinotropic agents in mammals, using isolated duodenum-pancreas from young chickens. D-glucose and D-glyceraldehyde require high concentrations to evoke either very weak or delayed insulin release; leucine and its ketoacid (α-KIC) are even totally ineffective. The chicken β-cell, however, remains sensitive to depolarizing agents (K^+), tolbutamide (which closes K^+ATP-dependent channels), and potentiators of insulin secretion (acetylcholine or cAMP; Rideau, 1988). Therefore, the initiation of insulin secretion by fuel nutrients, the critical and specific step of the β-cell, appears different in chickens and mammals, whereas potentiating mechanisms (arginine, acetylcholine, and cAMP in the presence of low glucose concentration) and membrane depolarization events (K^+ and arginine) are present in chickens as in mammals.

The key role of glucokinase (GK) in the regulation of insulin release and hepatic glucose utilization has been well described in mammals. Although the GK gene is not referenced in the chicken genome at Ensembl, we isolated a chicken GK cDNA and showed that the GK messenger is expressed in chicken liver and pancreas (Berradi, 2005 in Rideau et al., 2010). A human GK antibody identified a GK protein in chicken liver, the amount and activity of which were insulin dependent (Dupont et al., 2008). Furthermore, RO0281675 (a specific GK activator in mammals) caused severe hypoglycemia in chickens but, surprisingly, did so without significantly increasing insulin levels, contrary to results obtained in mammals (Rideau et al., 2010). Thus, liver glucose utilization is substantially enhanced following liver GK activation. Although GK is present in the chicken pancreas, pancreatic GK activation may not be sufficient to cause insulin secretion, which confirms the *in vitro* studies reported here and supports the conclusion that the coupling between intra-B-islet metabolism and insulin release is different in chicken B-islets. The lack of insulinotropic effect of leucine or α-KIC (metabolized in the mitochondria) suggests that the inefficiency is located beyond the pyruvate step in the chicken β-cell.

Isolated chicken B-islets are necessary to further understand the insensitivity of the chicken β-cell to "insulinotropic" fuel nutrients. Although functional islets were isolated in various mammalian species more than 40 years ago, isolation of avian islets of Langerhans has proven to be especially difficult due to the fact that the morphology of the isolated A- and B-islets had not been characterized. Ruffier et al. described isolation of functional A- (glucagon) chicken islets (Ruffier et al., 1998). Glucose-stimulated insulin release from B-islets isolated from the dorsal lobe of the chick pancreas has been reported (Datar et al., 2006). In our opinion, however, the specificity of these preparations remains to be established as the dithiocarbazone staining method stains both B- and A-islets in chickens (Ruffier et al., 1998).

Regarding resistance to diabetogenic drugs, the extreme resistance of birds to the diabetogenic drugs alloxan and streptozotocin (STZ) was described very early. In mammals, the β-cell specificity of these drugs is mainly due to the fact that they are selectively transported by the β-cell glucose transporter, GLUT2 (Lenzen, 2008). GLUT2 expression was reported in the liver and kidney in chickens; unfortunately, the pancreas was not examined (Kono et al., 2005). Within the mammalian β-cell, alloxan selectively inhibits glucose-induced insulin secretion through specific inhibition of glucokinase; in addition, it induces ROS formation, resulting in the selective necrosis of β-cells. STZ's effects are attributed to its specific alkylating potency, which modifies biological macromolecules and DNA fragments and ultimately destroys the β-cells (Lenzen, 2008). Compared with mouse islets, chicken islets generate smaller amounts of ROS under STZ. Consequently, less damage to proteins, lipids, and DNA can be expected in chicken than in mouse islets. These results may partly explain why STZ does not induce diabetes in chicken, even at high doses (Modak et al., 2007).

Despite the peculiarities present in chickens in the coupling between metabolism and insulin release, insulin release is under the control of multiple components *in vivo* and *in vitro*. Although glucose or a mixture of amino acids separately increases plasma insulin to a small extent, they act synergistically when combined *in vivo*. Re-feeding with gradually increasing amounts of food results in gradual rises in plasma insulin levels, adjusting glucose to a similar level. Changes in the glucose–insulin balance are observed in several experimental conditions or models (Table 27.1), including genetically fat and lean lines of chickens, dwarf chickens (*dw*/*dw*), hypothyroidism, corticosterone treatment, and chronic exposure to high temperature (Rideau, 1997). The incretin effect is not documented in chickens, but a variety of other stimuli, including nutrients (glucose and arginine), hormones (cholecystokinin, glucagon, corticosterone, and GH) (Rideau, 1988), and neuronal stimuli (Karmann et al., 1992), increase plasma insulin levels. The effects of ghrelin–obestatin and GLP-2 on insulin release are not known in birds. Conversely, insulin secretion is inhibited by epinephrine and somatostatin (Rideau, 1988). Although the existence of leptin in the chicken is still debated, a recombinant "chicken" leptin (or leptin analog) potently inhibits insulin secretion from the perfused chicken pancreas (Benomar et al., 2003).

27.4.3 Glucagon Release

Fasting markedly increases circulating concentrations of glucagon in chickens (Edwards, 1999 in Scanes, 2009). In modern meat-type chickens, plasma glucagon levels increased 3.5- to 3.7-fold after 6 h of fasting while plasma glucose was depressed by 11% (Christensen et al., 2013). Glucagon secretion is inhibited by glucose *in vivo* in domestic birds (Honey, 1980 in Rideau, 1988) and in wild species (Tzotze, 1998 in Scanes and Braun, 2012). Exogenous glucose (42 mM) inhibited glucagon release by 27% from isolated A-islets of Langerhans (Ruffier et al., 1998). Conversely, glucagon release is stimulated by amino acids, free fatty acids, cholecystokinin, somatostatin, and insulin *in vivo* (Scanes and Braun, 2012). A tonic suppression effect on glucagon by insulin is suggested in a model of insulin immune-neutralization in chickens (Dupont et al., 2008). As for insulin, the effect of gastrointestinal peptides and adipose tissue hormones on glucagon secretion is unknown in birds.

The mechanisms underlying the secretion of glucagon from α-cells are largely unknown in chickens. In mammals, α-cells contain a comparable secretory "machinery" as in β-cells: a glucose transporter (in this case, the ubiquitous GLUT-1), glucokinase, K^+ATP channels, L-type voltage-gated calcium channels, and secretory granules (Le Marchand and Piston, 2010). However, α-cell secretory activity is quite different from that of β-cells. The mechanisms underlying the glucose inhibition of α-cell secretory activity are poorly understood. Two nonexclusive models have been proposed: a direct inhibition by glucose, and an intra-islet paracrine inhibition arising from non-α-cells. The paracrine control might involve somatostatin released from δ-cells and insulin, zinc, or gamma-aminobutyric acid released from β-cells. Recently, Le Marchand and Piston suggested that in the absence of cell–cell contacts, isolated α-cells function similarly to β-cells (i.e., glucagon secretion increases as a function of glucose concentration). However, in the islet, glucose inhibits glucagon release downstream the calcium step, presumably at the level of vesicle trafficking or exocytotic machinery (Le Marchand and Piston, 2010).

27.4.4 Somatostatin

Somatostatin (also known as growth hormone–inhibiting hormone (GHIH) or somatotropin release-inhibiting factor

TABLE 27.1 Experimental or Genetical Models Exhibiting Changes in the Plasma Glucose–Insulin Relationship in Chickens[1]

	Fasting Plasma Levels		Glucose Tolerance			
Models	Glucose	Insulin	Glucose Disposal	Insulin Levels	Insulin Sensitivity	Fattening
Intermittent (IT) versus *ad libitum* feeding (C)	IT≥C	IT=C	IT>C	IT<C	ND	IT≥C
Corticosterone (cort) treatment.	Cort>C	Cort>C	Cort<C	Cort>C	Cort<C	Cort>C
Fat–lean lines (FL-LL)	FL<LL	FL≥LL	FL>LL	FL>LL	FL≥LL	FL>LL
High- and low-glucose lines (LGl–HGl)	LGl<HGl	LGl=HGl	LGl=HGl	LGl=HGl	LGl=HGl	LGlL>HGlL
High- and low-growth lines (HG–LH)	HG≤LG	HG>LG	HG=LG	HG>LG	ND	HG>LG
Dwarf (*dw*)–Normal (N) chickens	*dw*=N	*dw*=N	*dw*=N	*dw*<N	*dw*>N	*dw*>N

[1]*ND: not determined. Refeeding experiments have been performed following a fast in several of these models; results, not summarized in the table, can be found in Simon (1988) and in Simon et al. (2000) (LGl–HGl). Corticosterone was injected in doses of 5–6 mg/kg. Insulin sensitivity was evaluated through the hypoglycemic effect of exogenous insulin. Results of glucose tolerance in HG–LG chickens are unpublished data (Simon et al.).*

(SRIF)) is a 14 amino acid peptide that regulates the endocrine system. Chicken somatostatin is present in two forms, somatostatin-14 (SST-14) and somatostatin-28 (SST-28), which are encoded by the same gene (PSS1) as in mammals. Chicken pancreatic A-islets, B-islets, and D-cells contain only the SST-14 peptide form (Takayagani et al., 1996 in Trabucchi et al., 2003). Another somatostatin gene variant (PSS2) exists in many species, including chickens. PSS2 messenger is expressed in chicken pancreatic islets or pancreas and in a few specific brain structures, fewer than the structures expressing PSS1 messenger (Trabucchi et al., 2003).

27.4.5 Avian Pancreatic Polypeptide

APP was first isolated and characterized from chicken pancreas (Kimmel et al., 1968); it is a member of the neuropeptide Y family (PP, peptide YY (PYY), and NPY). PYY and PP are gut endocrine peptides almost exclusively expressed in the digestive system, whereas NPY is expressed in the central and peripheral nervous systems at all levels of the gut–brain axis. All three peptides are 36 amino acids long and act on G protein–coupled receptors; five receptor subtypes have been described. In mammals, PP is released from the endocrine pancreas following a meal and acts preferentially via Y4 receptors. It inhibits gastric emptying, intestinal electrolyte, water secretion intestinal motor activity, and peristalsis. PP also reduces appetite (Holzer et al., 2012). In chickens, APP is released in response to gut peptides and amino acids (Colca, 1982 in Rideau, 1988). Y4 receptors are expressed in a large number of peripheral tissues and in the brain (Lundell et al., 2002). APP primarily acts by inhibiting gastrointestinal tract motility and gall bladder and exocrine pancreas secretion in chickens (Hazelwood, 1993 in Hazelwood, 2000). It also exerts metabolic effects: liver glycogenolysis, hypoglycerolemia, and lowering of the plasma free fatty acid level. One study, however, suggests that APP increases food intake in white leghorn chickens (Denbow et al., 1988).

27.5 GLUCAGON AND INSULIN RECEPTORS

27.5.1 Glucagon Receptors

In mammals, the biological actions of glucagon are mediated by a specific glucagon receptor (GCGR; Authier and Desbuquois, 2008), a receptor belonging to G protein–coupled receptor subfamily B, which also includes the receptors for GLP-1, GLP-2, VIP, growth hormone-releasing hormone, and growth hormone–releasing hormone-like peptide. Stimulation of the glucagon receptor modulates adenylate cyclase, initiates the production of cAMP, and thereby activates extracellular signal-regulated protein kinase-1 and -2 via cAMP-dependent protein kinase A (cAMP–PKA; Figure 27.2). In addition, it also activates signaling pathways via cAMP-independent interactions, leading to stimulation of phospholipase C and release of Ca^{2+} from IP_3-sensitive intracellular Ca^{2+} stores.

The chicken glucagon receptor gene was cloned from adult brain tissue (Wang et al., 2008a); it encodes for a short glucagon receptor of 496 AA (GCGR-s) or a long receptor variant of 554 AA, designated glucagon receptor variant 1 (GCGR-v1). The chicken GCGR-s shares high AA sequence identity with that of human (70%), rat (69%), mouse (69%),

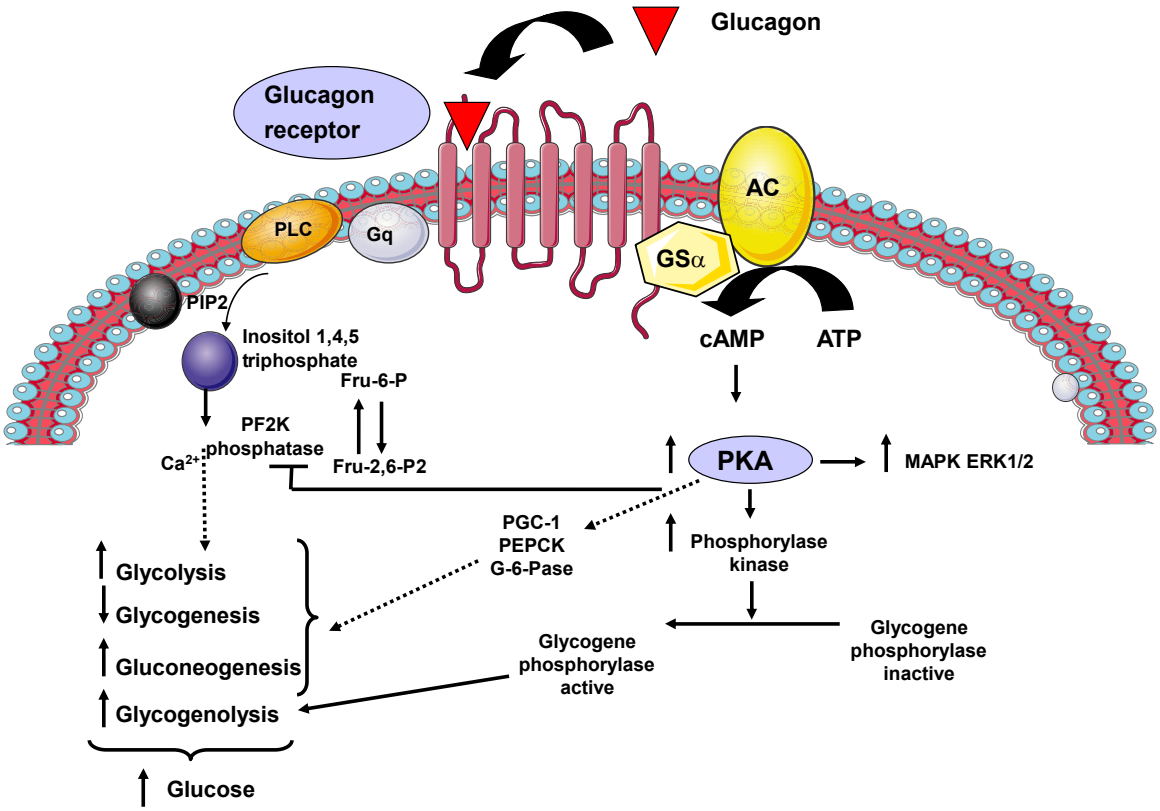

FIGURE 27.2 Glucagon receptor signaling.

and *Xenopus* (64%). Functional analysis confirmed that both GCGR-s and GCGR-v1 can be activated by glucagon and are functionally coupled to the cAMP-PKA signaling pathway. The glucagon receptor is widely expressed in all tissues, including the hypothalamus, with the greatest expression found in the liver, suggesting that glucagon plays a wide range of roles in both hepatic and nonhepatic chicken tissues through the two receptors, GCGR-s and GCGR-v1 (Richards and McMurtry, 2008). Recently, Wang et al. identified a novel ligand–receptor pair, named GCGL and GCGL receptor (GCGLR), from chicken brain (Wang et al., 2012). GCGL is a novel GCG-like peptide of 29 amino acids that shares high amino acid sequence similarity with mammalian and chicken GCG (62–66%). GCGLR is a GCGL-specific receptor, which shares relatively high amino acid sequence identity with chicken GCGR and structurally related receptors (GLP1R, GIPR, and GLP2R). GCGL mRNA expression is mainly detected in the central nervous system, spinal cord, and testis, whereas GCGLR is more widely expressed in chicken tissues (Wang et al., 2012).

27.5.2 Insulin Receptor

Early studies on ontogeny, structure, binding affinity, binding characteristics, number, internalization, and up- and downregulation of insulin receptors (IR) in chicken or turkey tissues have already been reviewed (Simon, 1989). Since then, changes in IR number have been described in the hypothalamus, at least at the level of IR messenger, in layer and broiler-type chicks under ad libitum conditions (Shiraishi et al., 2011a); changes in hypothalamic IR mRNA in response to photoperiodism are dependent upon gonad hormones (Anraku et al., 2007). In chicken liver plasma membranes, hepatocytes, and thymocytes, insulin-binding capacity (IR number) is lower than in rat or veal (in Simon, 1989), which may contribute to the low insulin sensitivity of chickens. However, in crude liver membranes (i.e., plasma and intracellular organite membranes), the IR number is about the same in chickens and rats (Dupont et al., 2004). A high proportion of IR may therefore be internalized in chicken liver (Krup and Lane, 1981, 1982 in Simon, 1989). Chicken IR shows a heterotetrameric structure (two α and two β subunits linked by disulfide bonds, as described in mammals and other species; reviewed in Simon, 1989). The α subunit (about 135 kDa) is entirely within the extracellular compartment and binds insulin; the β subunit (about 95 kDa) contains a large hydrophobic fragment (inserted into the membrane), crosses the cell membrane, and extends into the intracellular compartment. In chickens, as in other species, the α subunit of brain or muscle receptors is smaller than that of liver receptor α subunit, in part as a result of differences in glycosylation (reviewed in Simon, 1989).

In mammals, both IR α and β chains are synthesized from a single mRNA, which is encoded by 22 exons. In

mammals, exon 11 is alternatively spliced, which results in two IR isoforms (IR-A and IR-B) that differ by the absence or presence of 12 amino acids at the C-terminus of the α subunit, respectively. IR-A and IR-B isoforms display differences in ligand affinity binding, kinase activity, receptor internalization, and recycling as well as intracellular signaling capacity and tissue distribution (De Meyts, 2012). According to Hernández-Sanchez et al., the region corresponding to exon-11 is missing in chicken IR; chicken tissues would only express the IR-A type (i.e., the IR type showing the highest insulin affinity) (Hernandez-Sanchez et al., 2008). This may account for the fact that chicken IRs exhibit much higher affinity for IGFs than mammalian IRs. It may also explain why chicken and duck IRs do not discriminate among chicken, pork, and duck insulins very well (Chevalier et al., 1996).

In its intracellular part, the IR β subunit is a tyrosine kinase activated by autophosphorylation following insulin binding to the α subunit. The chicken IR tyrosine kinase activity shows the same features as those from other species (reviewed in Kato et al., 2000; Simon, 1989). Chicken liver or kidney IR tyrosine kinase activities (basal and maximal activities) are regulated, for instance, by nutritional conditions (e.g., fasting or re-feeding), as in mammals. In contrast, muscle and adipose tissue IR kinase activity, as well as β subunit tyrosine phosphorylation, do not decrease in the fasting state or increase in re-fed animals, despite alterations in plasma insulin (Adamo et al., 1987; Dupont et al., 2008, 2012). Thus, for still unknown reasons, the regulation of the tyrosine phosphorylation of IR β subunit and kinase activity differs between species and tissues. As depicted in Figure 27.3 (steps highlighted in blue for chicken tissues), once activated, the IR tyrosine kinase phosphorylates several intracellular substrates on specific tyrosine residues, which represents the proximal and early events initiating and propagating the insulin signal through a cascade of reactions leading to the multiple actions of insulin. Phosphorylated IR substrates activate directly or indirectly various protein (serine–threonine) or lipid kinases, including phosphatidylinositol 3′-kinase (PI3K), protein kinase B (Akt), P70S6K, and mitogen-activated protein kinase (MAPK)–extracellular signal-regulated kinase (ERK)-1/2. Several of these postreceptor steps also regulate insulin cell sensitivity, enabling alterations of insulin sensitivity without changes in insulin receptor number or kinase activity.

27.5.2.1 Proximal IR Substrates

In mammals, at least 11 intracellular IR substrates have been identified (reviewed in Taniguchi et al., 2006; Siddle, 2012). These include the family of IRS (insulin receptor substrate) proteins (IRS-1–6) and Shc (Src homology collagen) protein. Four different IRS proteins (IRS-1–4) have been reported in various mammals, and two additional IRS proteins have been detected in humans (IRS5/DOK4 and IRS6/DOK5). These last two additional IRS proteins are involved in insulin signaling but are not involved in PI3K activation (the major insulin-signaling step). Other IR substrates such as Gab1, Dok, APS, SH2B, Cbl, and Crk have been also described in mammalian tissues or cells (cited by Siddle, 2012).

The coding region of chicken IRS-1 gene has been cloned and sequenced (Taouis et al., 1996). The deduced chicken IRS-1 protein (cIRS-1) presents high sequence identity with its human, rat, and mouse homologs. cIRS-1 is at least present in the liver, muscle, and adipose tissue and interacts with the insulin receptor (Dupont et al., 1998 in Dupont et al., 2009, 2012). Interestingly or surprisingly enough, the tyrosine phosphorylation of cIRS-1 and PI3K activity (as discussed further in this chapter) is accordingly dependent upon nutritional conditions or insulin status in the liver but not in muscle or adipose tissue (Dupont et al., 1998 in Dupont et al., 2009, 2008, 2012), suggesting a tissue-specific regulation and a relative insulin refractoriness in chicken muscle and adipose tissue. Coding sequences have recently been described for IRS-2, IRS-4, Crk, Cbl, and APS chicken homologs (Ensemble release 71, April 2013, at http://www.ensembl.org/Gallus_gallus/index.html); they are located on chromosomes 1, 4, 19, 1, and 19, respectively. However, the presence of these substrates as proteins and their insulin sensitivity remain to be established in chicken tissues. Cbl and Crk, which in mammals mediate insulin signals and are associated with lipid rafts, are upregulated, at the messenger level, in chicken adipose tissue by fasting (Ji et al., 2012). In mammals, this pathway stimulates glucose uptake, in addition to and independently of PI3K activation. Whether these potential substrates contribute to the apparent refractoriness of PI3K activity to insulin that is observed in chicken skeletal muscle and adipose tissue remain unknown. It should be noticed, however, that insulin stimulation of glucose transport in chicken adipose tissue, if any, is very poor (as discussed further in this chapter).

In a chicken hepatoma cell line (LMH cells), cIRS-1 repression substantially increases Shc expression (Taouis et al., 1998). Shc is phosphorylated on tyrosine residues in response to insulin and therefore serves as an additional IR substrate in the absence of IRS-1. Chicken liver, muscle, and adipose tissue express homologs of the three mammalian Shc isoforms (Dupont et al., 2008, 2012). Interestingly, tyrosine phosphorylation of Shc (52 kDa) is dependent on insulin status: it increases after re-feeding or insulin injection and is inhibited after insulin immuno-neutralization in chicken liver but also, surprisingly, in leg muscles, in contrast to IRS-1. Also surprisingly, neither insulin privation nor fasting alters Shc tyrosine phosphorylation in adipose tissue (Dupont et al., 2009, 2012). In chicken liver, Shc, mainly the 52 kDa isoform, interacts with IR, whereas the

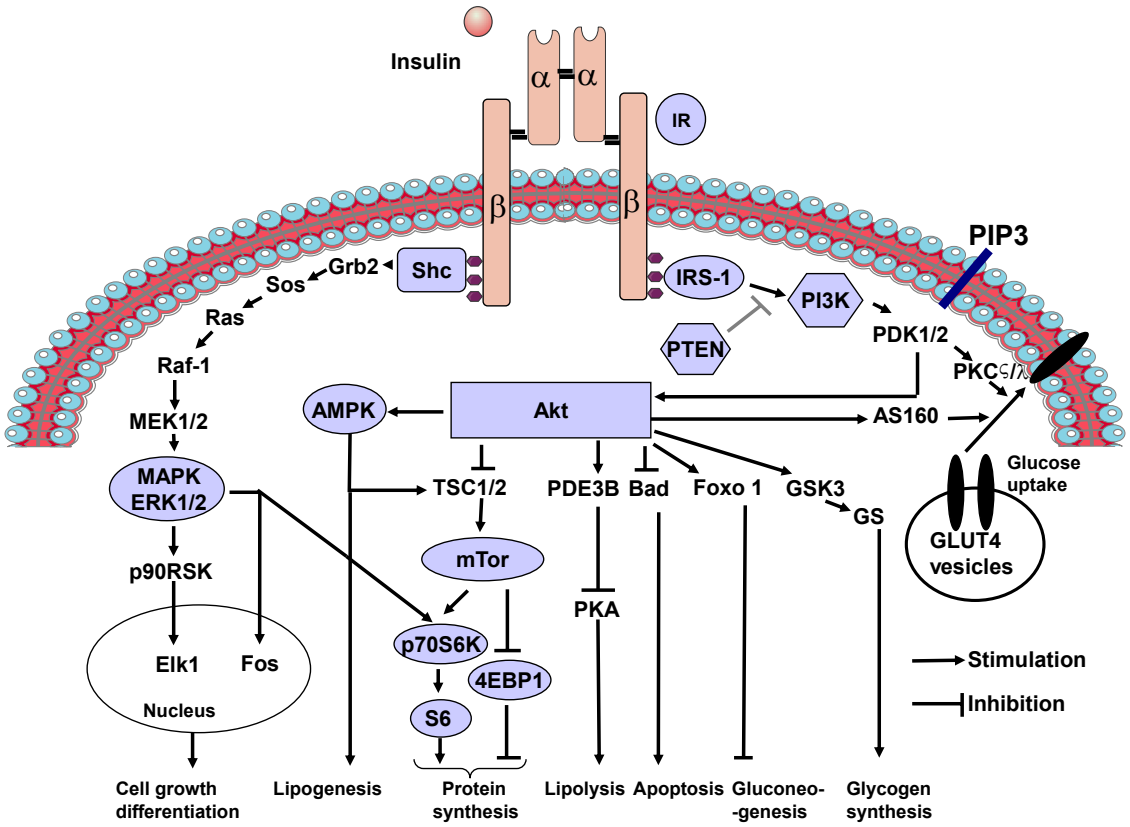

FIGURE 27.3 **Insulin receptor signaling. (Adapted from mammals; only steps highlighted in blue have been characterized in chicken tissues).**

46 kDa isoform associates with IRS-1 (Dupont et al., 1998 in Dupont et al., 2009). The 52 kDa Shc isoform also interacts with the p85 regulatory subunit of PI3K. Shc (52 kDa) is thus a key substrate for the insulin receptor in the chicken because, first, it is able to associate with PI3K and, second, in contrast to IRS-1, the extent of its tyrosine phosphorylation is dependent on insulin levels. Furthermore, in liver, Shc (52 kDa) phosphorylation is inhibited after insulin immuno-neutralization (Dupont et al., 2008). The possible existence of different subtypes of IR complexes signaling through IRS-1 or Shc has been investigated in the liver. The presence of a large complex involving IR, IRS-1, Shc (mainly the 52 kDa isoform), and the regulatory subunits of PI3K has been demonstrated; and a third complex, including IRS-1 and the 46 kDa Shc isoform, is also present in chicken liver (Dupont et al., 1998 in Dupont et al., 2009). No such interactions have been described in mammalian tissues, and the functions of these complexes in chicken liver and their presence in other chicken tissues remain to be established.

27.5.2.2 PI3K–Akt

PI3K has been characterized in chicken liver, leg muscle, and adipose tissue (Dupont et al., 1998 in Dupont et al., 2009, 2012) and in LMH cells (Taouis et al., 1998 in Dupont et al., 2009). Liver PI3K activity depends upon the nutritional state (prolonged fasting versus refeeding) in several experimental models (Dupont et al., 1998, 1999 in Dupont et al., 2009). Furthermore, PI3K activity increases in response to insulin injection and is inhibited following insulin immuno-neutralization (Dupont et al., 1998 in Dupont et al., 2009; see also Dupont et al., 2008). This is in agreement with the changes observed for early steps of the insulin-signaling cascade (tyrosine phosphorylation of IR β subunit, IRS-1, and Shc). Conversely, in muscle, the PI3K activity and, as previously mentioned, tyrosine phosphorylation of IR and IRS-1 are totally unresponsive to insulin levels in experimental models that alter insulin sensitivity, such as long-term corticosterone treatment and genetically selected fat and lean lines of chickens (Dupont et al., 1999 in Dupont et al., 2009). As mentioned in this chapter, only the phosphorylation of the 52 kDa Shc isoform is reduced in muscle by fasting and increased by re-feeding. Comparison of the responses to exogenous insulin in chickens and rats suggests that this phenomenon is specific to chicken. Furthermore, PI3K activity in leg muscle is about 30 times greater in the chicken than in the rat (Dupont et al., 2004). This "constitutive" hyperactivity of PI3K in chicken muscle may overstimulate the feedback inhibitory pathway described in mammals (as discussed in this chapter), thereby desensitizing chicken muscle to insulin. The p85 regulatory

subunit of PI3K itself exerts strong inhibitory control of IRS signaling in mammals (Taniguchi et al., 2006). However, lipid phosphatases such as PTEN (**p**hosphatase and **ten**sin homolog deleted on chromosome 10) may also contribute to this relative insulin insensitivity of the early steps of insulin signaling in chicken muscle. We have detected PTEN in chicken tissues, including muscle (Vaudin et al., 2006); however, the role of PTEN in the control of insulin signaling in chicken tissues remains to be determined. In adipose tissue, insulin signaling is even more peculiar; insulin privation did not alter early steps and PI3K activity, but also other downstream elements such Akt (see next paragraph; Dupont et al., 2012).

Akt has been detected in several chicken tissues including liver, muscle (Bigot et al., 2003; Dupont et al., 2008), adipose tissue, and granulosa cells (Dupont et al., 2012; Tosca et al., 2006). The phosphorylation of Akt on Ser 473 is increased following feeding of posthatched chicks (Bigot et al., 2003); this is prevented when feeding is delayed (48 h), then rapidly restored following food intake. In fed chickens, insulin immuno-neutralization significantly decreases Akt phosphorylation in both liver and muscle, but not in adipose tissue (Dupont et al., 2008, 2012). Thus, insulin is presumably involved in Akt activation in chicken muscle, despite the fact that chickens exhibit particular features in the early steps of the insulin-signaling cascade (IR, IRS-1, and PI3K). This issue remains unresolved. Potential mechanisms involved in the atypical feature found for insulin signaling in chicken muscle and adipose tissue have been discussed in Dupont et al. (2008, 2012).

27.5.2.3 P70S6K

p70S6 kinase, a further downstream step, has been characterized in a quail muscle (QM7) cell line and in chicken skeletal muscle (Tesseraud et al., 2003, http://www.sciencedirect.com/science/article/pii/S001664800800378X; Duchêne et al., 2008 in Dupont et al., 2009). p70S6K activity increases significantly in both pectoralis and gastrocnemius muscles after re-feeding for 30 min following 16 h starvation, and also in fasting chickens after a single insulin injection (Bigot et al., 2003). Similarly, p70S6K activity in the muscle of neonatal chicks is correlated with the plasma insulin concentration, strongly suggesting an insulin-dependent p70S6K activation (Bigot et al., 2003). In the liver, stimulation of phosphorylation of P70S6K1 and activation of S6K (using specific artificial substrate) was not detectable (Dupont et al., 2008), although insulin stimulation of phosphorylation of S6 ribosomal protein was observed in the same conditions (Duchene et al., 2008b). Furthermore, p70S6K phosphorylation decreases in leg muscles but not in adipose tissue in response to insulin immuno-neutralization (Dupont et al., 2008, 2012). These findings and those for Akt are again surprising in view of the relative insulin refractoriness of chicken muscle to exogenous insulin (Dupont et al., 2004). However, p70S6K has been found to be involved in another feedback loop, which attenuates the ability of insulin to activate PI3K. Indeed, there is evidence in mammals that p70S6K inhibits insulin signaling by increasing the serine–threonine phosphorylation of IRS-1. In chicken muscle, re-feeding and insulin injection increase the phosphorylation of both p70S6K on key residues (T389, T229, and T421/S424) and its downstream target, the ribosomal protein S6 (downstream insulin-signaling steps). However, in these conditions, the phosphorylation of IRS1 on serine 632 and serine 635 residues is also induced (Duchene et al., 2008b). In mammals, the phosphorylation of these sites inhibits the insulin signal. Thus, the AKT/p70S6K may inhibit IRS1 tyrosine phosphorylation in chicken muscle.

27.5.2.4 MAPK–ERK1/2 Pathway

MAPK–ERK has been identified in various chicken tissues (Duchene et al., 2008a). In contrast to mammals, ERK1 is not present in bird tissues; ERK2 is the only phosphorylated isoform detected (Duchene et al., 2008a). It is activated in chicken myoblasts and LMH cells *in vitro* by insulin (Duchene et al., 2008a). U0126, an inhibitor of the MAPK–ERK pathway, completely abolishes insulin-induced S6K1 phosphorylation and activity in chicken myoblasts *in vitro*, implicating MAPK–ERK2 in the control of S6K1 by insulin in avian cells (Duchene et al., 2008a). MAPK–ERK2 phosphorylation in chicken liver muscle and adipose tissue *in vivo* is strongly reduced by insulin immuno-neutralization (Dupont et al., 2012, 2008). However, the role of MAPK–ERK2 in insulin action *in vivo* in chicken has not been investigated. This signaling could be crucial to chicken growth, and this pathway may participate in the insulin-dependent regulation of p70S6K, because Shc, which is upstream, seems to be a key IR substrate in chicken muscle.

From the elements of insulin signaling thus far studied in chickens, insulin signaling appears to work in chicken liver as expected from the knowledge gained from mammals. In contrast, in muscle and adipose tissue, the insulin cascade appears refractory, suggesting the presence of inhibitory counterregulatory mechanisms in these tissues.

27.6 GENERAL EFFECTS OF GLUCAGON AND INSULIN

27.6.1 Insulin and Embryonic or Posthatch Development

The insulin gene is expressed early during embryonic development in extra-pancreatic tissues prior to development of the pancreas, showing specific regulations (de la Rosa and de Pablo, 2011). Insulin accelerates the growth of embryos

explanted at Hamburger Hamilton stage 4, without increasing mitoses; some specific developmental genes are upregulated (Patwardhan et al., 2004). A fine tuning of insulin gene expression is required to sustain adequate morphogenesis. In chicken neurulating embryos and chicken embryo retina, proinsulin is expressed but not cleaved to insulin. Whereas this precursor is considered to exert marginal (if any) biological activity in peripheral tissues, it exerts anti-apoptotic effects in those tissues at this developmental stage, probably through a hybrid insulin–IGF receptor (in de la Rosa and de Pablo, 2011). Furthermore, two transcription-induced chimerisms have been identified with the adjacent tyrosine hydroxylase gene (*TH*-insulin; in de la Rosa and de Pablo, 2011). (In humans, a similar mechanism has been described between the insulin gene and *IGF2*, the other adjacent gene.) The insulin gene is also expressed in the neural tube and somites of chicken embryos. The addition of insulin (or IGFs) to other specific factors in the incubation medium cocktail stimulates somite cell proliferation and myogenesis (Pirskanen et al., 2000). This effect is blocked by an insulin antibody and insulin receptor antibody, showing that insulin acts as a myogenic signal early in embryogenesis. Insulin also supports *in vitro* multiplication of 1 day old broiler muscle satellite cells and delays their differentiation (Sato et al., 2012). Surprisingly, an opposite effect is observed between insulin and IGF1 for MyoD and myogenin messengers. Insulin or tolbutamide administration to day-old broiler chicken increases Pax7 messenger (a striated cell marker) in breast muscle at 3 days of age and their body weight at 50 days without changing their body composition (Sato et al., 2012). These interesting effects deserve further characterization. In satellite cell–derived myotubes, insulin (at high doses, though, compared with IGF1) stimulates glucose (as discussed in this chapter) and amino acid transport and protein synthesis and inhibits proteolysis (Duclos et al., 1993a,b).

27.6.2 Insulin–Glucagon and Food Intake

Pioneer studies suggested that insulin contributes to the regulation of food intake (through inhibitory or stimulatory mechanisms; in Simon, 1989). Intracerebroventricular injection of insulin (through the melanocortin system) or glucagon inhibits food intake in young leghorn chickens (Honda et al., 2007; Shiraishi et al., 2011b and quoted references). Surprisingly, insulin is inefficient in young broiler chickens in fasted or fed conditions (Shiraishi et al., 2011b and quoted references), suggesting a difference in their set point or sensitivity; in broiler chickens, plasma insulin levels are higher, but they appear to decrease hypothalamic IR mRNA expression (Shiraishi et al., 2011b). Insulin immuno-neutralization in fed growing chickens decreased food intake, most likely by inducing very high plasma glucose levels (Dupont et al., 2008).

27.6.3 Insulin and the Endocrine System

Insulin interacts with glucagon (see Section 27.1) and with other endocrine systems. As early as 1 h after insulin immuno-neutralization (Dupont et al., 2008), plasma T_3 levels decreased (no reliable measurements were obtained for T_4). After 5 h of insulin deprivation, liver D2- and D3-deiodinase messengers decreased or increased, respectively. Thus, insulin is another partner involved in bird liver T_4 metabolism (Darras et al., 2006 in Dupont et al., 2008). The IGF system also appears partly insulin dependent. Liver *IGFBP1* messenger (microarray and qRTPCR measurements) and plasma IGFBP1 protein levels increased after insulin immuno-neutralization (plasma IGF1 was not measured). Microarrays also revealed that liver *IGFBP2* and muscle *IGF1R* messengers increased or decreased, respectively (similar impairments are found in diabetic patients; Paalsgard et al., 2009 in Simon et al., 2012). In another study (Nagao et al., 2001), 2 day fasting decreased plasma IGF1 and increased *IGFBP2* messenger in the liver and gizzard of white leghorn chickens (but not in brain or kidney); exogenous insulin further decreased plasma IGF1 levels and largely inhibited liver and gizzard *IGFBP2* messenger (6 h re-feeding also inhibited liver and gizzard *IGFBP2* messenger but accordingly increased plasma IGF1 levels).

27.6.4 Insulin and Glucose Metabolism

The severe and rapid hyperglycemia induced by insulin deprivation in fed chickens certainly depends upon multiple changes in glucose metabolism in several tissues. In liver, where glucose transport is not insulin dependent, glucose utilization was probably greatly depressed as suggested by the drop in liver GK messenger and protein contents (see the earlier discussion about the existence and the regulation of liver GK activity). In mammals, other insulin-dependent mechanisms are inhibition of liver gluconeogenesis and glucose production. Gluconeogenesis is considered to escape insulin control in chicken liver (Section 27.1). In our transcriptome study, 27 messengers from the glycolysis–gluconeogenesis or pyruvate metabolism pathways were differentially expressed in liver following insulin deprivation, including *G6PC2* (glucose 6-phosphatase catalytic, 2) messenger, which increased, suggesting that liver glucose production may also be insulin inhibitable in chicken liver. Unfortunately, this was not assessed in euglycemic–hyperinsulinemic clamp experiments performed on chickens (Chou and Scanes, 1988; Hamano, 2006). Indirect evidence (prolonged fasting and corticosterone experiments) suggests that insulin also inhibits kidney gluconeogenesis by inhibiting cytosolic phosphoenolpyruvate carboxykinase activity (Bisbis et al., 1994a,b and quoted references).

Insulin greatly stimulates glucose uptake in muscles and adipose tissues of mammals by recruiting insulin-sensitive

Glut-4 transporters at the cell surface from an intracellular pool (Figure 27.3). So far, no Glut-4 glucose transporter has been identified in chickens or house sparrows (*Passer domesticus*) as protein or messenger. This may be the consequence of the lack of cross-reactivity of antibodies or the absence of Glut4 in chicken or birds since no Glut-4 homolog sequence is found in the chicken Ensembl database (an ortholog gene to the human Glut-4 (*SLC2A4*) gene is, however, described in the anole lizard and several fish species). Functional and immunoreactive Glut-4 transporters have been observed in duck leg muscle (Thomas-Delloye et al., 1999 in Dupont et al., 2009). Only chicken Glut-1, -2, -3, and -8 have been characterized as messengers and/or proteins (Carver et al., 2001; Seki et al., 2003; Kono et al., 2005; Swaezea and Braun, 2006 in Zhao et al., 2012; Humphrey et al., 2004). It has been hypothesized that Glut-8 (encoded by the *SLC2A8* gene) may act in chickens as Glut-4 does in mammals (Kono et al., 2005; Zhao et al., 2012). *In vivo*, exogenous insulin increases glucose uptake moderately in some muscles but not in adipose tissue (Tokushima et al., 2005). (Surprisingly, insulin stimulated or inhibited ^{3}H-2DG uptake in liver and brain, respectively.) Thus, an insulin-sensitive glucose transport is present in chicken; however, it requires extensive characterization.

Currently, an increasing number of studies report quantitative trait loci (QTLs) as controlling growth and/or body composition and some physiological parameters in various avian species. In several cases, these QTL regions harbor glucose- and/or insulin-dependent genes. This aspect cannot be reviewed here, but some references can be found in Nadaf et al. (2009).

27.6.5 Insulin–Glucagon and Lipid Metabolism

Several transcription factors controlling mRNA expression of lipogenic enzymes also appear insulin-sensitive in chicken liver *in vivo* (SREBP1, PPAR-gamma and THRSP alpha (spot-14), and FASN messengers; Dupont et al., 2008). Carbohydrate-responsive element-binding protein (ChREBP, encoded by the *MLXIPL* gene) is another transcriptional factor involved in glucose metabolism, glucotoxicity, and/or lipogenesis in liver, adipose tissue, and pancreas in mammals (Leclerc et al., 2012). ChREBP is also activated in parallel with lipogenesis in chicken liver (Proszkowiec-Weglarz et al., 2009). In our insulin neutralization experiment, several other enzyme messengers involved in lipogenesis or fatty acid oxidation decreased or increased, respectively, following insulin deprivation (Simon et al., 2012), extending the role of insulin in chicken liver lipid metabolism. In abdominal fat tissue, 5 h of fasting altered the level of 2016 messengers. Plasma glucagon increase certainly accounts for a major part of these changes (Ji et al., 2012). Insulin neutralization in fed chickens altered the expression of only 92 genes, 72 of which were also differentially expressed by 5 h of fasting. All genes that were affected by both treatments changed in the same direction (up- or downregulated in both groups). Most messengers that were specifically altered by insulin neutralization (but not by fasting) were either poorly or not described; however, glucagon precursor (class B-preproglucagon) and glucagon receptor precursor were in this category and were up- and downregulated, respectively. A local insulin-dependent paracrine glucagon regulation, which needs full characterization, is suggested in chicken adipose tissue. In general, a contribution of insulin to adipose tissue development and metabolism (in addition to its control of liver lipogenesis) can be expected, despite the very atypical feature exhibited by chicken adipocytes.

Differentiation of chicken adipocyte precursors (obtained from the stromal vascular fraction of fat tissue) or transdifferentiation of fibroblasts, epithelial oviduct, or primordial germ cells into adipocytes has been successfully performed using media rather similar to those used for mammalian adipocyte differentiation (Khuong and Jeong, 2011; Li et al., 2010; Liu et al., 2010; Ramsay and Rosebrough, 2003). Insulin is required but unable to support differentiation alone; IGF1 or T3 are unable to replace insulin (Ramsay and Rosebrough, 2003). Chicken serum and dexamethasone can be deleted, provided oleic acid is introduced into the differentiation medium. Unless oleic acid exerts a specific effect, this supports the conclusion that to overcome their intrinsically low lipogenic activity and achieve a full adipocyte phenotype, chicken adipocyte precursors need exogenous fatty acids (Liu et al., 2009; Matsubara et al., 2005, 2008). Several transcription factors are involved in adipogenesis: C/EBPalpha, PPARgamma, and SREBP1 in chicken (Liu et al., 2009, 2010; Sato et al., 2009; Wang et al., 2008b) and duck (Xiong et al., 2010).

In adipocytes of mammals, lipolysis is under the control of several lipases, including the adipose triglyceride lipase, encoded by the *PNPLA2* gene, and the hormone-sensitive lipase (HSL), encoded by the *LIPE* gene (Zechner et al., 2009). HSL (*LIPE*) disruption in normal or *ob*/*ob* mice leads to several changes in the endocrine pancreas and adipocytes that resemble the chicken feature (see Osuga et al., 2000; Wang et al., 2001; Haemmerle et al., 2002 quoted in Zechner et al., 2009; Mulder et al., 2003; Harada et al., 2003; Sekia et al., 2009). Although not identified in chicken, the *LIPE* gene is present in the anole lizard and several fish. If the *LIPE* gene is really missing in chicken, some of the chicken physiological peculiarities may be due to this.

27.6.6 Insulin and Protein Metabolism

In addition to its general effects on protein metabolism (see Section 27.1; Tesseraud et al., 2007a), insulin acts in the ubiquitin–proteasome proteolytic pathway. It inhibits the

expression of atrogin-1 messenger in quail muscle (QT6) fibroblasts (Tesseraud et al., 2007b) and *in vivo* in chicken muscle (Dupont et al., 2008). Following insulin immunoneutralization, several messengers coding for enzymes of the oxidative pathway decreased. This pathway is also altered in muscle of human diabetics (in Simon et al., 2012).

27.6.7 Insulin and Gene Expression

In mammals, insulin stimulates the translation of preexisting mRNA and coordinates (stimulates or inhibits) the expression of multiple genes in various tissues. Multiple insulin responsive elements (IRE) have been identified on target genes (other IREs are likely to be identified; Mounier and Posner, 2006). To our knowledge, the characterization and the functionality of IREs, as such, are still missing in chickens. The fact that several transcription factors or enzymes involved in lipid metabolism are also insulin sensitive in chickens (as discussed in this chapter) suggests that major IREs have been conserved or have co-evolved in chickens. A total of 1573 and 1225 signals were altered by insulin deprivation in liver and muscle, respectively, including several transcription factors. Several messengers have been associated with energy expenditure, insulin resistance, metabolism sensing, obesity, and/or diabetes in mammals (see Table 3 in Simon et al., 2012). The chicken elongation factor-2 (EF-2) gene, a major factor in protein synthesis in mammals, is also under the control of insulin and 8-bromo-cAMP or phorbol ester (Lim and Kim, 2007). Insulin deprivation in fed (but not fasting) chickens decreased *EGR1* (early growth response 1) messenger in liver and muscle but not in adipose tissue. However, *TOE1* (target of egr 1, member 1) was also specifically decreased by insulin deprivation and not by fasting in adipose tissue (Ji et al., 2012). *EGR1* target genes are largely unknown, particularly in the field of metabolism.

Finally, microRNAs (miRNAs) represent another mechanism in the regulation of gene translation. At least miR-196 and miR-200b showed significant and opposite changes in response to insulin neutralization (an increase in liver versus a decrease in muscle; Bouhallier, Rouault, and Simon, unpublished data). Gene targets of miR-196 and miR-200b need to be identified; so far, miR-196 has been involved in chicken embryo development (McGlinn et al., 2009) and miR-200b in chicken liver lipid metabolism (Hu et al., 2012).

27.7 EXPERIMENTAL OR GENETICAL MODELS

Table 27.1 summarizes results about fasting plasma glucose–insulin relationships, glucose tolerance, insulin sensitivity, and fattening in various experimental or genetic chicken models. Most of these results have been discussed in previous publications (the effect of prolonged fasting has also been investigated, as discussed in this chapter). The table is shown to support some general considerations. It should be noted that in all these experiments, the feeding pattern of chickens has been consistently synchronized with light–dark cycles. In these conditions, as in mammals, the fasting plasma glucose level appears as an indicator or a central node, which reflects or integrates general metabolism. Although the primary mechanism is unknown, changes in glucose–insulin balance and/or insulin sensitivity are associated with changes in fattening. In contrast to obese mammals, fat chickens have low plasma glucose and do not develop insulin resistance. Conversely, chickens from a low-glucose line are fatter than their counterparts. Only the corticosterone model behaves like obese mammals (showing higher plasma glucose and impaired insulin sensitivity). As discussed here, changes in insulin signaling are present in the models thus far investigated. Changes in glucose tolerance are not consistently associated with changes in body composition: in a commercial broiler cross, chickens exhibiting fast or slow plasma glucose regulation at 2 and 4 weeks of age following an oral glucose load did exhibit fast or slow glucose disposal at 8 weeks of age but did not differ in fasting or glucose-induced plasma insulin levels and body composition, which remains unexplained (Simon, 1980). One can hypothesize that, as in FL chickens, enhanced glucose-induced insulin levels are required to increase fattening without necessarily leading to insulin resistance. *In vitro*, perfused pancreas from fat chickens released less insulin during the first phase in response to glucose, or to arginine or acetylcholine in the presence of glucose, than pancreas from lean chickens, which remains unexplained in Rideau (1988). In general, chickens appear to be controlled within a much narrower range for their body composition than mammals. Whether the endocrine pancreas of birds plays a part in this remains an open question and a challenge for the future.

27.8 SUMMARY AND CONCLUSION

Previous reviews, summarized in the Section 27.1, revealed several features of the chicken endocrine pancreatic physiology. The present chapter is focused on glucagon and insulin; it highlights new knowledge about chicken embryo development, glucagon (and glucagon-related peptides), bird insulins, glucagon and insulin release, glucagon and insulin receptors, and major general effects of these hormones. Many results highlighted in this review point out further chicken peculiarities at the level of endocrine pancreatic physiology. Chickens (and birds in general) developed several species specificities during evolution. The most original ones concern the refractoriness of glucose-induced insulin release and the insulin signaling in muscle and adipose tissue. One unidentified inefficient metabolic step makes

glucose a poor insulinotropic nutrient in chickens. Although several elements of insulin signaling pathways have not been investigated yet, several steps of the IR cascade appear insensitive in muscle; the feature is even worse in adipose tissue. In contrast, IR signaling appears "normal" in chicken liver. Revealing mechanisms or steps accounting for these chicken peculiarities may provide important information, including for human diabetes pathology. Glucagon physiology appears more complex in chicken than in mammals: the glucagon gene encodes several transcripts, it is expressed in adipose tissue, two types of glucagon receptors are present, and an insulin-dependent paracrine glucagon regulation is suggested in adipose tissue. In the fed status, insulin is coordinating the endocrine balance to permit the development or the maintenance of an active anabolism. From a practical point of view, finding the way to favor pleiotropic anabolic actions of insulin in muscle and minimize liver lipogenic and adipogenic actions of insulin would be highly profitable for human nutrition and poultry production. This chapter also pointed out many shortcomings or new areas to explore. In short, the secretory "machinery" of A- and B-islets needs to be fully characterized. Chicken is the unique model to provide such possibilities. In addition, nothing is known about the physiological actions of GLP-2, oxyntomodulin, miniglucagon, glicentin, or GRPP (gastrin-releasing pancreatic peptide) in chicken. Full characterization of IR signaling and the subsequent steps up to the control of gene expression certainly also offer large areas for future research. Finally, chicken glucose transporters (and their presence and functionality) need to be characterized. Although chicken is inconvenient because it requires the development of technical tools for each area to explore, it remains an almost unexplored experimental animal model of large interest for comparative endocrinology and physiology.

Chapter 28

Reproduction in the Female

Alan L. Johnson
Center for Reproductive Biology and Health, The Pennsylvania State University, University Park, PA, USA

28.1 INTRODUCTION

The avian lineage evolved from ancestral, oviparous amniotes that include reptiles and the archosaurs (theropod dinosaurs and crocodilians). Oviparity represents the ancestral form of reproduction in all archosaurs, and it is the only form of reproduction utilized by birds. Whereas all modern crocodilians have two functional ovaries, only the left ovary is functional in the majority of avian species (Figure 28.1). Significantly, avian fossils from two species of an extinct lineage (enantiornithine birds of the Early Cretaceous period) have revealed that these ancestors possessed a single, functional left ovary (Zheng et al., 2013). This is consistent with the hypothesis that the loss of one ovary to reduce body weight occurred early in avian evolution, perhaps even preceding the capacity for true flight. Interestingly, viviparity has evolved nearly 100 times within the reptilian lineage that includes lizards and snakes; thus, it is unclear why there is no incidence of viviparity within the avian lineage. One line of reasoning is that because extant birds are endothermic and can precisely control the process of egg incubation and embryo development, there may be no thermoregulatory advantage to viviparity in birds.

28.2 DEVELOPMENT AND FUNCTION OF THE FEMALE REPRODUCTIVE SYSTEM

The female gonads develop from a thickening of the ventromedial surface of the embryonic mesonephros and are initially composed of an outer epithelial cortex and an underlying medulla. Cortical and medullary cords are formed and colonized by the primordial germ cells (PGCs) that originate within the epiblast, move to the germinal crescent, then migrate to the ovary via the vascular system. By day 2.5 of incubation, PGCs, initially numbering about 450, begin to exit the vasculature at the germinal ridge by extravasation in response to chemotactic signals, including stromal cell-derived factor 1 (SDF1) and its receptor, C–X–C chemokine receptor type 4 (CXCR4) (Stebler et al., 2004). By day 4 of incubation, the distribution of PGCs within the left ovary of the chicken exceeds that in the right ovary, and this increase may be facilitated by factors that inhibit meiosis and promote germ cell proliferation; these include stem cell factor, ciliary neurotrophic factor, fibroblast growth factor, and follicle-stimulating hormone (FSH) (Gonzalez-Moran, 2007; He et al. 2012, 2013; Karagenç and Petitte, 2000), plus several microRNAs (miRNAs, which are endogenous noncoding small regulatory RNAs) (Lee et al., 2011). Proliferating PGCs form aggregates in which cells are joined via intercellular bridges and their cell cycles become synchronized. The isolation and culture of avian PGCs *in vitro* have been reported (van de Lavoir et al., 2006), and such methods may provide an opportunity to genetically modify avian PGCs and to produce transgenic birds.

Genetic sex in all birds is determined at fertilization, with the female being the heterogametic sex (ZW) and the male homogametic (ZZ). The evolutionary origin of genetic sex determination in Aves is obscure since all crocodilians

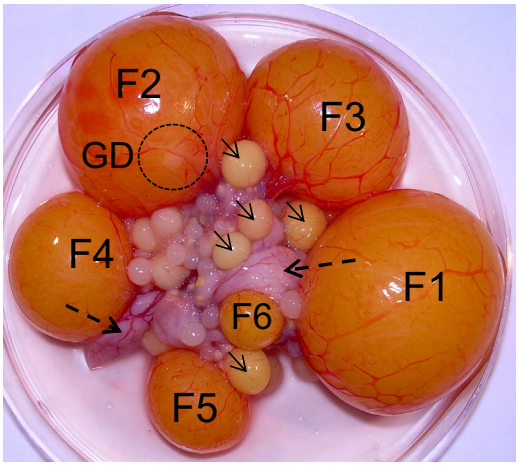

FIGURE 28.1 **Functional left ovary of the laying hen.** F1–F5 represent hierarchal, preovulatory follicles; and F6 represents the preovulatory follicle most recently selected from the cohort of prehierarchal follicles (arrow heads). Dashed arrows, postovulatory follicles. Dotted line surrounds the opaque germinal disc (GD) region. *Photograph by Dr O. Ocón-Grove.*

display temperature-dependent sex determination. While the double sex and mab-3 related transcription factor 1 (*DMRT1*) gene represents a likely candidate for male sex determination (much like the sex-determining region Y gene in mammals), the mechanisms by which the DMRT1 protein directs sex determination remain unclear. *In ovo* knockdown of *DMRT1* mRNA during early development using RNA interference selectively reduces DMRT1 protein expression and results in the feminization of genetically male gonads (Smith et al., 2009). By day 10 of incubation, anatomical asymmetry between the left and right ovary becomes evident, and the degeneration of the right ovary is initiated via programmed cell death (apoptosis). In genetic females, R-spondin 1 (*RSPO1*) gene expression (one of the earliest known genes controlling the female genetic developmental program in mammals) becomes elevated within the left ovary at the time of differentiation. This coincides with female-specific activation of the Forkhead box L2 (*FOXL2*) gene, increased expression of aromatase, and estrogen synthesis (Hudson et al., 2005). R-spondin 1, the protein product of *RSPO1*, activates the canonical Wnt/β-β-catenin signaling pathway required for female somatic cell differentiation and germ cell commitment into meiosis. In the chicken, the R-spondin 1 protein is localized to the outer cortical zone of the developing ovary, the site of primordial follicle formation and germ cell differentiation. Finally, there is evidence for a number of miRNAs that are differentially expressed in the gonad as early as day 3 of incubation. Several of these miRNAs have been implicated in gonadal sexual differentiation (Cutting et al., 2012).

The initial development of the left ovary is directed via the homeobox gene, *PITX2*, which promotes somatic development of the gonad cortex and supports the proliferation and differentiation of PGCs (Guioli and Lovell-Badge, 2007; Rodríguez-León et al., 2008). With increased expression of R-spondin 1, the left gonad develops a differentiated surface epithelium where eventual follicle development occurs (Smith et al., 2008). Expression of mRNAs encoding luteinizing hormone (LH) and FSH receptors occurs by day 4 of incubation (before sexual differentiation), and FSH treatment on day 14 stimulates proliferation of the ovarian surface epithelium, oogonia within the cortex, and somatic cells within the medullary cords (Akazome et al., 2002; Méndez et al., 2003). Germ cell meiosis in the domestic chicken embryo is initiated by incubation day 15.5 by the actions of retinoic acid and LH (Smith et al., 2008; He et al., 2013). This sequence of events is not unlike that in mice, where PGC migration occurs from about embryonic day 8.5 to 12.5, and meiosis is initiated by embryonic day 13.5 (Saitou et al., 2012).

In the domestic hen, the appearance of a meiotic nucleus and Balbiani body (a concentration of cell organelles shifted to one pole of the cell) is characteristic of germ cells located in the left ovarian cortex, but neither characteristic is found in the left medulla or the right ovary. Aromatase activity and estrogen synthesis within medullary tissue play key roles in the differentiation of the ovary, and differences between left versus right ovarian development depend upon the selective expression of the estrogen receptor within developing cortical tissue of the left ovary (Smith and Sinclair, 2004; Ishimaru et al., 2008). Unlike mammals, the differentiation of avian embryonic gonads is not as strictly regulated by genetic sex since the administration of an estrogen synthesis inhibitor prior to gonad differentiation will induce testis development in a genetic female (reviewed in Ayers et al., 2013).

The female embryo develops undifferentiated Müllerian (paramesonephric) ducts early in embryonic development. Both embryonic ovaries express anti-Müllerian hormone (AMH) and produce estrogen. AMH expression is regulated via the transcription factor, steroidogenic factor-1 (SF1), and can be initiated, *in vitro*, by several factors (including vitamin D and bone morphogenetic proteins-4 and -6 (BMP4 and BMP6, respectively)) (Johnson et al., 2008; Ocón-Grove et al., 2012). The right Müllerian duct eventually regresses (beginning by day 8 in the duck) in response to AMH. By contrast, estrogen derived from the left ovary protects the left Müllerian duct from the apoptosis-inducing effects of AMH, thus enabling development of the left oviduct (Takada et al., 2006).

28.2.1 Late-Embryonic and Posthatch Ovary

While the reproductive system of virtually all females within the avian order Galliformes consists of a single left ovary and its oviduct, on rare occasions a functional right ovary and oviduct may be present. By comparison, among the Falconiformes and in the brown kiwi (a ratite; order Struthioniformes), both left and right gonads and associated oviducts may be functional, although the ovaries often remain asymmetrical in size. In sparrows (Passeriformes) and pigeons (Columbiformes), about 5% of specimens are reported to have two developed ovaries, but again, some size asymmetry and difference in ovulation frequency often exist between the two ovaries (Kinsky, 1971).

The left ovary develops within the abdominal region ventral to the caudal vena cava and adjacent to the left kidney and adrenal gland. The developing ovary is eventually suspended from the body wall primarily by the mesovarium. The hilus serves as a conduit for vasculature, nervous innervation, and smooth muscle that integrates ovarian function with environmental, endocrine, and central nervous system input (reviewed in Gilbert, 1979). The number of oocytes in the chick embryo increases from approximately 28,000 on the ninth day of development to an approximate 680,000 on the 17th day, and subsequently decreases to some 480,000 by the time of hatching, when oogenesis is believed to terminate (Hughes, 1963). This is in contrast to essentially

all amphibians, many fishes, and some reptiles where oogenesis continues within the adult female. The ovary of immature birds consists of a mass of small ova, of which as many as 2000 are visible to the naked eye. At the time of hatch, avian oocytes are mostly in meiotic prophase I. Only a relatively few of these (250–500) will reach maturity and ovulate within the life span of most domesticated species, and considerably fewer mature in wild species.

The organization of oocytes into primordial follicles occurs around the time of hatch in most birds. Following hatch and prior to sexual maturation, the left ovary remains small and undeveloped. PGCs become surrounded by a single epithelial granulosa cell layer, and these primordial follicles are loosely arranged in clusters (or nests). The oogonia are mostly in the diplotene stage of meiotic prophase I, and chromosomes display the typical lampbrush configuration from which a high rate of RNA synthesis occurs. An inner perivitelline membrane layer (homologous to the mammalian zona pellucida) is deposited between the granulosa cells and the oocyte cell membrane (Figure 28.2). Glycoproteins of the perivitelline membrane form a matrix that subsequently serves functions critical to the fertilization process, including the interaction of spermatozoa with the oocyte and inducing acrosomal exocytosis (Rodler et al., 2012).

Granulosa cells surrounding the perivitelline layer eventually form cytoplasmic projections that extend into this layer and into the oocyte. Initially, a single layer of theca cells surrounds the granulosa layer separated by the basal lamina (Gilbert, 1979). The basal lamina of the domestic hen follicle is approximately 1 µm thick and consists of a chondroitin sulfate–modified collagen and the glycoprotein, fibronectin, and other components deposited by both the granulosa and theca layers.

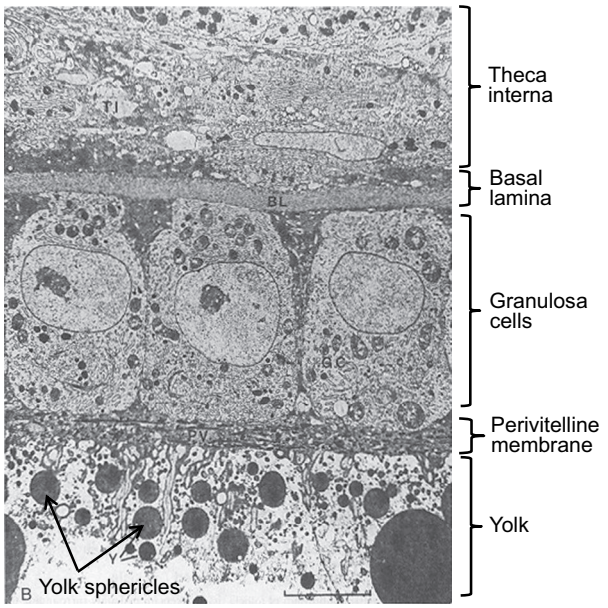

FIGURE 28.2 Layers of tissue from slow-growing follicles. Note that the granulosa layer is cuboidal in shape at this early stage of development, and that the outer theca layer (externa) is not shown. *From Perry and Gilbert (1979).*

28.2.2 Sexually Mature Ovary

The length of time required to reach sexual maturation depends upon the species, and it may be as short as several weeks after hatch (Japanese quail) to as long as 2 to 3 or more years (e.g., kiwis, penguins, and condors). Sexual maturation in the domestic hen will occur at about 5 months of age when hens are raised under a nonstimulatory photoperiod (less than 12 h of light per day), but it can be advanced significantly by photostimulation beginning at about 2 months of age. The functionally mature ovary of most birds is arranged with an obvious hierarchy of follicles (Figure 28.1). As in mammals, both sexual maturation and recrudescence of the gonads at the onset of seasonal breeding are initiated by changes within the neuroendocrine axis and involve, among other factors, thyroid hormones (Nakao et al., 2008) and gonadotropin-inhibitory hormone (GnIH) (see Chapter 30 on the hypothalamus). These and additional hormones and growth factors indirectly (e.g. 3,3′,5-triiodothyronine; T_3) or directly (gonadotropins) impact gene expression at the level of the ovary. Gene expression can also be modified by miRNAs acting at a posttranscriptional level. For instance, there is evidence that a large number of miRNAs are differentially expressed in the ovary from sexually immature versus mature chickens, and in developing ovarian follicles relative to the stage of maturation (Kang et al., 2013). The growth of follicles at puberty or with seasonal breeding is an energetically expensive process and increases resting metabolic rates by 27% in the great tit (*Parus major*; Nilsson and Råberg, 2001) and 22% in the European starling (*Sturnis vulgaris*; Vézina and Williams, 2002).

The activation and growth of primordial follicles to the primary follicle stage are associated with the formation of the theca interna layer (from mesenchymal cells). The developing theca interna layer is separated from the cuboidal-shaped granulosa layer by the basal lamina (Figure 28.2). Growth to the prehierarchal follicle stage (6–8 mm) entails the accumulation of lipoprotein-rich white yolk, plus the differentiation of the theca into interna and externa layers. Vasculature and nervous innervation reaches the follicle through the pedicle and radiates through the theca layer. Immediately following selection into the preovulatory hierarchy, preovulatory follicles begin to rapidly grow from approximately 9 mm in diameter to 40+ mm over the course of days (Figure 28.3). Granulosa cells from preovulatory follicles become squamous in shape to facilitate the uptake of large amounts of vitellogenin and very-low-density lipoprotein (VLDL), except within the germinal disc region. Ovulation of the largest preovulatory follicle eventually

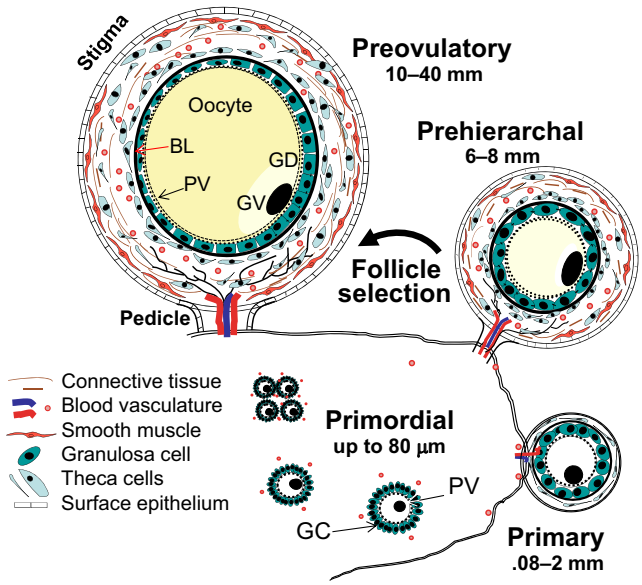

FIGURE 28.3 Follicles within the mature hen ovary. Primordial follicles consist of the germinal vesicle (GV) contained within a perivitelline membrane (PV) and surrounded by granulosa cells (GC). Primary follicles become further organized by a basal lamina (BL) separating the GC layer from a single layer of theca cells in primary follicles and eventually theca interna and externa layers in prehierarchal and preovulatory follicles. Increasing amounts of yellow yolk (vitellogenin and very-low-density lipoprotein) are accumulated beginning at follicle selection. BL, basal lamina; GD, germinal disc; GV, germinal vesicle; PV, perivitelline membrane. See the text for further details. *Adapted from Johnson and Woods (2007).*

occurs at the region of the comparatively avascular stigma region. The mature ovary is supported by a blood supply from the ovarian artery, which usually arises from the left renolumbar artery but may branch directly from the dorsal aorta (Hodges, 1965). Within the fully developed ovary, the percentage of blood flow is greatest to the five largest preovulatory follicles and significantly increases with increased follicle size and at the time of ovulation (Scanes et al., 1982). The ovarian artery divides into many branches and eventually leads to each follicle stalk (pedicle). All veins from the ovary unite into the two main anterior and posterior veins, which subsequently drain into the posterior vena cava.

Both adaptive and innate immune responses have been described within the domestic hen ovary, and these systems function to protect against colonization and infection by microbial pathogens, as well as to maintain normal functions of the ovary. Monocytes, macrophages, and activated B and T cells expressing major histocompatibility complex class II (MHC-II$^+$) molecules have been localized to the theca layer of healthy cortical follicles plus growing prehierarchal and preovulatory follicles, and more prominently in both theca and granulosa layers of postovulatory and atretic follicles. Cell-mediated immunity within ovarian stromal and theca tissues is mediated via T cells (CD4$^+$ and CD8$^+$ cells) and represents an effective measure against intracellular pathogens such as *Salmonella* (Barua et al., 2001; Barua and Yoshimura, 2004). Moreover, there is considerable evidence for a functional innate immune system consisting of β-defensins (small cationic antimicrobial peptides that exhibit a direct lytic action on microorganisms; Abdelsalam et al., 2012) and Toll-like receptors (pattern recognition receptors that activate cytokines, antimicrobial peptides, and immunocompetent cells; Woods et al., 2009). A total of 14 avian β-defensin genes (AvβD1–14) have been identified and these attack a wide range of microorganisms, including Gram-positive and Gram-negative bacteria, fungi, and yeast.

Innervation to the ovary is provided by both sympathetic (primarily adrenergic) and parasympathetic fibers (Gilbert, 1969; Dahl, 1970; Unsicker et al., 1983). This innervation consists of both extrinsic and intrinsic neural systems (Madekurozwa, 2008), and provides a number of neurochemicals (e.g., catecholamines, serotonin, and acetylcholine) and neuropeptides (e.g., neurotropins, vasoactive intestinal peptide (VIP), and galanin) to the ovary and its follicles. Such factors function in diverse roles as in the initial organization of primordial follicles in the embryonic and early posthatch ovary, the growth and differentiation of follicles in the adult ovary, the regulation of blood flow, and steroidogenesis.

As puberty approaches and the slow growth of follicles resumes, the theca layer of primary follicles differentiates into discrete theca interna and externa layers with distinct steroidogenic profiles. As the follicle grows, the theca layer becomes increasingly more vascularized except for the stigma (the point of rupture during ovulation), which contains fewer underlying small veins and arteries. The largest arteries from the follicle stalk are directed toward the fastest growing follicles, branch into arterioles, and pass through the theca to the basal lamina to form arterial capillaries. There are also an increasingly greater number of neurons present within the theca layer as the follicle progressively matures. While granulosa cells from early-developing follicles (<2 mm) are closely packed and cuboidal, they eventually form a single cell layer and become squamous in shape as the follicle grows (Gilbert, 1979).

The germinal vesicle is localized within the germinal disc region and includes the oocyte nucleus and the overlying granulosa layer (Figure 28.3). The disc appears as a white plaque due to a localized, restricted passage of yolk precursors. This region contains maternal RNA used for protein synthesis prior to the onset of the transcription from the zygotic genome. Additional extra-embryonic RNA is localized within the cytoplasmic layer directly under the perivitelline membrane, and is proposed to be required for oocyte development (Olszanska and Stepinska, 2008). The total amount of maternal RNA deposited in the avian oocyte is considerably greater than in mammals, but comparable to that in *Xenopus*. In preovulatory follicles, granulosa cells within the germinal disc region remain relatively

undifferentiated (steroidogenically inactive) and mitotically active, while the outer granulosa layer becomes steroidogenically active but mitotically inactive (Yao and Bahr, 2001). Oocytes remain arrested at the first meiotic prophase stage during follicle development, and, in the domestic hen, resume meiosis (undergo germinal vesicle breakdown) 4–6 h prior to ovulation. One microarray study identified no less than five genes differentially expressed within the germinal disc region that correlate with enhanced fertility; these genes may eventually be useful as markers of fertility in the domestic hen (Elis et al., 2009).

The ovary of the sexually mature chicken maintains numerous primordial follicles smaller than 1 mm diameter that remain embedded within the outer ovarian cortex. These follicles can exist in a quiescent state for months to years until activated (possibly by the removal from inhibitory AMH signaling) to begin an extended period of growth and differentiation. As follicles initiate development ("initial recruitment"), they project from the surface of the cortex and become suspended by a stalk (an extension of the ovarian cortex) through which blood vasculature and several nerve bundles reach each follicle. Typically, there are numerous slow-growing follicles measuring approximately 2–6 mm in diameter that contain small amounts of a protein-rich white yolk. The selection of a single follicle per day into the preovulatory hierarchy occurs from a cohort of 6–8 mm prehierarchal follicles (numbering approximately 8–12; Figure 28.1). The most recently selected follicle (9–12 mm) represents that which has initiated differentiation and rapid growth. In the domestic hen, there are typically four to six large, yolk-filled, preovulatory follicles (ranging in size from >12 to 45^{+} mm in diameter). This final growth phase prior to ovulation in domestic fowl, ducks, and pigeons generally lasts for 4–6 days (up to 25 days or more in the brown kiwi; Jensen and Durant, 2006). The number of preovulatory follicles can range from one or perhaps two for species laying a single egg (e.g., kiwi and emperor penguin) to eight or more in species that lay 12 to 18 eggs in a clutch (e.g., wild turkey and ring-neck pheasant). Importantly, the maintenance of both prehierarchal follicles in an undifferentiated state together with rapidly differentiating preovulatory follicles represents a fundamental distinction between the avian and mammalian reproductive strategies. Specifically, in eutherian mammals the selection of a dominant follicle or follicles in each estrous or menstrual cycle is rapidly followed by atresia in all growing but subdominant follicles. By contrast, the ability to produce a full clutch of eggs requires that a viable, prehierarchal cohort of follicles be maintained such that a single follicle can be selected for final growth and differentiation on a daily or near-daily basis.

Interestingly, the avian perivitelline layer does not prevent polyspermy. Accordingly, at insemination, more than one male pronuclei may be found in the egg cytoplasm, but only the one located in the center of the germinal disc forms the zygote nucleus. It is not yet known how a specific sperm is selected or at which stage between insemination and fertilization sperm selection takes place. Nevertheless, the remaining sperm degenerate and disappear, presumably due to the actions of DNases I and II (Stepinska and Bakst, 2006). Fusion of the male and female pronuclei (syngamy) initiates embryo development almost immediately, and a number of cell divisions occur by the time the ovum has become incorporated into the egg and the egg is laid.

28.2.3 Follicle Selection and Establishment of the Preovulatory Hierarchy

The process of follicular selection (also referred to as "cyclic recruitment") represents the rate-limiting stage for the development of mature oocytes. This process ultimately determines the reproductive capacity for vertebrate species whose strategy emphasizes a limited number of offspring combined with significant parental investment (as compared to most bony fish and amphibians). A fundamental question yet to be defined pertains to the mechanisms by which a single follicle is selected from the prehierarchal cohort each day. To date, the most proximal marker of follicle selection in the hen (chicken and pheasant) ovary is the initial ability of the FSH receptor to initiate cell signaling via cyclic adenosine monophosphate (cAMP) specifically within the granulosa layer from a single prehierarchal follicle per day (Tilly et al., 1991a; Kim et al., 2013). One hypothesis currently under investigation is that this selection process entails the removal of inhibitory cell signaling that prevents FSH receptor signaling (e.g., promotes receptor desensitization) until the time of selection; this inhibitory process also precludes the selection of more than one prehierarchal follicle per day (Johnson, 2011). At the time of selection, the initial activation of the cAMP signaling pathway rapidly (1) induces the transcription and translation of key steroidogenic enzymes (e.g., CYP11A and CYP17) plus steroidogenic acute regulatory (STAR) protein and, consequently, initiates the process of steroidogenesis; (2) increases the expression of antiapoptotic proteins, thus enhancing cell survival; (3) promotes a transition from FSH receptor dominance to LH receptor dominance; and (4) initiates lipid-rich yolk accumulation within the selected follicle. During this final phase of development, the follicle of the domestic hen will, on average, transport up to 2 g of yolk per day and increase in volume by a factor of 3500–8000.

With the exception of immunoglobulins, the major yolk proteins are formed in the liver. Yolk synthesis is regulated primarily by gonadotropins and steroid hormones (predominantly estrogen, and to a lesser extent androgens). Uptake of VLDLs (which function mainly to transport triglycerides, phospholipids, and cholesterol) and vitellogenins (VTG1, VTG2, and VTG3; these are large, multidomain phosphoglycolipoproteins) (Finn, 2007) from blood capillaries into the

follicle occurs through spaces within the theca layer. From here, they pass through the basal lamina via a selective process that depends on size and molecular charge. These particles then pass between granulosa cells to the perivitelline membrane of the oocyte. The size of these intercellular spaces is dependent upon the stage of follicular growth. For instance, the relatively narrow intercellular space of the primordial follicle allows ferritin and other small molecules to cross. At the time follicles reach the prehierarchal stage, follicles begin to accumulate lipoprotein-rich, white yolk, but transport remains limited by tight junctions between granulosa cells (Schuster et al., 2004). By comparison, during the rapid growth of preovulatory follicles, the shape and organization of granulosa cells change to accommodate an increasing flow of egg yolk precursors that accumulate at the basal lamina of the follicle. These substances finally diffuse through the perivitelline membrane to reach the major yolk precursor receptor, LR8, on the oocyte (Schneider, 2009). This receptor is related by sequence homology to mammalian low-density lipoprotein (LDL) receptors. Significantly, a point mutation within the extracellular domain of the chicken LR8 results in a conformational change in the translated protein that significantly limits oocyte uptake of serum-derived yolk precursors; the site of this point mutation is identical to that in the human LDL receptor that causes familial hypercholesterolemia (Elkin et al., 2012). Finally, yolk proteins are further processed within the oocyte to phosvitin, lipovitellin, triglycerides, cholesterol, and phospholipids by one or more of the proteases and protease inhibitors found in egg yolk or the perivitelline membrane (Bourin et al., 2012). It is estimated that deposition of yolk into the maturing follicle is terminated approximately 24 h before ovulation.

In the highly productive laying hen, the decrease in egg production at the end of the first-year laying cycle results from a reduction in the number of follicles selected into the preovulatory hierarchy and to an increase in the incidence of follicle atresia. As a result, fewer follicles receive a proportionately greater quantity of yolk, resulting in a larger egg size. Eventually, yolk proteins are taken up by the developing embryo primarily for tissue growth, while the yolk lipids represent the main source of energy. The ultrastructure of follicles at different stages of development has been well described in Wyburn et al. (1965), Rothwell and Solomon (1977), Perry et al. (1978a,b), and Gilbert et al. (1980).

28.2.4 Follicle Atresia

Ovarian follicles that initially begin to grow but fail to reach the fully differentiated stage at which they are ovulated become atretic; the loss of viability and resorption of such follicles occur via apoptosis (Tilly et al., 1991b). Atresia can be passively initiated by the loss of gonadotropin support (e.g., with the initiation of incubation or onset of molt, and following hypophysectomy) or by destruction of the germinal disc region (Yoshimura et al., 1994), or actively initiated via one or more death domain-containing receptors from the tumor necrosis factor (TNF) receptor superfamily (Bridgham et al., 2003). Each of these mechanisms indirectly initiates a cascade of enzymatic activity within the granulosa cell layer consisting of initiator and effector caspases (Johnson and Bridgham, 2002) and endonucleases, with subsequent cleavage of chromatin DNA into internucleosomal fragments. This is followed shortly thereafter by apoptotic cell death within the theca layer (Madekurozwa and Kimaro, 2008). Both 3β-HSD and 17β-HSD enzyme activities have been identified in follicles during the early stage of follicle atresia; however, this activity and consequently all steroid production are rapidly lost as atresia progresses. Atresia occurs with a comparatively high incidence among cortical and primordial follicles and slow-growing (<1–5 mm) follicles, occurs occasionally within the prehierarchal cohort of follicles (6–8 mm), and under normal physiological conditions is rarely found among preovulatory (9–45 mm) hierarchal follicles (the latter sometimes referred to as "bursting atresia").

The virtual absence of atresia in preovulatory follicles is associated with increased resistance to apoptosis within the granulosa layer (Tilly et al., 1991b). This increased resistance results in large part from increased expression of antiapoptotic proteins induced by cAMP signaling. Factors that promote cell viability include B cell lymphoma-1 (Bcl2) members (e.g., BCL2, BCLx, and MCL1), inhibitor of apoptosis proteins (IAPs), Flice-like inhibitory protein (FLIP), and survivin. Included among the factors implicated in mediating apoptosis are members of the BCL2-related family of proteins (BAX and BAD), and FADD-like IL1 beta-converting enzyme (FLICE), the interleukin-converting enzyme (ICE)-related family of enzymes, as well as a select group of proto-oncogenes (e.g., c-MYC) and tumor suppressor genes (e.g., p53). It is significant to note that (1) genes from each of these groups are expressed in developing chicken ovarian follicles, (2) the level of constitutive expression for each gene (apoptosis-inducing or apoptosis-suppressing) is correlated to inherent granulosa cell susceptibility or resistance to cell death, and (3) the level of mRNA expression for such genes is generally regulated by the same physiological factors (e.g., growth factors and gonadotropins) that promote hen follicle viability (Johnson, 2003).

28.2.5 Ovulation and Postovulatory Follicles

The preovulatory surge of LH is a primary stimulus for both germinal vesicle breakdown (e.g., condensation of chromatin, extrusion of the first polar body, and formation of the second maturation spindle) in the F1 follicle, followed by the physical process of ovulation. In avian species studied to date, peak circulating levels of LH typically precede

ovulation by 4–6 h. The preovulatory LH surge occurs coincident with increased secretion of progesterone, and studies conducted *in vivo* have demonstrated a stimulatory interaction between LH and progesterone such that in the absence of progesterone secretion, a fully potentiated LH surge fails to occur. In the domestic hen, the largest preovulatory (F1) follicle produces a significantly greater amount of progesterone during the LH surge compared to less mature follicles. This enhanced capacity for progesterone production is related to particularly high levels of STAR protein (which regulates the transport of cholesterol from the outer to inner mitochondrial membrane) expression specifically within the F1 follicle granulosa layer (Johnson and Bridgham, 2001). Unlike mammals, there is no apparent increase in circulating FSH coincident with the preovulatory LH surge in the domestic hen.

Rupture of the F1 follicle and the release of the oocyte at ovulation are facilitated by coordinated events localized along the stigma. These include enzyme activation, physical forces brought about by smooth muscle contraction, and localized apoptosis. Postovulatory follicles contain the granulosa and theca layers that remain after ovulation (Figure 28.1). Immediately following ovulation, steroid production decreases in the postovulatory follicle (within approximately 24 h) due in large part to the loss of gonadotropin-induced signaling via cAMP and the consequent decline in STAR protein expression plus the steroidogenic enzymes, 3β-HSD and 17β-HSD (Dick et al., 1978; Johnson et al., 2002). Structural regression of the postovulatory follicle is associated with an infiltration of immune cells plus the production of cytokines, and it occurs via the process of apoptosis (Sundaresan et al., 2008; Tilly et al., 1991b). Almost complete resorption of the structure occurs over a period of 6–10 days in the chicken, but may take several weeks or even months in the mallard, pheasant, and grouse. In these species, the residual structures provide a means for studying ovulation rates within wild populations. Removal of the most recent postovulatory follicle is reported to abolish nesting behavior and, in particular, the granulosa layer has been demonstrated to be functional in timing oviposition (Gilbert et al., 1978). There is no structure in birds functionally analogous to the corpus luteum of mammals.

28.2.6 Domesticated Hen Ovary as a Model for Human Ovarian Cancer

Recent studies have provided evidence for the domestic hen ovary as an important, nonprimate model for human ovarian cancer. The high rate of ovarian cancers in the laying hen (up to 35% develop the disease by 3.5 years of age) is attributed to the near-daily incidence of ovulation and the prolonged duration of ovulation (up to 365 eggs produced in one year). This results in the development of an epithelial-origin cancer with a number of common pathological features and histological subtypes with the human cancer. In particular, ovarian cancers in both women and the domestic hen produce, with high frequency, copious amounts of ascites fluid and are highly metastatic (Johnson and Giles, 2013).

28.2.7 Reproductive Tract and Sperm Storage Glands

The left oviduct of the domestic hen develops rapidly after 16 weeks of age and becomes fully functional just prior to the onset of egg production (at approximately 20 weeks). The oviduct is suspended within the peritoneal cavity by dorsal and ventral ligaments, and consists of five distinguishable regions: the infundibulum, magnum, isthmus, shell gland, and vagina (Figure 28.4). (For details on general oviduct histology, see Aitken, 1971; Bakst, 1998; Parizzi et al., 2008; on the infundibulum and magnum, see Wyburn et al., 1970; for the isthmus, see Hoffer, 1971; Solomon (1975); and for the shell gland, see Breen and de Bruyn, 1969; Nevalainen (1969); Wyburn et al. (1973).)

Subsequent to ovulation, the ovum is engulfed by the infundibulum (a tissue not directly connected to the ovary), where it resides for approximately 18 min (range: 15–30 min). Occasionally, the ovum fails to be picked up by the infundibulum (an "internal ovulation") and is reabsorbed, usually within 48–72 h. Infundibular activity appears not to be controlled by ovulation *per se*, as foreign objects placed into the abdominal cavity prior to ovulation will also be taken up, and there are reports that entire unovulated follicles may be engulfed and later laid as fully developed eggs. Fertilization of the ovum occurs in the infundibulum, and it is here that the first layer of albumen is produced in the chicken.

The ovum next passes to the largest portion of the oviduct, the magnum (a length of 33 cm in the chicken), where in the mature female the majority of albumen is formed. Estrogen stimulates epithelial stem cells to develop into three

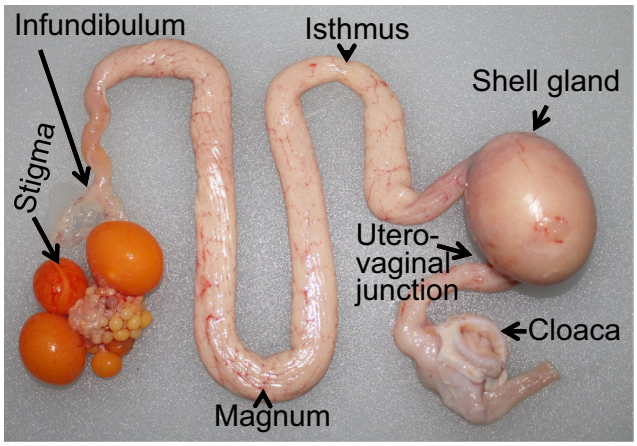

FIGURE 28.4 Ovary and reproductive tract from the domestic hen. Note the prominent stigma (site of ovulation) visible on the third largest preovulatory follicle. *Photograph by Dr O. Ocón-Grove.*

morphologically different cell types: tubular gland cells, ciliated cells, and goblet cells. Tubular glands are responsible for the production of ovalbumin, lysozyme, and conalbumin under the stimulatory control of estrogen, while goblet cells synthesize avidin following exposure to progesterone and estrogen (Tuohimaa et al., 1989). A measurable amount of calcium secretion occurs within the magnum, but at no time during the laying cycle is calcium secretion greater than the basal rate of secretion found in the shell gland (Eastin and Spaziani, 1978a). The ovum remains in the magnum approximately 2–3 h.

The isthmus is clearly distinguishable from the magnum. It has a thick circular muscle layer muscle, and glandular tissue is less developed compared to in the magnum. This tissue is characterized by a layer of epithelial cells with underlying tubular gland cells. The production of mucin by glandular tissues within the lower reproductive tract (isthmus, shell gland, and vagina) provides a barrier to prevent invasion by pathogenic agents. Both inner and outer shell membranes are formed during the 1–2 h (mean time: 1 h and 14 min) passage through the isthmus. There is some evidence to suggest that shell formation, particularly the mammillary cores, is initiated in the distal portion of the isthmus.

The shell gland (uterus) is characterized by a prominent longitudinal muscle layer lined medially with both tubular gland and unicellular goblet cells. Maturation of these characteristics, together with the induction of the arginine vasotocin receptor (VT3), is promoted by estrogen. Prior to calcification, the egg takes up salts and approximately 15 g fluid into the albumin from the tubular glands, a process termed "plumping"; this fluid contains carbonic anhydrase, acid phosphatase, and esterase activity, plus bicarbonate and a variety of additional ions (Salevsky and Leach, 1980). The ovum remains in the shell gland for 18–26 h, depending on the cycle length.

Calcification within the shell gland is associated with stimuli initiated by ovulation or by neuroendocrine factors that control and coordinate both ovulation and calcium secretion. Osteopontin (a phosphoprotein) is secreted from epithelial cells of the shell gland and is incorporated within the developing eggshell; its function has been linked to both the structural integrity of the egg and the termination of shell calcification. In addition, expression of the calcium-binding and calcium transport protein, calbindin, occurs at the onset of egg production and is lost with the termination of egg laying. Evidence suggests that distension of the shell gland by the egg is not a stimulus for initiating a high rate of calcium secretion, which is characteristic of calcification, nor is autonomic innervation involved. Calcification of the egg at first occurs slowly, increases to a rate of up to 300 mg/h over a duration of 15 h, then again slows during the last 2 h before oviposition; shell pigments (discussed further in this chapter) are deposited via ciliated cells of the shell gland epithelium during the period from 3 to 0.5 h prior to oviposition.

The vagina is separated from the shell gland by the uterovaginal sphincter muscle and terminates at the urodeum of the cloaca. There are numerous folds of mucosa, which are lined by ciliated and nonciliated cells, and a few tubular mucosal glands that may have a secretory function. The vagina has no role in the formation of the egg but, in coordination with the shell gland, participates in the expulsion of the egg. The cloaca is divided into three compartments, the coprodeum (most anterior), urodeum, and proctodeum. During oviposition, a urodeal fold can form a thin membrane across the rectum to prevent feces contamination of the egg. Prolapse of the oviduct (eversion of the vagina and protrusion through the ventral opening) can occur in commercial chickens and turkey hens, and may result in death due to shock. Prolapse has been associated with premature photostimulation, inadequate body size due to early lay, large (often double-yolked) eggs, and obesity.

In birds, spermatozoa are stored in specialized sperm storage tubules (SSTs) located at the uterovaginal junction (the primary site of storage) and infundibulum (a secondary site of storage). It is estimated that only 1–2% of inseminated sperm (only morphologically "normal") enter the SSTs, indicating that some process of selection occurs. The SSTs are lined by a single layer of nonciliated cells and provide a mucosal surface where spermatozoa can remain viable for a period of 7–14 days in the chicken and for up to 10 weeks in the turkey hen; the longer storage time in the turkey is attributed to a greater total number of SSTs. This storage capacity enables a precise synchrony between ovulation and fertilization on a daily basis. Following oviposition of each egg, spermatozoa are released from these tubules and migrate to the infundibulum for fertilization. Uterovaginal junction glands are apparently devoid of innervation and contractile tissue, but possess a well-developed vascular system (Tingari and Lake, 1973; Das et al., 2008; Bakst, 2011). Evidence suggests that spermatozoa fill the uterovaginal glands in a sequential fashion without mixing so that with successive inseminations, sperm from the latest insemination is most likely to fertilize an ovum. Tubular glands are also found in the turkey urodeum and, to a lesser extent, the ventral proctodeum. Bakst and Akuffo (2008) have proposed that sperm that initially accumulated within these glands at insemination may eventually be carried by tubular secretions to vaginal SST.

Both the innate and acquired immune systems are well developed within the oviduct (Ozoe et al., 2009), yet SSTs represent an immuno-privileged site. Overall immunocompetence, including increased expression of defensins, is enhanced at sexual maturation and is supported by adequate levels of estrogen (Anastasiadou et al., 2013). The blood supply to the oviduct and shell gland of the domestic hen has been described by Hodges (1965). For a review of the vasculature to the oviduct of additional avian species, see Gilbert (1979). Blood flow to the shell gland of the hen is

increased during the presence of a calcifying egg compared to times when no egg is present. For additional details on blood flow, see Chapter 30.

The oviduct is innervated by both sympathetic and parasympathetic nerves. Innervation of the infundibulum is via the aortic plexus, and the magnum by the aortic and renal plexuses (Hodges, 1974). Sympathetic innervation of the shell gland is via the hypogastric nerve, which is the direct continuation of the aortic plexus. Parasympathetic pelvic nerves, which constitute the left pelvic plexus, arise from the pelvic visceral rami of spinal nerves 30 to 33. Cilia are found along the entire length of the oviduct, and a likely function of these cilia is that of sperm transport. Egg transport is primarily accomplished by contractions of the oviduct; oviduct musculature functions as a stretch receptor, and the mechanical stimulus is produced by the ovum itself (Ariamaa and Talo, 1983). Changes in electrical activity and oviduct motility have been recorded in the magnum, isthmus, and shell gland during the ovulatory cycle, with the greatest frequency of electrical activity and contractions occurring in the shell gland at the time of oviposition (Shimada and Asai, 1978). Both α- and β-adrenergic receptors are present throughout the length of the oviduct and have been shown to affect oviduct motility (Crossley et al., 1980).

28.3 OVARIAN HORMONES

28.3.1 Embryo and Posthatch Ovary

The developing chick embryo begins to express steroidogenic enzymes and synthesize measurable amounts of steroids within the first week of incubation. These steroidogenic enzymes include CYP11A1, 3β-HSD, CYP17, 17β-HSD, and CYP19A. Genetic females selectively express CYP19 and synthesize estradiol-17β. Asymmetric expression of the CYP19 gene in the ovary occurs by day 6.5, when gonadal differentiation is first recognized. There is clear evidence for the local action of several steroids as indicated by ovarian expression of intracellular estrogen receptor α, androgen receptor, and progesterone receptors A and B, plus the membrane progesterone receptor γ, beginning early in embryonic development (Gonzalez-Moran et al., 2013). Expression of both LH and FSH receptors occurs by mid- to late embryonic development. Following hatch, the production of ovarian steroids within the ovarian stroma remains relatively low and nonresponsive to gonadotropins up to the beginning of sexual maturation.

Between the time of hatch and the onset of lay in the domestic hen, there is an early LH peak at about 1 week of age, and a prepubertal LH rise beginning approximately 15 weeks post hatch that is highest about 3 weeks prior to sexual maturity. The hen ovary is unresponsive to stimulation by either mammalian gonadotropins or avian pituitary extracts until 16–18 weeks of age. In contrast, the pituitary becomes less responsive to exogenous gonadotropin-releasing hormone (GnRH) as the onset of puberty approaches (Wilson and Sharp, 1975); this change is probably the result of negative feedback by increasing steroid secretion by the ovary.

Ovarian steroidogenesis can be demonstrated as early as day 3.5 of incubation. Circulating concentrations of estradiol-17β increase 2–3 weeks before the onset of lay, whereas levels of progesterone begin to increase about one week prior to lay, and both steroids initiate the development of the reproductive tract (Williams and Sharp, 1977). Moreover, the surge in estrogen production alters the function of osteoblasts to begin forming medullary bone that serves as a labile source of calcium for impending egg production.

Several protein hormones and growth factors have been described in the immature ovary in addition to AMH (discussed in this chapter). Bone morphogenetic protein 7 (BMP7) is preferentially expressed in the left ovary during early embryo development (Hoshino et al., 2005; Oréal et al., 2002), but it is not clear whether BMP7 represents part of the differentiation mechanism or is simply a result of the process. Other factors reportedly expressed in the immature ovary without any specific function yet ascribed include BMP2, BMP3, BMP4, transforming growth factor beta (TGFβ), growth hormone (and its receptor), GnRH-I, inhibins, and activins (Onagbesan et al., 2004; Johnson et al., 2006; Hrabia et al., 2008).

28.3.2 Mature Ovary

It is now well established that ovarian function is regulated not only by hypothalamic GnRH and pituitary gonadotropins (FSH and LH), but also by a diverse group of endocrines, neuropeptides, growth factors, and cytokines acting in a paracrine and/or autocrine fashion within the mature ovary. These factors have variably been associated with regulating granulosa and theca cell survival and apoptosis, cell proliferation, gonadotropin receptor expression, and steroidogenesis plus the maintenance of the oocyte.

28.3.2.1 Ovarian Stromal Tissue and Slow-Growing Follicles

Prior to sexual maturation, whole, small white (<1–3 mm diameter) follicles produce dehydroepiandrosterone, androstenedione, and estradiol in response to LH *in vitro*. The inability of these follicles to produce progesterone at this stage of development is indicative of steroidogenesis via the Δ5 pathway (Robinson and Etches, 1986). The theca layer from prehierarchal (6–8 mm) follicles, as well as ovarian stromal tissue, is also steroidogenically active primarily via the Δ5 steroidogenic pathway (Kowalski et al., 1991; Levorse and Johnson, 1994). Both LH and FSH, acting via their respective receptors, can initiate cAMP signaling and stimulate steroid production from theca tissue.

By contrast, granulosa cells from prehierarchal (6–8 mm) follicles are incapable of synthesizing progesterone due to the absence of both CYP11A1 and STAR expression. While granulosa cells from prehierarchal follicles express 3β-HSD activity and can actively convert exogenously added pregnenolone to progesterone *in vitro*, these cells fail to produce any significant amount of progesterone *in vivo*. Despite the inability of granulosa to produce detectable levels of sex steroids at this stage of development, these cells express both FSH receptor mRNA and VIP receptor (*VPAC1* and *VPAC2*) mRNAs, but undetectable levels of LH receptor mRNA. FSH receptor mRNA expression within the granulosa layer is maintained at elevated levels by several autocrine and paracrine factors, including TGFβ1, activin A, bone morphogenetic protein-6 (BMP6), and BMP4 (Woods and Johnson, 2005; Kim et al., 2013). Nevertheless, at this stage of development, both the FSH receptor and the VIP receptors (all of which represent G protein-coupled receptors) remain in a desensitized state (e.g., fail to generate cAMP in response to their respective agonist). Significantly, this inhibition of cell signaling has been linked to inhibitory mitogen-activated protein kinase activity (Johnson and Woods, 2009). Several epidermal growth factor receptor ligands (EGFRLs) together with their receptors, ErbB1, ErB2, and ErbB4, are expressed within these follicles. The EGFRLs include epidermal growth factor (EGF), TGFα, betacellulin, heparin-binding EGF-like growth factor, amphiregulin, epiregulin, and neuregulins (Woods et al., 2005). Collectively, these findings are significant in that they help to explain how prehierarchal follicles are maintained in a relatively undifferentiated state *in vivo*, despite a continued exposure to circulating concentrations of FSH and VIP, the latter of which is provided, at least in part, via theca innervation (Johnson et al., 1994).

Kit ligand mRNA levels are highest in granulosa cells from follicles <5 mm, and its expression is increased when cultured with oocyte-conditioned medium; this cytokine is proposed to play a role in regulating the slow growth of small, undifferentiated follicles (Kundu et al., 2012). Additional autocrine and paracrine factors found expressed within slow-growing follicles prior to selection include brain-derived neurotropic factor, growth hormone, growth and differentiation factor-9 (GDF9), inhibins, activins, follistatin, and TNFα (Ahumada-Solórzano et al., 2012; Onagbesan et al., 2009).

28.3.2.2 Hierarchal Follicles

At follicle selection, the granulosa layer acquires FSH and VIP responsiveness (e.g., initiates receptor-mediated cAMP production) and begins the transition from being predominantly FSH dependent (in granulosa cells from follicles ~12 mm in diameter) to becoming primarily LH dependent (in hierarchal follicles >12 mm). Subsequent to follicle selection, active receptor-mediated cAMP signaling within the granulosa layer is directly responsible for the production of CYP11a enzyme and STAR protein to initiate steroidogenesis and LH receptor expression (Johnson and Bridgham, 2001). LH-induced adenylyl cyclase responsiveness and progesterone production continues to increase within the granulosa layer as a follicle approaches the time of ovulation. Progesterone is the primary steroid involved in potentiating the preovulatory surge of LH that precedes ovulation by 4–6 h. By contrast, FSH-induced cAMP formation and steroidogenesis are comparatively low in hierarchal follicles. Fully potentiated steroid production by preovulatory follicles is best described by a three-cell model (Porter et al., 1989) and occurs predominantly via the Δ4 steroidogenic pathway. The granulosa layer produces predominantly progesterone that serves as a precursor for androstenedione and testosterone synthesis within the theca layer, and to a lesser extent by granulosa cells. The granulosa layer does not express CYP19 enzyme, and thus does not synthesize estrogen.

The theca layer also expresses CYP11A activity; however, the predominant steroid product of the theca interna layer is androstenedione, while cells in the theca externa synthesize estrogen. Steroid production by the theca layer is predominantly under the regulatory control of LH acting via the adenylyl cyclase–cAMP second messenger pathway. LH receptor mRNA is expressed in theca tissue of all hierarchal follicles (Johnson et al., 1996). The theca adenylyl cyclase system is highly sensitive to LH, and much less responsive to FSH. There is also evidence for LH-stimulated steroid production occurring within each of the follicle layers via the phosphoinositide 3-kinase–inositol 1,4,5-trisphosphate (IP3) pathway and calcium mobilization. In addition, activation of the protein kinase C second messenger system attenuates LH-induced steroid production by granulosa and theca cells. Included among the potential physiological factors that may act via protein kinase C are growth factors (e.g., TGFα and EGF) and prostaglandins (Tilly and Johnson, 1991).

A primary function of the somatic cell layers (granulosa and theca) is to support the viability of the oocyte and maintain meiotic arrest until ovulation. In recent years, an ever-increasing number of factors have been implicated in directly or indirectly modulating the function of the granulosa and theca layers (see Table 28.1). For instance, inhibin A is produced at the highest levels by the granulosa layer of the four largest preovulatory follicles and influences ovarian function by inhibiting FSH (but not LH) secretion (Johnson PA et al., 1993). By comparison, activin A is produced by the theca layer and increases both LH receptor and FSH receptor expression in cultured granulosa cells (Johnson et al., 2006). BMP15 and GDF9 are preferentially expressed by granulosa cells within the germinal disc, and have been implicated in regulating cell proliferation and steroid production (Elis et al., 2007; Johnson et al., 2005).

TABLE 28.1 Partial List of Factors Reported to Be Expressed and/or to Act within the Avian Ovary

Factor	Proposed Function(s)	Reference(s)
Activins, follistatin, and inhibins	Follicle-stimulating hormone (FSH) secretion; FSH and luteinizing hormone receptor expression	Onagbesan et al. (2004)
Adiponectin	Steroidogenesis (?)	Chabrolle et al. (2007)
Anti-Müllerian hormone	Follicle recruitment; FSH responsiveness	Wojtusik and Johnson (2012)
Arginine vasotocin	Oviposition	Baeyens and Cornett (2006)
Bone morphogenetic proteins (BMPs)		
BMP2, -3, -4, -5, -6, and -7	FSH receptor expression; granulosa differentiation	Onagbesan et al. (2003)
BMP15	Steroidogenesis; cell proliferation	Elis et al. (2007)
Growth and differentiation factor-9	Granulosa cell proliferation	Johnson et al. (2005)
Calcitonin	Follicle maturation (?)	Krzysik-Walker et al. (2007)
Cytokines		
Tumor necrosis factor α	Regulates steroidogenesis; apoptosis	Witty et al. (1996) and Onagbesan et al. (2000)
Interleukins	Postovulatory follicle regression; innate immunity	Sundaresan et al. (2008) and Abdelsalam et al. (2012)
Epidermal growth factor (EGF) receptor ligands		
EGF, transforming growth factor α, betacellulin, and amphiregulin	Cell differentiation, proliferation, and apoptosis	Woods et al. (2005) and Woods and Johnson (2007)
Fibroblast growth factors	Granulosa cell proliferation	Lin et al. (2012)
Follicle-stimulating hormone	Granulosa cell differentiation	Johnson and Woods (2009) and Bruggeman et al. (2002)
Gonadotropin-inhibitory protein	Follicle differentiation (?)	Bédécarrats et al. (2009)
Ghrelin	Steroidogenesis, cell proliferation, and apoptosis	Sirotkin et al. (2006)
Growth hormone	Modulates steroidogenesis	Ahumada-Solorzano et al. (2012)
Insulin-like growth factors (IGF1 and 2)	Follicle growth and differentiation	Onagbesan et al. (1999)
Luteinizing hormone	Steroidogenesis, ovulation, and cell viability	Johnson and Bridgham (2001)
Melatonin	Gonadotropin responsiveness (?)	Sundaresan et al. (2009)
Neurotropins (nerve growth factor and brain-derived neurotrophic factor)	Steroidogenesis	Jensen and Johnson (2001)
Prolactin	Steroidogenesis	Tabibzadeh et al. (1995)
Prostaglandins (PGE and PGF2α)	Apoptosis; cell proliferation	Li et al. (1997) and Manchanda et al. (2001)
Transforming growth factors (TGFβ1)	FSH receptor expression	Woods and Johnson (2005)
Thyroxine and triodothyronine	Modulates steroidogenesis	Sechman (2013)
Vasoactive intestinal peptide	Granulosa cell differentiation; steroidogenesis	Johnson et al. (1994)
1,25-dihydroxyvitamin D_3	Regulates anti-Müllerian hormone expression	Wojtusik and Johnson (2012)

Sturkie's Avian Physiology, G. Causey Whittow, Ed., Academic Press.

28.4 ENDOCRINE AND PHYSIOLOGIC FACTORS AFFECTING OVULATION AND OVIPOSITION

Ovulation in the domestic hen generally follows an oviposition within 15–75 min except for the first ovulation of a sequence, which is not associated with oviposition. Neither the premature expulsion of the egg (which can be induced with prostaglandins or other agents) nor a delayed oviposition (affected by epinephrine or progesterone) influences the time of ovulation. Ovulation occurs via a rupture along the follicle stigma, and this process likely involves multiple, often redundant factors that include proteolytic enzymes (e.g., collagenase and plasminogen activator), vasoactive substances, and the process of apoptosis.

28.4.1 Ovulation

28.4.1.1 Gonadotropin-Releasing Hormone (LH-Releasing Hormone)

Avian species express two different forms of gonadotropin-releasing hormone (GnRH-I or GnRH-II; see Chapter 30); however, only GnRH-I appears to be directly involved in regulating LH secretion. Injection of GnRH-I induces ovarian steroid production and premature ovulation, whereas *in vivo* administration of GnRH antiserum has been shown to block ovulation. These effects are mediated via the pituitary and LH secretion, and there is no evidence of a direct ovulation-inducing effect of either GnRH moiety within the ovary.

28.4.1.2 Luteinizing Hormone

Plasma concentrations of LH in the domestic hen (and most other birds studied to date) peak 4–6 h prior to ovulation (Johnson and van Tienhoven, 1980). This preovulatory surge provides a direct stimulus for germinal vesicle breakdown and for subsequent ovulation. Some workers have reported an additional peak of LH at 11–14 h prior to ovulation; however, the significance of this second peak has not been established. In addition to these ovulatory–oviposition cycle-related peaks, there occurs a crepuscular (occurring at the onset of darkness) peak of LH, which has a periodicity of 24 h and has been proposed to act as a timing cue for the subsequent preovulatory LH surge (Wilson et al., 1983).

Injection of LH into laying hens almost always increases plasma concentrations of progesterone, estrogens, and androgens; however, the ovulatory response is dependent on the stage within the sequence. For instance, LH treatment 11–14 h prior to the first ovulation of a sequence results in premature ovulation, whereas the same treatment before a midsequence ovulation commonly results in follicle atresia and blocked ovulation (Gilbert et al., 1981). Passive immunization of laying hens with antiserum generated against partially purified chicken LH results in the cessation of ovulation for approximately 5 days and extensive atresia of existing follicles (Sharp et al., 1978).

28.4.1.3 Follicle-Stimulating Hormone

A rise in plasma FSH has been observed 15 h prior to ovulation in the domestic hen (Scanes et al., 1977), and this occurs coincident with an increase in FSH binding to ovarian tissue (Etches and Cheng, 1981). Other researchers find less pronounced cycle-related fluctuations in circulating FSH (Krishnan et al., 1993). A primary role for FSH is related to granulosa cell differentiation and the induction of steroidogenesis in prehierarchal follicle granulosa cells (as discussed in this chapter), but there is little evidence for circulating levels of FSH serving to initiate ovulation. In fact, FSH receptor mRNA expression decreases as preovulatory follicles mature (You et al., 1996). Although injection of recombinant FSH is capable of inducing ovulation in mammals (Tapanainen et al., 1993), this apparently has not been tested in avian species.

28.4.1.4 Ovarian Steroids

Highest concentrations of plasma progesterone are found 4–6 h before ovulation and coincide with the preovulatory LH peak. This increase is predominantly the result of progesterone secretion by the granulosa layer from the largest preovulatory (F1) follicle (Etches, 1990). Systemic and intraventricular injection of progesterone can induce both a preovulatory surge of LH and premature ovulation, while administration of progesterone antiserum prior to the preovulatory surge of progesterone can block ovulation. Evidence suggests that the preovulatory LH surge is preceded by an increase in progesterone in view of the findings that (1) in the absence of the normal preovulatory rise in progesterone (blocked by the steroidogenesis inhibitor, aminoglutethimide), there is no preovulatory increase in plasma LH; and (2) intramuscular injection of progesterone in aminoglutethimide-treated laying hens induces a normal preovulatory LH surge in the absence of any increase in plasma testosterone or estrogen (Johnson and van Tienhoven, 1984). Moreover, results from a study of hypophysectomized hens suggest that progesterone, in the absence of preovulatory gonadotropin, can induce ovulation (Nakada et al., 1994).

Progesterone circulates in the blood bound to a high-affinity corticoid-binding globulin or to albumin and other γ-globulins. Progesterone-specific receptors have been demonstrated in the hypothalamus and pituitary of the domestic hen, and the number of receptors is influenced by the reproductive state. In the oviduct, progesterone receptors are present in surface epithelial cells, tubular gland cells, stromal fibroblasts, and smooth muscle cells in the arterial walls and myometrium (Yoshimura and Bahr, 1991a). These findings provide evidence for a role of progesterone

in the production of avidin, contraction of the myometrium, and shell formation. Moreover, progesterone receptors are expressed within granulosa, theca, and germinal epithelial cells of preovulatory follicles (Isola et al., 1987; Yoshimura and Bahr, 1991b). The localization of such receptors associated with the stigma region provides a physiological mechanism by which progesterone may mediate a direct effect on ovulation.

Peak preovulatory concentrations of testosterone occur 6–10 h prior to ovulation, whereas highest levels of 5α-dihydrotestosterone (DHT) occur approximately 6 h before ovulation. The increase in testosterone at this time is the result of secretion from at least the four largest follicles. The role of androgens in ovulation is, as yet, unclear. Intraventricular injections of testosterone fail to release LH or induce premature ovulation, and peripheral injections of testosterone that generally result in unphysiologically high circulating concentrations of testosterone are required to stimulate LH secretion and induce ovulation. Moreover, ovulation can occur in the absence of any preovulatory increase in plasma testosterone. Both granulosa and theca cells of prehierarchal and hierarchal follicles express an androgen receptor, and androgens regulate steroidogenesis via a paracrine and/or autocrine action (Lee and Bahr, 1990; Yoshimura et al., 1993). As in the male, androgens are responsible for the growth and coloring of the comb and wattles at the time of sexual maturation, and they synergize with estrogen to induce medullary ossification.

Both estradiol-17β and estrone show highest plasma concentrations 4–6 h before ovulation with a smaller, more inconsistent rise in estrogens 18–23 h before ovulation. Preovulatory follicle secretion of estradiol increases in each of the four largest follicles 3–6 h prior to ovulation and is greatest in the third and fourth largest follicles. Overall, however, the majority of estrogen produced by the ovary originates from small (1–2 mm) follicles (Robinson and Etches, 1986). Like testosterone, estrogens are unlikely to be involved in the direct induction of LH secretion or ovulation, as injection of estradiol in laying hens either inhibits or has no effect on ovulation or LH secretion. Moreover, ovulation can occur in the absence of a preovulatory increase in plasma estrogens.

Ovarian estrogens have a variety of additional functions related to reproduction, including the regulation of calcium metabolism for shell formation, induction of its own receptor in the oviduct, and induction of progesterone receptor expression in the ovary and reproductive tract. Treatment of immature Japanese quail and young female chickens with estradiol enhances growth of the oviduct and promotes the formation of tubular secretory glands and epithelial differentiation. Moreover, estradiol induces the synthesis of ovalbumin, conalbumin, ovomucoid, and lysozyme in the oviduct and vitellogenin in the liver. Secondary sex characteristics, such as the color and shape of plumage, and sexual behavior, are also under the control of estrogens. Sexual differentiation of the female brain is under the influence of estrogen, as indicated by the finding that treatment of female quail embryo with an antiestrogen results in behavioral masculinization.

28.4.1.5 Corticosterone

Plasma concentrations of corticosterone display both a daily (photoperiod-related) rhythm and a peak coincident with oviposition. The role of corticoids on the ovary and in the ovulatory process is unclear, as both facilitatory and inhibitory actions have been described. While there is some evidence to suggest that the adrenal gland, via corticosterone secretion, regulates the timing of the preovulatory LH surge (Wilson and Cunningham, 1980), there is no ovulation-related increase in circulating corticosterone. Injection of corticosterone, deoxycorticosterone, or ACTH induces premature ovulation; however, it is unlikely to act at the level of the hypothalamus and/or pituitary to directly induce LH release. In several wild species, seasonal increases of plasma corticosterone are associated with egg laying (e.g., white-crowned sparrow, European starling, and Western meadowlark) or with brooding behavior (e.g., pied flycatcher), whereas in others (e.g., Canada goose) there is apparently little change or a decrease in corticosterone during the breeding season. Absolute plasma levels of corticosterone can be misleading, however, as the capacity of the corticosteroid-binding globulin may also fluctuate with season (Breuner et al., 2003).

28.4.1.6 Prolactin

It is well documented that prolactin is associated with parental behavior and may also play a role in osmoregulation, especially in marine birds; there no clear relationship between circulating prolactin and the LH surge. Prolactin secretion from the anterior pituitary is primarily under the stimulatory control of VIP (see Chapter 30). Circulating levels of prolactin increase at the onset of egg laying through incubation in many species of birds, and prolonged elevated prolactin levels have an antisteroidogenic effect on the ovary, in part via inhibition of steroidogenic enzyme gene expression (Tabibzadeh et al., 1995), and act on the neuroendocrine system to reduce hypothalamic GnRH levels and inhibit LH stimulation of the ovary (Rozenboim et al., 1993). During the ovulation–oviposition cycle of the domestic hen, circulating levels of prolactin are highest approximately 10 h and lowest 6 h prior to ovulation, though it is unlikely that prolactin plays a direct role in the ovulatory process. Prolactin levels are also elevated during the summer months in response to increasing photoperiod. Expression of prolactin receptor mRNA and prolactin binding has been detected in crop sac mucosa, liver, brain, ovary, and oviduct (Tanaka et al., 1992).

28.4.1.7 Other Factors

Preovulatory follicles produce prostaglandins, and the secretion of prostaglandin (PG) F2α by the F1 follicle is greatest around the time of ovulation. PGF2α, PGE2, acetylcholine, and oxytocin increase the contraction of smooth muscles in the connective tissue wall of the follicle *in vitro* and may, in combination with proteolytic enzymes, play a role in the rupture of the stigma at ovulation (Yoshimura et al., 1983). Nevertheless, it is clear that PGs are not obligatory for ovulation to occur as neither the administration of prostaglandins nor the injection of indomethacin into the follicle affects the timing of ovulation.

Gonadotropin-inhibitory hormone (GnIH) was originally described as a factor that suppresses pituitary LH secretion, but both GnIH and GnIH receptor have subsequently been identified in the chicken ovary (Bédécarrats et al., 2009). Ligand binding to the GnIH receptor inhibits cAMP signaling, and it is speculated that GnIH may serve to modulate the growth and differentiation of ovarian follicles.

28.4.2 Oviposition

Expulsion of the egg (oviposition) involves the relaxation of abdominal muscles and sphincter between the shell gland and vagina and the contraction of smooth muscles of the shell gland. The majority of research to elucidate the mechanisms controlling oviposition has been performed in the quail and domestic hen, and has implicated neurohypophyseal hormones, prostaglandins, acetylcholine, galanin, and hormones of the preovulatory and postovulatory follicles.

Administration of oxytocin and arginine vasotocin (both of neurohypophyseal origin) can induce premature oviposition in laying hens. Arginine vasotocin activity in the blood of the laying hen is reported to be highest at the time of oviposition, and its actions are mediated via its receptor, VT3. Release of arginine vasotocin from the neurohypophysis is stimulated by various factors, such as prostaglandins (PGF2α, PGE1, and PGE2), estradiol-17β and progesterone, angiotensin-II, and acetylcholine. Although removal of the neurohypophysis fails to affect the pattern of timing of oviposition, it is likely that an additional source of arginine vasotocin is the preovulatory follicle granulosa and/or theca layer. The oviposition-inducing actions of oxytocin may be mediated via prostaglandins, as administration of indomethacin, a prostaglandin synthesis inhibitor, blocks oxytocin-induced premature oviposition.

There is much evidence suggesting that prostaglandins directly induce uterine (shell gland) contractions, and that this is mediated via extracellular Ca^{++} entry and myosin light chain kinase phosphorylation. Exogenous administration of PGF2α stimulates shell gland contractility, relaxes the vagina, and induces premature oviposition (Shimada and Asai, 1979; Takahashi et al., 2011). In contrast, treatment with indomethacin or aspirin depresses the peak of prostaglandins in the plasma and, in pre- and postovulatory follicles, suppresses uterine contractility and delays oviposition. Injection of PGE1 induces premature oviposition in chickens and Japanese quail, while passive immunization with PGE1 antiserum delays oviposition in the domestic hen. Further evidence that prostaglandins mediate the oviposition inducing activity of arginine vasotocin is that plasma prostaglandins are significantly elevated at the time of arginine vasotocin-induced premature oviposition, and that arginine vasotocin stimulates the biosynthesis and release of prostaglandin from the shell gland.

Endogenous concentrations of prostaglandins E and F increase within ovarian follicles beginning 4–6 h prior to the expected time of oviposition. The highest and next highest concentrations were observed at oviposition in the largest preovulatory follicle and most recent postovulatory follicle (Saito et al., 1987). Increased prostaglandin production and secretion from one or more of these sources is reflected by significantly elevated plasma concentrations of the prostaglandin metabolite 13,14-dihydro-15-keto prostaglandin F2α, coincident with the time of oviposition. Cyclooxygenase, the rate-limiting enzyme of prostaglandin synthesis, is selectively expressed within granulosa cell layer, the cortical interstitium, the ovarian surface epithelium, and within the most recent postovulatory follicle (Hales et al., 2008). Among factors that have been shown to promote prostaglandin production within the granulosa layer are TGFα and TGFβ (Li et al., 1994). Removal of either the most recent postovulatory follicle or the largest preovulatory follicle results in a 1–7 day delay in oviposition (Rothchild and Fraps, 1944); the factor(s) may be a peptide, possibly analogous or identical to the neurohypophyseal hormones or prostaglandins. Despite the fact that the shell gland contractility is influenced by epinephrine and norepinephrine, there is no evidence that these catecholamines influence the timing of oviposition.

28.5 REPRODUCTIVE SEASONALITY, BREEDING, AND OVULATION–OVIPOSITION CYCLES

Seasonal reproduction is regulated according to a circannual rhythm, and this rhythm is phased by an increasing photoperiod that is detected by photoreceptors within the brain. A recent model suggests that photoperiod-induced thyrotropin hormone (TSH) from the pars tuberalis initiates triiodothyronine (T3) production within the mediobasal hypothalamus. In turn, T3 initiates seasonal gonadotropin-releasing hormone production and pituitary gonadotropin secretion (Yoshimura, 2013; for additional details, see Chapter 30 (Hypothalamus/Pituitary)).

Breeding cycles among species of birds can be classified according to the length of the cycle and the time of the

year at which each species becomes reproductively active. Continuous breeders, such as the domestic hen or Khaki Campbell duck, are under optimal conditions reproductively active throughout the year, but these are not common. Most wild species that breed in temperate, subarctic, and arctic zones display yearly cycles, while birds adapted to tropical or desert climates may breed with cycles less than a year, at 6-month intervals, or when favorable conditions exist (e.g., rain and food availability). One example of an opportunistic breeder is the zebra finch (*Taeniopygia guttata*), which has adapted to the semiarid and arid regions of Australia. Ovarian growth in the female begins shortly after hatch and this continues throughout the first 3 months posthatch, when it enters an indefinite resting stage. Following an appropriate ultimate cue (e.g., rainfall), follicles are selected into the rapid growth phase and are ovulated within 1 to 2 weeks (Sossinka, 1980). This raises two important questions as to how the ovary maintains an appropriate milieu to support long-term prehierarchal follicle viability (e.g., prevent cellular apoptosis and consequent atresia over a period from weeks to months), and how the presence of ultimate factors becomes translated into appropriate cellular signals to initiate follicle selection into the preovulatory hierarchy (for additional information on opportunistic breeders, see Hau, 2001). Given that the process of reproduction in the majority of birds is closely synchronized with the availability of food and an appropriate climate, it is possible that any significant climate change could negatively impact the timing of migration and the optimal time for reproduction.

Seasonal growth of the ovary is stimulated in almost all species by increasing photoperiod. Such species initially respond to increasing day length with increased hypothalamic secretion of gonadotropin releasing hormone (GnRH), which initiates pituitary gonadotropin (FSH and LH) production and secretion. In some birds (e.g., Japanese quail), an increase in GnRH secretion occurs within the first day of photostimulation. Subsequently, additional stimuli (proximal factors such as quality and abundance of food or nesting sites, temperature, or interactions with a male) are often required to initiate follicular growth and maturation. Nevertheless, there are a few species known to initiate reproductive activity during a season of decreasing or short (<12 hours light) photoperiod (e.g., emperor penguin, *Aptenodytes forsteri*; crossbills, *Loxia* spp.); this is likely a reflection of seasonally available food resources required for raising offspring.

Wild birds generally produce one or more eggs in a clutch and then terminate lay to incubate the eggs. The number of eggs per clutch and total number of clutches vary with species, age of the female and season. For example, some birds, such as the sooty tern (*Sterna fuscata*), lay a single egg to incubate. The king penguin (*Aptenodytes patogonica*) will lay but one egg, and breeding will not necessarily occur on a yearly basis. In contrast, the European partridge will lay a single clutch per year consisting of as many as 12 to 20 eggs. The pigeon usually lays two eggs per clutch and averages eight clutches per year; the interval between clutches is approximately 45 days in the fall and winter and from 30 to 32 days in the spring and early summer. Within a species, the size and number of eggs laid tend to increase with age, and the largest improvement occurs between the first and second breeding seasons. In starlings, this increase in performance subsequent to the first year is associated with a greater amount of vitellogenin production in females that have experienced a prior period of photostimulation (Sockman et al., 2004). In bobwhite quail, clutch size declines with advancing season, from a mean high of 19.2 eggs in early May to 11.3 eggs in late July.

Some species of birds produce a replacement clutch when eggs are destroyed or removed from the nest early enough in the breeding season (examples are the Mallard duck, *Anas platyrhynchos*; Northern Lapwings, *Vanellus vanellus*; and Gentoo Penguins, *Pygoscelis papua*). These species are considered indeterminate layers because they produce a number of developing follicles that is greater than the number of eggs normally laid. If eggs are removed as they become laid, such species will continue to produce eggs well beyond the normal clutch size. The stimulus (or cue) to continue laying due to egg loss may be visual or tactile. Determinate layers fail to lay additional eggs on the removal or destruction of eggs in the nest. In these species, the number of preovulatory follicles generated is equal to the number of eggs ovulated. Examples of determinant layers include Yellow Warblers (*Dendroica petechia*), Red-winged Blackbirds (*Agelaius phoeniceus*), and Pied Flycatchers (*Ficedula hypolueca*). In seasonal (or noncontinuous) breeders, the ovary undergoes periods of growth and regression. The weight of the European starling ovary may vary from 8 mg during the regression phase to 1400 mg at the height of the breeding season.

28.5.1 Ovulation–Oviposition Cycle and Rate of Lay

The ovulation–oviposition cycle (the time from ovulation of an ovum to the oviposition of the calcified egg) of the domestic hen generally ranges from somewhat longer than 24–28 h in length, and ovulations proceed uninterrupted for several days, or as long as 1 year or more in extreme instances. The number of eggs laid on successive days is called a sequence, and each sequence is separated by one or more pause days on which no egg is laid. The term "clutch" is sometimes used synonymously with sequence, although the former term is generally considered more appropriate to describe the group of eggs laid by nondomesticated species prior to incubation behavior. The 24+h ovulation–oviposition cycle is characteristic of the chicken, turkey, and bobwhite quail. By contrast, the interval between successively laid eggs in the pigeon is reported to be 40–44 h and in the Khaki Campbell duck is 23.5–24.5 h.

In the domestic hen, the longer the sequence, the shorter the duration of the ovulation–oviposition cycle. The delay, or "lag", in hours between the oviposition of successive eggs in a sequence is not constant (Table 28.2). The differences in lag time within a sequence represent mainly variation in the amount of time between oviposition and the subsequent ovulation; this interval typically ranges from 15 to 75 min. It is clear that even when the lag between the oviposition of successive eggs approaches 24 h, there remains a progressive shift toward laying the egg later and later in the day. As the sequence becomes shorter, the lag becomes greater and the length of the ovulation oviposition cycle deviates more from 24 h. The total lag time between the first ovulation of a sequence (C1 ovulation) and last ovulation of a sequence (Ct ovulation) is greater in chickens (4–8 h depending on the sequence length) than in Japanese quail (1.5–5 h). The normal release of LH in the domestic hen is restricted to a 4–11 h period (the "open period") beginning at the onset of the scotophase (dark phase). The timing and regulation of the "open period" are as yet incompletely understood. For further details concerning the ovulation–oviposition cycle and the sequence, see Fraps (1955) and Etches (1990).

A chicken typically ovulates the first egg of a sequence early in the photophase, and the timing of ovulation is synchronized by the onset of the scotophase. In comparison, Japanese quail ovulate the first egg of the clutch 8–9 h after the onset of the photophase, and this appears to be synchronized by the timing of the light phase. The "rate of lay" refers to the number of eggs laid in a given period of time, irrespective of the regularity or pattern of laying. For example, a chicken laying at the rate of 50% for 60 days produces 30 eggs, the same number of eggs as another that lays at a rate of 75% for 40 days. On reaching sexual maturity (at ~20–22 weeks of age), the domestic hen lays with an erratic pattern (sequences with two or more pause days, or occasionally more than one egg per day) and with a high incidence of abnormal (soft-shelled and double-yolked) eggs for the first 2 weeks. Six to ten weeks after the onset of egg laying, production peaks (frequently at a rate of 90% or more) and gradually decreases over a period of 40–50 weeks, depending on whether the chicken is a laying or broiler breed. Subsequently, egg production progressively declines and the hen begins a period of molt. A typical laying strain of chicken will produce 280 or more eggs in a 50-week production period.

The physiological mechanisms responsible for regulating ovulation cycles in birds have been the topic of study for decades (Bastian and Zarrow, 1955; Etches and Schoch, 1984; Silver, 1986). Conventional models clearly predict that the primary signals involve multiple oscillatory sites at a central level (likely including the retina, pineal, and medial basal hypothalamus) and a local ovarian clock. It has been demonstrated that clock-related genes (e.g., Per2, Per3, Clock, Cry1, and Bmal1) are expressed in ovarian follicles from Japanese quail (Nakao et al., 2007) and the chicken (Tischkau et al., 2011); levels of clock proteins vary with photoperiod and stage of ovulatory cycle within both the granulosa and thecal layers. Such data provide evidence not only for a functional clock within the avian ovary, but also for the role of this local clock in regulating follicle growth, steroidogenesis, the rate of lay, and the timing of ovulation.

28.5.2 Parthenogenesis

Parthenogenesis (embryonic development from an unfertilized oocyte) has been documented in turkeys; 32–49% of infertile eggs may initiate development, but most embryos

TABLE 28.2 Composition of the Hen's Egg

From Romanoff and Romanoff (1949).

die at an early stage (Olsen, 1975; Cassar et al., 1998). Genetic selection can increase the incidence of parthenogenesis in turkeys, and viable poults are homozygous diploid males that are often sexually competent. Cytologic studies indicate that parthenogenesis in turkeys is initiated from a haploid oocyte and proceeds to the diploid state after a meiosis that is unaccompanied by cytokinesis (mitosis). Parthenogenesis has also been reported to occur in the domestic hen (<5% of eggs, with only a single parthenogenetic adult reported), in Chinese painted quail (*Coturnix chinensis*), and in the zebra finch (*T. guttata*) (Sarvella, 1970; Parker et al., 2012; Schut et al., 2008).

28.5.3 Maternal and Environmental Effects on the Embryo

Almost all birds provide some form of parental care that can be described as female-only care, male-only care, biparental care, cooperative breeding, or brood parasitism (conspecific or heterospecific) (Cockburn, 2006). Perhaps the exception is represented by the Australian brush turkey (*Alectura lathami*; one species from a lineage of galliformes, the megapodites), which uses geothermal heat provided by mounded soil and vegetation for egg incubation. At hatch, the chicks are fully developed and independent from any parental care. Moreover, there is evidence for temperature modification of the sex ratio at hatch in these birds in that a comparatively low incubation temperature (~31 °C) results in a 75:25% male–female ratio, whereas incubation at 34 °C results in approximately 28% male offspring. Many bird species can directly influence embryonic development not only via genetics but also by nongenetic input (e.g., the type and amount of yolk deposition, various hormones, and RNA transcripts). There is additional evidence that the embryo itself can perceive and actively adjust their own development in response to their environment. For instance, some embryos sense and respond to photoperiodic, olfactory, and auditory cues, and some are known to communicate via vocalizations prior to hatch (reviewed in Reed and Clark, 2011).

Several studies provide evidence for maternal modifications of offspring sex ratio based upon the predicted cost and survival of producing one sex or the other. This possibility is afforded largely because the avian female is heterogametic and because the sex-determining division in avian meiosis occurs prior to ovulation and fertilization. Among the mechanisms proposed to influence the sex ratio in birds are epigenetic modifications to bias the segregation of sex chromosomes, sex-specific fertilization, sex-specific incubation, and effects of maternal sex steroids (Rutkowska and Badyaev, 2008; Pike and Petrie, 2003). With respect to the latter, it is suggested that maternal plasma steroid levels may affect preovulatory mechanisms to influence the primary sex ratio (the ratio at fertilization), whereas steroids deposited during egg formation would influence the secondary sex ratio (ratio at hatch) (Goerlich-Jansson et al., 2013). Finally, the amount of maternally deposited progesterone (and/or androgen) in the eggs of the rockhopper penguin (*Eudyptes chrysocome*) is inversely related to body mass in the embryos, chicks, and adults; in turn, body mass is directly related to survivability. Thus, it is proposed that the selective regulation of yolk progesterone deposition may represent a strategy to regulate brood numbers according to food availability and expected survival (Poisbleau et al., 2011).

28.5.4 Photorefractoriness, Broodiness, Molt, and Reproductive Senescence

The final stage of an annual reproductive cycle consists of photorefractoriness, a state where the reproductive system no longer responds to changes in photoperiodic or supplemental cues. Absolute photorefractoriness is analogous to the prepubertal state, and both states are associated with a very low synthesis and content of hypothalamic GnRH and the absence of ovarian support by circulating gonadotropins. In passerine birds, photorefractoriness is programmed early in the reproductive season by the presence of thyroid hormones and a long photoperiod. High circulating levels of prolactin are thought to hasten the onset of photorefractoriness. In starlings, a transition toward photorefractoriness begins when the photoperiod exceeds 12L:12D and corresponds to a time when circulating concentrations of prolactin (PRL) are increasing. Peak concentrations of circulating PRL in starlings coincide with the onset of ovarian regression. This photorefractory state is terminated by a short photoperiod (less than 12L:12D) for some critical, species-dependent interval of time, after which GnRH production and secretion can be renewed. By comparison, relative photorefractoriness, such as occurs in quail, entails the regression of the ovary, but there is no marked decline in hypothalamic GnRH. Thus, recrudescence can occur during continued exposure to this photoperiod (Dawson, 2008). Nonphotoperiodic cues such as temperature, rainfall, social cues, and food availability can affect the timing of the onset of photorefractoriness, but there is no evidence that such cues influence the termination of photorefractoriness (Dawson and Sharp, 2007).

Often occurring coincident with photorefractoriness and regression of the ovary is the process of molt. This represents the replacement of old feathers with new, and is an important but one of the most energetically costly and inefficient endeavors experienced by birds. Accordingly, the timing of molt usually does not overlap with migration or reproduction; nevertheless, there are several examples when molt is initiated during egg laying, incubation, or chick rearing (Williams, 2012). When overlap does occur, molt proceeds over a longer period of time, the growth rate of feathers is

significantly reduced, and/or birds devote more time to feeding and less time to feather care. While little is yet known regarding the proximal environmental or physiological control of molt, in starlings there appears to be a clear association with prolactin levels and, specifically, decreasing levels of prolactin after a seasonal peak (Dawson, 2006). Immunization against VIP, the prolactin-releasing hormone in birds, inhibits photoperiodically induced prolactin secretion and molt. In commercial egg-laying flocks, forced molt represents a method to synchronize the termination of lay to maximize the production rate plus size and quality of eggs during a second year of lay. Forced-molting programs generally involve some form of stress such as withdrawing feed for the short term, providing a low-density diet, or creating an imbalance of nutrients.

Broody behavior is induced by elevated prolactin and consists of terminating egg production, initiating the incubation of eggs, and caring for the young. Broody females exhibit increased body temperature, reduced food and water consumption, plus aggressive and defensive behaviors. The onset of incubation occurs coincident with regression of the ovary and accessory reproductive tissues such as the oviduct and comb. In present-day commercial egg-producing hens, broodiness is virtually nonexistent (especially in Mediterranean breeds such as the white leghorn), but still exists in the bantam hen and broiler breeder, and is common in turkeys and geese. Broody behavior may be accompanied by the development of an incubation (or brood) patch, and the increased vascularity, edema, and thickening of the epidermis occur under the regulation of estrogen and prolactin. Incubation activity stimulates the development of the crop sac in the pigeon; proliferation of this gland is under the direct control of prolactin. In the ring dove, endogenous estrogen production, stimulated by FSH secretion, induces the female to nest build. In turn, the initiation of nest-building activity in the male is dependent on the hormonal environment and behavior of the female.

As occurs with photorefractoriness, the regulation of prolactin gene expression and secretion with broodiness occurs primarily via hypothalamic VIP. Induction of incubation behavior in turkey hens can be initiated by administration of prolactin, and active immunization against prolactin reduced the incidence or delayed the onset of broodiness in turkeys and bantam hens (March et al., 1994; El Halawani et al., 1995). VIP secretion is promoted by hypothalamic dopamine via a stimulatory dopamine receptor (DRD1). Dopamine can also inhibit the secretion of prolactin via an inhibitory receptor (DRD2) at the level of the pituitary (Youngren et al., 2002). Treatment of hens with a dopamine receptor antagonist resulted in the termination of broodiness by inhibiting secretion of prolactin. Behavioral broodiness in the female is preceded by decreases in circulating concentrations of LH, progesterone, testosterone, and estradiol, while growth hormone tends to be lower only while hens are caring for the young. Beginning with and during the period of lay, a basal production of prolactin is maintained by ovarian estrogens. With the initiation of broodiness, the circulating concentrations of prolactin are increased dramatically and remain elevated throughout incubation. This elevation in prolactin is accomplished in part by a transdifferentiation of pituitary somatotropes (growth hormone secreting cells) into cells that produce both prolactin and growth hormone (mammosomatotropes). Among species in which the male assumes the predominant role of incubation (e.g., Wilson's phalarope, *Phalaropus tricolor*), levels of prolactin are higher in the male than in the female (Oring et al., 1988). For further information, see Sharp (2009).

Evolutionary theories predict that any decline in reproductive performance with age (e.g., reproductive senescence) is related not only to environmental conditions to which the species or individuals within a species are exposed, but also to the rate of lay early in life. Thus, both species and individuals within a species that invest the most in early reproduction are most likely to undergo early senescence and also die sooner (Reed et al., 2008). Reproductive aging can be defined as any decline in reproductive performance, and includes a decrease in fitness of the offspring. By comparison, ovarian senescence constitutes a significant decline or loss of the primary follicle reserve within the ovary, and/or the significant loss of oocyte quality and capacity for fertilization. Reproductive senescence and the gradual decline in egg production in the domestic hen are associated with an increase in atresia of slow-growing follicles, plus a decrease in the rate of follicle selection into the preovulatory hierarchy (Waddington et al., 1985).

Holmes et al. (2003) have described female reproductive aging in birds according to three paradigms. The first is characterized by a relatively short life span with moderately rapid declines in fertility (e.g., many Galliformes, including chicken, quail, turkey, and pheasant). A second model consists of moderately slow-aging birds with a somewhat longer life span where the slow decline in reproductive success correlates closely with increased mortality (e.g., passerine songbirds, including the great tit, *P. major*, and small raptors like the European sparrow hawk, *Accipiter nisus*). The third model is characterized by long life spans, slow aging, and negligible reproductive declines in either sex. For instance, neither the common tern (*Sterna hirundo*; Nisbet et al., 1999) nor the Nazca boobie (*Sula granti*; Anderson and Apanius, 2003) appears to show an appreciable decline in reproductive effort even after 20 years of reproductive activity. Some terns and gulls have been reported to actually increase the number of offspring they successfully fledge with advancing age, although this may be more related to posthatch survival and parental behaviors than to enhanced ovarian fecundity. On the other hand, some species within the order Psittaciformes (parrots and cockatoos, which represent some of the longest living

birds) may breed for up to two decades, but they also live for many years past the termination of breeding (Young et al., 2011). These proposed models, although not yet rigorously tested, raise important questions regarding the role of the ovarian environment in promoting long-term germ cell survival and viability.

28.6 COMPOSITION AND FORMATION OF THE YOLK, ALBUMEN, ORGANIC MATRIX, AND SHELL

The avian amniotic egg is unique among vertebrates and, not unexpectedly, expresses several genes that have no apparent orthologs within nonavian lineages. These include the eggshell proteins, ovocalyxin-36 (a proposed pattern recognition molecule that contributes to innate immunity), ovocleidin-17, and ovocleidin-116 (a novel eggshell matrix protein), plus two unique ovalbumin proteins (ovalbumin X and Y) resulting from gene duplication (Tian et al., 2010). Components of the avian egg include the yolk, the albumen, the organic matrix, and the crystalline shell. Each component has been described in reviews by a number of workers, and the reader is referred to the following literature for more details: Gilbert (1971a,b), Simkiss and Taylor (1971), Hincke et al. (2008), and Solomon (2010). There appears to be some uniformity among many species of birds as to the density of yolk and albumen and the proportion of egg yolk relative to egg weight. However, variations do occur in the lipid, amino acid, and carbohydrate content of albumen and yolk, with precocial species (e.g., from the orders Anseriformes and Galliformes) having a higher energy density than altricial species (e.g., the pigeon, *Columba livia*, and pelican, *Pelecanus occidentalis*) (Roca et al., 1984; Bucher, 1987). Many of the egg membrane and shell matrix–related proteins (e.g., collagen, carbonic anhydrase, calbindin, vitamin D receptor, and osteopontin) are formed specifically in the eggshell gland or are present there in high concentrations (Arias and Fernandez, 2001; Soledad Fernandez et al., 2001).

The calcified eggshell is a unique mineralized structure that protects the growing embryo from dehydration, physical trauma, and infection by microorganisms, and it allows gaseous exchange while buffering against temperature fluctuations to maintain appropriate developmental conditions for the embryo. In addition to these functions, the eggshell contributes to embryo growth and development by acting as the major source of calcium; by late incubation, approximately 80% of the chick's calcium is derived from the eggshell. The two most likely routes of egg contamination by bacteria originate before shell formation from an infection of reproductive organs, or before and/or after oviposition via the penetration of pores in the eggshell; however, there is no apparent correlation between pore number and incidence of contamination.

28.6.1 Yolk

Egg yolk serves to provide the lipids and many, varied proteins required for embryonic growth. It is composed of a clear, yellow fluid (plasma) and suspended particles (granules containing lipovitellin and phosvitin, both derived from vitellogenin). The final composition of yolk in the hen's egg consists of approximately 36% lipid (by wet weight) compared to 17% protein. The greatest proportion of yolk is water (~50%) with lesser amounts of free carbohydrates (~1%) and inorganic elements (1–2%) (Anton, 2007). Of the major classes of lipids, approximately 70% are triacylglycerols, 25% are phospholipids, and 5% are cholesterol and cholesterol esters. Several antioxidants (e.g., carotenoids and vitamins) are also abundant in the egg yolk. Yolk is usually deposited in concentric bands that result from a nonuniform pattern of daily feed intake. One component responsible for conveying passive immunity to the developing embryo is the avian-specific antibody, IgY. Recently, a chicken yolk sac IgY receptor was characterized (FcRY, a member of the mannose receptor family); this receptor is responsible for selective IgY transport from yolk to the embryonic circulation (Tesar et al., 2008).

28.6.2 Albumen

There are four distinct layers of albumen in the fully formed egg: (1) the chalaziferous (inner thick) layer attached to the yolk, (2) the inner thin (liquid) layer, (3) the outer thick layer, and (4) the outer thin (fluid) layer. Approximately one-fourth of the total albumen by weight is found in the outer thin layer, and slightly greater than one-half in the outer thick layer. The inner layer represents ~17% of the total albumin, while the chalaziferous layer plus chalazae provides 2.7% of the total. One function of the egg albumen layer is to prevent invasion of microorganisms into the yolk (as discussed here), as well as to serve as a source of water, protein, and minerals to the embryo during development. The chalazae are two fiber-like structures at each end of the egg that permit a limited amount of rotation but little lateral displacement of the yolk.

In the domestic hen, the initial albumen layer is deposited by the caudal region of the infundibulum. The majority of albumen proteins are deposited by tubular gland cells of the magnum, while avidin is synthesized by the goblet cells under the influence of progesterone and estrogen. The discrete layers of albumen are the result of consecutive deposition either by different regions of the magnum or by changes that occur within the shell gland and with movement of the egg through the oviduct.

The major proteins found in albumen include (1) ovalbumen, 54% of total the albumen; (2) ovotransferrin (binds iron), 13%; (3) ovomucoid, 11%; (4) ovoglobulins (type G2 and G3), 8%; (5) lysozyme, 3.5%; and (6) α and β ovomucin, 1.5–3.0%. There are also several characteristic

proteins present in lesser concentrations, including avidin (approximately 0.05% of total protein), flavoprotein- and thiamine-binding proteins, ovomacroglobulin, and cystatin. Ovalbumen, synthesized in the laying hen oviduct, serves as a source of amino acids for the embryo during development, and, based on its homology to the serpin family of protease inhibitors, it may also suppress enzyme activity in the egg. Ovotransferrin acts primarily as an iron chelator, thereby helping to prevent bacterial growth within the egg. Ovomucin is a serine protease inhibitor and represents the major inhibitor of protease (primarily trypsin) activity in the egg; targeted enzymes may be produced by invading microorganisms. Alternatively, ovomucoid may serve to modulate the enzymatic degradation of albumin during embryo development.

Alpha-ovomucin (a glycoprotein) and β ovomucin (60% carbohydrate by weight) are insoluble, fibrous proteins that are responsible for the gel-like qualities of egg white, particularly in the thick layers. Ovomucins block the invasion of microorganisms, and they may express antiviral properties. The main biologic function of egg albumen lysozyme is lytic activity against gram-negative bacterial cell walls.

Several egg proteins are known for their ability to bind specific substrates (e.g., ovotransferrin binds iron, copper, and zinc; flavoprotein binds riboflavin; and avidin binds biotin and iron), and others act as protease inhibitors (ovomucoid, ovoinhibitor, cystatin, and ovomacroglobulin). Avidin is a progesterone-dependent secretory protein; its biologic role in the egg is likely related to its ability to sequester essential nutrients from bacteria by chelating minerals and inhibiting bacterial growth. Cystatin has antimicrobial and antiviral activities via its ability to inactivate proteases necessary for microbial metabolism or invasion of host tissues. While hens carrying a load of pathogenic bacteria will actively increase the export IgY to the egg yolk, it appears that antimicrobial proteins and peptides (e.g., defensins) are constitutively transferred from the oviduct to the albumen plus eggshell membranes and the eggshell; such proteins are active against a wide range of microbes (Bedrani et al., 2013).

28.6.3 Organic Matrix

The organic fraction of the eggshell consists of shell membranes, the mammillary cores, the shell matrix, and the cuticle. Although these components constitute only a small fraction of the entire eggshell, their integrity is critical to its formation and strength.

28.6.3.1 Shell Membranes

Shell membranes are organized into an inner membrane (~50–70 μm thick; remains uncalcified) and outer membrane (~15–25 μm; penetrates the adjacent mammillary cones of the calcified shell), and they are produced by the proximal isthmus region of the oviduct over a 1–2 h period. These membranes interface with the chorioallantoic membrane during embryonic development (Figure 28.5). The proteinaceous, disulfide-rich membranes lie adjacent to one another except at one end, where they part to form the air cell. There is some question as to whether epithelial cells or tubular gland cells of the isthmus are responsible for the secretion of the membranes. The membranes consist of a meshwork of protein fibers, cross-linked by disulfide and lysine-derived bonds, with small fibrous protuberances of uncertain function. The membranes are composed of type I, V, and X collagens (10%). The remainder of the fibrous component is composed of protein (70–75%) and glycoprotein (Leach, 1982). The membranes are semipermeable and permit the passage of gases, water, and crystalloids but not albumen. There is no relationship between thickness of the membranes and thickness of the shell, but membrane thickness does decrease with the age of the hen. Shell membrane thickness also decreases during incubation, which allows for increased water and oxygen permeability.

28.6.3.2 Mammillary Cores

The mammillary cores, which are projections from the outer membrane surface (Figure 28.5), represent the initial sites of calcification. They are composed largely of protein, but they also contain carbohydrate and mucopolysaccharides, and are formed by the epithelial cells of the isthmus. The mammillary cores represent the greatest proportion of organic material in the eggshell. Different species of birds have evolved eggs with shells containing different mammillary densities that meet calcium requirements imposed by different growth rates and modes of development. Precocial bird species grow slowly but have high mammillary density, while altricial bird species grow rapidly but have low mammillary density (Osterström and Lilja, 2012).

28.6.3.3 Shell Matrix

The organic shell matrix is a series of layers of proteins (glycoproteins and proteoglycans) plus acid mucopolysaccharide on which calcification takes place. The nonmineral components represent approximately 2% of the total organic composition of the eggshell. The matrix plus calcified crystals make up the outer palisade layer of the shell. The innermost region of the shell has a greater density of matrix compared to the outer regions. Both calcium-binding protein and carbonic anhydrase have been identified within the matrix. Deposition of the matrix occurs soon after the egg reaches the shell gland.

28.6.3.4 Cuticle

The outermost surface of the egg is often (but not always) covered by a thin waxy cuticle composed of polysaccharide,

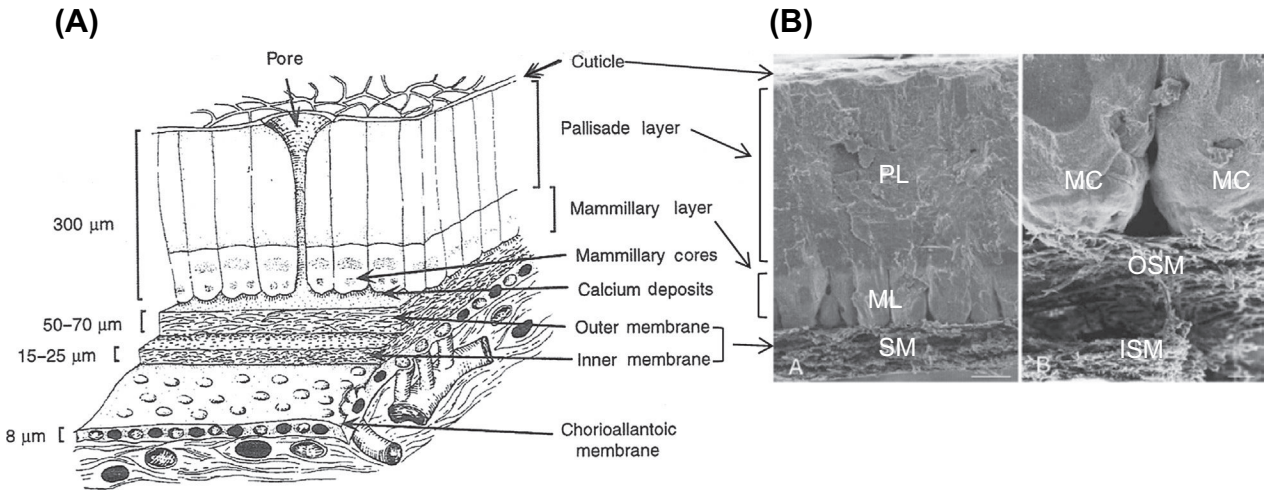

FIGURE 28.5 **(A) Diagram of a section through the shell and membranes of a hen's egg, showing the outer crystalline structure and the inner organic material that remains after calcium carbonate has been dissolved.** *(Adapted from Rahn et al. (1979). Copyright 1979 by Scientific American, Inc. All rights reserved.)* **(B) Scanning electron micrographs of a shell cross-section. ISM, inner shell membrane; OSM, outer shell membrane; MC, mammillary core; ML, mammillary layer; PL, palisade layer.** *From Hincke et al. (2000).*

lipid, and protein. Among the 47 different proteins identified are those with known antimicrobial activity (e.g., lysozyme C, ovotransferrin, ovocalyxin-32, cystatin, and ovoinhibitor) (Rose-Martel et al., 2012). The cuticle may be unevenly distributed over the entire surface, ranging in depth from 0.5 to 12.8 µm; the average dry weight of the cuticle in a 60 g chicken egg is 12 mg. Its function is primarily to protect the egg from water evaporation and microbial invasion; it is unlikely to add to the structural integrity of the shell. The cuticle, when present, is formed during the last 30 min prior to oviposition.

28.6.4 Layers of Crystallization

The eggshell is composed of three calcified layers; the mammillary, palisade, and vertical layers. The amount of calcium deposited in each egg typically represents about 10% of the body stores of calcium of the bird. Endogenous stores of calcium in females from smaller bird species may not be sufficient to meet calcium demand during egg laying, and thus they may be forced to forage specifically for calcium-rich food items (e.g., snails) during egg production and when providing nourishment for the nestlings (Wilkin et al., 2009).

The calcified portion of the shell can be arbitrarily divided into the mammillary knob layer, the palisade layer, and the outer surface, the vertical crystal layer (Figure 28.5). Collectively, these layers represent the major portion of the avian eggshell, are largely responsible for its mechanical strength, and consist of approximately 97% inorganic material. The degree of elasticity within the shell reflects interactions between the inorganic and protein components. While calcium is the predominant cation, the shell also sequesters a significant amount of magnesium in the form of magnesium carbonate; manganese is likely required for the development of the mammillae because of its role in the synthesis of mucopolysaccharides (Leach and Gross, 1983; reviewed by Hincke et al., 2012).

28.6.4.1 Mammillary Knob Layer

Outward crystallization of the mammillary cores results in the formation of the mammillary knob layer; some crystals grow inward to fuse with the outer egg membrane. In addition, calcium deposits radiate from the bottom of the mammillary cores to penetrate the outer shell membrane. Formation of the mammillary knobs occurs in the shell gland during the first 5 h of calcification. The passage of water during plumping stretches the shell membranes and increases the distance between the tips of the mammillae. Crystals that form laterally grow and eventually abut with crystals from other mammillae, whereas those that grow outward may extend to the shell surface. At some points, the crystals do not grow completely together, leaving pores with a diameter of 0.3–0.9 µm.

28.6.4.2 Palisade Layer

The crystallized palisade (or spongy) layer (approximately 200 µm thick) is composed mainly of crystalline calcium carbonate in the form of calcite and represents the greatest portion of the shell (Solomon, 2010). Calcification of this layer is initiated 5–6 h after the entrance of the egg into the shell gland, during the process of plumping. The palisade layer is arranged as columns situated directly over mammillary knobs that are perpendicular to the surface. As calcification proceeds, adjacent columns fuse to enhance the structural integrity.

28.6.4.3 Surface Crystal Layer

The outermost layer of calcification is designated the surface crystal layer. The crystalline structure is denser than that of the palisade region and lies perpendicular to the shell surface. The overall thickness of this layer ranges from 3 to 8 μm. The slow phase of shell formation corresponds to the formation of the mammillary layer, while the fast phase represents growth of the palisade and surface crystal layers.

28.6.4.4 Respiration via the Eggshell

Shell pores within the egg are simple funnel-shaped openings that arise at the shell surface and protrude through to the mammillary knob layer; they occupy approximately 0.02% of the eggshell surface. In most species, pores traverse the shell radially and branch longitudinally along the axis of the egg. The pores are the result of areas of incomplete crystallization. The number of pores (ranging from 7000 to 17,000) is generally related to metabolic demand prior to the initiation of lung function within the embryo; the number of pores per unit area decreases with increasing egg weight. The function of eggshell pores is to serve as a mechanism of chemical communication between the air cell of the egg and the external environment during embryo development (Tullett, 1984; Rahn and Paganelli, 1990). The exchange of oxygen, carbon dioxide, and water occurs predominantly via passive diffusion, and a 79 g turkey egg is estimated to exchange the equivalent of 271 of gas (oxygen, carbon dioxide, and water vapor) during the 28-day incubation period (Rahn et al., 1987). The average diffusive water loss during incubation for 117 species of birds is 15%; the loss is determined by the difference in water vapor pressure between the egg and nest environment. Inner and outer shell membranes play a minor role in limiting the flow of oxygen, carbon dioxide, and water vapor, while the major resistance to passage of these substances comes from the inner end of the pore. Therefore, air cell gas tensions are determined predominantly by the number and size of the pores and thickness of the shell relative to the metabolic rate of the embryo. The total area of pores on a turkey egg with a surface area of 90 cm^2 is calculated to be 2.2 mm^2.

Almost all avian eggs require turning during the process of incubation. Failure to do so prevents an even reduction of shell membrane thickness that reduces oxygen uptake and water permeability; in turn, this results in both decreased hatchability and delayed hatching. The elliptical shape of the avian egg provides for an air chamber at the blunt end that increases in volume as incubation progresses. There is a progressive increase in gas exchange and in pore density from the sharp end to the blunt end of the shell. The asymmetrical shape assures that the sharp end faces down during incubation to promote maximal gas exchange at the blunt end (Mao et al., 2007).

28.6.4.5 Eggshell Pigmentation

Egg coloration has been proposed to function as a mechanism to camouflage, mimic host eggs, filter solar radiation, or even indicate a female's genetic fitness and egg quality. Eggshell pigments include protoporphyrin (brown eggs; a pro-oxidant synthesized by shell gland epithelial cells), bilirubin (yellowish), and biliverdin (blue–green). In particular, the latter two are blood-derived bile pigments or can be synthesized in the shell gland, and both possess strong antioxidant activities. It has been suggested that eggshell color intensity (positively related to the concentration and amount of carotenoids) may serve as an indication of egg viability and subsequent fitness of the offspring. The synthesis and accumulation of pigment in the shell gland appear to be stimulated by progesterone.

28.6.5 Calcium Availability

Calcium requirements are increased dramatically both at the initiation of ovarian activity during puberty to promote medullary bone formation, and subsequently during each ovulatory cycle. The shell gland transports 2.0–2.5 g of calcium within a period of 11–15 h for the calcification of a single egg. A commercial hen that lays 280 eggs in a production year will use a quantity of calcium for the purpose of shell formation corresponding to 30 times the calcium content of the entire body. In general, calcium transport and homeostasis related to eggshell calcification are regulated by parathyroid hormone, calcitonin, and 1,25 dihydroxyvitamin D_3, and are mediated via at least five groups of proteins (calbindins, Na^+–Ca^{2+} exchangers, membrane localized calcium-ATPases, epithelial calcium channels, and tight junction proteins; this latter group is required for paracellular transport of calcium). A detailed description concerning mechanisms of absorption and changes in uptake by the intestine and shell gland relative to age and egg production are beyond the scope of the present discussion, and the reader is referred to Chapter 30 (on digestive tract) and Bar (2009).

28.6.5.1 Sources of Eggshell Calcium

Calcium for eggshell formation is provided via the blood following absorption from the intestine (duodenum and upper jejunum) or resorption from bone (principally medullary bone, but also cortical bone under conditions of calcium deficiency). Significantly, Ca^{2+} absorption is noticeably increased specifically during the period of shell calcification, and the mechanisms mediating this rhythmicity appear to be vitamin D related. Resorption of calcium from bone is regulated by both parathyroid hormone and 1,25-dihydroxyvitamin D_3, while absorption through the gut is facilitated by 1,25-dihydroxyvitamin D_3 only. The relative importance of the two organs as sources of calcium depends

on the concentration of dietary calcium. Laying hens consume approximately 25% more feed on days when eggshell formation occurs than on days when it does not. When the recommended concentrations of calcium in the food are 3.6–4.0%, a majority of the eggshell calcium can be derived directly from the intestine. Yet increased intestinal absorption during shell calcification is not sufficient to satisfy the high Ca^{2+} requirement for shell calcification; thus, as much as 20–40% of the shell calcium is derived from bone. The bone reservoir is subsequently replenished with Ca^{2+} from the intestinal source during the periods of eggshell gland inactivity. It is likely that these relationships vary depending on the time of day. When hens are provided constant free access to feed, much of the daily intake occurs early in the photoperiod; the remainder is consumed at the end of the photoperiod. However, much of the shell is formed during the night, when generally no calcium is consumed and when the calcium content of the digestive tract is gradually decreasing. Therefore, medullary bone is the primary source of shell calcium during the latter hours of darkness.

Blood calcium circulates in two forms, as nondiffusible protein bound calcium and as diffusible ionized calcium. Nondiffusible calcium is bound by plasma calcium–binding proteins, vitellogenin and albumin. Estrogen treatment increases total plasma calcium, in part by stimulating the production of blood calcium–binding proteins. Similarly, total plasma calcium increases several weeks before laying, and the increase is attributable to an increase in the protein-bound, but not in the diffusible, fraction. During the ovulation–oviposition cycle, concentrations of ionized calcium peak (0.057 mg/mL) 4 h after oviposition, then decrease significantly during the period of shell calcification (minimum of 0.049 mg/mL). On the other hand, plasma concentrations of total calcium (ionized plus inionized) fluctuate only minimally (between 0.2 and 0.26 mg/mL) during the ovulation–oviposition cycle.

Feeding a calcium-deficient diet to laying hens causes a significant decrease in plasma ionized-calcium concentrations, a significant decrease or complete cessation of lay, and regression of the ovary within 6–9 days. However, birds on the same diet injected with crude chicken pituitary extracts continued to lay for a more prolonged period, despite a comparable decrease in ionized calcium (Luck and Scanes, 1979a). Basal concentrations of LH in birds fed a calcium-deficient diet (0.2% Ca) are significantly lower compared to birds on a calcium-rich diet (3.0% Ca), but between the two groups the LH-releasing activity of exogenously administered GNRH is similar (Luck and Scanes, 1979b). These results suggest that pituitary LH synthesis and release, and the ability of the ovary to respond to gonadotropins, are resistant to a calcium deficiency. Mongin and Sauveurl (1974) determined that voluntary calcium consumption by laying hens increases at the time the egg enters the shell gland, and given a choice between a calcium-deficient diet (1.0% Ca) and a diet supplemented with calcium-rich oyster shell, hens will preferentially consume the calcium-rich diet during the period of eggshell calcification. (For a recent review, see Hincke et al., 2012.)

28.6.5.2 Vitamin D

Vitamin D plays an important role in the regulation of calcium metabolism via the metabolically active metabolite, 1,25-dihydroxyvitamin D_3. Conversion to this form occurs by the 1-hydroxylation of 25-hydroxyvitamin D_3 in the kidney under the hormonal control of estradiol and parathyroid hormone. For instance, renal 1-hydroxylase activity increases just prior to the initiation of egg laying, at a time corresponding with an increase in circulating estrogen and total plasma calcium. In addition, 1-hydroxylase activity during the ovulation–oviposition cycle increases at the time of ovulation. The increase in activity is followed by an increase in circulating concentrations of 1,25-dihydroxyvitamin D_3 4 h after ovulation, and elevated levels persist until 10 h after ovulation or after the initiation of eggshell formation. Among the proteins induced by 1,25-dihydroxyvitamin D_3 is osteopontin, a multifunctional, highly phosphorylated protein expressed by epithelial cells of the isthmus and shell gland specifically during the period of egg calcification. Once secreted, osteopontin is found in nonmineralized shell membrane fibers, the mamillary cores, and the outermost part of the palisade (Fernandez et al., 2003). For additional information regarding vitamin D and calcium metabolism, see Bar (2008).

28.6.5.3 Calcium Mobilization from Medullary Bone

In the long bones (e.g., the humerus, femur, and tibia), medullary bone lines the endosteal surface and grows with a system of interconnecting spicules that may completely fill the narrow spaces. Medullary bone forms in female birds during the final 10 days before egg laying under the influence of primarily estrogen, which stimulates osteoblast function. This type of bone is unique to birds and crocodilians, and it can be readily induced in intact male birds by administration of estrogen or in castrated males by estrogen and testosterone. Gonadal steroids apparently act directly on osteoblasts in the medullary cavity, and independently of calcium intake. In addition, it is unlikely that 1,25-dihydroxyvitamin D_3 mediates the transfer of calcium to medullary bone at this time, as the appearance of this bone occurs 1–2 weeks prior to the increase in renal 1 hydroxylase activity and the elevation of plasma total calcium.

During the ovulation–oviposition cycle, periods of intense medullary bone formation alternate with periods of severe bone depletion. Commercial hens fed a high-calcium diet are generally able to replenish the calcium lost from medullary bone during shell calcification when shell

formation is not taking place, but on a low-calcium diet the cortical bone of the femur is eroded, while medullary bone is maintained in a fairly constant amount. Under these conditions, the new medullary bone that forms is only partially calcified, and an increase in the number of osteoblasts is indicative of a more rapid turnover rate. Accordingly, continuous lay over a prolonged period of time is associated with increased susceptibility to osteoporosis. At the termination of lay, medullary bone is gradually lost and the formation of new structural bone is initiated. For additional information, see Whitehead (2004).

28.6.5.4 Calcium Absorption and Secretion by the Shell Gland

Our understanding of mechanisms mediating calcium transfer across the shell gland, as well as the hormonal regulation of the process, is still incomplete. The presence of Ca^{2+}-ATPase and calbindin, two critical components of the transcellular transport pathway, provide support in which Ca^{2+} is transported via both a transcellular pathway and an alternative or complementary paracellular passive transport pathway (Bar, 2009). As discussed in this chapter, the initiation of egg production is associated with increased 1,25-dihydroxyvitamin D_3 synthesis and accumulation in the intestine and shell gland, and calcium transport as well as concentrations of the calcium-binding protein, calbindin-D28K, increase in both organ systems during egg production. Calbindin is expressed in tubular gland cells of the shell gland and in the distal portion of the isthmus, but apparently not in the proximal isthmus or magnum. Calbindin synthesis in the intestine is regulated primarily by 1,25-dihydroxyvitamin D_3, yet its production in the shell gland apparently requires ovarian steroids and other, as yet unidentified, factors in addition to 1,25-dihydroxyvitamin D_3 (Bar et al., 1990). While levels of calbindin mRNA increase during the ovulatory cycle at a time coincident with shell calcification, there is little to no change in the tissue levels of calbindin protein; such results indicate posttranslational control of calbindin levels (Nys et al., 1989).

Calcium secretion from the shell gland increases approximately 7 h after ovulation, reaches a maximum as the shell is being formed, and decreases to the basal secretion rate after shell formation is complete but before the expulsion of the egg. The presence of an egg within the shell gland is not likely to be the major stimulus for the initiation of calcium secretion but appears to be more closely related to ovulation. The hormonal signals that affect changes in the rate of calcium secretion are unknown, although estrogen involvement has been suggested (Eastin and Spaziani, 1978a). Similarly, termination of a high rate of calcium secretion is not related to egg removal, as calcium deposition decreases fully 2 h before eggs are laid. Movement of calcium across the shell gland, which may occur by both diffusion and active transport (Eastin and Spaziani, 1978b), involves expenditure of metabolic energy. In the aged hen, calcium deposition and eggshell weight and density are related to shell gland levels of calbindin (Bar et al., 1992).

28.6.5.5 Carbonate Formation and Deposition

The mineral content of the eggshell consists of about 97–98% calcium carbonate, while the remainder consists of magnesium carbonate and tricalcium phosphate. Carbonate in the shell is derived from blood bicarbonate or is synthesized from CO_2 by carbonic anhydrase located in oviduct tissue and the shell. In addition, luminal carbonate ion content is supplemented by bicarbonate in fluid flowing from the magnum to the shell gland. The secretion from the shell gland of HCO_3, like that of calcium, is accomplished by active transport and may be influenced by luminal HCO_3 concentrations. The net amount of calcium secretion is functionally linked to HCO_3 production and to luminal HCO_3 concentrations. For further information on carbonate–bicarbonate production and calcium bicarbonate interactions and secretion, see Eastin and Spaziani (1978b).

Chapter 29

Reproduction in Male Birds

Jorge Vizcarra
Department of Food and Animal Sciences, Alabama A&M University, Huntsville, AL, USA

Rebecca Alan and John Kirby
College of the Environment and Life Sciences, University of Rhode Island, Kingston, RI, USA

29.1 INTRODUCTION

Reproduction is a process that can be organized into distinct developmental and functional phases. In the case of the male, these include fertilization, formation of a patent reproductive tract, production of sperm, manifestation of male-specific behavioral patterns, and expulsion of sperm from the body. This perspective can provide insight that may be missed if reproduction is viewed primarily as an isolated act. For example, although the reproductive tract is fully functional only in the adult, it is formed, for the most part, prior to hatching. Furthermore, although spermatogenesis is associated with puberty, spermatogenesis is not constrained by chronological age but rather by the extent to which testicular cells proliferate and differentiate which, in turn, is coupled to the developmental limitations of gonadotropin secretion. Finally, androgens essential to the function of the reproductive tract, the appearance of secondary sexual attributes, and male behavior may have detrimental effects upon the development of immune and connective tissue if the hormonal signal appears during the period of rapid prepubertal growth and differentiation. Thus, this chapter will discuss the process of reproductive system development and function in the male bird.

29.2 REPRODUCTIVE TRACT ANATOMY

29.2.1 Testis

The gross morphology and relative position of the male reproductive organs are shown in Figure 29.1. For detailed reviews, see King (1979); Lake (1981); Nickel et al. (1977). Paired reproductive tracts lie along the dorsal body wall. Each tract consists of a testis, an epididymis, and a highly convoluted deferent duct running alongside the ureter. The testes are connected to the body wall by a mesorchium. This peritoneal fold not only serves as an attachment for the testis but also as a conduit for nerves and blood vessels as well. Each testis is an aggregate of anastomosing seminiferous tubules, with associated interstitial tissue enveloped by a connective tissue capsule. The testicular capsule is an important component of the contractile mechanism of the testes and is composed of three layers, including the tunica serosa, tunica albuginea, and tunica vasculosa. Of these three layers, the tunica albuginea represents the main tissue layer and comprises cellular elements that alternate with thick bundles of collagen fibers. The testicular capsule is, in general, thinner in birds than in mammals; however, studies in ratite birds have revealed a capsule that is considerably thicker than that of other bird species (Aire and Ozegbe, 2007; Ozegbe et al., 2008).

The testis contains two types of parenchymal tissue: the interstitial tissue and the seminiferous epithelium. The interstitial tissue contains blood and lymphatic vessels, nerves, peritubular epithelial cells, and Leydig cells, whereas thin concentric layers of myoepithelial cells, fibroblasts, and connective tissue fibrils overlie the basal lamina of the seminiferous tubule (Rothwell and Tingari, 1973). The seminiferous epithelium within the seminiferous tubules of sexually mature males is compartmentalized into basal and adluminal regions via tight junctions between adjacent Sertoli cells (Bergmann and Schindelmeiser, 1987; Osman, 1980). The seminiferous epithelium contains developing germ cells in distinct associations referred to as *stages*. The stages are arranged sequentially in a helix that extends along the length of the seminiferous tubule (Lin and Jones, 1990).

In birds, the left testis is commonly larger than the right, which may either be a byproduct of evolutionary selection for asymmetry in the female reproductive tract or an adaptation to facilitate flight (Birkhead et al., 1998; Denk and Kempenaers, 2005). The overall size of the testis scales

Sturkie's Avian Physiology.

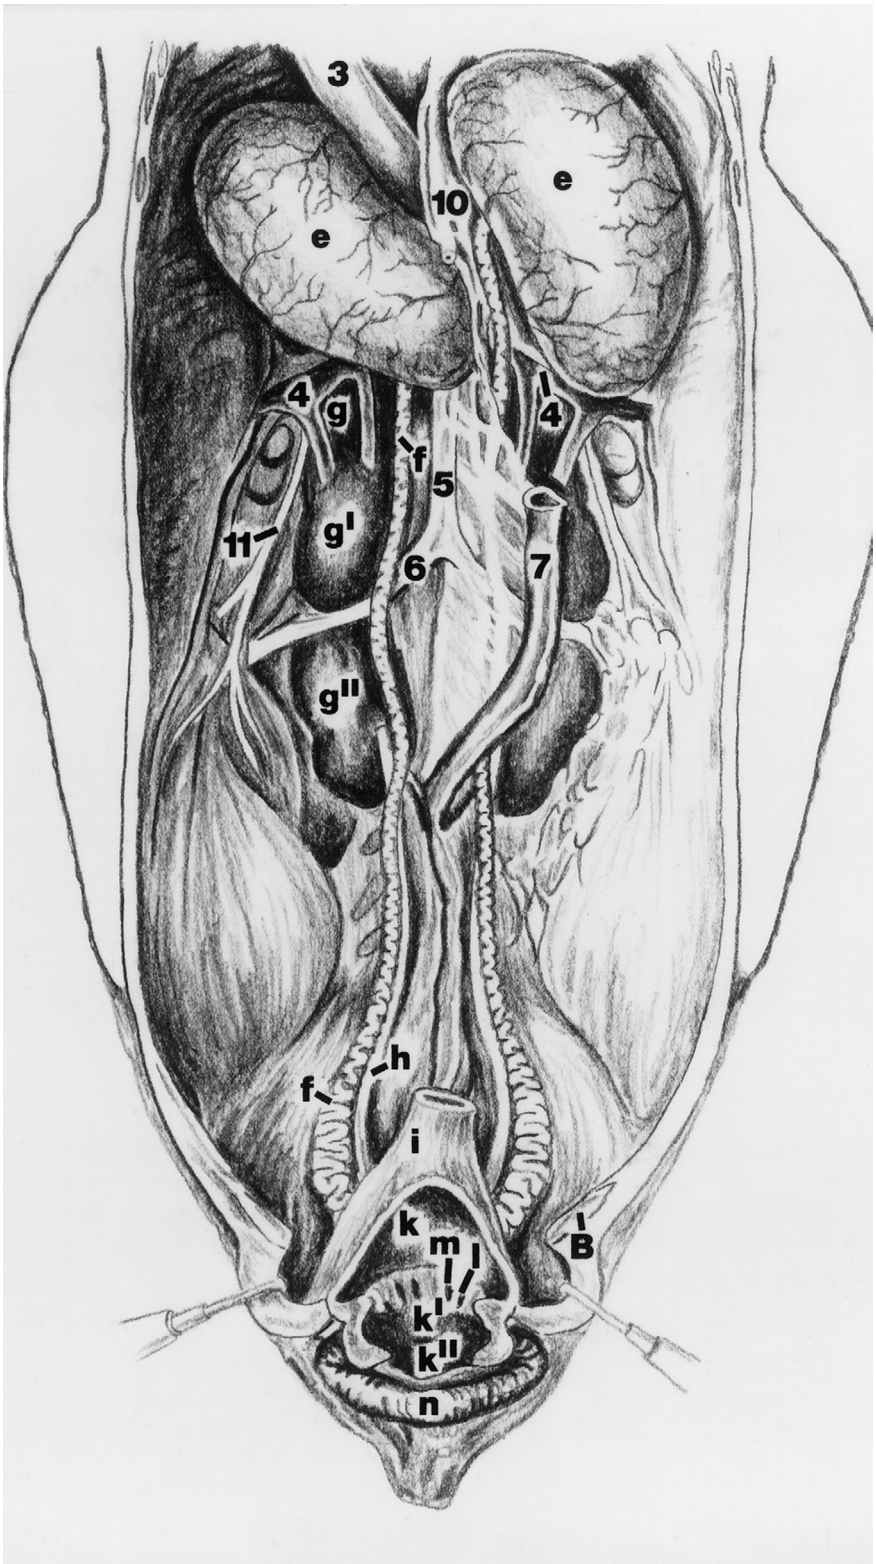

FIGURE 29.1 **Topography of the dorsal body wall of the rooster.** Paired testes (e) are located anterior to the cranial lobe of the kidneys (g). The deferent ducts (f) run alongside the ureters (h) towards the cloaca (k–k″), ultimately opening (l) into the urodeum (k′). Abbreviations: b, pubis; e, testis; f, ductus deferens; g, cranial; g′, middle, and g″, caudal lobes of the kidney; h, ureter; I, colon; k, coprodeum; k′, urodeum, k″, proctodeum; l, opening of left ductus deferens; m, opening of left ureter; n, anus. *Modified from Nickel et al. (1977).*

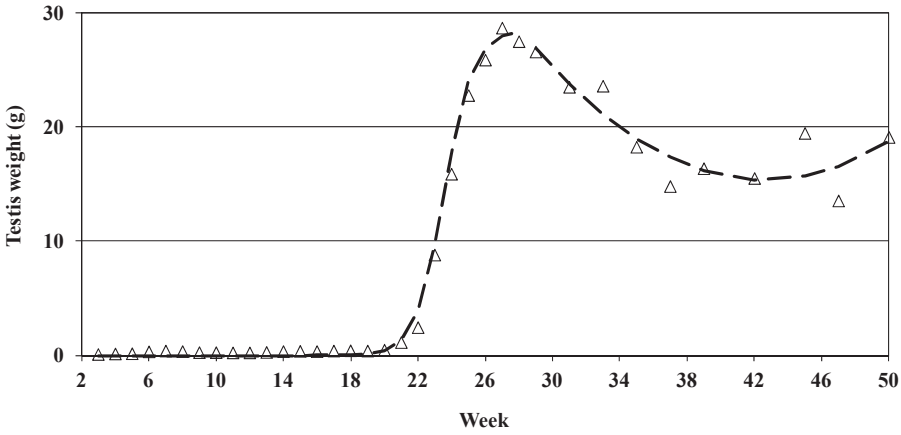

FIGURE 29.2 Least squares regression (lines) and means (symbols) for testis weight in male broiler breeders. Males on a "pedigree" breeder program were reared on a 23L:1D photoperiod and unrestricted food and water intake for 6 weeks. At 7 weeks, males were placed on a restricted diet and the photoperiod was reduced to 8L:16D. At week 18, birds were photostimulated (16L:8D) until the end of the experiment. Each symbol represents an average of 30 testes. *Modified from Vizcarra et al. (2010).*

allometrically to body mass; however, once controlled for body mass, testes size is often larger in bird species that experience a higher degree of sperm competition (Moller, 1991; Moller and Briskie, 1995; Pitcher et al., 2005). Sperm competition occurs when the sperm of two or more males is present in the female reproductive tract and must compete for egg fertilization. Although many bird species are socially monogamous, extrapair copulations often occur. Species that participate in extrapair copulations more frequently experience a more intense degree of sperm competition and have developed larger testis than species that do not frequently participate in extrapair copulations (Moller, 1991; Moller and Briskie, 1995; Pitcher et al., 2005).

In male broiler breeders, no significant differences were observed in the weight of the right and left testis from 2 to 50 weeks of age ($n = 2700$; Vizcarra and Kirby, unpublished results). Testes of male broiler breeders reared under a "pedigree" breeding program had an exponential increase in weight after photostimulation (18 weeks of age; Figure 29.2). Within 10 weeks (i.e., week 18–28), testis weight increased from 0.4 to 28 g. However, after 28 weeks of age, testis weight was significantly decreased, reaching a minimum weight of 15 g by week 42 (Figure 29.2). The reason for the testicular weight regression after 28 weeks of age, is not completely clear at this time. Decreased follicle-stimulating hormone (FSH) concentrations might be responsible for testicular weight regression (Vizcarra et al., 2010).

29.2.2 Excurrent Ducts

The excurrent ducts or excurrent canals are ducts associated with the male reproductive tract that derive from the mesonephros and encompass the efferent ducts, epididymis, and deferens ducts. The epididymis is located on the dorsomedial aspect of the testis, which is referred to as the hilus

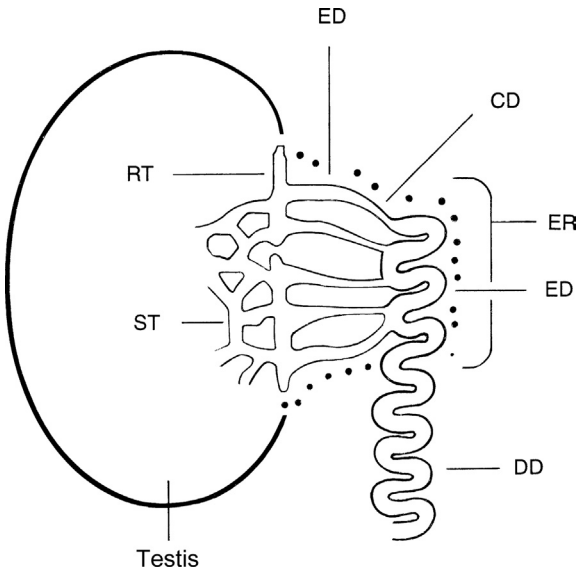

FIGURE 29.3 Schematic of the excurrent ducts of the testis. ST, seminiferous tubules; RT, rete testis; ED, efferent duct; CD, connecting duct; ER, epididymal region; ED, epididymal duct; DD, deferent duct. *Reproduced with permission from Academic Press, London and redrawn from Lake (1981).*

(Figure 29.3). The epididymis is actually a series of ducts that ultimately empty into the deferent duct. The ducts within the epididymis include the rete testis, efferent ducts, connecting ducts, and the epididymal duct. The epididymal ducts and the deferent duct are referred to collectively as the excurrent ducts of the testis. Seminiferous tubules connect with the rete testis at discrete sites along the testis–epididymal interface (Tingari, 1971). Osman (1980) identified three distinct types of junctures between the seminiferous tubules and rete testis of the rooster: (1) a germ cell free epithelium of modified Sertoli cells that abruptly gives way to a rete-like epithelium, referred to as a terminal segment and tubulus rectus,

respectively; (2) a terminal segment that connects directly to the rete testis; and (3) anastomosis of a seminiferous tubule with the rete testis. Tubuli recti have also been observed in quail testes (Aire, 1979a).

The rete testis has intratesticular, intracapsular, and extratesticular regions (Aire, 1982). As depicted in Figure 29.3, the rete testis exists as lacunae. In some avian species, including domestic fowl, quail, guinea fowl, and ducks, the rete testis is lined with simple cuboidal and simple squamous epithelial cells (Aire, 1982), whereas in ratite birds, such as the ostrich, the epithelium contains cuboidal and columnar cell types (Aire and Soley, 2000, 2003). In gallinaceous birds, the rete testis exits the hilus after coursing through the testicular capsule before entering the epididymis, which is in close proximity. In contrast, the rete testis of ratite birds makes up a much lower volumetric proportion of the epididymal tissue, and the rete testis travels a relatively larger distance from the testicular capsule before entering the epididymis (Ozegbe et al., 2010). Unlike the rete testis, the efferent ducts are wide at their proximal ends and narrow at their distal ends in many bird species (Aire and Soley, 2003; Simões et al., 2004); however, in ratite birds, both ducts are of similar height and diameter, which makes them less easily distinguished from one another (Aire and Soley, 2000; Ozegbe et al., 2006). On a volumetric basis (Table 29.1), the efferent ducts are the principal excurrent duct within the epididymis (Aire, 1979b; Aire and Josling, 2000). In most bird species, the efferent duct mucosa is highly folded, especially in the proximal portion (Aire, 1979a; Aire and Josling, 2000; Bakst, 1980; Simões et al., 2004; Tingari, 1971). In ratite birds, however, neither the proximal nor distal efferent ducts possess mucosal folds and they are regular in outline both internally and externally, which differs from other species (Ozegbe et al., 2006). In general, the efferent duct mucosa is characterized by a pseudostratified columnar epithelium that contains ciliated and nonciliated epithelial cells (Aire, 1980; Budras and Sauer, 1975; Hess and Thurston, 1977; Simões et al., 2004; Tingari, 1972) as well as sparsely distributed intraepithelial lymphocytes (Aire and Malmqvist, 1979a). The epithelium of the connecting ducts is also composed of pseudostratified columnar cells (Aire, 1979a; Aire and Josling, 2000; Bakst, 1980; Hess and Thurston, 1977; Tingari, 1971, 1972). The distinguishing attributes of the connecting tubules are a narrow luminal diameter relative to that of adjacent excurrent ducts and the smooth contour of the mucosal surface (Aire, 1979b; Aire and Josling, 2000; Bakst, 1980; Tingari, 1971).

TABLE 29.1 Species Variation in Volumetric Proportions (%) of Epididymal Structures[a]

	Species		
Structures	**Chicken**	**Japanese Quail**	**Guinea Fowl**
Rete testis	13.3	9.9	10.7
Proximal efferent ductules	27.6	40.8	45.7
Distal efferent ductules	7.7	15.2	16.2
Connecting ducts	2.3	1.7	0.7
Epididymal duct	7.6	2.4	1.8
Connective tissue	38.7	27.3	22.6
Blood vessels	2.5	2.7	2.3
Aberrant ducts	0.3	—	—

[a]*Adapted from Aire (1979a).*

The tortuous epididymal and deferent ducts are characterized by low mucosal folds covered with nonciliated pseudostratified columnar epithelial cells (Aire, 1979b; Aire and Josling, 2000; Bakst, 1980; Simões et al., 2004; Tingari, 1971). In gallinaceous birds, the epididymal duct constitutes between 2.5 and 10% of the total epididymal volume (Aire and Josling, 2000), whereas in ratite birds the volumetric proportion of the epididymal duct is as much as tenfold higher (Ozegbe et al., 2010). Based upon histological and morphological evidence, the deferent duct is a continuation of the epididymal duct. Luminal diameter gradually increases by threefold between the cranial epididymal duct and the distal deferent duct (Tingari, 1971). One notable difference between the epididymal duct and the deferent duct are the layers of dense connective tissue and smooth muscle surrounding the mucosa of the latter (Aire and Josling, 2000; Tingari, 1971). A dense capillary network envelopes the excurrent ducts from the level of the proximal efferent ducts to the deferent duct (Nakai et al., 1988). The distal deferent duct straightens and then abruptly widens at its juncture with the cloaca. This structure, known as the receptacle of the deferent duct, has a bean-shaped appearance when it is engorged with semen. Each deferent duct terminates in the cloacal urodeum as a papilla immediately below the ostium of a ureter (Figure 29.4).

29.2.3 Accessory Organs

Accessory reproductive organs include the paracloacal vascular bodies, dorsal proctodeal gland, and lymphatic folds (Fujihara, 1992). The accessory reproductive organs are either in proximity to or are an integral part of the cloaca. As shown in Figure 29.4, the paracloacal vascular body is found alongside the receptacle of the deferent duct, and lymphatic folds exist within the wall of the proctodeum.

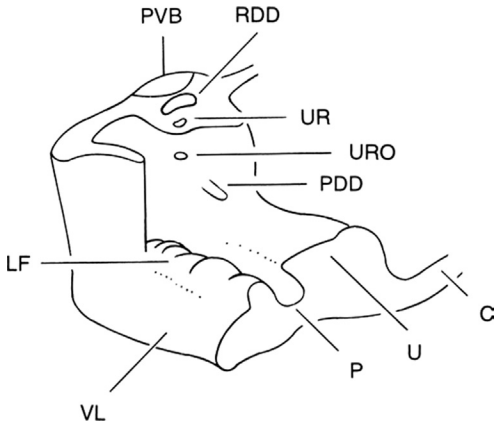

FIGURE 29.4 Schematic of the lower left quadrant of the cloaca. Before entering the cloacal wall, the deferent duct straightens then widens to form the receptacle of the deferent duct. The paracloacal body, also seen sectioned but shaded, is attached to the lateral aspect of the receptacle. The papilla of the deferent duct is within the urodeum of the cloaca. *PVB, paracloacal vascular body; RDD, receptacle of the deferent duct; C, ventral wall of coprodeum; U, ventral wall of urodeum; P, ventral wall of proctodeum; VL, ventral lip of vent; LF, lymphatic folds. Reproduced from King (1981), with permission from Academic Press.*

An intromittent phallus exists in only 3% of bird species (Herrera et al., 2013), including ratites and the waterfowl. In chickens, the phallus is nonintromittent and sperm is passed to the female via the "cloacal kiss" during mating (Briskie and Montgomerie, 2001). The cloacal kiss entails the union of the male and female cloacae for a few seconds. During copulation or in response to massage, a nonintromittent phallus forms a tumescent lymphatic tissue, which is everted through the vent immediately before ejaculation. As reviewed by Fujihara (1992), the paracloacal vascular bodies are essential for lymphatic tissue tumescence, as they are the sites where lymph is formed by ultrafiltration of blood. Thus, phallus erection in birds is lymphatic. In mammals, penile erection is blood-vascular and, during ejaculation, semen is transported via the urethra. However, in birds, semen is transported by the sulcus spermaticus, an external groove present in the phallus (Brennan et al., 2010).

Courtship behavior in male birds consists of searching and approaching a potential female (for an extensive review, see Ball and Balthazart, 2004). For instance, quails display a series of sexual behaviors that include mounting and aggressive pursuit for mating (Hutchison, 1978). Most of the evidence suggests that the medial portion of the preoptic area (POA) of the brain is responsible for the control of male behavior (Adkins and Adler, 1972; Konkle and Balthazart, 2011). The POA is significantly larger in males than females, and male castration causes a reduction of the volume of this area (Panzica et al., 1987). In addition, castration reduces the normal sexual behavior in males and exogenous testosterone restores the normal behavior (Ball and Balthazart, 2004). In castrated males, estrogen can also restore normal behavior, but co-injection of testosterone and an aromatase inhibitor blocks this effect (Balthazart et al., 1997). It is now widely recognized that aromatization of testosterone in the POA is responsible for the normal courtship behavior observed in male birds (Cornil et al., 2011; Wade and Arnold, 1996).

29.3 ONTOGENY OF THE REPRODUCTIVE TRACT

29.3.1 Overview

The adult male reproductive tract is derived from two embryonic organs: a gonad and its associated mesonephros. However, the formation of the mesonephros precedes that of the gonad (Figure 29.5). In fact, the gonad arises from the ventromesial surface of the mesonephros (Figure 29.6). As reviewed by Romanoff (1960), three distinct pairs of excretory organs appear sequentially during embryonic development: the pronephros, mesonephros, and metanephros. The most anterior organ, the pronephros, disappears by day 4 of incubation in the chicken. Nonetheless, the pronephric duct, also known as the Wolffian duct, persists through time to (1) induce the formation of the mesonephric tubules, (2) induce the formation of the Müllerian duct, (3) temporarily link the mesonephros with the cloaca, and (4) ultimately serve as the deferent duct in males. The critical point in the ontogeny of the reproductive tract is gonadal differentiation; prior to this point in time, the embryo has bipotential gonads and the rudiments of oviducts and deferent ducts in the form of the Müllerian and Wolffian ducts, respectively.

Sex determination in mammalian species is associated with the expression of the *SRY* gene located in the Y chromosome of the heterogametic XY male. The major function of the *SRY* gene is to facilitate Sertoli cell differentiation (via Sox9) that, in turn, promotes testis development as previously reviewed (Knower et al., 2003). In contrast to mammalian species, male birds are homogametic and females are heterogametic (ZZ and ZW gonosomes, respectively). Thus, the molecular mechanism of sex determination in birds is different from mammalian species. Because females are heterogametic, one possibility is that the W chromosome is responsible for female development. In this scenario, a factor (similar to the *SRY* gene in male mammals) will be coupled to female differentiation. However, very few W-linked genes have been reported in the literature (Hori et al., 2000; O'Neill et al., 2000), suggesting that other mechanisms are responsible for male development. A second possibility is that a gene in the Z chromosome triggers male development when two copies of the gene are present. The Z chromosome "dosage" theory states that higher doses of a gene can initiate male differentiation if the additional copy is transcribed and

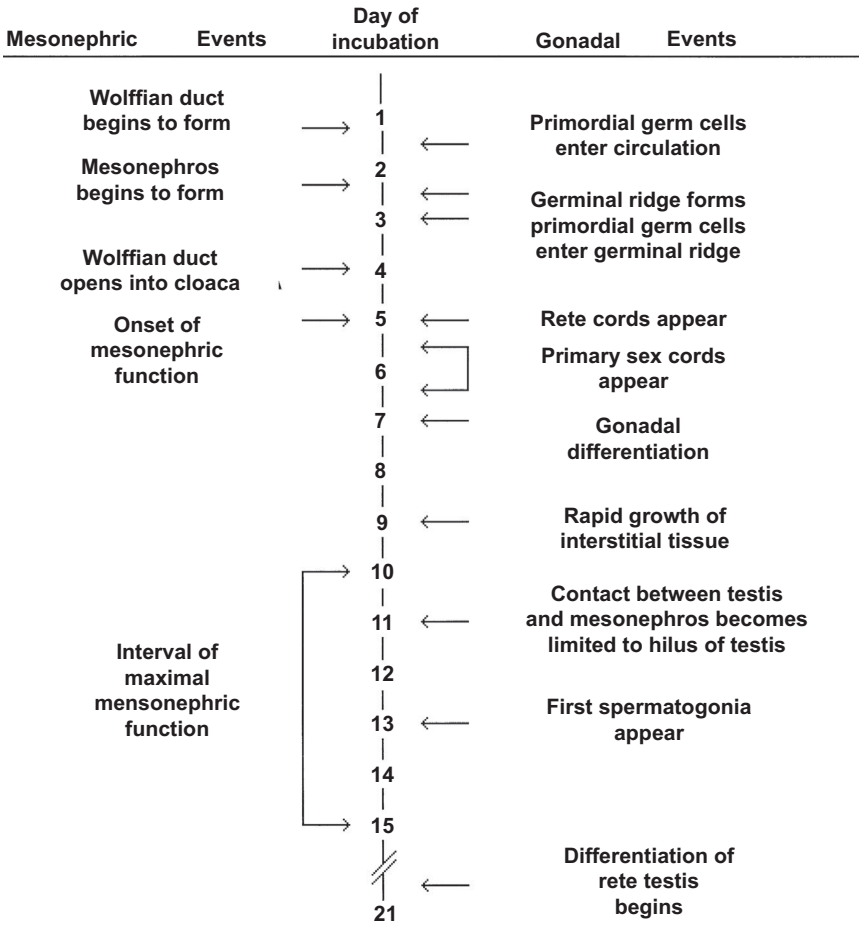

FIGURE 29.5 **Chronology of developmental events *in ovo* associated with the formation of the male reproductive tract in *Gallus domesticus*.** See text for details.

translated in higher doses of the resulting protein. It has been shown that the Doublesex and Mab-3 Related Transcription factor 1, encoded by the *DMRT1* gene, is a male sex-determining factor in chickens (Smith et al., 2009). In all birds studied to date, the *DMRT1* gene is present in the Z chromosome and absent in the W chromosome (Chue and Smith, 2011). Reduction of *DMART1* protein expression, using RNA interference (RNAi) technology in early male embryos, resulted in feminization of the gonads. These data and other support the Z chromosome "dosage" theory in birds (Chue and Smith, 2011; Nanda et al., 2008). Similar to mammalian species, there is evidence that activation of the male determining factor in birds facilitates Sertoli cell differentiation via Sox9 (Bagheri-Fam et al., 2010; Morais da Silva et al., 1996). Taken together, mammals and birds use a different molecular mechanism for sex differentiation (*SRY* and *DMRT1*, respectively). After genes are expressed, a common pathway that involves a Sertoli cell differentiation factor (Sox9) promotes testicular differentiation and development (Figure 29.7).

29.3.2 Formation of the Undifferentiated Gonad

Even though the gonad forms upon the ventromesial surface of the mesonephros, a fully differentiated mesonephros is not required for gonadal development (Merchant-Larios et al., 1984). The gonad is formed by the invasion of primordial germ cells into coelomic epithelium overlying a portion of the mesonephros (Figure 29.5), known as the germinal ridge (Clinton, 1998; Romanoff, 1960; Shimada, 2002). Primordial germ cells arise from endoderm along the anterior interface of the blastoderm's area opaca and area pellucida. After entering embryonic circulation, primordial germ cells are randomly distributed throughout the vasculature of the embryo (Meyer, 1964; Shimada, 2002). Subsequently, primordial germ cells colonize the germinal ridge (Fujimoto et al., 1976; Shimada, 2002). The undifferentiated gonad contains rete cords and primary sex cords in the anterior and middle regions, respectively (Romanoff, 1960).

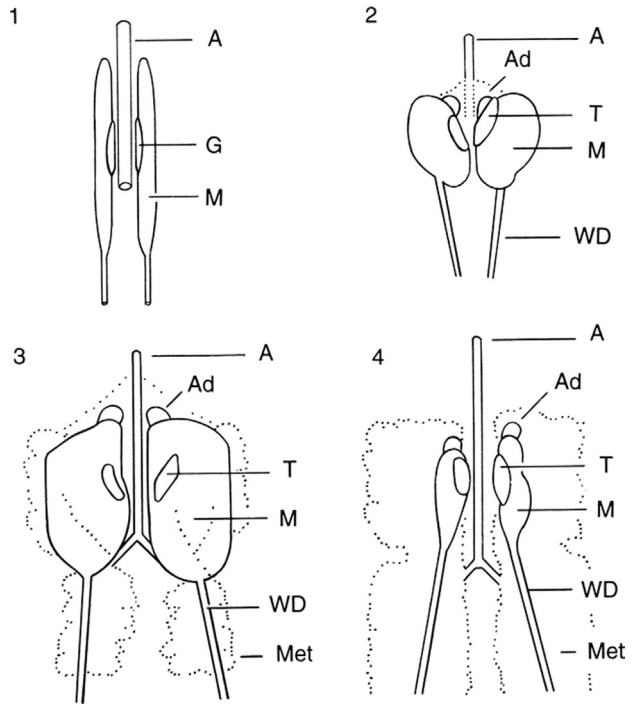

FIGURE 29.6 Stages in the development of the male urogential system. Numbers denote the first, second, third, or fourth quarter of incubation. The mesonephros forms before the differentiation of the gonad. After the metanephros becomes functional midway through incubation, mesonephric function declines and the mesonephros recedes apart from where it contacts the testis. FIGURE 29.7 Differential mechanisms for sex differentiation in mammalian and avian species. In mammals, the XY male uses the *SRY* gene, while in birds the ZZ male uses the *DMRT1* gene to facilitate Sertoli cell differentiation (via *Sox9*) that, in turn, promotes testis development.

29.3.3 Gonadal Differentiation and Müllerian Duct Regression

Gonadal differentiation in chick embryos occurs at approximately 6.5–7 days of incubation (Figure 29.5). In comparison to the ovary, the embryonic testis is characterized by a germinal epithelium that recedes with time, a thicker capsule, the absence of secondary or cortical sex cords, as well as the presence of primary sex cords surrounded by stroma (Clinton and Haines, 1999; Romanoff, 1960; Shimada, 2002). The primary sex cords contain numerous primordial germ cells and are anlage of the seminiferous tubules. Biochemically, gonadal differentiation is evident in terms of increased cyclic nucleotide concentrations (Teng, 1982), increased protein synthesis (Samsel et al., 1986), and the pattern of sex steroid synthesis (Guichard et al., 1977; Imataka et al., 1988; Mizuno et al., 1993). It is noteworthy that these traits become evident prior to the development of the pituitary–gonadal axis, which appears to become functional at 13.5 days of incubation in the chick (Woods and Weeks, 1969). It must also be noted that the interval of sexual bipotentiality differs among species.

Once the testes have formed, the Müllerian ducts cease development and undergo regression in a caudocranial direction (Hutson et al., 1985; Romanoff, 1960). Müllerian duct regression is attributable to anti-Müllerian hormone (AMH), also known as Müllerian inhibiting substance (Bruggeman et al., 2002; Smith and Sinclair, 2004). This hormone is a 7.4kDa gonad-specific glycoprotein (Teng et al., 1987), which, in the male, is derived from the progenitors of Sertoli cells found within the primary sex cords (Oreal et al., 2002; Stoll and Maraud, 1973). The gene encoding AMH is expressed in both males and females, but is consistently higher in males during sexual differentiation (Smith et al., 1999). Regression of the Müllerian ducts in males occurs because they contain insufficient circulating estrogen levels to counteract the effect of AMH, which may be a direct result of aromatase suppression by AMH itself (Bruggeman et al., 2002; Hutson et al., 1985; MacLaughlin et al., 1983).

29.3.4 Formation of the Excurrent Ducts

The excurrent ducts are derived from the mesonephros. As shown in Figures 29.5 and 29.6, the mesonephros is active throughout the second and third quarters of incubation. The functional unit of the mesonephros includes a malphigian corpuscle, proximal, intermediate, and distal tubules, as well as a connecting tubule. The latter connects the series of mesonephric tubules with the Wolffian duct. The malpighian corpuscle is a capillary tuft or glomerulus within a double-walled epithelial enclosure known as the Bowman's capsule.

The visceral epithelial layer adheres to the glomerulus. At the pole of the corpuscle where the afferent and efferent arterioles are attached to the glomerulus within, the visceral epithelium folds back upon itself to form the parietal epithelium. As the parietal epithelium extends away from the vascular pole, it is separated from the visceral epithelium by a lumen. While the mesonephros is functional, glomerular filtrate enters the lumen of the proximal tubule. After the metanephros becomes functional during midincubation (Romanoff, 1960), the mesonephros begins to degenerate except where there is contact with the embryonic testis. Consequently, the mesonephros undergoes a profound change in size during embryonic development (Figure 29.6).

During the last third of incubation, a subset of mesonephric tubules are converted into the excurrent ducts of the testis (Budras and Sauer, 1975) and the malphighian corpuscles in proximity to the rete cords fuse. The glomeruli undergo progressive degeneration while the simple squamous epithelial cells of the parietal epithelium differentiate into simple columnar cells. This tissue becomes the epithelium of the proximal efferent ducts. Proximal, intermediate, and distal mesonephric tubules are transformed into distal efferent ducts, connecting ductules become the connecting ducts, the Wolffian duct associated with the mesonephros becomes the epididymal duct, and the distal Wolffian duct becomes the deferent duct.

The transformation of the mesonephric ductules into the excurrent ducts of the testis is dependent on androgen production by the Leydig cells (Bruggeman et al., 2002; Maraud and Stoll, 1955; Stoll and Maraud, 1974), and is initiated shortly after the concentration of blood plasma testosterone has peaked *in ovo* (Woods et al., 1975). However, the entire process of ductule conversion in the chicken requires an interval of 8–10 weeks (Budras and Sauer, 1975; Marvan, 1969). During this time, mean plasma testosterone levels stay constant at about 12–13% of those observed in sexually mature males (Driot et al., 1979; Tanabe et al., 1979). In contrast to the mesonephric tubules, differentiation of the rete cords begins at about the time of hatching and is complete by 5 weeks of age (Budras and Sauer, 1975). The convolutions of the newly formed epididymal and deferent ducts increase until sexual maturity (Budras and Sauer, 1975). The final length of the deferent duct has been estimated to be 4 times greater than the linear distance between the epididymis and cloaca due to these convolutions (Marvan, 1969).

29.4 DEVELOPMENT AND GROWTH OF THE TESTIS

29.4.1 Proliferation of Somatic and Stem Cells in the Testis

The testis of the mature bird is organized into discrete, easily discernible cellular associations and functional compartments (Figure 29.8(D)). However, during embryonic and early posthatch development this organization is less apparent. The posthatch development of the fowl's testis can be divided into three distinct phases: (1) proliferation of spermatogonia and the somatic cells that support spermatogenesis (Sertoli, peritubular myoid, and interstitial cells); (2) differentiation and the acquisition of functional competence by somatic support cells; and (3) spermatogonial differentiation resulting in the initiation of meiosis. Although the boundaries of these phases are not clearly defined, this three-step process results in functional seminiferous tubules that can sustain spermatogenesis when the appropriate hormonal cues are present. There is some evidence that FSH may play an important role in embryonic gonad growth by stimulating cell division. Treatment with FSH increased the mitotic index in both the seminiferous tubules and peritubular cells of chicken embryo testis at around 14 days of development (Mi et al., 2004).

The testis of the young cockerel (approximately 0–6 weeks of age) is characterized by an abundance of interstitial tissue and seminiferous tubules with only a single layer of cells within the basal lamina (Figure 29.8(A)). The majority of cells located within the seminiferous tubules at this time are Sertoli cells and spermatogonia, with macrophages and mast cells observed as well (de Reviers, 1971a). The seminiferous tubules at this time are narrow (approximately 40 μm in diameter) with either a poorly formed lumen or no apparent lumen at all. This is a period of rapid cellular proliferation: although the tubules are only slowly growing in diameter, they are growing rapidly in length (de Reviers, 1971b). Even though the somatic and stem cells are proliferating, the absolute weight and volume of the testis is increasing slowly as the seminiferous tubules displace interstitial cells (de Reviers, 1971a; Marvan, 1969).

29.4.2 Differentiation of Somatic Cells within the Testis

Following a posthatching period of Sertoli cell proliferation, these cells become mitotically quiescent and differentiate (for a review see Russell and Griswold, 1993). In a study by de Reviers and Williams (1984), hemicastration was shown to result in compensatory hypertrophy of the remaining testis of males up to 8 weeks of age. As hemicastration typically results in significant hypertrophy only during the period of Sertoli cell proliferation in mammals, it is possible to postulate that Sertoli cells are proliferating in the fowl to about 8 weeks of age. A more recent study by Bozkurt et al. (2007) provides support for this hypothesis. In this study, the mitotic proliferation of Sertoli cells was observed in the testis of fowl from one to 10 weeks of age. Initially, the density of germ cell nuclei was less than that of Sertoli cell nuclei; however, by week 6, the volume density of the two cell types had converged and remained

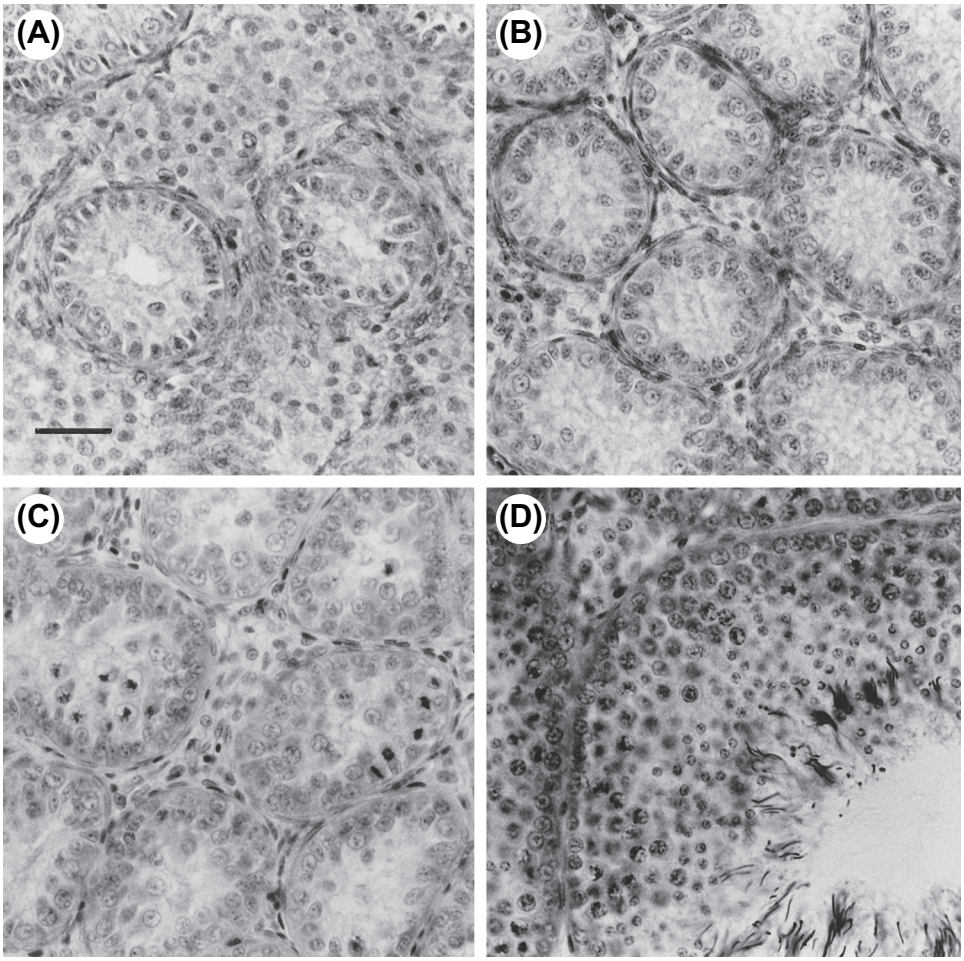

FIGURE 29.8 Cross-sections of testes of cockerels reared under 8 h of light (A–C) and of an adult male on 14 h of light (D). (A) Cross-section of a testis from a 14 day old male. Notice the simple single layer of spermatogonia and Sertoli cells in the tubules and the relative abundance of interstitial space. (B) Cross-section of a testis from a 56 day old cockerel. The single layer of cells within the seminiferous tubule has become taller and more complex. (C) Cross-section of a testis from a 140 day old cockerel. Notice the appearance of spermatocytes (cells with darkly stained chromatin) that have moved away from the basement membrane. (D) Cross-section of a testis from an adult male, which clearly demonstrates active spermatogenesis and the dramatic reduction in the relative area of the interstitium. The bar in (A) equals 20 μm; all of the micrographs are of equivalent magnification. *Photographs by the author.*

constant until the commencement of meiosis. In addition, clear labeling of both Sertoli and germ cells was observed from weeks one through seven but, by week eight, the only cells still labeled were germ cells. These data confirm that the cessation of Sertoli cell proliferation occurs around 8 weeks in domestic fowl.

Sertoli cells differentiate into highly polarized cells that extend from the basal lamina to the lumen of the seminiferous tubule. The mature Sertoli cell is a complex, columnar cell that contains numerous crypts into which developing sperm cells are embedded (Nagano, 1962; Sertoli, 1865, 1878). Sertoli cell functions are thought to be regulated by a myriad of endocrine and paracrine factors, although FSH and testosterone have been most thoroughly studied (Brown et al., 1975; Brown and Follett, 1977). A primary function of Sertoli cells is to provide a carefully regulated environment, including the sequestration of postmeiotic germ cells into the adluminal compartment is accomplished by the formation of tight junctions between adjacent Sertoli cells at a point basal to the maturing, meiotic, germ cell (Bergmann and Schindelmeiser, 1987; Pelletier, 1990). While tight junction formation appears to be androgen dependent in the fowl, tight junctions are maintained during periods of spermatogenic quiescence in the mallard (*Anas platyrhynchos*) (Pelletier, 1990). Another indicator of mature Sertoli cell function is the complex complement of proteins synthesized and secreted in response to androgen and/or FSH stimulation. While studied only superficially in male birds, spermatogenic stage-specific protein synthesis and secretion is well documented in other groups (see Russell and Griswold, 1993). As observed in other species, the close association of Sertoli and developing germ cells

in the fowl suggests that they are intimately involved in the regulation of germ cell development (Cooksey and Rothwell, 1973).

The growth of the seminiferous tubules is associated with a reorganization and reduction of the testicular interstitium (Figure 29.8(A)–(D)). Although the seminiferous tubule is the compartment where spermatogenesis will occur in the adult, Leydig cells of the interstitium are responsible for testicular androgen production. In the interstitium, there is the presence of mesenchymal cell-like Leydig cell precursors, which have vesicles of smooth endoplasmic reticulum and lipid droplets (Connell, 1972). The differentiation of these cells into their mature form is under the influence of luteinizing hormone (LH) (Brown et al., 1975; Driot et al., 1979; Narbaitz and Adler, 1966). Mature Leydig cells are formed following a continuum of cellular differentiation that occurs during the period of testicular growth leading to the prepubertal increases of circulating LH levels (Rothwell, 1973). Although limited testosterone production is observed during embryogenesis and early development, the capacity to produce testosterone at sexually mature levels requires the presence of a fully differentiated Leydig cell population (for a review of testicular steroidogenesis see Johnson, 1986). The mature Leydig cell of the rooster has extensive smooth endoplasmic reticulum, a prominent Golgi complex, mitochondria with tubular cristae, abundant lipid droplets, and lysosomal elements (Rothwell, 1973).

29.4.3 Initiation of Meiosis

During the period of Sertoli and Leydig cell differentiation, the population of spermatogonia increases in size and complexity. As described later in the chapter, spermatogonia undergo a series of transformations prior to committing to meiosis. However, once a spermatogonium is transformed into a preleptotene spermatocyte, it separates from the basement membrane and shifts toward the adluminal compartment of the seminiferous tubule. The onset of active meiosis is marked by the presence of pachytene and zygotene spermatocytes which are easily discernible due to their highly condensed and darkly stained chromatin (Figure 29.8(C)). The initiation of meiosis appears to occur only after the completion of Sertoli cell proliferation and an increase in circulating androgens is encountered (de Reviers, 1971a,b). The onset of meiosis can be significantly altered by manipulation of the photoperiod (Ingkasuwan and Ogasawara, 1966). When broiler breeders were reared on a 23L:1D photoperiod and *ad libitum* food and water intake for 6 weeks males showed precocious testicular maturation with zygotene or pachytene, or both, spermatocytes visible in all seminiferous tubules at 7 weeks of age. In contrast, when broiler breeders were reared on a 15L:9D photoperiod and *ad libitum* food and water intake for only 2 weeks, the structures previously described were not present at 7 weeks of age (Vizcarra et al., 2010).

29.4.4 Altering the Pattern of Testis Growth and Maturation

The temporal component of testicular maturation can be altered by manipulation of the endocrine milieu. Specifically, onset of meiosis and sustained spermatogenesis can be altered dramatically in the fowl by manipulating the photoperiod (Ingkasuwan and Ogasawara, 1966). Male fowl reared on a long photoperiod (14 h light or more per day) will typically have reached sexual maturity by 16–20 weeks of age (Ingkasuwan and Ogasawara, 1966; Sharp and Gow, 1983). However, as shown in Figure 29.8(C), when males are reared on short days (in this case 8 h of light per day) the onset of spermatogenesis is delayed. Eventually, male fowl became refractory to short days, FSH and LH levels increase, and spermatogenesis commences. Conversely, precocious puberty and the onset of spermatogenesis can be accelerated in the fowl by chronic treatment with tamoxifen, an estrogen receptor antagonist (Rozenboim et al., 1986). Males treated with tamoxifen exhibited adult behaviors and produced viable spermatozoa by 9 weeks of age, months ahead of their nontreated siblings (Rozenboim et al., 1986).

Testicular maturation can also be altered by exposure to estrogen and estrogen-like compounds. Rooster embryos exposed to ethinylestradiol, a synthetic form of estrogen, exhibited significant reduction in the average area of their seminiferous tubules. In addition, exposed birds had a decreased proportion of seminiferous tubules and an increase in the proportion of interstitial tissue (Blomqvist et al., 2006). In Japanese quail, male embryos exposed to ethinylestradiol became feminized and had ovary-like tissue within the testis along with persistent Müllerian ducts (Berg et al., 1999).

29.5 HORMONAL CONTROL OF TESTICULAR FUNCTION

29.5.1 Central Control of Testicular Function

Spermatogenesis is the process in which the division of spermatogonial stem cells ultimately yields sperm cells while a population of stems cells is maintained. This complex phenomenon occurs within the seminiferous epithelium and depends upon the availability of testosterone and FSH, the activity of Sertoli cells, as well as interactions between germ cells and Sertoli cells (Sharpe, 1994). Although spermatogenesis is controlled, in part, by cells

within the testis, the process is ultimately controlled by neurons within the central nervous system (CNS; see review by Sharp and Gow, 1983). Neurosecretory activity, in turn, is affected by somatic and environmental stimuli. Wingfield et al. (1992), have proposed a model accounting for the central integration of environmental information that affects gonadotropin secretion on a seasonal basis. The model is based upon the interplay of endogenous "predictive" rhythms and supplementary environmental information. The duration of the period of light in a subjective day (24 h period) is the principal environmental factor that stimulates spermatogenesis in galliform birds. As reviewed by Kuenzel (1993), photoreceptors that affect spermatogenesis are neither found within the retina nor the pineal gland. Most of the evidence suggests that the most plausible site associated with the photoperiodic response is the medial basal hypothalamus (MBH) via direct innervations of GnRH neurons by encephalic photoreceptors (Saldanha et al., 2001), or via the pars tuberalis of the adenohypophysis (Yasuo and Yoshimura, 2009; Yoshimura, 2006, 2010). It has been reported that the pars tuberalis synthesize and secretes β-TSH (thyroid stimulating hormone) when Japanese quails are exposed to long-day stimulation (Yoshimura et al., 2003). In turn, TSH is retrogradely transported to the MBH via non-classical mechanisms (Krieger and Liotta, 1979; Mezey et al., 1979). In the MBH, TSH regulates the expression of genes encoding type 2 (*Dio2*) and type 3 (*Dio3*) deiodinases. Thyroxine (T4) is converted (within the MBH) to the bioactive T3 (triiodothyronine) form that, subsequently, stimulates the photoperiodic response of the gonadal axis (Yoshimura et al., 2003).

29.5.2 Control of Adenohypophyseal Function in Males

Gonadotropin-releasing hormone (GnRH) is a decapeptide that plays a fundamental role in the release of gonadotropins from the pituitary gland, and is the primary hormone that regulates reproduction. Andrew Schally and his team isolated and synthesized for the first time the decapeptide GnRH, after the extraction of more than 250,000 pig hypothalami (Matsuo et al., 1971; Wade, 1978). In addition to GnRH, the occurrence of other two GnRH isoforms was first reported in chickens more than 10 years after of Dr Schally's initial report. The nomenclature used to distinguish different GnRH isoforms between mammalian and non-mammalian species have been described using a variety of phylogenetic and genomic synteny analyses (Kim et al., 2011; Millar et al., 2004; Roch et al., 2011; Tostivint, 2011). For the purpose of this chapter, we adopted the nomenclature based on the species in which they were first discovered, depicted in Table 29.2, and described elsewhere (Millar et al., 2004).

Chicken GnRH-I (King and Millar, 1982; Miyamoto et al., 1982) differs in only one amino acid compared with the mammalian form (cGnRH-I; [Gln8]-GnRH); whereas chicken GnRH-II (Miyamoto et al., 1984) differs in three amino acids (cGnRH-II; [His5-Trp7-Tyr8]-GnRH). The coordination of gonadotropin secretion via cGnRH is also modulated by the interaction of the GnRH peptide with its receptors. The Gonadotropin-releasing-hormone receptors (GnRHR) have the characteristic feature of a classical seven-transmembrane, G-protein-coupled receptor (Millar, 2003, 2005; Neill, 2002). Four vertebrate GnRHR lineages have been proposed using genome synteny and phylogenetic analyses; nonmammalian type I, nonmammalian type II, nonmammalian type III/mammalian type II, and mammalian type I (Kim et al., 2011).

Two GnRHRs have been identified in chickens (McFarlane et al., 2011; Shimizu and Bedecarrats, 2006). The nonmammalian type I receptor is predominantly express in the chicken pituitary gland (Joseph et al., 2009; Shimizu and Bedecarrats, 2006), whereas the nonmammalian type II receptor is not only expressed in the in the pituitary and the brain, but also in the in the gonads and other tissues (Sun et al., 2001a). The nonmammalian type I receptor

TABLE 29.2 Amino Acid (AA) Sequence of GnRH Isoforms

	1 2 3 4 5 6 7 8 9 10
Mammal (mGnRH)	**pGlu-His-Trp-Ser**-Tyr-Gly-Leu-Arg-**Pro-Gly**
Chicken-I (cGnRH-I)	**pGlu-His-Trp-Ser**-Tyr-Gly-Leu-Gln-**Pro-Gly**
Chicken-II (cGnRH-II)	**pGlu-His-Trp-Ser**-His-Gly-Trp-Tyr-**Pro-Gly**

The bolded regions represent the conserved NH_3- and COOH- terminal residues. The numbers represent the relative position of each AA in the GnRH peptide (1 represents the N-terminal AA).

in chickens (NCBI accession number: NP_001012627) has been previously referred as cGnRH-R-III (McFarlane et al., 2011), GnRHR1/III (Kim et al., 2011), or GnRHR2 (Shimizu and Bedecarrats, 2006), whereas the nonmammalian type II receptor in chickens (NCBI accession number: NP_989984) has been previously referred as cGnRH-R (Kim et al., 2011; Sun et al., 2001b) or cGnRHR 1 (Shimizu and Bedecarrats, 2006).

The affinity of the cGnRH-I peptide to the nonmammalian type II receptor is higher than the affinity of cGnRH-II peptide to the same receptor (Sun et al., 2001b). The nonmammalian type I receptor in the chicken pituitary is differentially expressed with respect to the reproductive status, and is associated with the control of gonadotropin secretion (McFarlane et al., 2011).

In the chicken, GnRHergic neurons arise within the olfactory epithelium on day 4.5 of embryonic development; reach the CNS by migrating along the olfactory nerve, and stop migrating by day 12 of embryonic development (Sullivan and Silverman, 1993). GnRHergic neurons are found within extrahypothalamic and hypothalamic sites (Kuenzel and Blahser, 1991). However, only those neurons whose axons terminate within the median eminence are believed to induce gonadotropin secretion *in vivo* (Mikami et al., 1988). Based upon immunocytochemical analysis, GNRH-positive axons are found within the median eminence by day 14 of embryonic development (Sullivan and Silverman, 1993). The significance of GnRHergic neurons was demonstrated well in advance of the purification of chicken GnRH with experiments that induced functional castration by either electrolytic lesions or deafferentation within the hypothalamus (Davies and Follett, 1980; Ravona et al., 1973). Axons of GnRHergic neurons terminate in proximity to capillaries within the median eminence of the hypothalamus. GnRH secreted from these axons reaches target cells within the adenohypophysis via the hypothalamo-hypophyseal portal vessels (Gilbert, 1979).

In avian species, only indirect measurements of the GnRH pulse generator is available by measuring plasma LH concentrations in frequent samples or in pituitary extracts (Chou and Johnson, 1987; Sharp and Gow, 1983; Wilson and Sharp, 1975). In addition, the episodic nature of LH and FSH was evaluated in unrestrained male broiler breeders using serial blood sampling (Vizcarra et al., 2004). Gonadotropin secretion in males is characterized by a pulsatile pattern with LH pulses being more frequent and having greater amplitude than FSH pulses (Figure 29.9). In chickens, LH- and FSH-containing gonadotrophs reside in separate cells within the pituitary gland (Proudman et al., 1999). We observed that there was a lack of synchrony between the episodic release of LH and FSH. Only 23% of the LH pulses were associated with FSH episodes, suggesting that in the adult male fowl LH and FSH secretion are regulated independently (Vizcarra et al., 2004).

Both cGnRH-I and -II stimulates gonadotropin release *in vivo* and *in vitro* in the chicken. However, most of the evidence indicates that cGnRH-I is the prime regulator of gonadotropin release in birds (Dawson and Sharp, 2007; Katz et al., 1990; Sharp et al., 1990; Stevenson et al., 2012; Ubuka and Bentley, 2009).

Nevertheless, the relative contribution and the potency of each cGnRH isoforms on the hypothalamic–pituitary–gonadal (HPG) axis of male birds is controversial. For instance, cGnRH-II was not found in the median eminence of the male white-crowned sparrow (*Zonotrichia leucophrys gambelii*), suggesting that in these species cGnRH-II does not regulate pituitary gonadotropin secretion (Meddle et al., 2006). On the other hand, concentrations of FSH in small cockerels were not affected by cGnRH-I challenges (Krishnan et al., 1993).

In immature cockerels (Chou et al., 1985) and male turkeys (Guemene and Williams, 1992), GnRH-II was more potent than GnRH-I *in vitro* and *in vivo* to release LH, suggesting that very small doses of GnRH-II at the pituitary level might be sufficient to induce gonadotropin release. However, no significant differences were observed between cGnRH-I and cGnRH-II, in LH releasing activity from young cockerels' pituitary samples (Hattori et al., 1986). When the LH response to cGnRH-I and -II was evaluated in cockerels, both peptides were equally potent (Sharp et al., 1987). However, in a similar experiment, the response to cGnRH-II, in terms of LH release was consistently greater than the response to GnRH-I in male chickens (Wilson et al., 1989). These data suggests that there may be age differences in the LH response to both decapeptides. Whether this differential response is due to different steroid inhibitory feedback mechanism is still unknown. The negative feedback of testicular steroids on GnRH-I have been reported in starlings (*Sturnus vulgaris*). Castrated male starlings significantly increased immunoreactive GnRH-I in the rostral POA of the hypothalamus, suggesting that this may represent the neuroanatomical location that mediates steroid negative feedback (Stevenson and Ball, 2009).

Active immunization against cGnRH-I and cGnRH-II in adult broiler breeder males was associated with a differential response on the ability to produce an immune reaction (Vizcarra et al., 2000). Titers were increased in cGnRH-I but not in cGnRH-II treated birds compared with BSA immunized males (Figure 29.10). Concentrations of LH and FSH in frequent samples were not affected by treatment; however, testis weight was significantly decreased in cGnRH-I birds compared with the other treatments (Figure 29.11). Taken together, these data support the idea that cGnRH-I is the prime regulator of gonadotropin release in male birds.

Behavioral, visual/auditory cues, and the breeding season also regulates GnRH-I and -II in birds. In male ring doves (*Streptopelia risoria*) and male starlings (*S. vulgaris*), courtship interaction increases cGnRH-I synthesis (Mantei

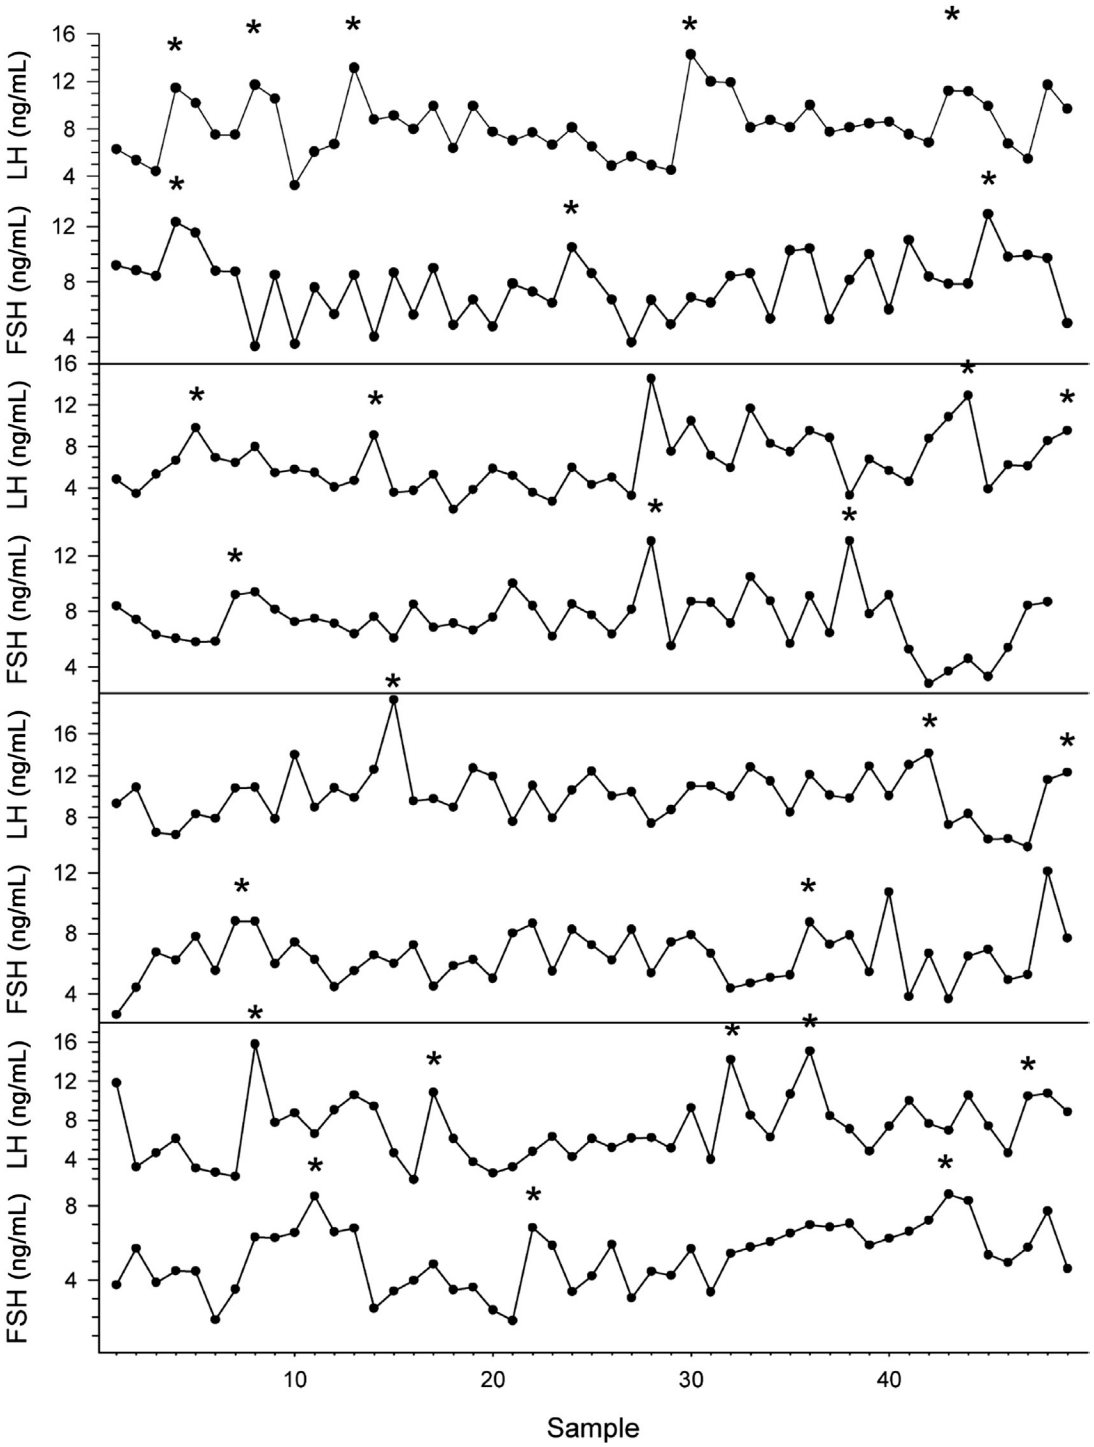

FIGURE 29.9 Pulsatile secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in plasma of four birds. Blood samples were obtained every 10 min for 8 h. Asterisks indicate the presence of a pulse of LH or FSH, as determined by Pulsar. *Adapted from Vizcarra et al. (2004).*

et al., 2008; Stevenson and Ball, 2009), suggesting that sexual behavior can have a significant effect on the HPA axis. In most seasonal breeder birds, the stimulation of the gonadotropic axis is influenced by photoperiod (for a review see Dawson and Sharp, 2007). Hypothalamic photoreceptors transduce the energy from light into a biological signal that regulates the secretion of GnRH. Encephalic photoreceptors are in close proximity with GnRH-I neurons, indicating that brain photoreceptors communicate directly with GnRH-neurons and terminals (Saldanha et al., 2001). During the breeding season, GnRH-I increases in males birds including the house finches (*Carpodacus mexicanus*), the dark-eyed juncos

(*Junco hyemalis*), and the European starlings (*S. vulgaris*) (Cho et al., 1998; Deviche et al., 2000; Foster et al., 1987). However, the contribution of GnRH-II during the breeding season (if any) is far from being fully elucidated. In nonbreeding mature male Zebra finch (*Taeniopygia guttata*) the number of cGnRH-II neurons is significantly reduced during the nonbreeding compared with the breeding season, but the area and optical density of the stained cells did not differ (Perfito et al., 2011).

Until recently, there was no known neuropeptide that directly inhibited gonadotropin secretion; however, Tsutsui et al. (2000) isolated gonadotropin-inhibitory hormone (GnIH), a hypothalamic dodecapeptide from the Japanese quail. This dodecapeptide consists of 12 amino acids in the sequence Ser(62)-Ile(252)-Lys(233)-Pro(226)-Ser(38)-Ala(194)-Tyr(173)-Leu(148)-Pro(104)-Leu(108)-Arg(45)-Phe(52) with RFamide at the C-terminus. GnIH significantly inhibits LH and FSH release in cultured quail cells (Tsutsui et al., 2000) and also inhibits circulating LH *in vivo* when administered continuously via osmotic pump (Ubuka et al., 2006). Interestingly, chronic GnIH treatment inhibits photoinduced testicular development, causes decreased plasma testosterone and testicular apoptosis, and results in decreased spermatogenic activity in the testis of adult quail (Ubuka et al., 2006). Similarly, testicular growth and plasma testosterone are suppressed in immature quail (Ubuka et al., 2006). Osugi et al. (2004) found that GnIH injected simultaneously with GnRH inhibited plasma LH surge in song sparrows and decreased LH concentrations in breeding free-living Gambel's white-crowned sparrows. GnIH reactive neurons were found to be localized within the paraventricular nucleus and mesencephalic regions of the hypothalamus in quail, white-crowned sparrows, and European starlings (Bentley et al., 2003; Tsutsui et al., 2000; Ubuka et al., 2003; Ukena et al., 2003). In addition, the GnIH receptor was found to be expressed in the thecal cells, Leydig cells, germ cells, and epididymis in male quail, which suggests roles for the hormone in regulating: gonadal steroid synthesis and release, differentiation of germ cells, and sperm maturation (Bentley et al., 2003, 2008).

Melatonin may be a key factor involved in GnIH neural functions because the neurons of male quail have been found to contain a receptor for melatonin (Ubuka et al., 2005). Administration of melatonin via injection stimulated the expression of GnIH in a dose-dependent way in birds that had undergone pinealectomy and orbital enucleation (Ubuka et al., 2005). In addition, hypothalamic explants from quail exposed to long-day photoperiods released greater amounts of GnIH during dark periods than during light periods *in vitro*. Conversely, LH concentrations decreased during dark periods. GnIH expression also increased under short-day periods when the duration of nocturnal melatonin secretion typically increases (Chowdhury et al., 2010). These results suggest a role for melatonin in stimulating the release of GnIH in birds and subsequently inhibiting gonadal activity and sex steroid levels by deceasing gonadotropin synthesis and release.

29.5.3 Effects of Gonadotropins on Testicular Function

Gonadotropins exert their effects on the testis by binding to specific cell-surface receptors on two distinct types of testicular parenchymal cells: Leydig and Sertoli cells. These cells have been described in detail by Rothwell (1973) and by Cooksey and Rothwell (1973), respectively. The principal role played by each type of cell has been determined by experiments in which one type of gonadotropin has been administered to hypophysectomized males, sexually immature males, or, in the case of Leydig cells, cells in culture (Brown et al., 1975; Ishii and Furuya, 1975; Ishii and Yamamoto, 1976). Such experiments have demonstrated that the principal effects of LH and FSH are exerted upon Leydig cells and Sertoli cells, respectively.

Leydig cells contain the steroidogenic enzymes necessary for the production of androgens (reviewed in Johnson, 1986) and respond rapidly to LH through rapid increases in the second messenger cAMP (Maung and Follett, 1977). The principal steroids secreted by Leydig cells include testosterone and androstenedione, a precursor of testosterone (Galli et al., 1973; Nakamura and Tanabe, 1972; Sharp et al., 1977). The concentration of testosterone in the general circulation is in the range of 5–15 nM, secreted as discrete pulses (Figure 29.12), which closely follow LH pulses (Bacon et al., 1991; Driot et al., 1979; Vizcarra et al., 2004), and are several times less than that in the testicular vein (Ottinger and Brinkley, 1979). The association between LH and testosterone pulses averaged 83% in unrestrained male broiler breeders fitted with jugular cannulas and free access to feed and water (Vizcarra et al., 2004). Testosterone in the adult male is essential for spermatogenesis, maintenance of the excurrent ducts and secondary sexual attributes, the expression of specific behaviors, and, as mentioned above, altering the pattern of GnRH secretion. These actions, as well as the inactivation of the hormone, depend upon transformation of testosterone by enzymes such as aromatase, 5α-reductase, and 5β-reductase (for reviews see Balthazart, 1989; Ottinger, 1983).

Although FSH is known to affect Sertoli cells, the means by which FSH works is only poorly understood in birds. As reviewed by Walker and Cheng (2005), studies in other vertebrates have shown that the FSH receptor is a seven transmembrane G-protein, and FSH binding is known to activate at least five different signaling pathways in Sertoli cells. These pathways include the cAMP-PKA, MAP kinase, phosphatidylinositol 3-kinase (pI3-K), calcium, and phospholipase A_2 (PLA_2) pathways. It has been proposed that oligomerization of FSH receptors may provide a mechanism for bringing together the components of these multiple signaling pathways in order to refine and control intracellular signaling. It is

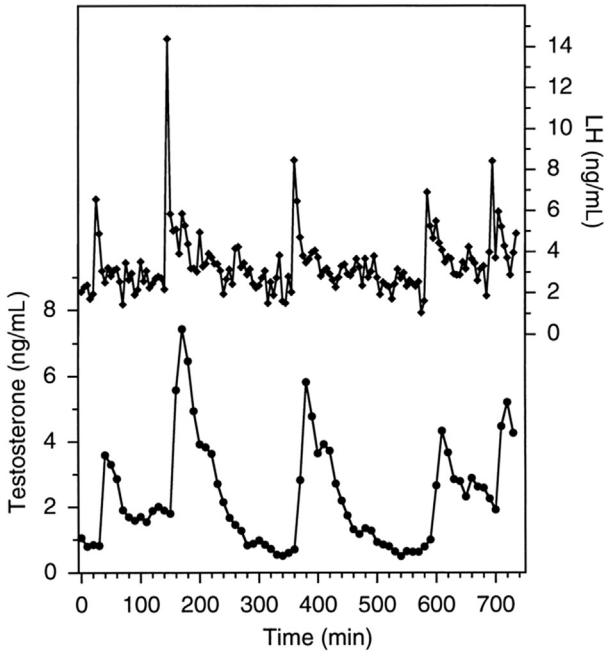

FIGURE 29.12 The pattern of pulsatile changes in circulating luteinizing hormone (LH; upper panel) and testosterone (lower panel) in an adult male domestic turkey (*Meleagris gallopavo*). The peaks of the discrete LH pulses occur prior to those of testosterone, demonstrating the close relationship between LH secretion and that of testosterone. *Figure and data kindly provided by Dr. Wayne Bacon, Ohio State University.*

well established that testosterone is absolutely essential for maintaining spermatogenesis and, unlike LH, the effect of FSH is potentiated by testosterone (Tsutsui and Ishii, 1978). As evidenced by the inability of exogenous testosterone to maintain spermatogenesis in hypophysectomized quail (Brown and Follett, 1977), LH and FSH appear to be essential for spermatogenesis in galliform birds. However, in male broiler breeders, more than 90% of the variation on testis weight was explained by changes in FSH, while only 35% of the variation in testis weight was explained by changes in LH concentrations (Vizcarra et al., 2010). These results indicate that FSH is the most important regulator of Sertoli cell proliferation and differentiation. Although sperm production depends on the number of Sertoli cells (de Reviers and Williams, 1984; Sharpe, 1994), the process is ultimately controlled by the hypothalamus-pituitary-gonadal axis.

29.6 SPERMATOGENESIS AND EXTRAGONADAL SPERM MATURATION

29.6.1 Spermatogenesis

To date, spermatogenesis in galliform birds has been most fully characterized in the Japanese quail (*Coturnix coturnix japonica*). Four types of spermatogonial cells have been described in *Coturnix* (Lin and Jones, 1992; Lin et al., 1990).

These have been designated as spermatogonia A_d, A_{p1}, A_{p2}, and B. The letter subscripts indicate intensity of staining and denote "dark" and "pale," respectively. The numerical subscripts denote ultrastructural differences (Lin and Jones, 1992). Spermatogonia A_d are stem cells. Based upon the model of stem cell renewal and spermatogonial proliferation proposed by Lin and Jones (1992), each division of an A_d spermatogonium yields A_d and A_{p1} daughter cells. Thus, spermatogenesis in *Coturnix* commences with the mitosis of an A_d spermatogonium. Cell types derived from each A_{p1} spermatogonium include A_{p2} spermatogonia ($n=2$), B spermatogonia ($n=4$), primary spermatocytes ($n=8$), secondary spermatocytes ($n=16$), and spermatids ($n=32$). Secondary spermatocytes and spermatids are formed by the first and second meiotic divisions, respectively.

Spermiogenesis is the transformation of spermatids into sperm cells without further cell division. Spermiogenesis in *Coturnix* entails 12 distinct morphological *steps* (Lin and Jones, 1993; Lin et al., 1990). In comparison, 8–10 steps have been reported for *Gallus* (de Reviers, 1971b; Gunawardana, 1977; Tiba et al., 1993), 10 steps for the guinea fowl (Aire et al., 1980), 12 steps for the turkey (Aire, 2003), and 6 steps for the house sparrow (Goes and Dolder, 2002). Spermiogenesis entails formation of an acrosome and an axoneme, loss of cytoplasm, and replacement of nucleohistones with nucleoprotamine, which accompanies nuclear condensation (Gunawardana, 1977; Gunawardana and Scott, 1977; Nagano, 1962; Okamura and Nishiyama, 1976; Oliva and Mezquita, 1986; Sprando and Russell, 1988; Tingari, 1973). The reductions in cytoplasmic and nuclear volumes are striking; mature rooster sperm embody only 3% of the initial spermatid cell volume (Sprando and Russell, 1988). In summary, the seminiferous tubules contain Sertoli cells and a broad array of differentiating germinal cells including the various types of spermatogonia, spermatocytes, and spermatids.

However, germinal cells are not found in a physical continuum of differentiation within the seminiferous epithelium. Rather, they are found in distinct cellular associations. The cellular associations in *Coturnix* occupy an average of 17,902 μm^2 and contain an average of 13.5 Sertoli cells per association (Lin and Jones, 1990). There are 10 cellular associations in *Coturnix*, and each is referred to as a *stage* of the seminiferous epithelium (Figure 29.13). The seminiferous epithelium passes through each successive stage as a function of time at any fixed point. Once a complete series has been finished, a new series is initiated. Consequently, the series of stages is referred to as the cycle of the seminiferous epithelium. The duration of the cycle in *Coturnix* is 2.69 days (Lin et al., 1990). In comparison, the duration of the cycle of the seminiferous epithelium in *Gallus* has been estimated to be 3–4 days (de Reviers, 1968; Tiba et al., 1993). The time between the division of an A_d spermatogonium and spermiation, known as the duration of

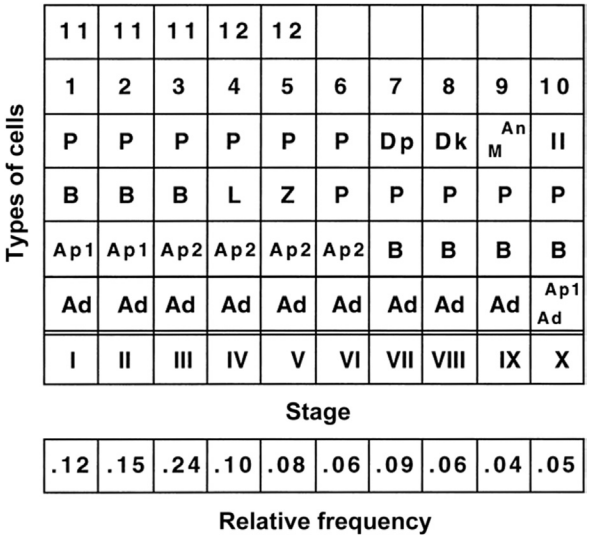

FIGURE 29.13 The cycle of the seminiferous epithelium of *Coturnix coturnix japonica*. The relative frequency of each cellular association, or stage, is shown below the stage's number. Ad, dark type A spermatogonia (stem cell); Ap1 and 2, pale type A spermatogonia; B, type B spermatogonia; L, leptotene primary spermatocytes; Z, zygotene primary spermatocytes; P, pachytene primary spermatocytes; Dp, diplotene primary spermatocytes; DK, diakinesis of primart spermatocytes; M, metaphase primary spermatocytes; An, anaphase primary spermatocytes; II, secondary spermatocytes; 1–12, step 1 through step 12 spermatids. *Adapted from Lin et al. (1990).*

spermatogenesis is 12.8 days in *Coturnix* (Lin and Jones, 1992). Thus, 4.75 cycles of the seminiferous epithelium are required to produce 32 sperm cells from a single A_d spermatogonium at any fixed point within the seminiferous epithelium.

A complete series of stages in the context of a seminiferous tubule is referred to as a *spermatogenic wave*. As shown in Figure 29.14, these waves in *Coturnix* are arranged helically along the length of seminiferous tubules (Lin and Jones, 1990). It must be noted that while sequential stages may be contiguous in space (Figure 29.14), they are not observed at a common frequency (Figure 29.13) because duration of each of the stages ranges from 2.5 to 15.5 h (Lin et al., 1990). Consequently, the prevalence of any given stage is directly proportional to the stage's duration (Lin et al., 1990).

Daily sperm production may be defined as the number of sperm produced per gram of testis per day. Daily sperm production in *Coturnix* has been estimated to be 92.5×10^6 sperm per gram of testis per day (Clulow and Jones, 1982). This estimate is equivalent to the DSP of $80–120\times10^6$ sperm per gram of testis reported for *Gallus* (de Reviers and Williams, 1984), though the estimate was much higher for barred Plymouth Rock and Nigerian domestic fowl (*Gallus domesticus*) ($2.41\pm1.17\times10^9$ and $0.076\pm0.71\times10^9$, respectively) (Orlu and Egbunike, 2009). These values denote the number of fully formed sperm released per day from the seminiferous

epithelium into the lumen of the seminiferous tubules. This phenomenon is defined as spermiation, which in *Coturnix* would be limited to the seminiferous epithelium in stage V (Figure 29.13). At the time of spermiation, superfluous cytoplasm found alongside the sperm cell's head is jettisoned as a residual body (Lin and Jones, 1993; Sprando and Russell, 1988). Sperm cells released from the seminiferous epithelium are immotile (Ashizawa and Sano, 1990). Galliform sperm are vermiform cells (Figure 29.15) with a maximum width of 0.5–0.7 µm and a length of 75–90 µm (Thurston and Hess, 1987). They contain a conical acrosome, a slightly bent cylindrical nucleus, and a helix of 25–30 mitochondria surrounding the proximal portion of a long flagellum, which accounts for approximately 84% of the cell's length (for review, see Thurston and Hess, 1987). The sperm of passerine birds tends to have a pointed, helical acrosome and ranges in length from 46.8 to 287.6 µm with the flagellum accounting for 79–95% of the total length (Helfenstein et al., 2009; Lupold et al., 2009). One exception to this general trend is the Eurasian bullfinch, in which the sperm acrosome is rounded, not helical, and the midpiece size is extremely short (Birkhead et al., 2006). In these birds, extra-pair copulation frequency is rare in comparison to other passerines. It may be that a lack of sperm competition in this species could explain the marked difference in sperm morphology (Birkhead et al., 2006).

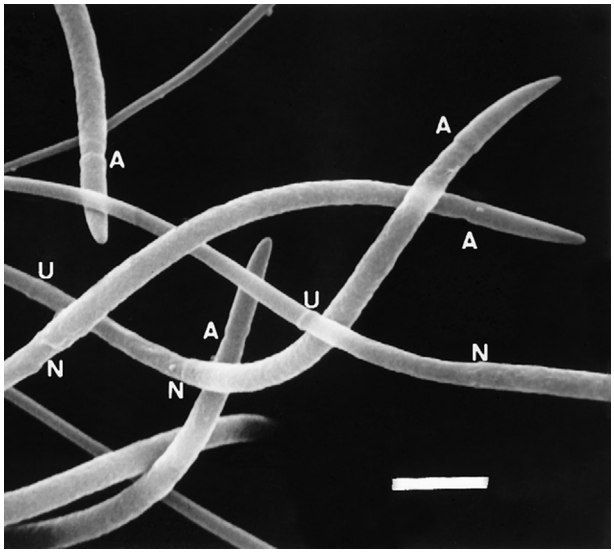

FIGURE 29.15 Scanning electron micrograph of chicken sperm cells. The constriction at the anterior end of the sperm cell (A) marks posterior boundary of the acrosome. The nucleus extends posteriorly from (A) to the neck region (N), which marks the anterior end of the midpiece. The midpiece, site of the anterior portion of the axoneme and the highly modified mitochondria, extends back to the raised annulus (U). The tail of the sperm extends from the annulus to the cell's termination. At the nucleus, chicken sperm are about 0.5 µm in diameter, with the overall length of the cell approximately 90 µm. Bar = 2 µm. *Adapted from Bahr, J.M., Bakst, M.R., 1987.* Reproduction in Farm Animals*, fifth ed. Philadelphia, PA: © Lea & Febiger.*

29.6.2 Extragonadal Sperm Transport and Maturation

Following spermiation, sperm cells are suspended within fluid secreted by Sertoli cells. Sperm passage through the labyrinth of seminiferous tubules most likely depends upon the hydrostatic pressure of seminiferous tubule fluid and the contractility of the myoepithelial cells overlying the outer surface of the seminiferous tubule (Rothwell and Tingari, 1973). Sperm passage through the distal excurrent ducts, in particular the deferent duct, presumably depends upon peristalsis (de Reviers, 1975). Like spermatogenesis, sperm transport through the excurrent ducts has been characterized

most fully in the Japanese quail. Thus, an analysis of the phenomena and time-course of sperm transport through the excurrent ducts of *Gallus* has been estimated to take several days (de Reviers, 1975; Munro, 1938). Perhaps the most evident phenomenon that occurs during sperm transport through the excurrent ducts; as evidenced by a change in sperm concentration, is the absorption of seminiferous tubule fluid (Table 29.3). The concentration of sperm in the seminiferous tubule fluid of *Coturnix* is 3.8×10^4 per µl whereas the concentration of sperm within the distal deferent duct is 2.3×10^6 per µl (Clulow and Jones, 1988). This 60-fold increase in sperm concentration is largely due to seminiferous tubule fluid absorption at the level of efferent ducts. Nakai et al. (1989), demonstrated that the nonciliated epithelial cells in the proximal efferent ducts of *Gallus* incorporate fluid by pinocytosis.

The efferent ducts, which represent the principal excurrent duct within the epididymis (Figure 29.3), may be a critical site for sperm maturation. Due to extensive mucosal folding, apocrine secretion, the presence of ciliated cells, and epithelial cells with abundant microvilli, the efferent ducts appear to be a site where sperm are mixed with secretions as they are concentrated. Additional evidence of the importance of the efferent duct comes from studies of reproductive anomalies in turkeys and chickens. For instance, turkeys may ejaculate yellow rather than white semen (Thurston et al., 1982a). Epithelial cells within the efferent ducts of such turkeys have been shown to be hypertrophied, engorged with lipid droplets, and characterized by heightened phagocytosis of sperm (Hess et al., 1982). The latter phenomenon appears to be mediated by macrophages within the rete testis under normal conditions (Aire and Malmqvist, 1979b; Nakai et al., 1989), but can be mediated by epithelial cells in the excurrent ducts when the deferent duct is not patent (Tingari and Lake, 1972). Subfertile roosters with malformed proximal efferent ducts (Figure 29.16) provide a second example of the relationship between efferent duct function and reproductive performance (Kirby et al., 1990). The biochemical imbalances observed in semen from such roosters have been attributed to excurrent duct dysfunction (al-Aghbari et al., 1992).

TABLE 29.3 Estimates of Plasma Flux (Reabsorption) across the Epithelium Lining the Excurrent Ducts of Japanese Quail[a]

	Testicular Plasma	
Region	**Output (%)**	**µl/cm²/h**
Rete testis to proximal efferent ducts	6.3	8.0
Proximal to distal efferent ducts	85.8	100.4
Distal efferent ducts to connecting ducts	6.5	21.6
Connecting ducts to epididymal duct	0.4	2.1
Epididymal duct to proximal deferent duct	0.2	0.1
Proximal to distal deferent duct	0.2	0.2

[a]*Adapted from Clulow and Jones (1988).*

In review, sperm are suspended in seminiferous tubule fluid prior to their passage through the excurrent ducts. The volume of this suspensory fluid and its composition (Esponda and Bedford, 1985) are altered prior to sperm entry into the epididymal duct. The resultant medium is seminal plasma. The chemical composition of seminal plasma is distinct from blood plasma as evidenced by differences in electrolyte, free amino acid, and protein composition (Freeman, 1984; Lake, 1966; Lake and Hatton, 1968; Stratil, 1970; Thurston et al., 1982b). The maintenance of these differences along the length of the excurrent ducts has been attributed to tight junctions between adjacent epithelial cells lining the ducts (Nakai and Nasu, 1991).

Apart from proteins specific to the reproductive tract (Esponda and Bedford, 1985; Stratil, 1970), the principal differences between seminal and blood plasma involve glucose, glutamate, K^+, Cl^-, and Ca^{2+} (Table 29.4). At present, it is not understood how the composition of excurrent duct fluid affects sperm motility. While Esponda and Bedford (1985) have demonstrated that sperm maturation proteins do exist in *Gallus* and while Ashizawa et al. (1988) have reported that the Na^+-to-K^+ ratio associated with the midpiece of rooster sperm increases as a function of sperm passage through the deferent duct, such changes do not induce motility; for sperm within the deferent duct are immotile (Ashizawa and Sano, 1990). Nonetheless, sperm acquire the potential for motility as they pass through the excurrent ducts (Ashizawa and Sano, 1990; Clulow and Jones, 1982; Howarth, 1983; Munro, 1938). This potential is distinct from fertilizing ability in that testicular sperm have the capacity to fertilize oocytes, providing they are placed in the oviduct above the vaginal sphincter (Howarth, 1983). As shown by Allen and Grigg (1957), sperm need not be motile to ascend the oviduct above the vaginal sphincter. Thus, the fertilizing ability of testicular sperm may not depend upon motility as much as the ability of sperm cells to undergo an acrosome reaction in response to contact with the oocyte's inner perivitelline layer (Okamura and Nishiyama, 1978).

The deferent duct, particularly the distal portion, contains the bulk of the extragonadal sperm reserve (ESR).

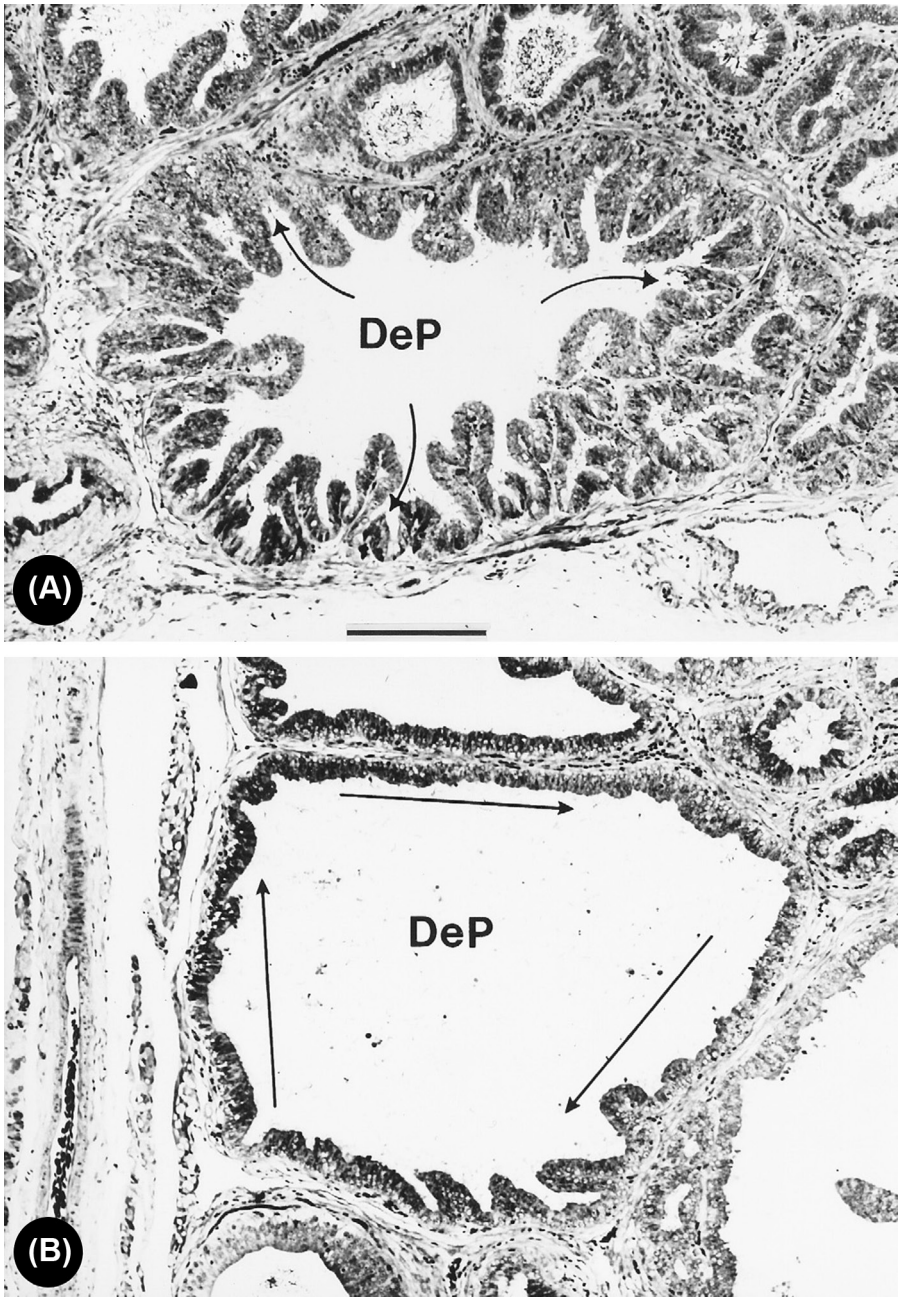

FIGURE 29.16 Cross sections through the proximal deferent ducts (DeP) of fertile (A) and subfertile (B) roosters. The presence of the *sd* allele in crossbred roosters (B) resulted in a twofold increase in DeP cross-sectional area and a 75% decrease in luminal surface area as compared to the wild-type (A) male. Males exhibiting this genetic defect of the DeP are characterized by poor semen quality, frequently exhibiting 30–90% dead and degenerate sperm in an ejaculate. *Reproduced with permission from the Society for the Study of Reproduction. From Kirby et al. (1990).*

In *Coturnix*, the number of sperm in the ESR is equivalent to the number produced daily by the testes and 92% of these are found within the different duct (Clulow and Jones, 1982). In contrast, the ESR in *Gallus* is equivalent to ≤3.5 times the daily sperm production, but 95% of the ESR is found in the deferent duct (de Reviers, 1975). In either case, the duration of sperm storage within the deferent duct is relatively brief. As stated above, these sperm are immotile prior to ejaculation. While Ashizawa and Sano (1990) have proposed that a temperature change accompanying ejaculation may initiate sperm motility in *Gallus*, it is also likely that accessory reproductive fluids play a role in the initiation of sperm motility (for reviews, see Ashizawa et al., 2000; Fujihara, 1992). In this regard, Ca^{2+} and HCO_3^- have been shown to be motility agonists *in vitro* (Ashizawa and Sano, 1990; Ashizawa and Wishart, 1987).

TABLE 29.4 Comparison of Selected Substances in Rooster Blood Plasma and Deferent Duct Fluid[a]

Substance	Blood Plasma	Deferent Duct Fluid
Glucose (nM/L)	15	—
Glutamate (mM/L)	< 1	100
Sodium (mEq/L)	160	142
Potassium (mEq/L)	5	34
Chloride (mEq/L)	115	40
Calcium (mEq/L)	5	1

29.7 SEASONAL GONADAL RECRUDESCENCE AND REGRESSION

29.7.1 Photoperiodic Control of Gonadal Regression and Recrudescence

Many bird species, especially long-distance migrants, face the challenge of a narrow reproductive window because of an intense selective pressure to restrict breeding to the time of year when food is most abundant (reviewed in Dawson, 2008). Typically, male birds have regressed gonads for most of the year with gonadal recrudescence occurring only immediately prior to reproduction. Birds are generally viewed as being long-day breeders (with some exceptions) such that the HPG axis responds to increasing day lengths with a marked increase in gonadotropin secretion and gonadal growth (reviewed in Ball and Ketterson, 2008). The exact time and rate of gonadal maturation varies between bird species; however, it has been suggested that, as photoperiod increases during the spring, a critical threshold point is reached at which gonadal recrudescence is triggered. This threshold has been termed the critical photoperiod. A study in Japanese quail provides support for this hypothesis and found that the rate of gonadal maturation was low when the photoperiod was less than 11.5 h of light per day and maturation became rapid light exposure was increased to 12 h per day (Follett and Maung, 1978).

While gonadal maturation in the spring is in response to an increase in photoperiod, longer photoperiods at the end of the breeding season induce a condition termed photorefractoriness, which causes the gonads to regress (reviewed in Dawson, 2008; Robinson and Follett, 1982). Two forms of photorefractoriness, absolute and relative, have been identified in various bird species. In the absolute form, continued exposure to long photoperiods leads to spontaneous gonadal regression after which a further increase in photoperiod does not induce renewed gonadal maturation until the next breeding season. This state has been successfully demonstrated in species such as the European starling, tree sparrow, and white-crowned sparrow and is only dissipated when birds experience short days in autumn. Such exposure to short photoperiods is thought to induce reacquisition of photosensitivity (reviewed in Ball and Ketterson, 2008). In contrast, relative photorefractoriness is evident when a decrease in photoperiod is necessary to induce gonadal regression, but this regression occurs under a photoperiod that is still longer than the one which induced maturation earlier in the year. In addition, exposure to long photoperiods can inhibit regression and even induce recrudescence (reviewed by Dawson, 2008). In general, it is thought that birds with early, predictable breeding seasons tend to become absolutely photorefractory whereas those with later or less predictable breeding seasons are more likely to exhibit relative photorefractoriness.

29.7.2 Other Factors Affecting Gonadal Maturation and Regression

Due to the vast variety between and within species, birds exhibit plasticity in both gonadal maturation and regression. Though photoperiod plays an important role in regulating these processes, non-photoperiodic cues such as breeding location, temperature, rainfall, and food availability are also important in determining the rate and timing of recrudescence and regression. For example, Caro et al. (2006) observed two separate populations of blue tits and noticed that, not only did one population breed earlier than the other, but earlier breeding birds exhibited a faster rate of testicular development than did their later breeding counterparts. White-crowned sparrows breeding at low latitudes experienced inhibition of gonadal maturation and delayed onset of photorefractoriness at low temperatures, but the same were not true for birds of the same species breeding at mid latitudes (Wingfield et al., 2003). Retarded rates of testicular recrudescence were also observed in juncos subjected to low temperatures between 4 and 8 °C (Engels and Jenner, 1956). In willow tits, high temperatures were shown to accelerate testicular maturation, but the same effect was not evident in great tits (Silverin and Viebke, 1994). These data may suggest that temperature is more likely to affect species with longer and more flexible breeding seasons.

Interestingly, rainfall has been shown to affect gonadal maturation in several tropical bird species. For example, two populations of rufous-collared sparrows separated by only 25 km were observed to have highly asynchronous reproductive physiology based on local rainfall patterns (Moore et al., 2006). In the rufous-winged sparrow, though seasonality is known to be photoperiodically controlled, the exact time of breeding occurs in response to

rainfall (Deviche et al., 2006). Darwin's finches undergo gonadal maturation at drastically different times in different years in direct response to rainfall, yet the gonads have been shown to fully regress between breeding seasons (Hau et al., 2004). Another factor which may influence seasonal recrudescence is the availability of food resources. Food availability at stopover has been directly linked to gonadal maturation during spring migration. For example, Garden Warblers experiencing limited food conditions at stopover had significantly slower testicular recrudescence and decreased testosterone in comparison to birds allowed to eat *ad libitum* (Bauchinger et al., 2009). It is clear that many factors, both intrinsic and extrinsic, have the potential to influence patterns of seasonal gonadal recrudescence and regression. The mechanisms driving such patterns are complex and likely overlap with one another. As research in this area progresses, it will be important to investigate how these mechanisms interact in order to better understand the various factors that drive reproductive success in the male bird.

Chapter 30

Reproductive Behavior

Pierre Deviche
School of Life Sciences, Arizona State University, Tempe, AZ, USA

ABBREVIATIONS

ACTH Adrenocorticotropic hormone
AVT Arginine vasotocin
cGnRH-I Chicken gonadotropin-releasing hormone-I
CORT Corticosterone
DHT 5α-dihydrotestosterone
FSH Follicle-stimulating hormone
GnIH Gonadotropin-inhibitory hormone
GnRH Gonadotropin-releasing hormone
HPA Hypothalamo–pituitary–adrenal axis
HPG Hypothalamo–pituitary–gonadal axis
LH Luteinizing hormone
PRL Prolactin
POA Preoptic area
T Testosterone

30.1 INTRODUCTION

For a species to persist, reproduction is arguably the most important life history stage. In most species, reproduction is associated with the expression of some type of reproductive behavior, an orderly sequence of behavioral events that can include visual and auditory displays, copulation, nest building, oviposition, incubation, and care (including food provisioning) to young. Reproductive behavior is a crucial target of selection, and understanding its proximate bases can, therefore, help us address issues related to the persistence and evolution of organisms. Within vertebrates, reproductive behavior is widespread and exhibited by representatives of all classes, and it is thought to have evolved well before the emergence of birds. Indeed, similar to modern birds, nonavian maniraptoran dinosaurs probably exhibited a daily oviposition pattern, produced eggs with a complex shell microstructure, and protected their clutch (Zheng et al., 2013). As well, based on correlative analysis of clutch size and adult bone morphology, Varricchio et al. (2008) conclude that some Cretaceous dinosaurs exhibited paternal care and possibly had a polygamous mating system (Varricchio et al., 2008). More recently, ancestral phoenicopterids from the early Miocene are thought to have built floating nests, as do some of their extant relatives (grebes: Grellet-Tinner et al., 2012).

Given its distant origin, it is not surprising that within each vertebrate class, reproductive behavior varies enormously with respect to complexity, seasonal timing, duration, and control mechanisms. Birds have long been considered to be choice models to investigate the mechanisms that control the expression of reproductive behavior. Being endotherms, they thrive in diverse environments ranging from cold and hot deserts across a wide range of latitudes and altitudes to tropical and equatorial forests, as well as oceanic islands. Many species are, therefore, readily accessible to researchers. In addition, all aspects of avian reproductive behavior, as well as avian social systems, which range from social monogamy to polygyny and polyandry (dunnock, *Prunella modularis*: Langmore et al., 2002; Owens, 2002; spotted sandpiper, *Actitis macularius*: Rissman and Wingfield, 1984), are extremely diverse, and this diversity presents boundless opportunities for comparative work. Furthermore, many species are diurnal and colorful, and they sport a sexually dimorphic adult plumage. Their reproductive behavior often includes conspicuous visual (e.g., social displays, copulation, and parental feeding) and auditory (e.g., song) signals that are relatively easy to observe and quantify. Also of note, the expression of avian reproductive behavior is in many species seasonal and generally restricted to the time of year when environmental resources, in particular food, that are necessary for the optimal development of the offspring are most abundant and accessible. This expression is often regulated by hormones whose secretion likewise fluctuates seasonally. Not unexpectedly, therefore, birds have long been used as primary model organisms for correlative studies on hormones and reproductive behavior, and for mechanistic research aimed at identifying the hormonal and neural bases of this behavior during ontogeny and in adulthood. Finally, several species (chicken, *Gallus domesticus*; Japanese quail, *Coturnix coturnix japonica*; domesticated

Sturkie's Avian Physiology.

turkey, *Meleagris gallopavo*; ring dove, *Streptopelia risoria*; domesticated canary, *Serinus canaria*; and zebra finch, *Taeniopygia guttata*) have long been domesticated, and many aspects of their reproductive behavior and physiology have been studied extensively (see Sections 30.4.1, 30.6.2, and 30.6.5). This Knowledge gained from these studies, along with ready access, presents unsurpassed opportunities for in-depth mechanistic investigations (Ball and Balthazart, 2004; Balthazart et al., 2003).

30.2 REGULATION OF REPRODUCTIVE BEHAVIOR

The expression of reproductive behavior at maturity is regulated by a multitude of external factors—environmental and social—as well as internal factors, the nature and relative importance of which often vary interspecifically, between sexes, during ontogeny, as a function of adult age and experience, and according to the reproductive stage. A comprehensive review of the vast literature related to this regulation well exceeds the scope of the present chapter. Thus, we focus on a limited number of representative topics based on their potential interest to readers, progress made in the recent past, and the generality of conclusions that can be reached based on the available information. We begin with an analysis of environmental factors—in particular, light and food resources—and then social factors with well-documented effects on the reproductive system and behavior. Age and breeding experience can profoundly impact the adult reproductive system and the expression of reproductive behavior, and so we address the respective roles of these factors. Many studies have investigated the mechanisms by which peripheral hormones and neurohormones regulate reproductive behavior. We follow those sections with an analysis of this regulation, with particular attention paid to the role of gonadotropin-releasing hormone (GnRH), gonadotropin-inhibitory hormone (GnIH), arginine vasotocin (AVT), prolactin (PRL), gonadal steroids, and neurosteroids.

Three underlying themes run through the present chapter. First, we emphasize that gonadal hormones play an overwhelming role in the control of avian reproductive behavior. Any analysis of the mechanisms that regulate this behavior must, therefore, necessarily encompass a discussion of the mechanisms that control the activity of the reproductive system itself. For this reason, we provide examples drawn not only from the behavioral literature but also from the endocrine literature. Second, when addressing the (neuro)endocrine mechanisms that regulate reproductive behavior, one needs to take into account that this regulation is frequently reciprocal. For example, gonadal steroids profoundly influence the expression of reproductive behavior, but social and perhaps chemical signals from conspecifics can markedly affect the secretion of gonadal hormones. In some cases, even an individual's own behavior causes marked endocrine changes within this individual. Third, at the individual level, most endocrine systems do not operate independently but are functionally interrelated. Illustrating this point, gonadal steroids can markedly influence the production and secretion of behaviorally active neuropeptides such as adrenocorticotropic hormone and AVT. Furthermore, during stress, elevated secretion of hypothalamo-pituitary-adrenal (HPA) axis hormones can negatively affect aspects of reproductive physiology and behavior.

30.3 ENVIRONMENTAL FACTORS

Many environmental factors have the potential to influence the reproductive physiology and behavior of birds. These factors include weather-related events such as droughts (Reichert et al., 2012) and storms (Astheimer et al., 1995; Bolger et al., 2005), temperature (Ardia et al., 2009), and humidity (Cynx, 2001). Understanding the effects of these factors and how they affect reproduction is of considerable importance given the potential outcome of global climate change on biological systems (Beale et al., 2006; Senapathi et al., 2011; Shine and Brown, 2008; Moller, 2013), but this understanding is complicated by several factors. For example, weather-related events such as storms are generally perceived as stressful and often have negative reproductive consequences (e.g., they delay the onset of breeding and incubation behavior), but whether this is the case can be reproductive stage dependent (Wingfield, 1984). In addition, the effects of weather- or climate-related factors on the reproductive system can be direct (temperature: Ardia et al., 2009; Visser et al., 2009) but, alternatively or in addition, be indirect and result from changes, such as in food resources (drought: Bolger et al., 2005). Here we consider the role of two factors that have garnered considerable attention and have clear effects on the reproductive physiology and behavior of birds: light and food resources.

30.3.1 Light

In most avian species studied to date, exposure to sufficiently long days (i.e., above a minimum, species-specific threshold) stimulates a cascade of physiological events, including synthesis and secretion of chicken gonadotropin-releasing hormone-I (cGnRH-I). This stimulation ultimately causes gonadal development and increases the secretion of gonadal steroids (Dawson, 1999; Dawson et al., 2001; Stevenson et al., 2013), which play a primary role in the control of reproductive behavior (see Section 30.6.4). It is notable that even species such as the opportunistic zebra finch, which has traditionally been considered to be nonphotoperiodic, respond to very long days by activating their reproductive system (Bentley et al., 2000b). Due to its effects on the hypothalamo–pituitary–gonadal (HPG) axis, photostimulation in

many cases exert effects that are indirect and mediated by elevated circulating concentrations of gonadal hormones. Limited evidence, however, suggests in some conditions that photoperiod influences avian reproductive behavior independent of its effects of the HPG axis. For example, castrated, androgen-treated ring doves exposed to long photoperiods exhibit higher levels of nest-building activity than short-photoperiod-exposed birds (McDonald and Liley, 1978). The mechanism mediating this effect remains unclear and may be related to changes in body condition. Indeed, birds exposed to long days have more time to feed and gain energy daily than short-day-exposed birds, and they may consequently be able to devote more resources to energy-consuming activities such as those associated with breeding (Perfito et al., 2008). Stimulatory effects of artificial urban lights on the timing of the dawn chorus of songbirds, as well as on their laying dates and male pairing success (Kempenaers et al., 2010; Longcore, 2010), may likewise result from extension of the daily feeding time and access to more food resources. In free-ranging birds, separating behavioral effects of photoperiod that are mediated by changes in energy intake from those that are secondary to elevated HPG hormone secretion has proved challenging, and additional work on this subject is clearly warranted.

30.3.2 Food Resources

Resource availability has long been thought to exert a critical influence on the timing of reproduction, including the expression of reproductive behavior, with parents generally raising young when food is seasonally most abundant. This view is supported by correlative and manipulative studies. For example, crossbills (*Loxia* spp.) feed primarily on conifer seeds, the abundance of which varies greatly and often unpredictably in time and space (Benkman, 1992). In these birds, food availability (along with day length and social factors) plays a determining role in the timing of reproduction (Benkman, 1990; Hahn, 1995; Deviche and Sharp, 2001). Another illustration is provided by research on blue tits (*Cyanistes caeruleus*). Blue tits preferentially feed their young noctuid lepidopteran caterpillars, but will also feed them less preferred tortricid lepidopteran caterpillars, which are smaller but easier to obtain and have a different phenology than noctuids. In this species, an adjustment of the timing of reproduction that is associated with an increased proportion of noctuids fed to young results in heavier nestlings (Garcia-Navas and Sanz, 2011).

Food resource manipulations—supplementation or restriction—are commonly used to investigate the role of these resources. With some exceptions (Harrison et al., 2010), food supplementation generally promotes the activity of the reproductive system as assessed by gonadal development, plasma levels of reproductive hormones, laying date, and expression of reproductive behavior (Hahn, 1995; Brommer et al., 2004; Schoech et al., 2004; Watts and Hahn, 2012). It is noted that these effects are, however, susceptible to modulation by various factors, including photoperiod and social interactions (Hahn, 1995) and predation pressure (Zanette et al., 2003). photoperiod and social interactions (Hahn, 1995), and predation pressure (Zanette et al., 2003). In addition, the interpretation of the findings from food manipulation studies needs to consider that short-term reproductive effects of food supplementation may differ from long-term effects. For example, food supplementation to song sparrow (*Melospiza melodia*) parents has transgenerational behavioral effects, causing these parents to produce more offspring than control parents. However, this apparent advantage is mitigated by the fact that food-supplemented parents produce smaller eggs and nestlings than control birds and that their male offspring have a smaller song repertoire—and are thus presumably less fit—than the offspring of control parents (Zanette et al., 2009; Figure 30.1).

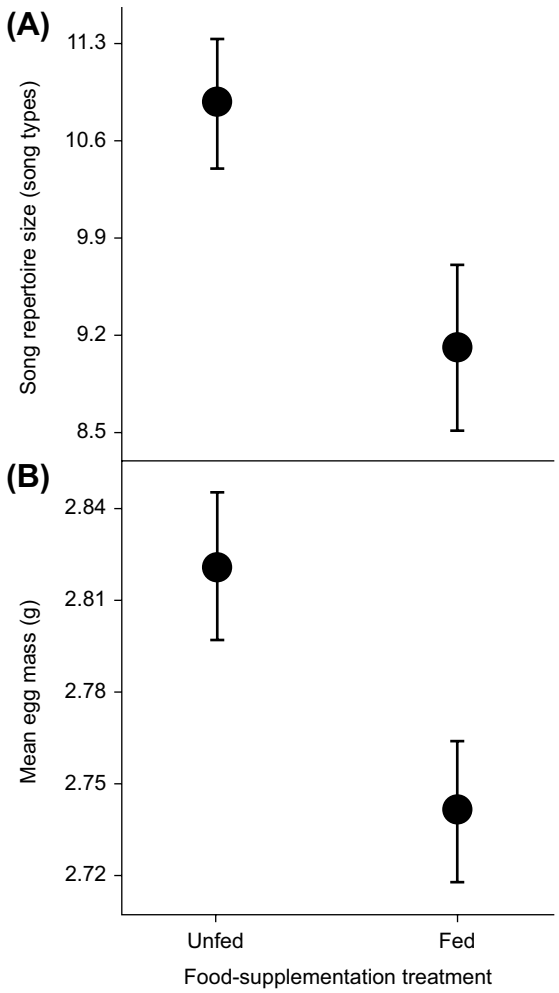

FIGURE 30.1 Food supplementation to song sparrow parents decreases (A) the song repertoire size of their sons ($p = 0.030$), and (B) the mean egg mass ($p = 0.017$). *Reprinted from Zanette et al. (2009) with permission.*

Food restriction generally results in effects in the opposite direction compared to those of food supplementation (Bauchinger et al., 2009). In the hen, this manipulation leads to lower plasma luteinizing hormone (LH) and gonadal steroids, as well as decreased mass of reproductive organs, and these changes are reversed in response to re-feeding (Richard-Yris et al., 1987). Endocrine effects of food restriction in hens are reproductive stage specific, however, with plasma follicle-stimulating hormone being lower in food-restricted than *ad libitum*–fed birds prior to sexual maturity, but not in egg-laying birds (Bruggeman et al., 1998). Similar to the situation in females, food restriction in males leads to reproductive deficits such as reduced sperm quality and semen volume (Cerolini et al., 1995). In the male zebra finch, no testicular development occurs following transfer from short to long day length in food-restricted males, but this transfer stimulates testicular recrudescence in *ad libitum*–fed birds (Perfito et al., 2008). In this opportunistic breeder, food availability, therefore, apparently plays a more important role than day length in the control of HPG axis activity.

30.3.3 Case Study: Urbanization

The diversity of environmental factors to which birds can respond and of the effects of these factors (e.g., migration: Tryjanowski et al., 2013; reproduction: Partecke and Gwinner, 2007; Davies et al., 2013; community structure: Gagne and Fahrig, 2011; Schlesinger et al., 2008; parasite infection: Sitko and Zalesny, 2012) is well illustrated by research on the effects of urbanization. Urbanization is associated with massive and in most cases largely irreversible environmental changes, including an increase in ambient noise, temperature (heat island effect: Zhang et al., 2010b), and nocturnal illumination, and differences in plant community composition and phenology (Mimet et al., 2009) that can in turn drive alterations in the food resources that are available to herbivores and carnivores. These changes, acting separately and/or cumulatively, and directly and/or indirectly, have the potential to profoundly affect the reproductive physiology and behavior of urban birds. The net consequences of urbanization on fitness remain, however, debated and poorly understood. On the one hand, urban birds frequently have an advanced reproductive phenology compared to corresponding nonurban birds (Davies et al., 2013; Dominoni et al., 2013), and this advancement has the potential to increase their reproductive output and fitness by increasing the duration of the annual breeding period. On the other hand, urban birds are exposed to physical factors that can be perceived as stressful and that adversely affect physiological and behavioral processes. One such factor is anthropogenic noise (noise pollution). Correlative evidence strongly suggests that noise pollution has a detrimental influence on breeding success and individual fitness (eastern bluebird, *Sialia sialis*: Kight et al., 2012; house sparrow, *Passer domesticus*: Schroeder et al., 2012). This conclusion is supported by experimental studies. For example, greater sage grouse (*Centrocercus urophasianus*) that are experimentally exposed to chronic noise show elevated excretion of glucocorticoid metabolites, suggesting enhanced stress levels, and decreased lek attendance (Blickley et al., 2012). The reproductive effects of noise pollution are, however, often species specific and can be complex. Illustrating this, exposure to elevated ambient noise level does not substantially affect plasma corticosterone (CORT) or reproductive behavior in the Australian black swan (*Cygnus atratus*) (Payne et al., 2012). In addition, by disrupting predator–prey interactions, ambient noise can in some situations in fact *increase* breeding success (Francis et al., 2009). A few studies have examined the relationships in birds between urbanization and the acute stress response (increased plasma glucocorticoids in response to capture and restraint: Fokidis et al., 2009; Partecke et al., 2006). Urban European blackbirds (*Turdus merula*) show a lower response to acute stress than forest conspecifics (Partecke et al., 2006). For the most part, however, the physiological (including endocrine) bases of differences between urban and corresponding nonurban birds remain poorly understood, and this research topic is ripe for new correlative and manipulative investigations.

30.4 SOCIAL FACTORS

Studies over many years, using a variety of experimental models and carried out in field and laboratory settings, consistently demonstrate that social interactions between conspecifics can influence all aspects of their reproductive behavior. Research on this subject also shows that an individual's own behavior can influence its physiology, including the production and secretion of behaviorally active hormones and neurochemicals, and this influence can in turn lead to behavioral modifications. The modulation of reproductive behavior by social factors is often complex, and with a few exceptions (e.g., the ring dove; see Section 30.4.1) the proximate underlying mechanisms—including the sensory modalities involved and the pathways that underlie sensory information processing—remain poorly understood. This topic provides rich opportunities for new and exciting research.

30.4.1 Effects of Males on Conspecific Females

Intraspecific social interactions can profoundly affect the behavior and physiology of individuals of the opposite sex. In the female Japanese quail, plasma CORT increases as a result of mating (Rutkowska et al., 2011). This increase is not seen in females that interact with a male without opportunity for mating, but it is observed in females that interact

socially with other females. Thus, direct social interactions rather than the act of mating *per se* apparently elevate plasma CORT in these birds. The role of social interactions is shown also by work on Gouldian finches (*Erythrura gouldiae*), in which females that are experimentally paired with a non-preferred, poor-quality male have chronically higher plasma CORT than females paired with a preferred male (Griffith et al., 2011; Figure 30.2). Across species, lower stress levels in females that are paired with attractive mates may contribute to these females investing more in reproduction, as measured by egg size and food-provisioning behavior (Horvathova et al., 2012). In another type of investigation, exposure of females to conspecific song was found to induce behavioral and neural effects. For example, in several species, this exposure enhances female sexual responsiveness (song sparrow: Searcy and Marler, 1981; Pasteau et al., 2012; brown-headed cowbird, *Molothrus ater*: Freed-Brown and White, 2009) and activity level (European starling, *Sturnus vulgaris*: Riters and Teague, 2003). Exposing females to male songs also has physiological consequences that may influence fitness, as shown in canaries by the fact that females exposed to attractive male song repertoires deposit more testosterone (T) in their eggs than females exposed to unattractive male song repertoires (Gil et al., 2004).

The role of social interactions on the female reproductive system is further exemplified by work on captive willow tits (*Poecile montanus*), in which ovarian development is advanced in females paired with a male compared to females held in isolation (Silverin and Westin, 1995). This study did not isolate the factors that promote ovarian development, but other studies have addressed this question and demonstrate an important role for acoustic signals. For example, in song sparrows and domesticated canaries, exposure to conspecific song stimulates follicular development (Bentley et al., 2000a). The neuroendocrine mechanism mediating this stimulation is explored in the white-throated sparrow (*Zonotrichia albicollis*). In this species, male song rapidly (within 1 h) increases the secretion of LH and the expression of the immediate early gene, early growth response-1, in the mediobasal hypothalamus, but not in GnRH-producing neurons, suggesting behaviorally induced secretion of the peptide (Maney et al., 2007).

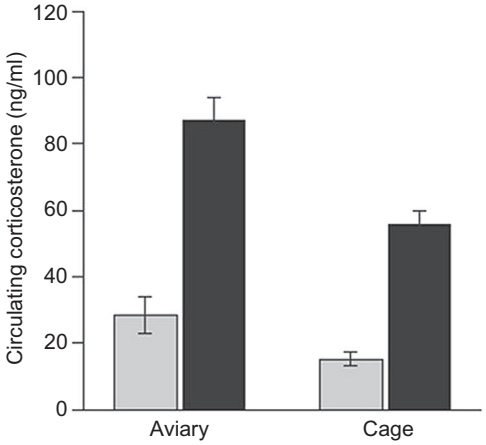

FIGURE 30.2 Baseline plasma corticosterone (CORT) during the egg-laying period in female Gouldian finches paired either with a genetically compatible (gray bars) or with a genetically incompatible (black bars) conspecific male. During breeding, birds were held either in a group aviary (aviary) or in cages containing one pair of birds (cage). Irrespective of the setting, females paired with an incompatible male have higher plasma CORT than females paired with a compatible male. *Reprinted from Griffith et al. (2011) with permission.*

The most detailed investigations on the neural pathways that mediate reproductive effects of conspecific vocalizations in females have been conducted in the ring dove, a domesticated species that has long been used as an excellent model to unravel interactions between hormones and reproductive behavior (Lehrman, 1964; Lehrman and Friedman, 1969; McDonald and Liley, 1978; White, 1975). In the female ring dove, visual and auditory (but not physical) contact with a male stimulates the expression of courtship vocalizations (nest-coos) and ovarian development, and this effect is more pronounced after exposure to intact than castrated males (e.g., Lott et al., 1967). Females whose hypoglossal nerves (which innervate the vocal organ or syrinx) are sectioned show a reduction in their expression of nest-coos and, concurrently, in male courtship–induced ovarian development (Cohen and Cheng, 1979), leading to the remarkable hypothesis that a female's vocal behavior promotes her own ovarian development. The selectivity of this activation is demonstrated by the observation that plasma LH increases more in female doves that are exposed to female than male nest-coos (Cheng, 2008; Cheng et al., 1998). As neuronal track-tracing studies demonstrate, the self-stimulation of ovarian development involves the relay of auditory information to the midbrain nucleus intercollicularis (ICo). This brain region in turn communicates with the anterior hypothalamus, where some neurons themselves respond to auditory stimulation, through enkephalinergic projections (Cheng and Zuo, 1994). When stimulated, some hypothalamic neurons increase their secretion of GnRH, and this increase is in turn responsible for elevated gonadotropin secretion and ovarian development.

30.4.2 Effects of Females on Conspecific Males

The above studies conclusively show effects of males on the reproductive system of conspecific females, but there is also strong experimental evidence that females can in some cases influence the reproductive system of conspecific males. In the domesticated Japanese quail, the reproductive

maturation rate of photostimulated males that are held with females is faster than in isolated males; paired males also have higher plasma LH and T than isolated males (Delville et al., 1984). Parallel findings are reported in free-ranging birds: treatment of free-ranging female song sparrows with estradiol at the beginning of the breeding season increases their sexual behavior, and this increase correlates with elevated plasma T and territorial behavior in males residing in the same area (Wingfield and Monk, 1994). Similarly, estradiol administration to free-ranging female pied flycatchers (*Ficedula hypoleuca*) in breeding condition stimulates the aggressive behavior of their mates (Silverin, 1991). It must, however, be pointed out that the presence of females does not necessarily have stimulatory effects on the male reproductive system, and so great care must be exercised when trying to generalize findings across species. Illustrating this, in captive male willow tits exposed to long photoperiods, testicular maturation is *delayed* and birds regress their testes *earlier* when kept in the presence of a female than when in isolation (Silverin and Westin, 1995). It also needs to be stressed that experiments using estrogen-treated versus control females or comparing paired versus isolated males to study the role of social factors do not, by themselves, inform about the specific factors (e.g., visual and auditory) to which males respond behaviorally and physiologically. Even though most birds have a relatively poor sense of olfaction relative to many other vertebrates, olfaction may play a role to regulate the behavioral response of males to conspecific females. Supporting this conclusion, the courtship behavior of male chickens is apparently influenced by olfactory signals emanating from the female uropygial gland, a structure that has long been considered to be a potential source of pheromones (Zhang et al., 2010a; Hirao et al., 2009). Consistent with these findings, spotless starlings (*Sturnus unicolor*) can recognize the sex of conspecific individuals based on chemical olfactory cues that may be released by the uropygial gland (Amo et al., 2012).

30.4.3 Effects of Males on Conspecific Males

A great deal of research has investigated the effect of male behavior on the reproductive physiology and behavior of conspecific males, with particular attention given to the role of visual and auditory stimuli. Long-term (several weeks) studies find stimulating effects of hearing conspecific song on the HPG axis. For example, in the male rufous-winged sparrow (*Peucaea carpalis*), plasma LH is higher and testes develop faster in response to photostimulation for several weeks when birds are exposed daily to conspecific song than in control males not hearing this song (Small et al., 2008; Figure 30.3). Social stimulation can also induce short-term effects on the reproductive endocrine system. These effects are often assessed experimentally by presenting males with prerecorded conspecific vocalizations combined with a decoy bird (Balthazart et al., 2009; Wingfield, 1994b; Silverin et al., 2004). This situation, generally referred to as simulated territorial intrusion (STI), often provokes a strong aggressive response on the part of the challenged male (Wingfield, 1994a), and this response is in some cases associated with a rapid (within minutes) increase in plasma T (Wingfield and Hahn, 1994). Testosterone can exert rapid (within minutes to hours) physiological (Sachs and Leipheimer, 1988) and behavioral (Wright et al., 2009) effects, and it can enhance attention to novel conspecifics and other relevant stimuli (Archer, 1977). According to the Challenge Hypothesis (Wingfield et al., 1987; Wingfield and Goldsmith, 1990), elevated plasma T in response to social challenge may, therefore, function to enhance the persistence of a challenged individual's behavioral response even after the end of the challenge (Oyegbile and Marler, 2005; Wingfield, 1994b; Lynn et al., 2005). It should be pointed out that a social challenge of the above-described type often either fails to detectably increase (Addis et al., 2010; Deviche et al., 2012) or even decreases plasma androgens (Landys et al., 2007; for a review, see Goymann, 2009). This variability suggests a modulation of the response to STI by other factors. Indeed, it has been proposed that this response is contingent upon the mating system (Wingfield and Goldsmith, 1990; single versus multiple broodedness: Landys et al., 2007), the contribution of males to incubation (Hirschenhauser et al., 2003), and the duration of the breeding season and the breeding state (Goymann, 2009).

30.5 AGE AND EXPERIENCE

Ample evidence exists in birds that breeding performance is age related (Forslund and Part, 1995). For example, the reproductive output of stitchbirds (*Notiomystis cincta*) increases during the first years of life and then declines as birds become senescent (Low et al., 2007). As discussed by Forslund and Part (1995), age-related differences in breeding performance may result from many nonexclusive factors that include age *per se* but also breeding experience, foraging success, and reproductive effort. Disentangling the respective contribution of these factors has been a major impetus of numerous studies. Research on free-ranging birds clearly indicates in some species that breeding experience gained during previous breeding attempts influences the reproductive output positively and independently of age. Using sophisticated statistical approaches, these studies show that breeding experience *per se* increases the probability of breeding and/or the reproductive output in birds belonging to various families (greater flamingo, *Phoenicopterus roseus*: Pradel et al., 2012; black-legged kittiwake, *Rissa tridactyla*: Desprez et al., 2011; snail kite, *Rostrhamus sociabilis*: Reichert et al., 2012). The interplay of age and experience is illustrated by research on free-ranging

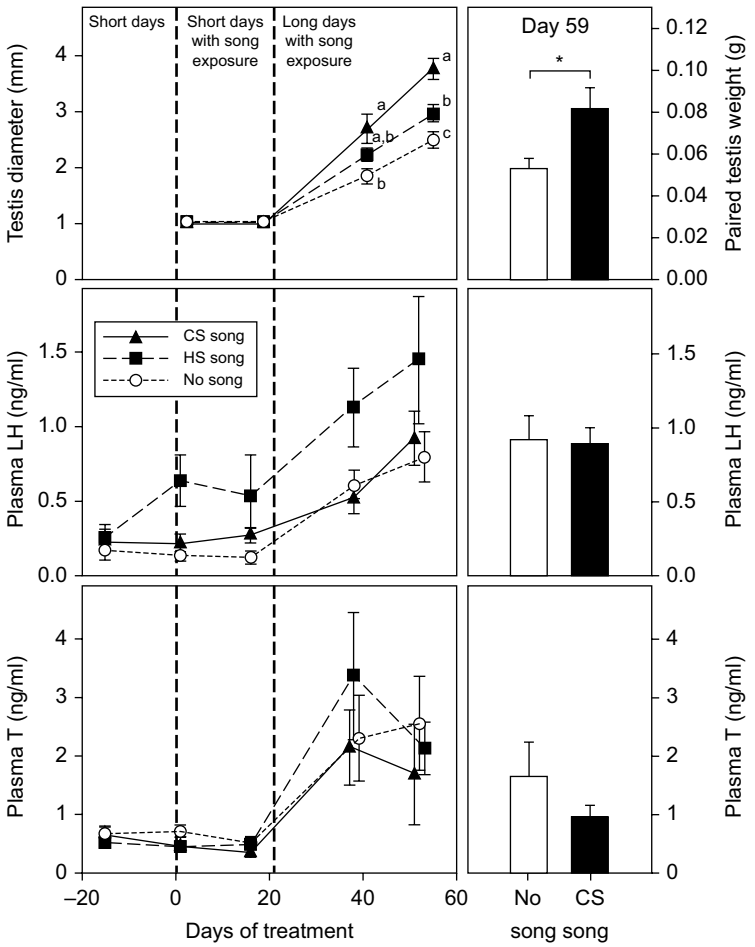

FIGURE 30.3 Left panels: Testis diameter (top left) and plasma luteinizing hormone (LH) and testosterone (T) in captive adult male rufous-winged sparrows exposed daily to conspecific song (CS Song), to heterospecific song (HS Song), or to no song (No Song). Birds were exposed to short days followed with exposure to a stimulating long photoperiod. On the same sampling day, different letters indicate significant differences between corresponding groups. lance-tailed manakins (*Chiroxiphia lanceolata*; DuVal, 2012). In this species, males begin to breed when they reach high (alpha) social status and at an age that varies individually. The reproductive success of these males increases as a function of age and breeding experience. However, as birds get older, senescence negatively affects their breeding success, but this effect is compensated by the positive influence of social experience. Manipulative studies likewise support the idea of age-independent effects of breeding experience. For example, inexperienced male ring doves display less courtship behavior than age-matched experienced males (Cheng et al., 1986). This difference is specific to this behavior, as indicated by the observation that the two groups of males show similar levels of agonistic behavior. In another study, Cichon (2003) compared the reproductive output of inexperienced and experienced female collared flycatchers (*Ficedula albicollis*) (Figure 30.4). These two groups of birds had similar breeding success, but broods from experienced females were heavier and larger than those of inexperienced females, suggesting a positive effect of experience on fitness.

An insight into the mechanisms by which experience proximately influences reproductive behavior is provided by research on Japanese quail (Cornil and Ball, 2010). In this species, the probability of copulation is higher in sexually experienced than naïve males. However, visual (without physical) contact with a female (versus a male or no bird) also enhances the occurrence of subsequent precopulatory behavior (latency to mate), indicating that male sexual performance is stimulated by sensory cues from females without actual sexual encounter taking place. Importantly, this study used castrated, T-treated birds, and behavioral effects of social experience were, therefore, not related to plasma T. Similarly, behavioral effects of social experience in the male ring dove (Cheng et al., 1986) do not result from differences in plasma T between naïve and experienced males. That the influence of a bird's social experience on its behavior can be modulated by sensory

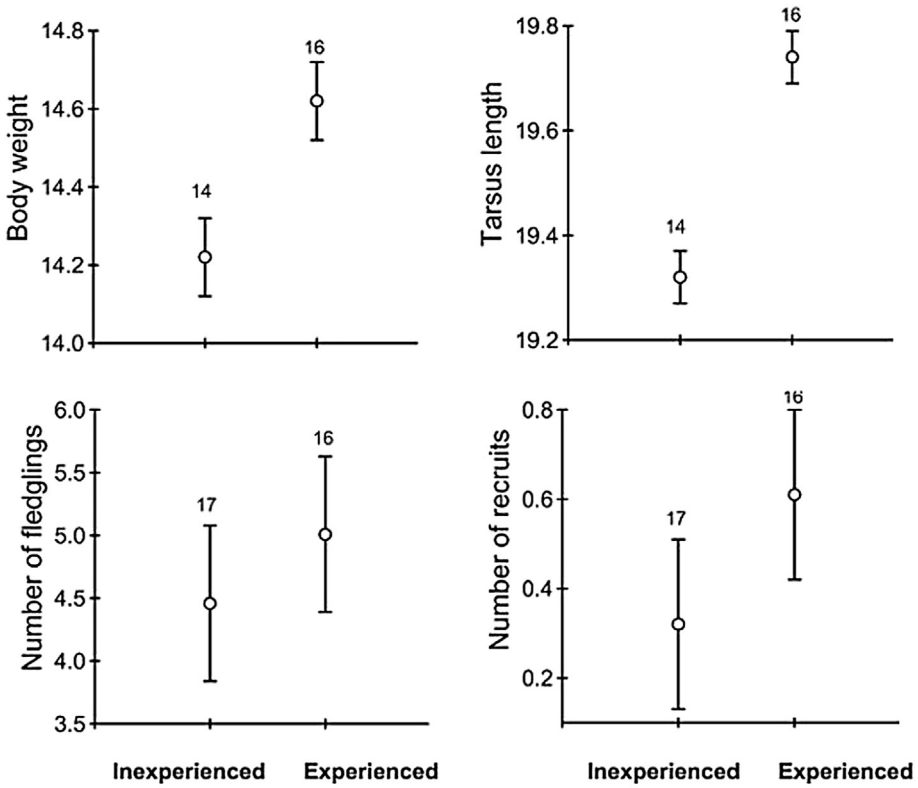

FIGURE 30.4 Breeding performance of 2 year old female collared flycatchers with (experienced) or without (inexperienced) previous breeding experience. Nestlings produced by inexperienced females were lighter (body mass on day 12 after hatching: $p=0.006$) and smaller (tarsus length: $p<0.001$) than those produced by experienced females, but there was no difference in the number of fledglings produced or subsequently recruited. Numbers above symbols refer to the number of nests studied. *Reprinted from Cichon (2003) with permission.*

cues provided by another bird is demonstrated by other type of work (Michel, 1976). In the ring dove, birds with previous nest-building breeding experience are more likely to initiate incubation in response to progesterone treatment than inexperienced birds. However, the propensity of a bird to enter the nest area and stand on the nest also depends on the breeding experience of its mate.

30.6 ENDOCRINE AND NEUROENDOCRINE REGULATION OF REPRODUCTIVE BEHAVIOR

Based on the observation of changes in aggressive and mating behavior resulting from castration or castration followed with testis reinsertion into the abdominal cavity of roosters, Berthold was among the first to postulate that the reproductive behavior of birds is influenced by internally produced substances (Quiring, 1944). Since then, this behavior has been shown to be regulated by a great variety of hormones and neuropeptides. This section presents an overview of the influence of the best-studied endocrine and neuroendocrine factors on specific aspects of reproductive behavior. However, the reader should be aware that other factors that are not discussed here due to space limitations play an influential role as well. These factors include opioid peptides and corticotropin-releasing hormone, which can inhibit copulation solicitation in females (Maney and Wingfield, 1998) and sexual behavior (opioids: Kotegawa et al., 1997), and catecholamines (Barclay et al., 1992; Rauceo et al., 2008).

30.6.1 Gonadal Steroids

Gonadal steroids (androgens, estrogens, and progestagens) have been the subject of most attention by far in terms of endocrine regulation of avian reproductive behavior. Their action mechanisms and behavioral effects are summarized in several recent reviews (Ball and Balthazart, 2010; Balthazart et al., 2010; Fusani, 2008), and the reader is referred to these publications for detailed information on this subject. Many studies on this topic are correlative and take advantage of the fact that most birds are photoperiodic (see Section 30.3.1). In these species, day length plays a critical role in the regulation of seasonal cycles, including gonadal development and the secretion of gonadal hormones, this secretion being dramatically higher during (compared to outside of) the breeding season. The seasonality of the reproductive system activity offers excellent opportunities to relate

cyclic (neuro)endocrine changes (e.g., in plasma steroid concentrations) (Osorno et al., 2010; Landys et al., 2010) and the brain expression of steroid-metabolizing enzymes (Soma et al., 2003) or steroid receptors (Fraley et al., 2010), with the occurrence of reproductive behavior. Numerous studies on the behavioral role of gonadal steroids have also been manipulative. Commonly used approaches in these studies include gonadectomy (El Halawani et al., 1986; Hagelin, 2001), peripheral or central administration of hormones (Seredynski et al., 2013; Hunt and Wingfield, 2004; Komisaruk, 1967; also see Sections 30.6.4 and 30.6.6), and treatment with pharmacological agents. Some such agents serve as specific agonists or antagonists for steroid hormone receptors (Delville and Balthazart, 1987), whereas others affect the production or metabolism of steroid hormones (Belle et al., 2005; Schlinger and Callard, 1990). Investigations on the centrally mediated effects of gonadal steroids also take advantage of the coupling of hormonal manipulations with localized brain lesions (Bailhache et al., 1993; Del Negro et al., 1998) or electrophysiological approaches (Meitzen et al., 2007).

Gonadal steroids influence aspects of reproductive behavior at all life stages, including during sexual differentiation (Adkins-Regan, 2009; Banerjee et al., 2012) and in adulthood, when they impact courtship (Fusani, 2008), singing (see Section 30.6.6), sexual receptivity, copulation, incubation, and parental behavior (O'Neal et al., 2008; Van Roo, 2004). Gonadal steroids also play important roles in the regulation of life history stages outside of the reproductive period, such as during preparation for migration (Tonra et al., 2011). They additionally influence metabolic processes and body condition (Deviche, 1992; Buchanan et al., 2001; Jaccoby et al., 1995) and immunity (Deviche and Cortez, 2005; Selvaraj and Pitchappan, 1985), although the pathways (direct versus indirect and mediated, e.g., by glucocorticoids) involved in this influence remain poorly understood (Buttemer et al., 2008; Owen-Ashley et al., 2004). We discussed relationships between gonadal steroids and aspects of social behavior in Section 30.4. The remainder of this section further exemplifies the importance of gonadal steroids in the control of reproductive behavior, in particular their relationships with the AVT system (see Section 30.6.4) and their critical influence on brain regions that are responsible for song production in oscine passerines (see Section 30.6.6).

30.6.2 Neurosteroids

It has become clear in the past 15 years that the vertebrate (including avian) brain is capable of neurosteroidogenesis (i.e., the synthesis of steroids *de novo* from cholesterol) (Schlinger and Remage-Healey, 2012; Ubuka et al., 2009). This conclusion in birds is based on the discovery, among others, that the brain expresses enzymes that are involved in the synthesis of steroids, including pregnenolone, progesterone, T, and estradiol, and this expression is region and developmental stage specific (London et al., 2006). The roles of these enzymes and their products in songbirds are well illustrated by research on brain aromatase, the enzyme that converts androgens to estrogens. Aromatase in the songbird brain is widely distributed and present, among others, in areas that are involved in the control of song production (e.g., the medial border of the HVC and robust nucleus of the arcopallium (RA); see Section 30.6.6) and auditory information processing (e.g., the caudiomedial mediopallium (NCM); Schlinger and Balthazart, 2012). Physiological and behavioral studies reveal that rapid changes in the brain production of estrogen result in behavioral changes. For example, local pharmacological inhibition of estrogen production within the left NCM of male zebra finches rapidly disrupts their ability to preferentially respond behaviorally to their own song versus conspecific song (Remage-Healey et al., 2010; Figure 30.5). Reciprocally, a bird's own behavior, as well as relevant external stimuli, can rapidly modify the brain production of estrogen. Indeed, in the male zebra finch forebrain, the expression of aromatase rapidly increases in response to the act of singing (but not to hearing song; Remage-Healey et al., 2009), and the forebrain concentration of estradiol rapidly increases during social interactions with females (Remage-Healey et al., 2008). In the male white-crowned sparrow (*Zonotrichia leucophrys*), a social challenge (simulated territorial intrusion) rapidly decreases the local concentration of estrogen in several brain regions (Charlier et al., 2011). Rapid, steroid hormone–mediated, and centrally mediated changes in behavior suggest that these hormones act via nonclassic (i.e. nongenomic) mechanisms (discussed further in this section). This proposition is supported by the fact that steroids can bind to cell membrane receptors and

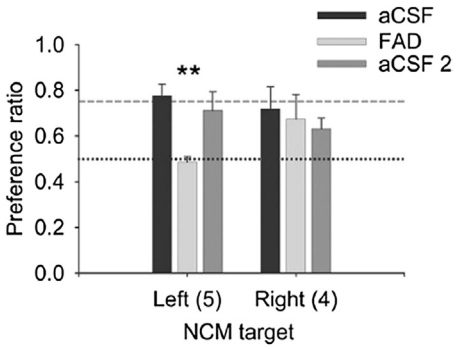

FIGURE 30.5 Influence of the aromatase inhibitor fadrozole (FAD) administered by *in vivo* retrodialysis into the auditory region caudal nidopallium (NCM) of the male zebra finch brain on behavioral preference for the bird's own song versus conspecific song. Control vehicle injections consisted of artificial cerebrospinal fluid (aCSF). Song preference was abolished by FAD administration into the left but not right NCM. *Reprinted from Remage-Healey et al. (2010) with permission.*

induce rapid nongenomic cellular effects (Heimovics et al., 2012).

The Japanese quail has proved to be a particularly profitable experimental model in which to investigate the rapid behavioral effects of neurosteroids and in particularly neuroestrogens. As anatomical and functional studies demonstrate, the quail preoptic area (POA) plays a critical role in the regulation of male sexual behavior (Balthazart et al., 1992; for reviews, see Balthazart et al., 2006; Panzica et al., 1996). This brain region is sexually dimorphic (it is larger in males than females, which do not show masculine sexual behavior) and is a target region for sex steroids: it contains androgen and estrogen receptors, and its volume decreases after castration and is restored following T treatment (Seredynski et al., 2011). The POA contains aromatase, and estrogen in the quail plays a critical role in the control of sexual behavior (Balthazart et al., 2009). Brain aromatase and, therefore, the local production of estrogens in the POA are regulated not only by slow-acting steroid-mediated genomic mechanisms that involve changes in transcription (Voigt et al., 2011) but also by nongenomic mechanisms that can rapidly (within minutes) enhance the local availability of estrogen (Balthazart et al., 2004). This stimulation can in turn stimulate a short-term increase in expression of some aspects of sexual behavior (Cornil et al., 2006a,b; Seredynski et al., 2011). Collectively, research on Japanese quail and the studies described here on songbirds firmly establish neurosteroids as important modulators of reproductive behavior (Schlinger and Remage-Healey, 2012).

30.6.3 Gonadotropin-Releasing and Gonadotropin-Inhibitory Hormones

GnRH in vertebrates plays an essential stimulatory role in the regulation of anterior pituitary gland gonadotropins. In mammals, GnRH also acts as a neurotransmitter and/or in a paracrine fashion to modulate sexual behavior, an effect that is presumably mediated by central GnRH receptors (Hsueh and Schaeffer, 1985). Limited evidence supports the view that GnRH has centrally mediated behavioral actions also in birds. Some of the original work on this subject was conducted in ring doves, in which synthetic GnRH administration stimulates courtship behavior, and this effect is apparently not mediated by LH or progesterone (Cheng, 1977). The brain of many vertebrates expresses at least two forms of GnRH: GnRH-I (cGnRH-I), which is released into the median eminence and stimulates the pituitary gland, and GnRH-II, which is normally not released into the median eminence but into extrahypothalamic brain regions. Central injection of GnRH-II to female white-crowned sparrows rapidly increases their expression of courtship behavior in response to hearing conspecific male song, and this effect is specific to GnRH-II, not being induced by cGnRH-I administration (Maney et al., 1997b). Thus, consistent with the situation in mammals (Hsueh and Schaeffer, 1985), GnRH in birds may act centrally to influence reproductive behavior. It should also be pointed out that, at least in some avian species, the brain contains a nonneuronal source of GnRH. This conclusion is drawn from studies on ring doves, in which the medial habenula contains immune (mast) cells that synthesize GnRH as well as other neurochemicals (Wilhelm, 2011). The activity of these cells is regulated by the endocrine (gonadal steroid) environment, and their number increases within hours in response to courtship (Zhuang et al., 1993), suggesting that their secretory products and in particular GnRH are involved in the control of reproductive behavior.

The discovery of GnIH, a neuropeptide with inhibitory effects on gonadotropin secretion and with fibers extending to a large number of brain areas (Tsutsui et al., 2000; Ukena et al., 2003), has prompted considerable research into its endocrine and behavioral functions. GnIH in birds is produced in the paraventricular nucleus (PVN). Centrally mediated roles for GnIH are suggested by the widespread brain distribution of immunostained GnIH fibers (Ubuka et al., 2008). In the female white-crowned sparrow, central treatment with GnIH inhibits courtship behavior (Bentley et al., 2006), thereby exerting effects that are opposite of those induced by GnRH-II treatment (Maney et al., 1997b; and discussed in this chapter). This behavioral inhibition may result from negative effects on GnRH function because midbrain regions where GnRH-II is produced contain GnIH fibers, and in the European starling, cGnRH-I- and GnRH-II-producing neurons express GnIH receptor mRNA (Bentley et al., 2008). Recent work using RNA interference (RNAi) of the GnIH gene in the Japanese quail provides further support for a centrally mediated behavioral role of this neuropeptide. Here, brain injection of small interfering RNA (siRNA) against GnIH precursor mRNA (GnIH siRNA) stimulated sexual behavior, and this stimulation was blocked by GnIH treatment (Ubuka et al., 2013). An emergent conclusion from studies on the behavioral role of GnIH is that it may function as an important inhibitory modulator of social interactions, including reproductive behavior (Calisi et al., 2011).

30.6.4 Arginine Vasotocin

A peptide whose behavioral role in birds has received considerable attention is AVT, the avian homolog of vasopressin. Given peripherally to zebra finches, AVT decreases courtship behavior, and this decrease is attenuated by T administration (Harding and Rowe, 2003). Zebra finches are opportunistic breeders whose reproduction is induced by water availability. AVT plays a major role in the control of water balance (Sharma et al., 2009). Thus, it is postulated in these finches that drought conditions stimulate

AVT secretion and the peptide in turn inhibits the reproductive system, including T secretion, thereby preventing reproduction during periods of unfavorable environmental conditions. Contrasting with its suppressive action after peripheral administration, AVT exerts centrally mediated stimulatory behavioral effects, as shown by studies reporting that brain injection of the neuropeptide stimulates singing (Voorhuis et al., 1991a; de Kloet et al., 1993; Maney et al., 1997a). Arginine vasotocin is synthesized in several brain regions, including the paraventricular and supraoptic nuclei and the nucleus of the stria terminalis (Panzica et al., 1999b), and AVT-immunostained fibers extend to a large number of brain areas, some of which are involved in the control of vocal behavior (the RA and mesencephalic nucleus intercollicularis: Kiss et al., 1987; Panzica et al., 1999b; Voorhuis and de Kloet, 1992). Binding sites for AVT in the avian brain are similarly widespread (Leung et al., 2009, 2011), and regions containing these sites are innervated by AVT fibers and terminals (Voorhuis et al., 1988b). Collectively, the neuroanatomical distribution of AVT and its receptors suggests that the peptide is involved in the control of multiple functions, including sexual behavior and GnRH secretion (Panzica et al., 2001).

As shown by a number of investigations, the central AVT system and the behavioral effects of the neuropeptide are steroid hormone sensitive. This conclusion is supported by work on canaries showing a sex difference in brain AVT immunostaining (Voorhuis et al., 1988a) and showing, in males of this species, that seasonal changes in AVT immunostaining parallel changes in plasma T (Voorhuis et al., 1991b). Manipulative studies, including gonadectomy and hormone replacement experiments, confirm an important, region-specific stimulatory role for gonadal steroids in the brain expression of AVT (Kimura et al., 1999; Plumari et al., 2004; Viglietti-Panzica et al., 1994) and AVT mRNA (Panzica et al., 1999a). In the castrated male Japanese quail, the effects of T administration on the brain expression of AVT are mimicked by treatment with estradiol but not the nonaromatizable T metabolite 5α-dihydrotestosterone (5α-DHT) (Viglietti-Panzica et al., 2001). Effects of T on brain AVT in this species may, therefore, require aromatization of this steroid. Similarly, when given to female quail, estradiol but not 5α-DHT mimics the stimulatory influence of T on the brain expression of AVT mRNA (Aste et al., 2013; Fig. 30.6).

It should be noted that while estradiol influences the central AVT system, there is also evidence that AVT may modulate the brain production of estrogen. Indeed, in the Japanese quail, aromatase-containing cells in brain regions that control reproductive behavior (e.g., the medial POA; see Section 30.6.2) apparently receive AVT innervation (Balthazart et al., 1997). Acute stress in quail rapidly (within minutes) upregulates their medial POA aromatase activity (Dickens et al., 2011), and there are indications that AVT contributes to mediating this effect (Dickens et al., 2013). Arginine vasotocin may accordingly be an important component of the neural system that controls rapid stress-induced changes in reproductive behavior. New research is clearly warranted to confirm this hypothesis and elucidate the precise nature of this regulation.

30.6.5 Prolactin

The secretion of PRL in birds is under complex regulation by environmental and physical factors. The main environmental factor that controls PRL secretion in many species is day length, with long days stimulating this secretion (Dawson et al., 2001; Sharp et al., 1998). Plasma PRL in these species is accordingly elevated in spring and summer (i.e. during the breeding period) (Gahali et al., 2001; Sharp et al., 1998), and then declines. Elevated plasma PRL toward the end of the breeding period is believed to contribute to, but not be responsible for, the seasonal gonadal regression that signals the end of the reproductive season (Dawson et al., 2001). On a shorter term basis, the secretion of PRL is influenced by factors associated with incubation. For example, the introduction of an artificial egg into the nest of yellow-eyed penguins (*Megadyptes antipodes*), before birds normally start laying, stimulates PRL secretion in females (but has the opposite effect in males; Massaro et al., 2007). Inversely, plasma PRL rapidly decreases in captive female common eiders (*Somateria mollissima*) that are deprived of their eggs (Criscuolo et al., 2002). And in the chicken hen, a precocial species, physical contact with chicks stimulates brooding behavior and precipitates a decrease in plasma PRL, suggesting a role for the hormone in the transition from incubation to brooding (Richard-Yris et al., 1998). Consistent with this conclusion, plasma PRL in this species is high during incubation and then rapidly decreases after hatching (Kuwayama et al., 1992). In the altricial canary, however, plasma PRL remains elevated in females after hatching and decreases gradually during rearing of the young (Goldsmith et al., 1981). Furthermore, plasma PRL in male canaries, which do not incubate or feed young, increases only slightly during the parental phase of the reproductive cycle (Goldsmith et al., 1981). Taken together, these studies support the hypothesis that PRL is involved in the control of parental behavior. It should be noted in some species (Adélie penguin, *Pygoscelis adeliae*; and emperor penguin, *Aptenodytes forsteri*) that the increase in plasma PRL that occurs during reproduction is apparently controlled endogenously rather than by day length or tactile stimulation (Lormee et al., 1999; Vleck et al., 2000). Sustained plasma PRL in the absence of tactile input in these species is thought to be necessary for breeding birds to maintain parental behavior despite the fact that they are absent from their nest for prolonged periods while foraging at sea.

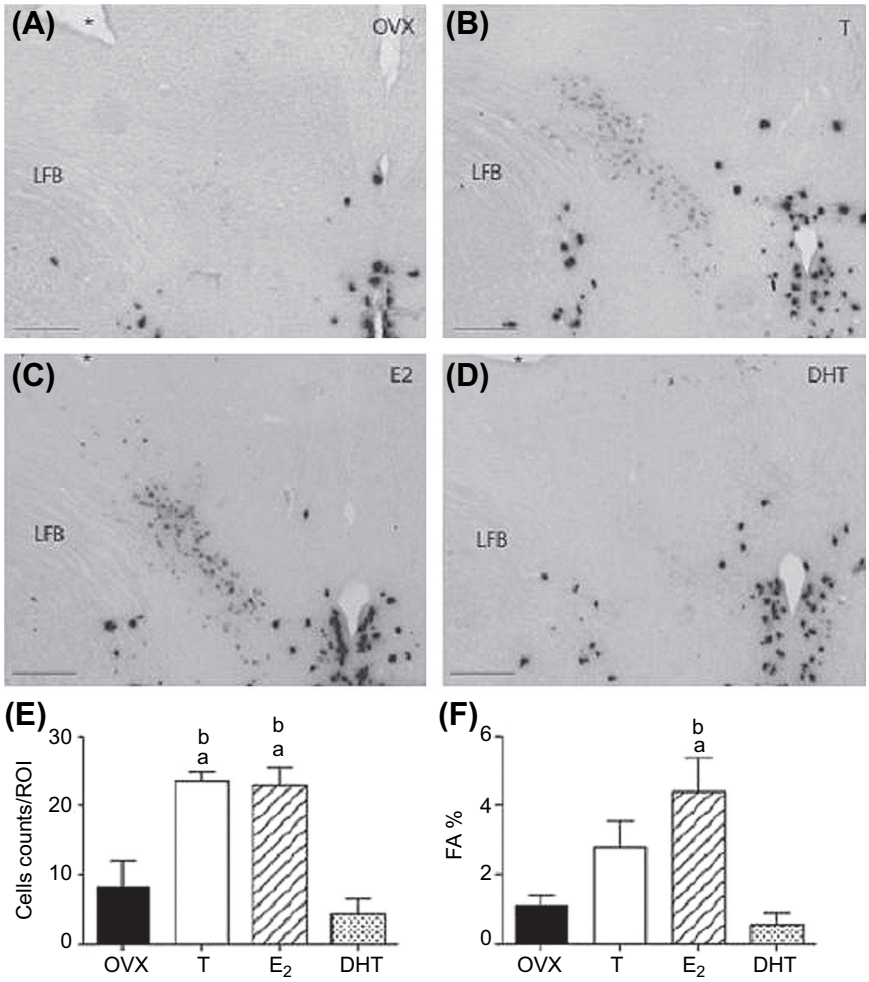

FIGURE 30.6 Regulation of arginine vasotocin (AVT) mRNA expression by gonadal steroids in the female Japanese quail brain. (A–D): Photomicrographs showing the distribution of AVT mRNA-expressing neurons in the caudomedial part of the bed nucleus of the stria terminalis after ovariectomy and one systemic injection of vehicle solution (OVX), testosterone (T), estradiol (E2), or 5α-dihydrotestosterone (5α-DHT). (E): Number of AVT mRNA-containing cells in the region of interest (ROI). This number is increased by T or E2, but not 5α-DHT, treatment. (F): Fractional area (FA) covered by mRNA hybridization signal in the same region. The FA is increased only after E2 administration. *Reprinted from Aste et al. (2013) with permission.*

The ring dove has proved to be a particularly informative model to study the involvement of PRL in the control of parental behavior. In contrast to the situation in many species, PRL secretion in doves does not change seasonally and is not photoperiod regulated, and these birds can breed year-round (Lea et al., 1986a). A role for nest-associated stimuli in the control of PRL secretion in this species is indicated by the observation that plasma PRL increases during incubation, but nest deprivation causes a rapid decline in hormone level (Lea et al., 1986b). Furthermore, injections of PRL enhance the persistence of incubation behavior (Janik and Buntin, 1985) and stimulate food provisioning to squabs (Buntin et al., 1991). Stimulatory effects on parental behavior (including feeding squabs) are also observed after intracerebroventricular administration of the hormone at doses that do not stimulate PRL-sensitive peripheral tissues such as the crop sac, indicating that these effects are mediated centrally (Buntin et al., 1991; Figure 30.7). Consistent with this proposition, the ring dove brain contains PRL-binding sites (Buntin and Ruzycki, 1987) and chemical lesion of the POA produces a deficit in parental behavior in response to PRL administration (Slawski and Buntin, 1995). Centrally acting PRL may be of peripheral (pituitary gland) origin. However, the dove brain contains PRL-immunopositive cells and fibers that project to several hypothalamic regions (Ramesh et al., 2000). Thus, in this species, centrally produced PRL binding to local receptors, perhaps in addition to PRL reaching the brain through systemic circulation, may activate parental behavior.

Stress is often associated with elevated secretion of CORT and can negatively influence parental behavior. Exposure to stressful conditions also often depresses plasma PRL (Angelier et al., 2013). These observations have led researchers to ask whether CORT and PRL normally exert opposite actions on parental behavior, and whether stress-related changes in

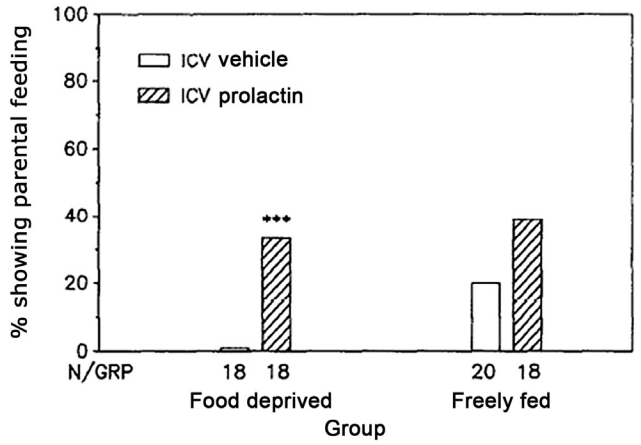

FIGURE 30.7 Stimulation of parental feeding behavior in nonbreeding ring doves by daily intracerebroventricular (ICV) injection of prolactin or vehicle solution. Birds were either fed *ad libitum* or food deprived for 16 h before behavioral testing. N/GRP refers to the number of birds in each experimental group. *** Denotes a significant difference with the vehicle-treated group. *Reprinted from Buntin et al. (1991) with permission.*

plasma CORT and PRL are mechanistically related. These questions have been studied extensively in some seabirds. Correlative evidence is provided by work on black-legged kittiwakes (Chastel et al., 2005). In this species, acute stress decreases PRL more in failed breeders than in breeding birds, suggesting that maintaining sufficiently high plasma PRL during stress may result in birds continuing to breed rather than abandoning their nest. Supporting this proposition, plasma PRL in Adélie penguins is low in birds that abandon their nest compared to birds that do not do so (Spee et al., 2010). However, pharmacological blockade of PRL secretion in this species does not cause nest desertion (Thierry et al., (2013), suggesting the involvement of additional factors. One such factor may be CORT because male penguins that abandon their nest have high plasma CORT (Spee et al., 2010), and CORT administration leads to nest desertion (Kleven et al., 2009). Thus, nest abandonment in this species may require high plasma CORT combined with low plasma PRL. In a more general sense, the above studies suggest in breeding birds that during periods of stress the parental decision to continue to breed can be at the expense of their own condition and survival, and this decision is critically influenced by baseline (prestress) and stress-induced plasma CORT and PRL (Angelier et al., 2009). The extent to which the PRL (decrease) and CORT (increase) stress responses are mechanistically related, however, remains largely conjectural (Angelier et al., 2013).

30.6.6 Case Study: The Oscine Vocal Control System

Acoustic signaling in some species is mediated by nonvocal signals such as those produced by wings (e.g., manakins: Schlinger et al., 2008) and tail feathers (e.g., some hummingbirds: Clark and Feo, 2008), but in many species this signaling is mediated primarily by vocalizations. The neural circuit that controls the perception and expression of vocal behavior in passerines has been the object of enormous attention. This circuit provides an exquisite model in which to investigate how hormones regulate reproductive behavior, the central mechanisms that mediate this regulation, and the reciprocal interactions between behavior and the (neuro)endocrine system. The control of vocal perception and output has been particularly well studied in oscine passerines. Many oscines produce complex, learned vocalizations (songs), the learning and production of which are controlled by a network of discrete and interconnected brain regions called the vocal control system (Nottebohm et al., 1976, 1982; Figure 30.7). Many suboscine passerines also produce complex songs, but in contrast to oscines, vocalizations in these species are generally thought to be innate rather than learned (but see Saranathan et al., 2007), and suboscine song control regions are correspondingly absent or rudimentary (Liu et al., 2013). In oscines, song control regions are typically larger in males than females in species in which males do most of the singing (Tobari et al., 2005; Tramontin et al., 1998), and this morphological difference is associated with cytoarchitectural (Del Negro and Edeline, 2002; Nealen, 2005), biochemical (Charlier et al., 2003; Riters and Ball, 2002; Sakaguchi et al., 2000), and physiological (Adret and Margoliash, 2002; Del Negro and Edeline, 2001) differences between sexes. The exact role of song control regions in females that do not normally sing remains incompletely understood. Some of these regions serve an auditory as well as motor function (Figure 30.8), and in females they may, therefore, regulate vocal behavior perception rather than output (Hamilton et al., 1997).

A remarkable feature of the adult oscine vocal control system is its neuroplasticity. In seasonal breeders, the size of song control regions such as the HVC and RA changes seasonally. These regions are larger during the breeding season, when birds are exposed to long photoperiods, gonads are developed and release large amounts of steroid hormones, and birds sing at a high frequency, than outside this season (Meitzen and Thompson, 2008; Nottebohm, 1981; Smith et al., 1997). The basis of these changes has been researched in particular detail for the HVC, a telencephalic region that plays a major role in song production. Seasonal changes in HVC volume are associated with cytoarchitectural changes, including neuron number, density, and life span (Bowers et al., 2011; Meitzen and Thompson, 2008; Nottebohm et al., 1994). Some vocal control regions including the HVC contain sex steroid receptors (Fraley et al., 2010; Gahr et al., 1987, 1993; Nordeen et al., 1987) whose density is regulated seasonally (Fusani et al., 2000; Soma et al., 1999), suggesting locally mediated roles for these hormones. Consistent with this view, considerable evidence indicates that gonadal steroids play many-faceted roles in the control of the vocal control system's plasticity in adulthood (Bottjer et al., 1986; Ball et al., 2003). These roles include regulation

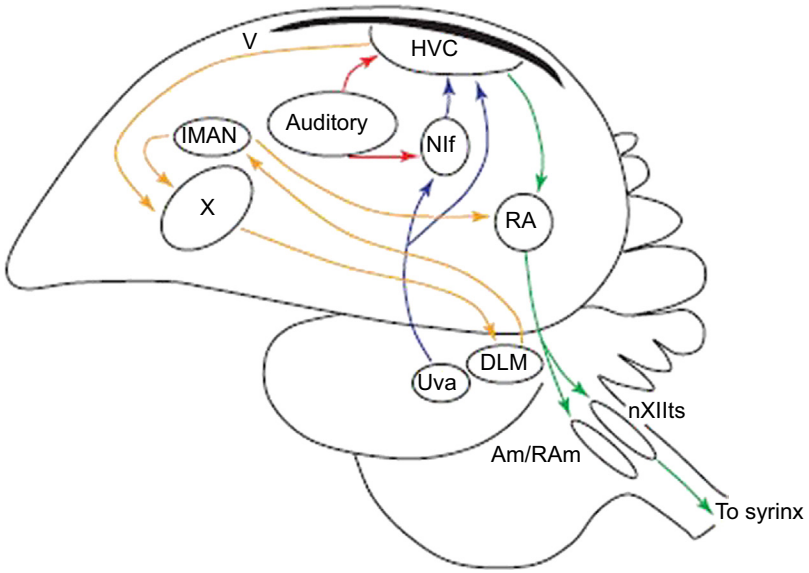

FIGURE 30.8 Projections of the major regions of the oscine brain vocal control system. The system consists of a motor pathway (green) that controls vocal output and includes projections from the HVC (correct full name; not an abbreviation) to the robust nucleus of the arcopallium (RA). A second pathway (orange) is essential for song learning and perception, and includes the medial portion of dorsolateral thalamus, the lateral magnocellular nucleus of the anterior neostriatum, area X, HVC, and RA. *Reprinted from Brenowitz and Beecher (2005) with permission.*

of the size of song control regions (Thompson et al., 2007; Tramontin et al., 2003), newborn neuron migration into the HVC, and the density and survival of existing neurons (MacDougall-Shackleton, 2012). Considerable attention has been devoted to the cellular and molecular mechanisms of action of steroids in song control regions (Thompson et al., 2012), and these studies have identified an important role for brain-derived neurotrophic factor (BDNF). In concert with T, BDNF is thought to promote the proliferation and survival of HVC neurons (Brenowitz, 2013; Alvarez-Borda et al., 2004; Rasika et al., 1999) and also to contribute to seasonal plasticity in the RA (Wissman and Brenowitz, 2009; Li et al., 2000). Furthermore, in the vocal control system the expression of numerous genes that are involved with diverse functions such as neurogenesis, apoptosis, and axonal growth changes seasonally (Thompson et al., 2012). A major challenge in the future is to identify the role of these genes' products and to determine whether and how steroids regulate the activity of these genes. Adding to this complexity, factors such as photoperiod (Dloniak and Deviche, 2001; Gulledge and Deviche, 1998) and social factors (Boseret et al., 2006) influence the size and cytoarchitectural characteristics of song control regions, and this influence is in some situations independent of gonadal steroids. Finally, while this chapter's discussion makes it clear that song control regions play an important role in the expression of vocal behavior, some of these regions are also influenced by sensory (acoustic) stimulation. For example, T administration to female canaries increases their HVC volume, but this increase is attenuated after deafening (i.e., in the absence of auditory stimulation) (Bottjer et al., 1986). The mechanism mediating this difference is not fully understood, and it may involve a role for the auditory stimulus-regulated production of neurosteroids (see Section 30.6.2), in particular estradiol (MacDougall-Shackleton, 2012; Remage-Healey et al., 2012; Soma et al., 2004).

31.1 INTRODUCTION

Parental care promotes the survival and well-being of the offspring, and species, at a cost of resources to the parents as well as the apparently sacrificial acts of individual parents (Gross, 2005). This important vertebrate behavior is the most obvious and pervasive example of altruism in the kingdom Animalia representing the original form of prosocial behavior from which all other animal behaviors are presumed to be derived (Rilling, 2013). The period between birth/hatching and recruitment into a breeding population is a critical phase and may be considered one of the least understood components of animal life histories (Clutton-Brock, 1991). The survival of the young until reproduction has marked effects on population growth and is more sensitive to environmental changes than adult survival (Stearns, 1992; Clark and Martin, 2007).

Among the major vertebrate taxa, behaviors in species in the class Aves are the most extensively studied, as birds exhibit an incomparable balance of tractability, diversity, and cognitive complexity (Rosenblatt, 2003; Kentner et al., 2010; Goodson et al., 2012). Reproductive efforts in birds are extended past fertilization with a variety of parental behaviors. Patterns of parental care range from brood parasitism, in which eggs are laid in the nests of a host species and no display of parental behavior, to intensively prolonged egg incubation and care of offspring by parents. More than 99% of the 9000 species of birds exhibit parental behaviors (Silver et al., 1985). Unlike other vertebrate species, more than 90% avian species exhibit biparental care (Kendeigh, 1952; Lack, 1968) in various degrees between species (Schradin and Anzenberger, 1999; Vleck and Vleck, 2011). More than 70% rear altricial young (Silver et al., 1985). These are poorly developed and helpless at hatch. They depend on their parents to provide food, heat, and protection for an extended period (Buntin, 1996). The remaining 30% species of birds rear precocial young (Buntin, 2010). These are well developed and able to leave the nest, follow their parents, and forage for food on their own after hatching. In precocial species, parental care after hatching consists of brooding the chicks to keep them warm, defense of the chicks, and leading them to food sources and shelter (Buntin, 2010).

Parental behavior is defined as the behavior of the parents that contributes to the survival of their offspring (Numan and Insel, 2003). Maternal behavior is defined as the collection of behaviors by the mother that can increase offspring survival (Krasnegor and Bridges, 1990). Nurturing behaviors analogous to maternal behaviors are called paternal behavior by fathers/male mating partners and alloparental behavior by older conspecifics (Kuroda et al., 2011). In birds, parental behavior includes nest preparation, egg laying into a preferred site such as a nest, egg incubation, and posthatch care of the young to independence (Rosenblatt, 2003; Ruscio and Adkins-Regan, 2004). Maternal care is limited to incubation and brooding or rearing behaviors (El Halawani et al., 1988a). Paternal care refers to behaviors performed by the mature male, which have a positive influence on development, growth, well-being, and survival of the offspring (Fernandez-Duque et al., 2009).

In the vast majority of birds, it is essential that one or both parents incubate their eggs until hatching and then provide posthatching care. The extent of parental care for the eggs and chicks is depended on the developmental maturity of the hatchling such as precocial and altricial chicks. Care of the young ranges from guarding and guiding in the most precocial species such as those within the orders Anseriformes and Galliformes to provisioning of all food and intensive brooding for thermoregulation such as within species within the orders Passeriformes and Psittaciformes (Vleck, 1998). However, there are some species with the

Sturkie's Avian Physiology.

most precocial chicks that require no posthatching care. For instance, in the family *Megapodiidae* (order *Galliformes*), the Australian brush-turkey (*Alectura lathami*) shows no parental care. They lay eggs in underground nests, and these eggs are subsequently incubated by external heat sources. The chicks hatch, then dig out of their nests by themselves, and develop independently of their parents and their siblings (Goth, 2002; Goth and Vogel, 2003). Common cuckoos (*Cuculus canorus*) and brown-headed cowbirds (*Molothrus ater*) are parasitic species. They lay their eggs in the nests of other (host) species and let them raise their young (Winfree, 1999; Kruger, 2007). Likewise, Goldeneye ducks (*Bucephala clangula*) show intraspecific brood parasitism, with some females laying their eggs in the nest of other females of the same species (Andersson and Eriksson, 1982).

31.2 BROODING (BROODINESS)

The term "brooding" (broodiness) in gallinaceous birds refers both to hens incubating their eggs (incubation behavior) or those caring for their young after hatching (brooding behavior) (Ramsay, 1953; El Halawani et al., 1988a). Thus, broodiness has two components: incubation and brooding behaviors. The former can only be induced in laying hens while the latter can be induced in both laying and nonlaying hens together with males. These two behaviors enable the development of fertilized eggs to hatching and the subsequent care of young until independence. Also, they are regulated by different neuronal circuits and associated with different patterns of hormone secretion (Sharp, 2009). Incubation behavior in birds is defined by sitting continually on their eggs until they hatch, whereas brooding behavior is related to the care of newly hatched chicks (Opel and Proudman, 1988; Sharp, 2009). Brooding behavior is characterized by adults of either or both sexes allowing chicks to approach and remain underneath the adults' wings. The adults assume a distinctive crouching posture exhibiting preening and feather fluffing, leading the chicks to food or away from danger, and in some species, calling to the young. Generally, hens develop maternal behavior gradually in four stages: brooding, titbitting (food calling), clucking, and showing normal broody behavior (Ramsay, 1953; Sherry, 1981). The incidence of maternal behaviors concurs with a pause in laying and a significant long-term fall in the plasma levels of reproductive hormones including pituitary hormones and gonadal steroids (Richard-Yris et al., 1983, 1988).

31.2.1 Physiology and Behavior Characteristics Marked by Cessation of Egg Laying and Readiness to Incubate

The physiology and behavior associated with incubation behavior are multifaceted. The behavioral patterns in the domestic turkey (*Meleagris gallopavo*) include the following: increased nesting activity, nest protection, and anorexia (El Halawani et al., 1988a). In chickens, incubation behavior is usually associated with increased body temperature, reduced feed and water intake, frequent nest occupancy, turning and retrieval of eggs, aggressive or defensive behaviors, characteristic clucking, and cessation of egg laying (Romanov et al., 2002). In bantam hens (*Gallus gallus domesticus*), the onset of incubation is related to an increase in nesting frequency and egg laying until the first day of incubation, when hens terminate their egg laying (Lea et al., 1981). A similar increase in nesting frequency is observed in turkeys before the onset of incubation (Haller and Cherms, 1961). Hens sit on their clutches and persistently turn their eggs, rearranging them to guarantee that they are all well covered. In addition to a dramatic increase in nesting time, the incubating bird generally undergoes gonadal regression, shows aggressive nest protection activity, issues warning vocalization, and develops brood patches (El Halawani et al., 1984).

Most incubating avian species develop a so-called "brood patch". This is a defeathered, edematous, and hyperemic (elevated blood flow) area of the skin and includes most of the caudal ventral thoracic and a portion of the cranial ventral abdominal regions. The brood patch develops prior to the initiation of incubation. It functions to facilitate heat transfer from the hen to the eggs and facilitates transmission of tactile stimuli from the embryos to the hen (Jones, 1971; El Halawani et al., 1988a). Birds eat and drink very little and lose body weights during incubation. Weight loss during the incubation period has been recognized in turkeys (Zadworny et al., 1985), bantams (Savory, 1979), Canada geese (*Branta canadensis*; Akesson and Raveling, 1981), mallard ducks (*Anas platyrhynchos*; Gatti, 1983), and native Thai chickens (*G. gallus domesticus*; Kosonsiriluk et al., 2008).

Termination of egg laying and the initiation of incubation behavior normally start after the hens accumulate a full clutch of eggs. Bantam hens accumulate about 10–20 eggs per clutch (Lea and Sharp, 1982). In some birds, such as red grouse (*Lagopus lagopus scoticus*), the same number of eggs are laid whether or not eggs are removed from the nests while the birds are still laying (Moss and Watson, 1982). Incubation behavior is terminated when the chicks are hatched, but it may persist for a prolonged period if the nest contains unhatched eggs. Many wild bird species will continue incubating infertile eggs for about 50% longer than the time normally required for hatching (Skutch, 1962).

31.2.1.1 Neuroendocrine Regulation of Incubation Behavior

The control of avian reproduction involves the interaction of external stimuli with neuroendocrine mechanisms. These critical environmental stimuli include sensory information

such as photoperiod, ambient temperature, and the presence of eggs or offspring (Curlewis, 1992). The primary components of the integrated reproductive neuroendocrine system in birds are the brain, especially the hypothalamus, the pituitary gland, and the gonad. This system is referred to as the hypothalamic–pituitary–gonadal (HPG) axis and includes neurotransmitters, neurohormones, neuromodulators, and hormones that play a pivotal role in the regulation of the avian reproductive cycle.

The neuroendocrine components of the reproductive system include the following:

- Gonadotropin releasing hormone-I (GnRH-I) stimulating the release of luteinizing hormone (LH) and follicle stimulating hormone (FSH).
- Vasoactive intestinal peptide (VIP), which increases prolactin (PRL) release.

Both systems are influenced by dopaminergic (DAergic) neurotransmission. The GnRH-I/FSH/LH system regulates the period of egg laying. GnRH-I stimulates the secretion of FSH and LH, which in turn are responsible for ovarian follicular growth and ovulation. On the other hand, the VIP/PRL system initiates and maintains maternal behaviors and may influence the onset of gonadal regression (Bhatt et al., 2003; Chaiseha and El Halawani, 2005).

31.2.1.1.1 Inhibition of the GnRH-I/FSH/LH System and the Termination of Egg Laying

The commencement of sexual maturity and the activation of the reproductive neuroendocrine system include the stimulation of both the GnRH-I/FSH/LH and VIP/PRL systems. Activation of the GnRH-I/FSH-LH system stimulates the development of the ovary and the formation of the hierarchy of follicles; the follicular production of estrogen, androgens, and progesterone; and the initiation of egg laying (sexual maturity) (Wineland and Wentworth, 1975; El Halawani et al., 1986). The combined action of estrogen, progesterone, and nesting activity further stimulates the VIP/PRL system (El Halawani et al., 1983; Porter et al., 1991; Chaiseha and El Halawani, 2005).

The onset of incubation behavior is marked by an increase in PRL and a decrease in circulating concentrations of LH and FSH; resulting in ovarian regression and decline in the plasma concentrations of the ovarian steroids levels, estrogen, and progesterone. Thereafter, circulating concentrations of LH continue to decline during the incubating period while those of PRL increase dramatically (Lea et al., 1981; El Halawani et al., 1984; Myers et al., 1989; Sharp et al., 1989; Porter et al., 1991) (Figure 31.1). These increasing PRL levels suppress the activity of the GnRH-I/FSH/LH system causing reduced ovarian steroid secretion, a cessation of ovulation, and ovarian regression (Youngren et al., 1991; Rozenboim et al., 1993b; Tabibzadeh et al., 1995). This signals the transition from egg laying activity to incubation behavior.

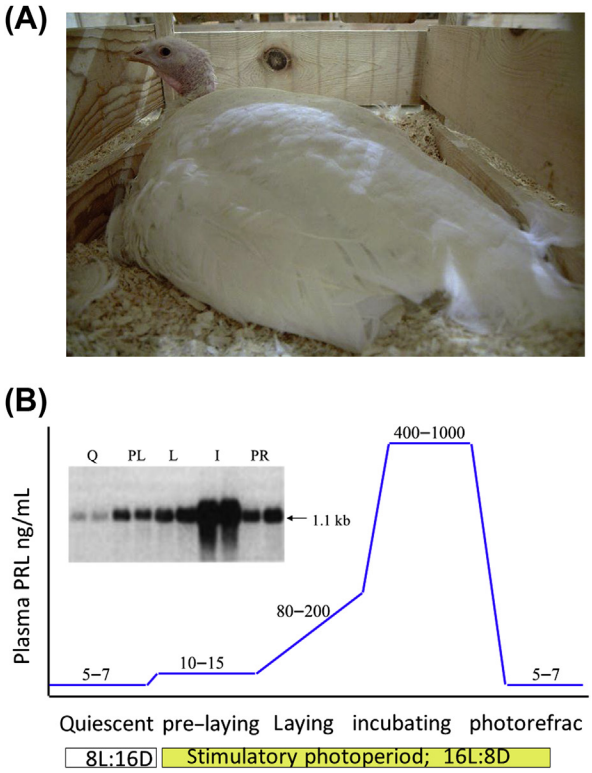

FIGURE 31.1 (A) Incubating turkey hen and (B) schematic profile of circulating prolactin (PRL) and PRL gene expression in turkey hens during various stages of their reproductive life cycles. *Based on Wong et al. (1991).*

It is well established that PRL is a causative factor for the reduced FSH and LH levels and subsequent ovarian regression, when birds make the transition from egg laying to egg incubation in bantam hens (*G. gallus domesticus*; Lea et al., 1981), canaries (*Serinus canaria*; Goldsmith et al., 1984), cockatiels (*Nymphicus hollandicus*; Myers et al., 1989), cowbirds (*Molothrus ater*; Hohn, 1959), domestic chickens (*G. gallus domesticus*; Sharp et al., 1977, 1979; Bedrak et al., 1981), Japanese quails (*Coturnix japonica*; Goldsmith and Hall, 1980), mallard ducks (*A. platyrhynchos*; Bluhm et al., 1983), native Thai chickens (*G. gallus domesticus*; Kosonsiriluk et al., 2008), pheasants (*Phasianus colchicus*; Breitenbach and Meyer, 1959), pied flycatchers (*Ficedula hypoleuca*; Silverin and Goldsmith, 1983), pigeons (*Columba livia*; Riddle et al., 1935), ring doves (*Streptopelia risoria*; Goldsmith et al., 1981), snow geese (*Anser caerulescens caerulescens*; Campbell et al., 1978), spotted sandpipers (*Actitis macularia*; Oring et al., 1986), turkeys (*M. gallopavo*; Cogger et al., 1979; Burke and Dennison, 1980; El Halawani et al., 1997), white-crowned sparrows (*Zonotrichia leucophrys pugetensis*; Wingfield and Farner, 1978; Hiatt et al., 1987), European wide starlings (*Sturnus vulgaris*; Dawson and Goldsmith, 1982), and zebra finches (*Poephila guttata*; Vleck and Priedkalns, 1985) (Figure 31.1).

High concentrations of PRL act both on the neuroendocrine system to inhibit LH secretion by reducing GnRH-I levels in the hypothalamus (Adkins-Regan et al., 2013) and directly on the ovary, inducing ovarian regression and inhibiting LH-induced ovarian steroid production (Rozenboim et al., 1993b). An inverse relationship exists between expression of LH and PRL genes in incubating turkey hens (Wong et al., 1992). Administration of PRL to laying domestic turkey hens has been demonstrated to suppress ovariectomy-induced increases in LH release while delaying the onset of egg laying and inducing incubation behavior (El Halawani et al., 1991). When incubation behavior is terminated, there is a decrease in circulating concentrations of PRL and a concomitant increase in circulating concentrations of LH levels (domestic turkey: El Halawani et al., 1988b; Knapp et al., 1988). In seasonally breeding birds, reproductive activity is terminated by increasing circulating concentrations of PRL, which in turn suppresses LH release, inhibits follicular development, and finally ends egg laying activity (Magang goose: Huang et al., 2008).

In the Thai hen (*G. gallus domesticus*), nest deprivation and the disruption of incubation behavior is accompanied by decreased circulating concentrations of PRL (Prakobsaeng et al., 2011) (Figure 31.2). Moreover, there is increased expression of GnRH-I mRNA in nest-deprived bantam chickens (Dunn et al., 1996) together with elevated circulating concentrations of LH and ovarian steroids (domestic turkeys: El Halawani et al., 1980; bantam chickens: Richard-Yris et al., 1998a). These neuroendocrine changes were reversed when hens renested (Sharp et al., 1988).

Circulating FSH, LH, and gonadal steroids levels are regulated by hypothalamic GnRH-I (El Halawani et al., 1988b; Sharp et al., 1990). GnRH-I is the primary hypophysiotropic factor stimulating the release of LH and FSH (Sharp et al., 1990). An association between hypothalamic GnRH-I mRNA, GnRH-I peptide content, and pituitary gonadotropins secretion during the avian reproductive cycle has been reported (Millam et al., 1989; Rozenboim et al., 1993a; Dunn and Sharp, 1999; Dawson et al., 2002). In seasonal breeders, GnRH-I neuronal activity is regulated by photoperiod (Sharp and Blache, 2003). Photostimulation increases the sensitivity of pituitary cells to GnRH-I (Davies and Follett, 1975) and increases GnRH-I gene transcription and its secretion (Dunn and Sharp, 1999). In temperate-zone birds, GnRH-I mRNA is abundant in the nucleus commissuraepallii (nCPa) of the hypothalamus with expression greater in laying hens than either those of the nonphotostimulated and incubating hens or photorefractory hens (domestic turkey: Kang et al., 2006).

In continuously breeding domesticated bird such as native Thai chickens, the number of GnRH-I neurons in the nCPa is highest in laying hens compared with those at other reproductive stages (Sartsoongnoen et al., 2012). Nest deprivation of incubating hens increases the number of GnRH-I immunoreactive neurons in the nCPa compared with those of the incubating hens. Taken together, these data indicate an association of the GnRH-I system in the nCPa with maternal behavior in the nonphotoperiodic native Thai chicken (Sartsoongnoen et al., 2012) (Figures 31.3 and 31.4).

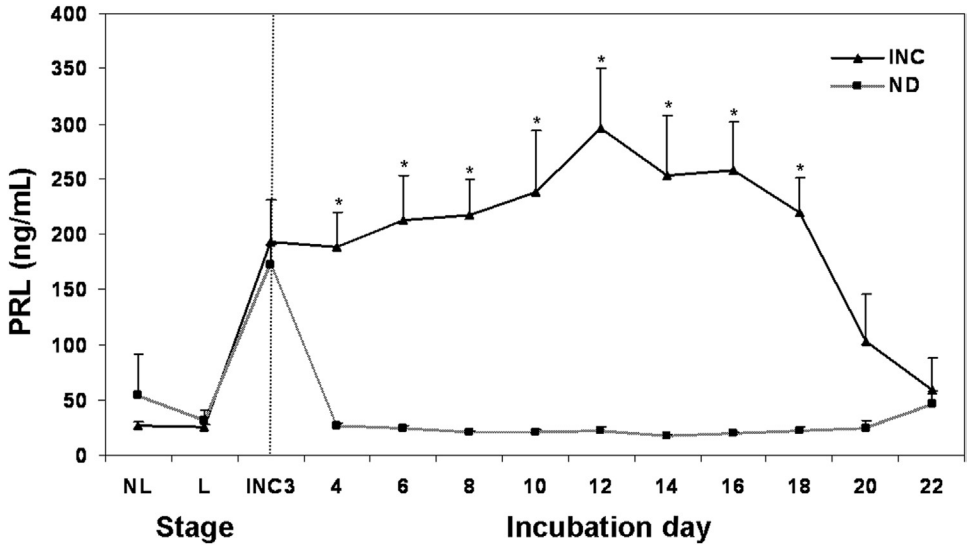

FIGURE 31.2 Changes in prolactin (PRL) level before and after initiation of incubation and nest deprivation of native Thai chickens. Hens were divided into two groups after day 3 of incubation (INC3); one group continued to incubate their eggs (INC) and birds in the second group were nest deprived (ND). Blood samples were collected prior to egg laying (NL), during egg laying (L), and following incubation and nest deprivation for determination of PRL levels. *From Prakobsaeng et al. (2011).*

31.2.1.1.2 Enhanced Prolactin Gene Expression and Secretion

PRL was discovered in 1932 (Riddle et al., 1932); its name is based on the findings that it both causes growth of the crop sac and the production of crop milk in pigeons together with promoting lactation in rabbits (Bern and Nicoll, 1968). The protein hormone, PRL, is synthesized in and secreted from the lactotrophs of the anterior pituitary gland (Freeman et al., 2000). There are more than 300 different physiological functions ascribed to PRL such as in growth, development, reproduction, behavior, metabolism, osmoregulation, immunoregulation, migration, and nurturing of the young in multiple vertebrates (Sinha, 1995; Bole-Feysot et al., 1998; Harris et al., 2004).

Prolactin is associated with reproductive cycles in multiple avian species (El Halawani et al., 1997). In both temperate zone and equatorial chickens, hyperprolactinemia is associated with incubation behavior and ovarian regression (Kosonsiriluk et al., 2008; Prakobsaeng et al., 2011). Moreover, circulating concentrations of PRL are very low in reproductively quiescent chickens and turkeys, increase during egg laying with further increases at the initiation of incubation, leading to the cessation of ovulation, egg laying, ovarian regression, and induction and maintenance of incubation behavior. Thus, it is well established that PRL plays a significant role in the onset and maintenance of incubation in birds (Sharp, 2009; Buntin, 2010). Circulating concentrations of PRL increase gradually at the onset of incubation behavior and are maintained at high levels during the incubation period and then decrease to the levels of reproductively quiescent birds when incubation behavior is terminated (El Halawani et al., 1980; Wentworth et al., 1983). Changes in PRL gene expression correlate well with circulating concentrations of PRL in the avian reproductive cycle, with PRL mRNA reaching a maximal during incubation (Talbot et al., 1991; Wong et al., 1991; Tong et al., 1997; Karatzas et al., 1997; Liang et al., 2006; Huang et al., 2008) (Figure 31.1).

Prolactin is involved in many aspects of reproductive physiology and behaviors in birds in the orders Galliformes and Columbiformes. It plays an important role in a series of parental behaviors by mediating increases in incubation

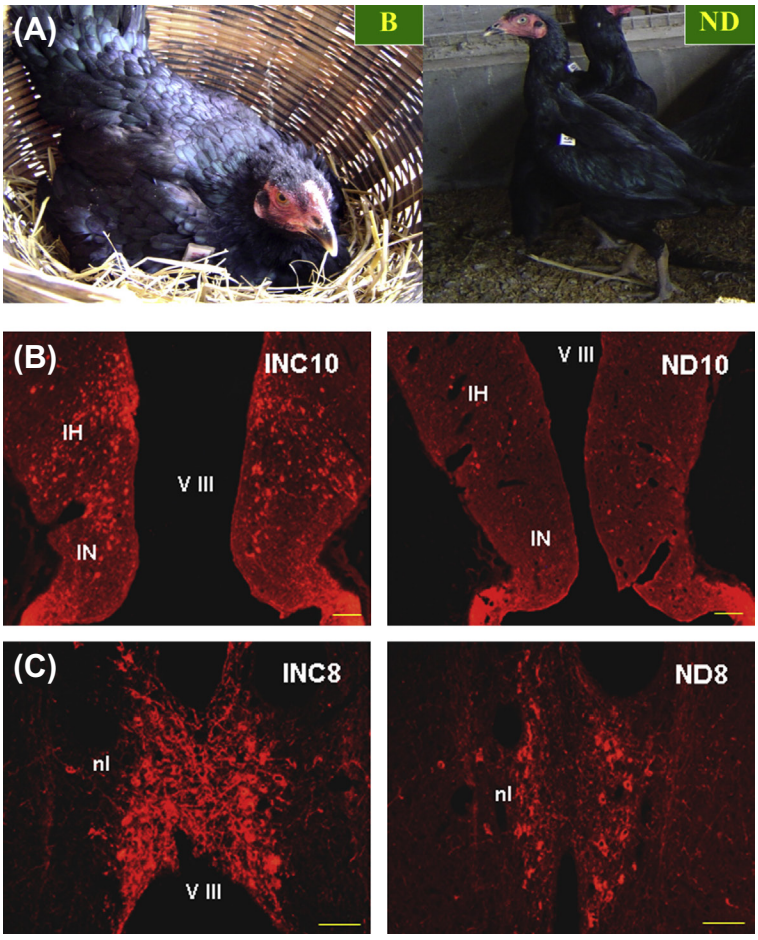

FIGURE 31.3 The distribution of (B) vasoactive intestinal peptide-immunoreactive (VIP-ir) neurons in the nucleus inferioris hypothalami-nucleus infundibula hypothalami (IH-IN) at day 10 and (C) tyrosine hydroxylase-immunoreactive (TH-ir) neurons in the nucleus intramedialis (nI) at day 8 following the initiation of incubation or nest deprivation of (A; B) incubating and (A; ND) nest-deprived native Thai hens.

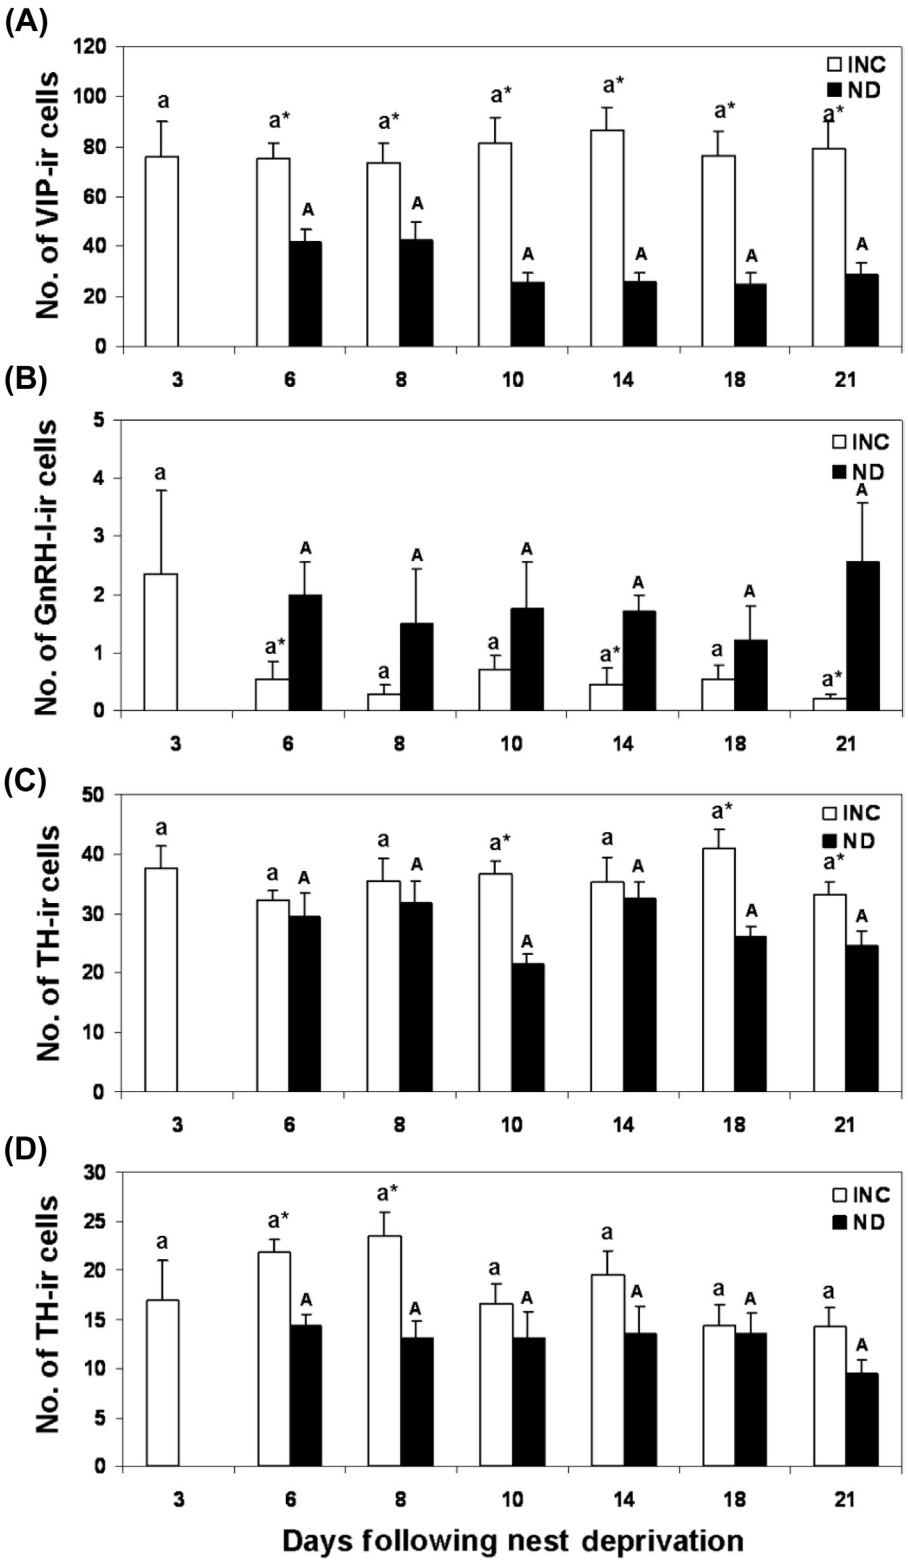

FIGURE 31.4 Changes in the numbers of: (A) vasoactive intestinal peptide-immunoreactive(VIP-ir) neurons in the nucleus inferioris hypothalami-nucleus infundibula hypothalami (IH-IN); (B) gonadotropin releasing hormone-I-immunoreactive neurons in the nucleus commissuraepallii (nCPa); (C) tyrosine hydroxylase-immunoreactive (TH-ir) neurons in the nucleus intramedialis (nI); (D) TH-ir neurons in the mamillaris of incubating (INC) and nest-deprived (ND) native Thai hens. *From Prakobsaeng et al. (2011).*

behavior, crop milk secretion, feeding of young, and nest defense (Silver, 1984; Buntin, 2010). Administration of exogenous PRL results in increases in parental behaviors (Pedersen, 1989; Buntin et al., 1991; Youngren et al., 1991), and active immune-neutralization against PRL reduces the incidence, delays the development, or completely prevents the occurrence of incubation behavior (March et al., 1994; Crisostomo et al., 1998).

Prolactin plays a role in terminating egg laying; thus it regulates the clutch size in species that lay more than two eggs per clutch, with the cessation of egg laying being associated with an increase in circulating concentrations of PRL (Bluhm et al., 1983; Hall and Goldsmith, 1983; Sockman et al., 2000). During the incubating period, there are indications that the suppression of FSH and LH secretion is independent of increased PRL secretion (Lea et al., 1996). In contrast, PRL may directly inhibit ovarian steroidogenesis; resulting in involution of the ovary with reduced ovarian steroidogenesis and regression of the oviduct (Porter et al., 1991; Rozenboim et al., 1993b).

31.2.1.2 Neuronal Regulation of Incubation Behavior

A wealth of information has confirmed the involvement of hypothalamic VIP, dopamine (DA), and GnRH-I in the regulation of the avian reproductive cycle (El Halawani et al., 1997, 2001; Sharp, 2009). The final common pathway governing the secretion of PRL, FSH, and LH is a system of peptidergic neurons whose axons terminate around portal capillaries in the external layer of the median eminence (ME). Among the best characterized hypophysiotropic releasing/inhibiting factors in birds are VIP, DA, and GnRH-I (Chaiseha and El Halawani, 2005).

31.2.1.2.1 Enhanced Dopaminergic Neurotransmission Regulating Incubation Behavior

Avian PRL secretion is regulated by both stimulatory and inhibitory hypothalamic factors. It is predominantly under tonic inhibitory control in mammals (Ben-Jonathan et al., 1989), with DA being the major PRL-inhibiting factor (PIF) (Ben-Jonathan and Hnasko, 2001). This is not the case in birds, with PRL being under tonic stimulatory control by the hypothalamus (Kragt and Meites, 1965; Bern and Nicoll, 1968). Removal of hypothalamic inputs results in the cessation of PRL secretion (Tixier-Vidal et al., 1966; Hall et al., 1986). It is now established that VIP is the avian hypothalamic PRL-releasing factor (PRF) with VIP increasing both PRL secretion and gene expression (El Halawani et al., 1997).

Dopaminergic neurotransmission is involved in both stimulation and inhibition of PRL secretion in birds and depends on multiple DA receptor subtypes (Youngren et al., 1995; Chaiseha et al., 1997) with an intact VIPergic system required for the stimulatory effects (Youngren et al., 1996b). There is co-expression of D_2 DA receptor mRNA in VIP neurons within the lateral hypothalamus (LHy) and infundibular nuclear complex (INF) (Chaiseha et al., 2003). It has been suggested that DA stimulates PRL secretion at the hypothalamic level via D_1 DA receptors residing in the INF, where the VIP neurons are located. Dopamine inhibits PRL secretion directly at the pituitary level via D_2 DA receptors by blocking the action of VIP (Chaiseha et al., 2003). Neurotransmitters and peptides including dynorphin, serotonin (5-HT), DA, and VIP stimulate PRL secretion along a common pathway. It has been proposed that synapses expressing κ opioid, 5-HTergic, DAergic, and VIPergic receptors are arranged serially with the VIPergic system as the final mediator (El Halawani et al., 2001) (Figure 31.5).

There are changes in DAergic activity and DA receptor subtype mRNA expression with reproductive/behavioral stage of the bird. Dopaminergic activity in the anterior hypothalamus is markedly increased in incubating hens compared to laying or nest-deprived bantam hens (Macnamee and Sharp, 1989). Moreover, DAergic activity is elevated at this time in the periventricular regions of ring doves (Lea et al., 2001). Hypothalamic expression of the stimulatory D_1 DA receptors is increased in hyperprolactinemic incubating laying hens. In contrast, the pituitary expression of the inhibitory D_2 DA receptors is increased in hypoprolactinemic photorefractory hens (Schnell et al., 1999; Chaiseha et al., 2003).

The hypothalamic distribution of DA neurons has been established in multiple avian species including domestic chickens (Knigge and Piekut, 1985; Moons et al., 1995), Japanese quails (Absil et al., 2001), pigeons (Kiss and Peczely, 1987; Durstewitz et al., 1998), zebra finches (Mello et al., 1998), budgerigars (*Melopsittacus undulatus*; Roberts et al., 2001), collared doves (*Streptopelia decaocto*; den Boer-Visser and Dubbeldam, 2002), turkeys (Al-Zailaie and El Halawani, 2000), canaries (Appeltants et al., 2001), and native Thai chickens (Sartsoongnoen et al., 2008). Dopaminergic neurons are dispersed in multiple hypothalamic nuclei (Reiner et al., 1994) being intermingled with VIP neurons in the INF, GnRH neurons in the preoptic area (POA), and with both VIP and GnRH terminals in the external layer of the ME (Contijoch et al., 1992; Fraley and Kuenzel, 1993). There appears to be a regional specificity in those DA neurons controlling either the VIP/PRL or the GnRH-I/FSH/LH systems. The ability of exogenous DA to increase VIP expression is limited to neurons in the INF, with this being correlated with pituitary expression of PRL and LH-β (Bhatt et al., 2003). Activation of the DA neurons in the nucleus mamillaris (ML) is associated with the activation of GnRH-I and VIP neurons and the subsequent release of LH and PRL (Al-Zailaie et al., 2006).

The distribution of tyrosine hydroxylase immunoreactivity (TH-ir), the rate-limiting enzyme for DA synthesis and

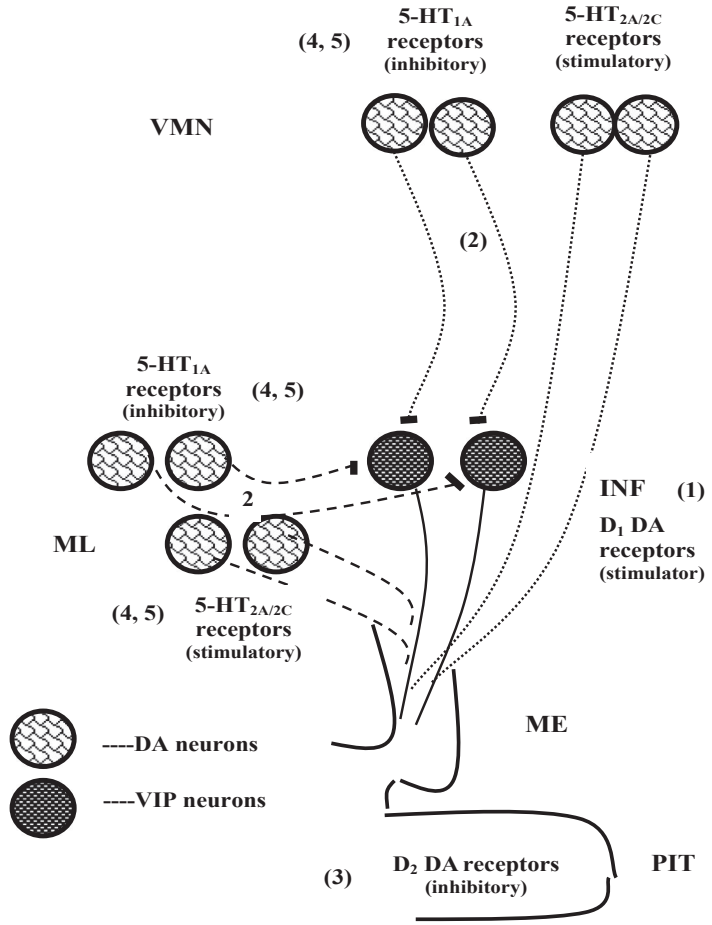

FIGURE 31.5 Schematic diagram showing the neuronal interactions between serotonin (5-HT) and dopamine (DA) and the control of vasoactive intestinal peptide/prolactin secretion. *From Chaiseha and El Halawani (2005).*

hence a marker for DAergic activity, has been reported in turkeys and other avian species. It is predominantly located within the diencephalon and mesencephalon (Kiss and Peczely, 1987; Bailhache and Balthazart, 1993; Moons et al., 1994; Reiner et al., 1994; den Boer-Visser and Dubbeldam, 2002). In the native Thai chickens, the number of TH-ir neurons in the nucleus intramedialis (nI) parallel the PRL levels; increasing during incubation and decreasing when incubation behavior is disrupted (Sartsoongnoen et al., 2008; Prakobsaeng et al., 2011) (Figures 31.4 and 31.6).

31.2.1.2.2 VIP Neurotransmission

VIP was first isolated from porcine duodenum (Said and Mutt, 1970; Mutt and Said, 1974). It is well established that VIP is the avian PRF, with PRL secretion and expression regulated by VIP secreted from neurons located in the INF of the caudomedial hypothalamus (El Halawani et al., 2001). Immunoneutralization against VIP prevents increased PRL secretion and expression and induction of incubation behavior while upregulating LH and FSH gene expression and extending the duration of egg laying. It does not, however, prevent gonadal regression and molting (Sharp et al., 1989; El Halawani et al., 1995, 1996; Talbot et al., 1991; Ahn et al., 2001).

Prolactin secretion parallels hypothalamic VIP immunoreactivity, VIP content in both the INF and ME, and VIP expression in the INF throughout the avian reproductive cycle (Mauro et al., 1989; Chaiseha et al., 1998; Chaiseha and El Halawani, 1999; Kosonsiriluk et al., 2008). VIP acts directly on the lactotrophs to stimulate PRL secretion (El Halawani et al., 1997). There are increases in the number and cell size of VIP neurons reported in the pigeons and ring doves when circulating concentrations of PRL are elevated (Peczely and Kiss, 1988; Cloues et al., 1990). Increased pituitary VIP receptor expression is also found in the laying or incubating turkey hens supporting PRL secretion being principally regulated by VIP at the pituitary level (Chaiseha et al., 2004). Tactile stimuli from the nests and eggs maintain the elevated circulating concentrations of PRL and upregulate VIP gene expression in the incubating hens (Silver et al., 1988; Buntin et al., 1991; Massaro et al., 2007).

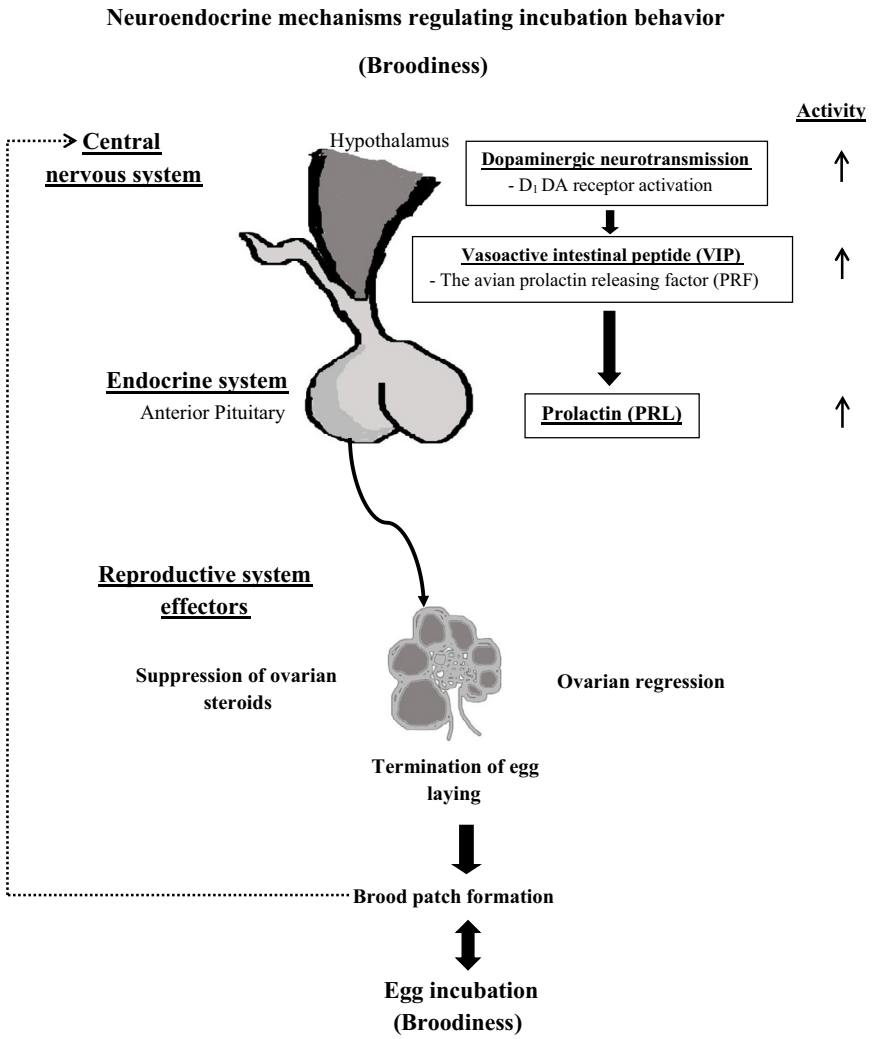

FIGURE 31.6 **Schematic diagram showing the neuroendocrine mechanisms regulating incubation behavior.**

VIP-containing neurons have been mapped in many birds such as Peking ducks (*A. platyrhynchos*; Korf and Fahrenkrug, 1984), Japanese quails (Teruyama and Beck, 2001), turkeys (Chaiseha and El Halawani, 1999), pigeons (Cloues et al., 1990), ring doves (Norgren and Silver, 1990), chickens (Kuenzel et al., 1997), dark-eyed juncos (*Junco hyemalis*; Saldanha et al., 1994), zebra finches (Bottjer and Alexander, 1995), and native Thai chickens (Kosonsiriluk et al., 2008). VIP neurons are extensively distributed throughout the hypothalamus (Macnamee et al., 1986; Hof et al., 1991; Chaiseha and El Halawani, 1999; den Boer-Visser and Dubbeldam, 2002; Kosonsiriluk et al., 2008). The number, distributed area, and density of VIP neurons are all higher in incubating than in laying hens (Sharp et al., 1989; Chaiseha and El Halawani, 1999; Kosonsiriluk et al., 2008). In native Thai chickens, VIP neurons are concentrated within the nucleus inferioris hypothalami (IH) and nucleus infundibula hypothalami (IN) with changes in the number of VIP neurons correlating with PRL levels in the reproductive cycle. The number of VIP neurons decreases concurrently with PRL levels in nest-deprived incubating birds, suggesting that VIP in the IH-IN plays a regulatory role in year-round reproductive activity in these continuous breeding birds (Kosonsiriluk et al., 2008; Sartsoongnoen et al., 2008; Prakobsaeng et al., 2011) (Figures 31.2, 31.4 and 31.6).

31.3 REARING BEHAVIOR

For reproduction to be successful, not only is sexual activity critical, but also care of the young is essential. The offspring need one or both parents to provide food, heat, and protection. This behavior, providing care and defense for the young, must be performed immediately after hatching of the offspring (Brunton and Russell, 2008). The onset of responsiveness is a prerequisite for all mother–offspring interactions. When the mother is exposed to the newly hatched chick, she receives a unique constellation of tactile,

visual, auditory, and olfactory external stimuli as well as changes in neuro/hormonal state (Numan and Woodside, 2010). These induce other behaviors promoting care and survival of the chicks (Swain et al., 2007).

Maternal experiences, neurotransmitters, neurohormones, neuromodulators, hormones, and stimuli from the young interact in a complex manner to promote maternal responsiveness in birds. The presence of chicks results in the expression of rearing behavior including such specific maternal behaviors as clucking and food-calling vocalizations. Hens display physical contact with the chicks by brooding them for longer durations after hatching, while clucking and food calling are regular behaviors exhibited in hens rearing chicks (Richard-Yris et al., 1998b). Galliforms are precocial with newly hatched chicks able to walk, feed, see, and hear. However, the chicks cannot effectively thermoregulate during the first two weeks of posthatch life. Therefore, brooding by the hens helps them to survive (Mills et al., 1997).

Rearing behavior consists of the hens allowing the chicks to nestle underneath their slightly raised wings while assuming a distinct crouching posture (Hess et al., 1976). Stimuli from the chicks are clearly involved in the establishment, appearance, and maintenance of this behavior. It can be induced in chickens, turkeys, and Japanese quail by introducing newly hatched chicks to them. The hens respond almost immediately with maternal care behaviors (Richard-Yris and Leboucher, 1987; Opel and Proudman, 1989). These behaviors are induced by physical contact between the hen and chicks, alone or in combination with visual and/or auditory stimuli from the chicks (Opel and Proudman, 1988; Richard-Yris et al., 1998b). A mother–offspring bond is then formed, with the chicks learning to respond to the food calling, distress call, and purring sound of the hens. The mother–offspring bond is strengthened by repeated exposure of the chicks to the hen (Wauters and Richard-Yris, 2001, 2002; Edgar et al., 2011), with this repeated exposure important for the development of posthatch species-specific maternal call recognition (Gottlieb, 1976; Jain et al., 2004).

31.3.1 Neuroendocrine Regulation of Rearing Behavior

Dopaminergic neurotransmission plays a pivotal role in both GnRH-I/FSH/LH and VIP/PRL systems in avian reproduction. A role for PRL in inducing avian parental behavior was first seen when injections of PRL induced brooding behavior in domestic chickens (Riddle et al., 1935). Neuronal interactions between GnRH-Iergic, VIPergic, DAergic, and mesotocinergic (MTergic) systems have been reported to be involved in rearing behavior (Thayananuphat et al., 2011; Chaiyachet et al., 2013a,b; Chokchaloemwong et al., 2012, 2013).

31.3.1.1 VIP/PRL-DA Neurotransmission and Suppression of the GnRH-I/FSH/LH System

PRL has a well-established role as an incubation-promoting hormone. However, it has also been implicated to be involved as a crucial factor to the onset and maintenance of the rearing behavior (Vleck, 1998; Sharp, 2009; Buntin, 2010). High circulating concentrations of PRL are associated with rearing behavior in chickens (Sharp et al., 1988; Hoshino and Wakita, 1989), turkeys (Proudman and Opel, 1981), mallard ducks (Goldsmith and Williams, 1980), Australian black swans (*Cygnus atratus*; Goldsmith, 1982), ring doves (Buntin, 1996), and native Thai chickens (Chaiyachet et al., 2013b).

Prolactin secretion is stimulated by exposure of hens to tactile and visual stimuli from the chicks with PRL facilitating the expression of maternal behaviors such as incubating, rearing and feeding (Angelier and Chastel, 2009). The transition from sexual to parental activity involved elevated PRL secretion (Sharp et al., 1998) with the circulating maternal care responses (Buntin, 1996). Either sharp declines (bantams; Sharp et al., 1979, 1988; Lea et al., 1981; barheaded geese; *Anser indicus*; Dittami, 1981; common eiders; *Somateria mollissima* Criscuolo et al., 2002; domestic ducks; Hall and Goldsmith, 1983; Hall, 1987; Japanese bantams; Zadworny et al., 1988; mallard ducks; Goldsmith and Williams, 1980; swans; Goldsmith, 1982; native Thai chickens; Chaiyachet et al., 2013b; turkeys; Wentworth et al., 1983) or slow decreases (spotted sandpipers, Oring et al., 1986; Wilson's phalarope, *Phalaropus tricolor*; Oring et al., 1988; red-necked phalarope, *Phalaropus lobatus*; Gratto-Trevor et al., 1990) of circulating concentrations of PRL in hens after hatching of the chicks have been reported in different birds (Schradin and Anzenberger, 1999). In precocial species, PRL secretion declines shortly after hatching, is moderately elevated during the rearing period, and thereafter decreases. In altricial species, PRL secretion increases after hatching while the chicks are being intensively fed and guarded (Buntin, 2010). Among species in which parental care is performed by the females only, there is a markedly larger increase in PRL secretion in females than in males (pied flycatcher; Silverin and Goldsmith, 1984; Angelier and Chastel, 2009). In contrast, in species in which parental care is performed only by the male, PRL secretion is higher in males than in females (Wilson's phalarope and red-necked phalarope; *P. lobatus*; Buntin, 1996; Buntin et al., 1998). A positive correlation between PRL secretion and the intensity/quality of parental care has been observed in many parental birds and cooperative breeders. In cooperatively breeding species, Florida Scrub-Jays (*Aphelocoma coerulescens*; Schoech et al., 1996) and Harris' hawks (*Parabuteo unicinctus*; Dawson and Mannan, 1991), PRL secretion in helpers are positively correlated with the rate of nestling provisioning (Angelier and Chastel, 2009).

In galliforms, PRL is released throughout the rearing period, with its secretion facilitated by the presence of chicks and the high PRL secretion maintaining the rearing behavior (Richard-Yris et al., 1995). In the presence of chicks, circulating concentrations of PRL begin to drop immediately after hatching and continue to decline for about one week after hatching (Zadworny et al., 1988; Leboucher et al., 1990). The presence of chicks modifies the rate of decline in PRL secretion (Opel and Proudman, 1989; Chaiyachet et al., 2013b). In native Thai chickens, circulating concentrations of PRL were higher in rearing than nonrearing hens (Chaiyachet et al., 2013b). The presence of chicks induces the emergence of specific maternal behaviors in many species (Richard-Yris et al., 1983; Richard-Yris and Leboucher, 1987; Opel and Proudman, 1988; Leboucher et al., 1990, 1993; Ruscio and Adkins-Regan, 2004). In the incubating hens, the substitution of chicks for eggs, or the appearance of chicks at hatching, is associated with an increase in circulating concentrations of LH and a marked decrease in circulating concentrations of PRL from the high levels presented during incubation period (Zadworny et al., 1988; Leboucher et al., 1993; Richard-Yris et al., 1998b). Furthermore, exposure to chicks can induce maternal behavior in the incubating, nonincubating, and ovariectomized hens, which exhibit marked differences in circulating concentrations of gonadal steroids and patterns of PRL secretion (Richard-Yris et al., 1987, 1988; Leboucher et al., 1993; Lea et al., 1996; Wang and Buntin, 1999).

In altricial species in the order Columbiformes, the parents jointly rear the young. Pigeons and doves feed their newly hatched chicks by regurgitating crop milk produced by epithelial mucosa cells of the crop sac gland. The epithelial cells proliferate in response to PRL and ultimately slough from the wall of crop sac (Wang and Buntin, 1999; Buntin, 2010). This rise in PRL secretion is accompanied with the onset and maintenance of incubation and rearing behaviors (Columbiformes) and also in free-living passerine species (Goldsmith, 1991; Buntin, 1996). The elevated PRL secretion during the early posthatching period may also promote the display of parental behaviors that are essential for transferring the crop milk to the young squabs in Columbiformes. After chicks achieve thermal independence, PRL secretion declines (Goldsmith, 1991; Buntin, 2010) (Figure 31.7).

The onset of PRL secretion, and its timing of elevation in relation to parental behaviors, varies considerably among biparental species. In some species, rearing behavior and

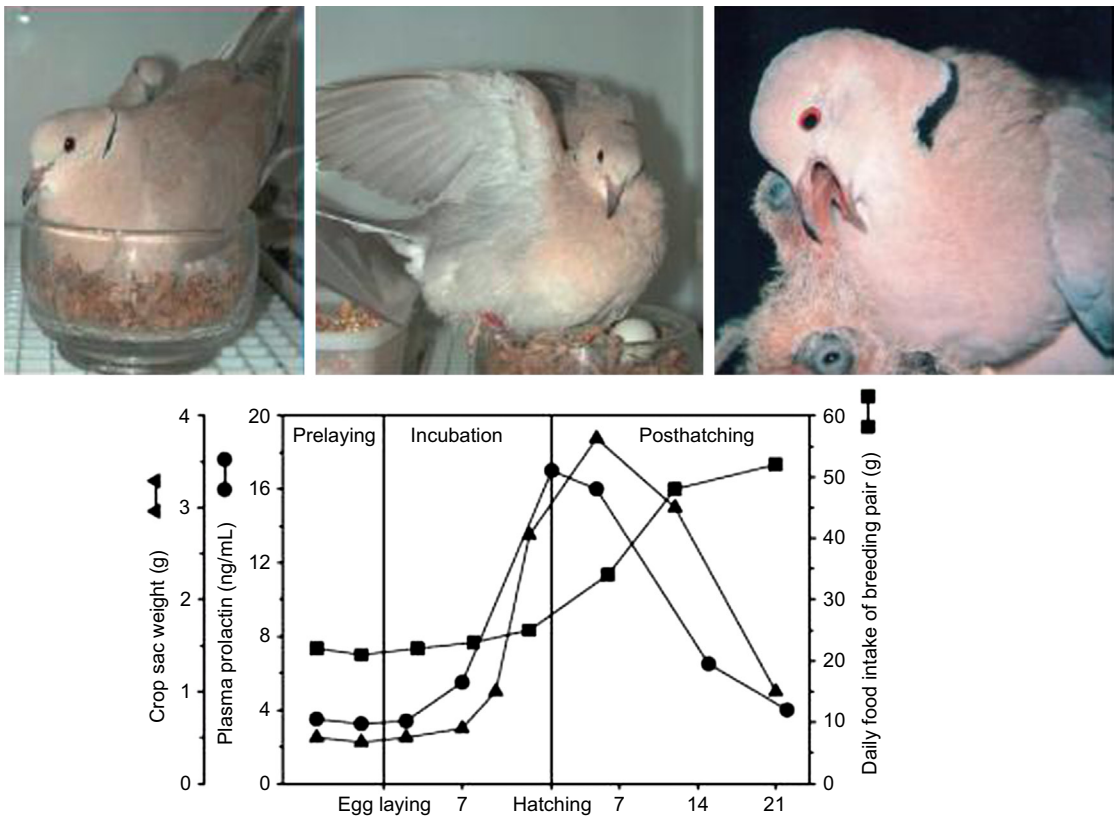

FIGURE 31.7 Prolactin (PRL) and parental behavior in ring doves. Rising PRL levels during the incubation and post-hatching periods of the breeding cycle maintain incubation behavior, facilitate nest defense, stimulate crop sac development and crop milk formation, increase parental foraging behavior, and promote parental regurgitation behavior to transfer crop milk and seeds to the young by both parents. *From Buntin (2010).*

elevated PRL secretion are responsive to visual and tactile stimulation from the nest and eggs; the onset of the increase of PRL secretion beginning near the time of hatching (bantams; Sharp et al., 1988; ring doves, Buntin, 2010; turkeys; Opel and Proudman, 1988). In other species, the onset occurs prior to incubation and chick rearing (king penguin; *Aptenodytes patagonicus*; Garcia et al., 1996; Adélie penguins; *Pygoscelis adeliae*; Vleck and Vleck, 2011). Male and female king penguins and ring doves show a steady increase in PRL levels as the incubation of eggs advances and the chick rearing period begins (Garcia et al., 1996). Male scrub-jay (*Aphelocoma c. coerulescens*; Schoech et al., 1996), canaries (Goldsmith, 1982), white-crowned sparrows (Hiatt et al., 1987), song sparrows (*Melospiza melodia*; Wingfield and Goldsmith, 1990) and European starlings (Dawson and Goldsmith, 1985) all exhibit elevated PRL secretion prior to hatching regardless of whether the males participate in incubation. This suggests that elevated PRL secretion may mediate the feeding of incubating females or of young nestlings in cooperatively breeding species. Thus, elevated PRL secretion in these birds is not solely a response to the stimulation from the eggs or chicks (Ziegler, 2000). There appears to be an inverse relationship between circulating concentrations of PRL and those of testosterone during the avian reproductive cycle. The circulating concentrations of testosterone are elevated for a longer time in polygynous than in monogamous species where there is an abbreviated peak of testosterone (Wingfield and Goldsmith, 1990).

Circulating concentrations of PRL decrease when the incubation period ends and the adults are allowed to hatch and rear their chicks in chickens, ducks, and Australian black swans (Sharp et al., 1979; Goldsmith and Williams, 1980; Goldsmith, 1982). In turkeys, this drop in circulating concentrations of PRL might be related to the pipping and hatching eggs, and the consequent transition to maternal behaviors (Wentworth et al., 1983; Opel and Proudman, 1989).

Rearing behavior is associated with low circulating concentrations of LH and ovarian steroids. The onset of maternal behaviors is accompanied by a prolonged decrease in circulating concentrations of LH, which in turn may be inhibited by increased PRL secretion (Opel and Proudman, 1980; Zadworny et al., 1989). The presence of chicks or the introduction of chicks induces a fall in PRL secretion and a moderate increase in circulating concentrations of LH and ovarian steroids in the incubating chickens (Richard-Yris et al., 1998b; Leboucher et al., 1993; Lea et al., 1996) and turkeys (Opel and Proudman, 1989). This indicates that maternal care, and in particular physical contact with the young chicks, plays a key role in producing these hormonal differences (Richard-Yris et al., 1995). Native Thai hens rearing chicks return to lay later than those not rearing, indicating that the physical stimuli from the chicks slows down the decrease of PRL secretion and inhibits secretion of gonadotropins and ovarian steroids. Disruption of rearing behavior results in an immediate increase in circulating concentrations of LH and estradiol together with a concurrent marked decrease in PRL levels (Chaiyachet et al., 2013b). Both circulating concentrations of LH and estradiol gradually increase after hatching or the presence of chicks to reach a maximum immediately after removal of the chicks. This increase is associated with increased GnRH-I mRNA and is thought to be regulated by the removal of the inhibitory effects of PRL (Kuwayama et al., 1992; Dunn et al., 1996; Richard-Yris et al., 1998b; Dunn and Sharp, 1999). Ovarian mass is positively correlated with GnRH-I gene expression in sexually mature passerine songbirds (Ubuka and Bentley, 2009).

Although PRL is not released at an increased rate in hens that are caring for their young, it appears to be involved in the initiation and/or maintenance of rearing (Sharp et al., 1979). This corresponds to the time when the levels of LH increase to the levels found during laying (Sharp et al., 1979). As the chicks grow older and become fledged, there is a progressive decline in rearing behavior in the adult, leading to a drop in PRL secretion (Boos et al., 2007; Riou et al., 2010). Shorebirds and red-necked phalaropes are facultatively polyandrous and only males care for the eggs and chicks. In these species, PRL secretion in broody males decreases gradually with increasing age of the brood (Gratto-Trevor et al., 1990). In some species (domestic chickens; Leboucher et al., 1990; pied flycatchers; ring doves; Buntin, 1996), stimuli from the young or from the parent–young interactions may promote or sustain the elevated in PRL levels. A definite threshold in PRL levels appears to be essential to promote and/or maintain posthatching care behavior. Although PRL levels are lower during the rearing period than in the incubation period, they are higher than in nonrearing birds, inferring that PRL is involved in parental care after hatching (Criscuolo et al., 2002; Boos et al., 2007).

Although there are high numbers of GnRH-I neurons in the nCPa of nonrearing native Thai hens, there are considerably fewer neurons when the birds are rearing ones. The number of GnRH-I neurons increases after removal of the chicks, suggesting that changes in GnRH-I neurons in the nCPa are key regulators of the avian reproduction irrespective of whether the birds are photoperiodic or equatorial breeders (Chaiyachet et al., 2013b). The number of VIP neurons, together with immunoreactivity and cell size, markedly increases during the incubating period and then decreases sharply during the rearing period (Cloues et al., 1990). At the onset of rearing behavior, the number of VIP neurons of hens caring for the young is lower than during incubation but higher in hens deprived of their chicks (Chaiyachet et al., 2013b). The increase in the number of VIP neurons correlates with an upregulation of VIP peptide and the amount of VIP in the hypophysial portal vasculature

(Mauro et al., 1989; Sharp et al., 1989; Cloues et al., 1990; Youngren et al., 1996a). It is concluded that VIP neurotransmission is playing a role in rearing behavior and, further, that the activity of the VIP/PRL system coupled to its contribution to rearing behavior are related to the extent to which maternal care is required for the hatched young.

The VIP/PRL system is not only a key regulator of incubation behavior but also has an involvement in the regulation of rearing behavior. There appears to be, however, a lower VIPergic threshold required for rearing behavior. Disruption of rearing behavior markedly decreases PRL secretion with a parallel decline in the number of VIP neurons and an accompanying increase in the number of GnRH-I neurons (Chaiyachet et al., 2013a,b) (Figure 31.8).

An association between the DAergic and GnRH/FSH/LH systems has been demonstrated in the turkeys. There are parallel changes in the number of activated DA neurons in the nucleus premamillaris (PMM), in the number of GnRH-I neurons in the nCPa, and an upregulation of GnRH-I gene expression in the nCPa (Kang et al., 2006; Thayananuphat et al., 2007). As might be expected, GnRH axons terminate in the ME and in close proximity to the terminals of the tuberoinfundibular DAergic neurons (Ugrumov et al., 1989). Dopaminergic axons and fibers are found intermingled with VIP neurons in the INF, GnRH neurons in the POA, and with both VIP and GnRH terminals in the external layer of the ME (Contijoch et al., 1992; Fraley and Kuenzel, 1993). The neuronal interactions between the VIP and DAergic neurons are also reported (Teruyama and Beck, 2001). Activation of DAergic neurons in the nucleus mamillaris lateralis is associated with the activation of GnRH-I and VIP neurons and secretion of LH and PRL (Al-Zailaie et al., 2006). Rearing native Thai hens had enhanced DAergic activity and elevated PRL levels when compared to that of hens deprived of their young. This suggests a role for the DAergic system in both incubation and rearing behaviors. Furthermore, the decline in DAergic activity and PRL levels during the disruption of rearing behavior supports the involvement of DA in rearing behavior in this equatorial precocial bird. These findings provide strong evidence for the association of the neuronal interactions between the GnRH-Iergic, DAergic, and VIPergic systems in the neuroendocrine regulation of reproductive activity and care of the chicks (Prakobsaeng et al., 2011; Chaiyachet et al., 2013a,b; Chokchaloemwong et al., 2012).

31.3.1.2 Enhanced Hypothalamic Mesotocin Expression

The hormonal basis of parental care behavior has been extensively studied in multiple vertebrates and collectively these

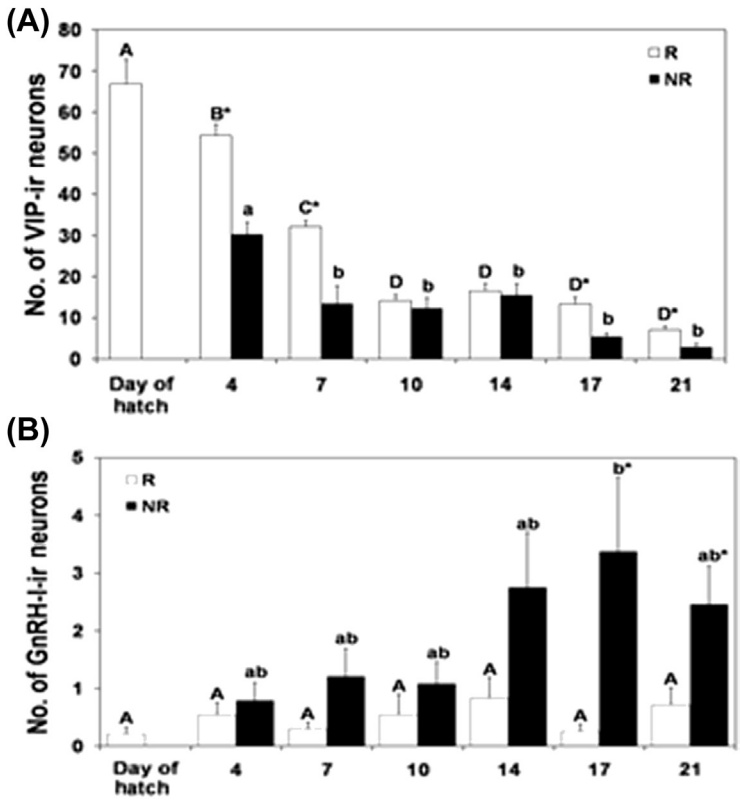

FIGURE 31.8 Changes in the numbers: (A) vasoactive intestinal peptide-immunoreactive neurons in the nucleus inferioris hypothalami-nucleus infundibula hypothalami (IH-IN); (B) gonadotropin releasing hormone-I-immunoreactive neurons in the nucleus commissuraepallii (nCPa) of rearing (R) and non-rearing (NR) native Thai hens. *Modified from Chaiyachet et al. (2013a,b).*

indicate a role of neurohypophysial nonapeptides (Acher, 1972; Goodson et al., 2012). These nonapeptides evolved more than 600 million years ago (Donaldson and Young, 2008). These neurohypophysial hormones are synthesized in magnocellular neurons of the hypothalamus and released from nerve terminals of the posterior pituitary gland or into the hypophysial portal blood via the ME. The best known neurohypophysial nonapeptides are arginine vasopressin (AVP) and oxytocin; these being found in most mammalian species. There are at least 14 additional neurohypophysial hormones that are found in non-mammalian vertebrates. In birds, the two hormones are arginine vasotocin (AVT) and mesotocin (MT), the avian homologs of AVP and oxytocin, respectively (Acher et al., 1970; Hoyle, 1998). They are synthesized in magnocellular neurons of the supraoptic and paraventricular nuclei (SON and PVN). MT neurons are found in several brain areas such as the nucleus supraopticus, pars ventralis (SOv), PVN, cerebellum, lateral septum (LS), optic lobe, pons, and medulla oblongata (Goossens et al., 1977; Bons, 1980; Robinzon et al., 1988).

Little is known of the physiological function(s) of MT in birds. The first evidence for a role of MT in rearing behavior was reported in turkeys (Thayananuphat et al., 2011). The number of MT neurons in the PVN and SOv increases in incubating hens compared with laying hens. In the incubating hens, there is high expression of the immediate early gene, c-fos, observed in MT neurons within the PVN and SOv. The majority of c-fos expression is observed in the DAergic neurons in the ventral part of the nucleus preopticus medialis (POM). The induction of c-fos mRNA expression in the MT neurons within the PVN and SOv in the incubating hens is stimulated by the presence of poults. Blocking MT or D_2 DA receptors prevents poults from brooding. This suggests that MT is involved in the onset of maternal activities (Thayananuphat et al., 2011). In birds, the brain areas that have been implicated in the regulation of parental behaviors are the POA, PVN, and ventromedial nucleus (Slawski and Buntin, 1995; Schoech et al., 1998; Lea et al., 2001). The expression of fos-ir in the brain of brooding ring doves and Japanese quail is higher in the POA, LHy, LS, MPOA, and bed nucleus of the stria terminalis than that of the parents not allowed to rear their young (Ruscio and Adkins-Regan, 2004; Buntin et al., 2006). Similarly, the distribution of MT neurons and fibers of native Thai chickens has been reported. The greatest densities are found predominantly within the SOv, POM, and PVN. The number of MT neurons is maximal after the hens have shifted from egg laying to rearing (Chokchaloemwong et al., 2013). This supports the view that the MTergic system plays an important role in neuroendocrine reorganization to establish and maintain maternal behavior. This is further supported by the analogous role of oxytocin neurons in similar nuclei in mammals (Chokchaloemwong et al., 2013) (Figures 31.9 and 31.10).

32.1 INTRODUCTION

The freshly laid avian egg contains most of the materials needed for embryonic growth and development, but lacks the oxygen and heat needed for successful development. Microscopic pores in the eggshell allow O_2 to diffuse into the egg from the environment and water vapor and CO_2 produced by the embryo to diffuse out. The adult bird has a key role in incubation, providing not only the heat necessary for embryonic development but also controlling the microclimate of the egg. In the poultry industry and for research purposes, the adult bird can be conveniently replaced by an incubator. The majority of research on avian incubation is undertaken using artificially incubated chicken (*Gallus gallus domesticus*) eggs. Thus, in this chapter, the chicken embryo is used to elucidate the development of physiological function during avian incubation, supplemented by additional species when data are available. Developmental physiology of the gas exchange, acid–base, cardiovascular, osmoregulatory and thermoregulatory systems are examined. The optimal conditions for artificial incubation are outlined and embryonic responses to incubation extremes are described.

32.2 THE FRESHLY LAID EGG

The mass of the freshly laid bird egg ranges from ~0.8 g in the bee hummingbird (*Mellisuga helenae*) to ~2 kg in the ostrich (*Struthio camelus*). The egg is composed of the eggshell and outer and inner shell membranes that encompass the albumen, which serves as a source of water and protein; and yolk, a source of necessary nutrients. The composition of the freshly laid egg is related to the maturity of the hatchling, which differs considerably between species.

Sturkie's Avian Physiology.

Hatchlings are divided into four major categories based on criteria such as mobility, amount of down, ability to feed, and locomotion. Precocial species are the most mature, and can walk, swim, or dive soon after hatching, while altricial species are the least mature and hatch naked, with eyes closed and are incapable of coordinated locomotion. Two intermediate categories—semi-precocial and semi-altricial—describe species that are within these extremes. The amount of yolk in the freshly laid egg is much greater in precocial species than in altricial species (Sotherland and Rahn, 1987). The yolk is only 16% of egg mass in the altricial red-footed booby (*Sula sula*), while in the highly precocial kiwi (*Apteryx australis*) it is 69% of egg mass. As most of the energy contained in the egg is in the lipid fraction, most of which is in the yolk, the energy content of precocial eggs is higher than that of altricial eggs. Furthermore, most of the water in the egg is in the albumen, and as the yolk/albumen ratio is lower in altricial than in precocial eggs, altricial eggs have relatively higher water compared with precocial eggs (Sotherland and Rahn, 1987).

32.3 INCUBATION

32.3.1 Incubation Period

Incubation encompasses the prenatal period, prior to "internal pipping" (IP), when the embryo penetrates its beak through the chorioallantoic and inner shell membranes into the air cell; and the perinatal or paranatal period from IP to when the embryo fractures the shell ("external pipping," EP) and hatches. The incubation period (I, days) increases with egg size and can be represented as follows:

$$I = 12 \cdot (\text{Egg mass})^{0.22} \tag{32.1}$$

where egg mass is in g (Rahn and Ar, 1974). In addition, as a first approximation, the product of incubation period and O_2 consumption $(\dot{M}O_2)$ at the stage where $\dot{M}O_2$ remains unchanged (i.e., plateau) is proportional to egg mass (Rahn et al., 1974):

$$I \cdot \dot{M}O_2 = c \cdot (\text{Egg mass}) \tag{32.2}$$

where c is a constant. Thus, for a given egg mass an egg that consumes less O_2 at the plateau stage needs a longer incubation period. Furthermore, because the $\dot{M}O_2$ at the plateau stage is matched to the shell gas conductance, for a given egg mass an egg with lower shell conductance requires a longer incubation period.

Apart from these general trends, eggs that are left unattended by the incubating parent for a period of time will exhibit cooling, and this results in slower embryonic growth and a longer incubation period. Some birds, notably tropical seabirds and petrels (Procellariiformes), have much longer incubation periods than that suggested by the general relationship (Whittow, 1980), even though they are incubated continuously.

32.3.2 Egg Water Content and Shell Conductance

As the embryo grows within the egg, water is lost and both the yolk and albumen diminish in mass. However, metabolic water is produced when fat in the yolk is oxidized. Part of the water is inevitably lost by diffusion through the pores in the shell to the microclimate of the egg. The rate of water loss $(\dot{M}H_2O,\ \text{mg/day})$ is determined by two factors: the water vapor conductance of the shell and shell membranes (GH_2O, mg/day/kPa) and the difference in water vapor pressure between the contents of the egg and the environment (ΔPH_2O, kPa) (Rahn and Ar, 1974):

$$\dot{M}H_2O = GH_2O \cdot \Delta PH_2O \tag{32.3}$$

GH_2O is a function of multiple factors, including shell geometry (effective pore area, A_p, thickness of the shell combined with shell membranes, L); water vapor diffusion coefficient (dH_2O); and the inverse product of the gas constant (R) and absolute temperature (T):

$$GH_2O = [(A_p/L) \cdot dH_2O]/RT \tag{32.4}$$

Both pore area and shell thickness increase in larger eggs (Ar et al., 1974). Although an increase in pore area increases GH_2O, an increase in shell thickness has the opposite effect, because it lengthens the diffusion pathway for water vapor. The water lost from the egg is replaced by air, enlarging the air cell at the blunt pole of the egg during development. Upon IP and EP, the rate of water loss from the egg increases, as water vapor can diffuse through the cracks (pip-hole) in the shell. The water loss from the egg over the entire incubation period amounts to ~18% of the mass of the freshly laid egg.

32.3.3 Heat Transfer

Many adult birds (typically but not always the female) play an important role in incubation of their eggs, by using their body and nesting material to alter the environment of the eggs. Most birds develop a seasonal bare patch of skin, the brood patch, on part of the thorax and abdomen. This directly contacts with the eggs, permitting a greater rate of heat transfer than if the patch were covered with plumage. Accompanying the loss of feathers is an increase in the size and number of blood vessels in the bare skin. The adult can adjust the rate of heat transfer to the egg by standing over or leaving the vicinity of the egg, but also by the closeness with which the bird applies its patch to the egg. The bird responds physiologically to variations in egg temperature (T_{egg}), increasing its metabolic heat production in response to cooling of the egg (Tøien et al., 1986; Rahn, 1991).

The amount of heat transferred to the eggs is directly proportional to the increase in heat production (Tøien et al., 1986). The efficiency of heat transfer to the eggs diminishes

with decreasing ambient temperature and clutch size. Heat stored in the incubating bird while flying and foraging (i.e., while not incubating the eggs) can be transferred to the eggs on return to the nest (Biebach, 1986). If the egg is very cold, "cold vasodilation" occurs in the brood patch, increasing the patch blood flow and temperature and therefore heat transfer to the egg (Mitgard et al., 1985). The brood patch temperature varies from 34.9 °C in the bonin petrel (*Pterodroma hypoleuca*) to 42.4 °C in the dusky flycatcher (*Empidonax oberholseri*). The brood patch temperature is 1.1–5.5 °C higher than the T_{egg} in numerous species (Rahn, 1991).

At the beginning of incubation, heat is transferred through the egg by conduction, and the surface of the egg on the opposite side to the brood patch may be 4 °C or more below the brood patch temperature (Rahn, 1991). As incubation proceeds, this temperature difference diminishes as the embryo's developing circulation assists in the distribution of heat and its increasing metabolism provides additional heat (Turner, 1987; Rahn, 1991). This effect of blood flow on heat flow is more important in large eggs than in small ones (Tazawa et al., 1988a). The main barrier to heat loss from the egg is a thin layer of air immediately adjacent to the shell, the boundary layer (Sotherland et al., 1987). If the egg is in a nest, the nest itself imposes an additional resistance to heat loss.

As the embryo grows, incubation likely becomes more a matter of regulating the balance between heat gain from the mother and heat loss through radiation from the egg surfaces, because the near-term embryo is producing considerable heat itself. The rate of heat loss from the egg is going to depend on many factors, though one of the more important ones may be the surface area-to-volume ratio of the egg. Thus, larger eggs (e.g., emu, ostrich) may have lower capacity for heat loss because of their smaller surface area-to-volume ratio. However, larger embryos may also show conventional metabolic scaling, with lower per-gram body mass rates of temperature production than smaller embryos. A study that integrates egg size, embryo metabolic rate, and incubation behavior changes during embryonic development is highly warranted.

32.3.4 Energy Use

As chicken embryos grow, their mass increases geometrically until growth rate slows during the last stages of development (Romanoff, 1967; Van Mierop and Bertuch, 1967; Tazawa et al., 1971a; Lemez, 1972; Clark et al., 1986; Haque et al., 1996). From the mean values of the above references, the geometrical increase in embryo wet body mass to day 16 of incubation is expressed by:

$$\text{Body mass (mg)} = 0.24 \cdot I^4 \qquad (32.5)$$

Of the energy measured as oxygen uptake $(\dot{M}O_2)$, the majority is utilized by the embryo to synthesize new tissues for growth and to meet the physiological demands for maintenance during development. In addition, toward the end of incubation, the embryo uses energy for active control of body temperature and hatching. Prior to this, it is assumed that prenatal $\dot{M}O_2$ is used for maintenance, which is proportional to body mass, and for growth, which is proportional to growth rate ($GR = \Delta Body\ mass/time$) as follows (Vleck et al., 1980; Mortola and Cooney, 2008):

$$\dot{M}O_2 = a \cdot (\text{Body mass}) + b \cdot \text{GR} \qquad (32.6)$$

where coefficients a and b express the daily average cost of maintaining 1 g of tissue ($mL\,O_2/g/day$) and the cost of growing it ($mL\,O_2/g$), respectively. During days 9 to 18 of the ~21 day incubation period of chickens, and excluding early development when $\dot{M}O_2$ of small embryos does not reflect total egg $\dot{M}O_2$ because of uptake by extra-embryonic tissues, a and b are estimated as ~15 $mL\,O_2/g/day$ and ~41 $mL\,O_2/g$, respectively (Mortola and Cooney, 2008). Therefore, the cost of growing 1 g of tissue averages ~3 times the cost of maintaining it. In addition, cooling due to low temperature incubation (35 °C) only decreases GR with a decrease in the cost of growth, but hypoxic incubation decreases not only GR but also the cost of maintenance. That is, cold incubation decreases GR without altering the partitioning of energy expenditure while hypoxia decreases GR and alters the partitioning of the energy.

Daily energy use increases as the embryo grows and is reflected in an increase in $\dot{M}O_2$. However, precocial and altricial birds show a different developmental pattern in embryonic $\dot{M}O_2$ (e.g., Vleck and Vleck, 1987). In altricials, $\dot{M}O_2$ increases at an increasing rate throughout incubation, lacking a plateau. In precocials, the rate of increase in $\dot{M}O_2$ plateaus before the egg is pipped and then increases again after pipping. For a given egg size and incubation period, altricials use less energy, and so have a lower incubation energy cost to hatching than precocials (Vleck et al., 1980). The high cost of incubation in precocials is due to their rapid growth early in development, which results in higher maintenance costs—that is, there is more tissue to maintain for a longer time (Vleck et al., 1980).

Based on the assumption that both precocials and altricials have an identical basic pattern of increase in $\dot{M}O_2$, including a plateau phase attributable to the shift of the gas exchange from the chorioallantoic membrane (CAM) to the lungs (Rahn and Ar, 1974), Prinzinger et al. (1995) defines the plateau phase as a clear interruption of the continuous exponential increase in $\dot{M}O_2$. This demonstrates no fundamental difference between both modes with respect to the presence of a plateau (Figure 32.1) (Prinzinger et al., 1995; Prinzinger and Dietz, 1995). They suggest that in small altricials the plateau lasts only a few hours and can be overlooked when $\dot{M}O_2$ measurement is not continuous or when many individual measurements are averaged. The extremely precocial mound-building birds (Megapodiidae) are one exception having no plateau phase as they lack the CAM-pulmonary transition within the egg (Vleck et al., 1984).

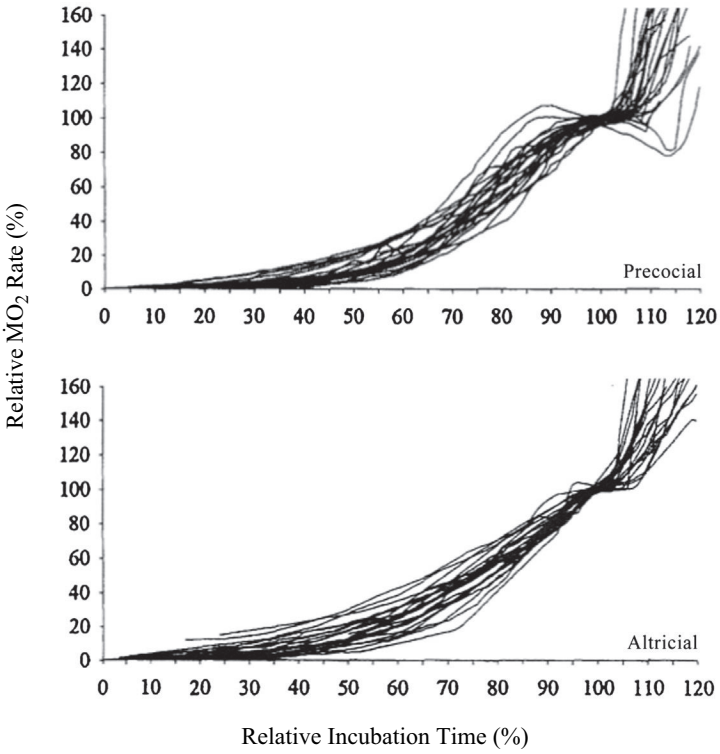

FIGURE 32.1 Developmental patterns of relative oxygen uptake ($\dot{M}O_2$, %) in precocial and semiprecocial species ($N=27$) (top) and altricial and semi-altricial species ($N=24$) (bottom) plotted against relative incubation time (%). The O_2 uptake and incubation time at the middle of plateau stage are both set at 100%. *Modified from Prinzinger and Dietz (1995), with permission from Elsevier.*

32.4 DEVELOPMENT OF PHYSIOLOGICAL SYSTEMS

32.4.1 Gas Exchange

The egg with its hard shell does not enable embryonic ventilatory movements, and thus there is no convective gas exchange until the embryo's lungs begin to function. Early in incubation, prior to a formation of the heart and even initially after the forming heart beats, O_2 can be adequately supplied from the environment to the embryo through diffusion. $\dot{M}O_2$ is normally maintained without blood convection, even in embryos whose main vessel from the heart is ligated or hemoglobin (Hb) is rendered functionless due to carbon monoxide exposure (Burggren et al., 2000, 2004; Mortola et al., 2010; Burggren, 2013). When gas transport by diffusion alone becomes inadequate, blood convection begins to meet O_2 demand during development, and three different gas exchangers sequentially function in the egg; the area vasculosa, the chorioallantois, and the lungs. Figure 32.2 shows the growth rate of the functional surface area of the area vasculosa and the chorioallantois (Ackerman and Rahn, 1981) and the associated $\dot{M}O_2$ of the chicken embryo. The area vasculosa is a well-vascularized region of the yolk sac that fans out from the embryo and rapidly grows around the yolk during days 3 to 5 of incubation. The blood vessels of the yolk sac connect with the dorsal aorta of the embryo by day 2 and blood begins to circulate through the embryo and the area vasculosa. The fine reticulation of the vitelline circulatory system plays the role of the main gas exchanger until the chorioallantois makes contact with the inner shell membrane around day 6 (Ackerman and Rahn, 1981). Subsequently, respiratory function transitions from the area vasculosa to the chorioallantois.

Beginning on day 5 of incubation, the mesenchyme covering the fundus of the allantoic sac comes into contact with the mesenchyme lining the chorion. The two membranes begin to fuse, and the growing allantoic sac flattens out beneath the chorion, which lies close to the eggshell. The outer limb of the flattened allantois, composed of the cohesive chorion and allantois, is the chorioallantois. The chorioallantois grows rapidly (Figure 32.2). It reaches almost the same size as the embryo by the time it makes contact with the shell membranes on day 6. By day 12, the chorioallantois extends to envelop the contents of the whole egg, lining the entire surface of the inner shell membrane.

The outer surface of the chorioallantois, the chorioallantoic membrane (CAM), is well vascularized (Wangensteen et al., 1970/71; Tazawa and Ono, 1974; Wangensteen and Weibel, 1982). Early in incubation, the capillaries lie on the mesenchymal surface of the CAM. They begin to migrate through the ectoderm on day 10 and lie on its thin layer late in incubation. In addition, relocation of the nuclei of the

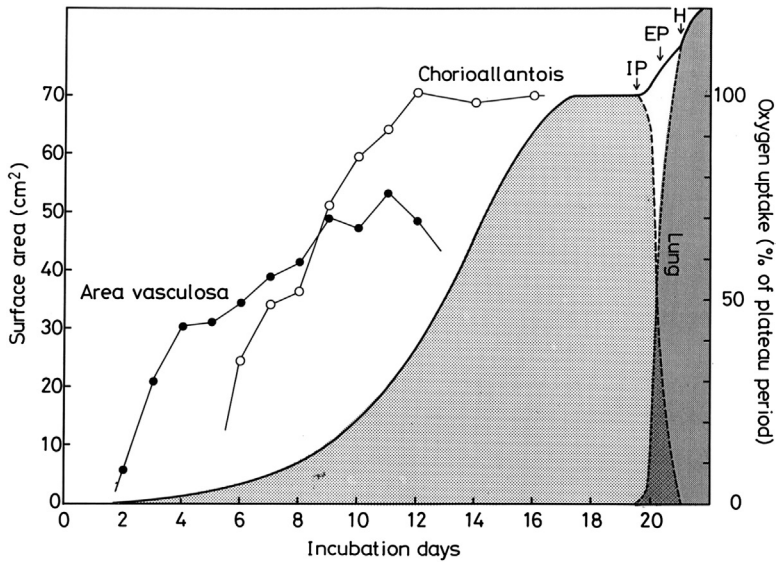

FIGURE 32.2 Daily changes in functional surface area of the area vasculosa and the chorioallantois (left ordinate), and developmental pattern of oxygen uptake ($\dot{M}O_2$) during the prenatal period (until internal pipping, IP) and perinatal period (from IP to hatching, H) (right ordinate). External pipping (EP) occurs during the perinatal period. $\dot{M}O_2$ is drawn diagrammatically with the plateau set at 100%. The lightly shaded area indicates $\dot{M}O_2$ by diffusion through the area vasculosa/chorioallantois and the heavily shaded area $\dot{M}O_2$ by the lungs. *From Ackerman and Rahn (1981), with permission from Elsevier.*

CAM capillaries occurs (Mayer et al., 1995). The endothelial nuclei randomly distribute around the capillary lumen early in incubation and are located progressively on the portion of the capillaries away from the shell membrane after the chorioallantois envelops the whole contents of the egg. Together with capillary migration, the relocation of endothelial nuclei results in progressive thinning of the gas diffusion pathway between the interstices of the inner shell membrane (airspace) and the capillary blood.

The CAM functions as a gas exchanger during prenatal development (prior to IP) until it degenerates when the embryo pips it and the inner shell membrane with the beak. The increase in $\dot{M}O_2$ of the chicken embryo during the first ~16 days of incubation is enabled by the extension of the CAM (Figure 32.2). The gas exchange of embryos before IP takes place by diffusive transport across the porous shell, two shell membranes, and capillary blood of the CAM (Wangensteen and Rahn, 1970/71; Wangensteen et al., 1970/71, Wangensteen and Weibel, 1982). Then, the chick breaks the shell and breathes environmental air by lung ventilation (EP). As the near-term embryo begins ventilating the lungs, they replace the gas exchange function of the CAM.

When the CAM envelopes all contents of the egg, the gas exchange by diffusive transport is expressed by:

$$\dot{M}O_2 = GO_2 \cdot (PIO_2 - PAO_2) \qquad (32.7)$$

$$= DO_2 \cdot (PAO_2 - P\bar{c}_{O_2}) \qquad (32.8)$$

where $\dot{M}O_2$ is oxygen uptake (mL/min), GO_2 is oxygen conductance of the shell and shell membrane (mL O_2/min/kPa), DO_2 is the diffusing capacity of the CAM and capillary blood (mL O_2/min/kPa), PIO_2 is the effective environmental oxygen partial pressure (kPa); PAO_2 is the airspace oxygen partial pressure (kPa), and $P\bar{c}_{O_2}$ is mean capillary oxygen partial pressure (kPa).

GO_2 is related to GH_2O by the diffusion coefficient ratio (dO_2/dH_2O = 0.23/0.27). GO_2 (in mL/min/kPa) is derived from GH_2O (in mg/min/kPa) by multiplying by a factor of 1.06. Because GO_2 in air is nearly constant during the prenatal incubation, PAO_2 decreases as the embryo grows and consumes more O_2 (Table 32.1). The increased difference of O_2 partial pressure between the environmental air and airspace is the driving force that meets the increased O_2 demand of the developing embryo. Concurrently with the decrease in PAO_2, $P\bar{c}_{O_2}$ also decreases. The O_2 flux from the airspace to the Hb of capillary blood (inner diffusion barrier) is facilitated by an increase in DO_2, which is expressed by:

$$DO_2 = 60 \cdot V_c \cdot F\bar{c}_{OX} \cdot Hct \qquad (32.9)$$

$$= \dot{Q}_a \cdot t_c \cdot F\bar{c}_{OX} \cdot Hct \qquad (32.10)$$

where V_c is capillary volume of the CAM (μL), $F\bar{c}_{OX}$ is mean corpuscular oxygenation velocity during the contact time per s per kPa, Hct is hematocrit, $\dot{Q}_a$ is blood flow through the CAM (mL/min), and t_c is the contact time of erythrocytes with O_2 when they pass through the CAM capillaries (s) (Tazawa et al., 1976b; Tazawa and Mochizuki, 1976) (Table 32.1).

DO_2 is increased by an increase in V_c, which depends on $\dot{Q}_a$ and t_c; $V_c = (\dot{Q}_a/60) \times t_c$ (Table 32.1). While $\dot{Q}_a$ increases about five-fold from days 10 to 18, the t_c halves,

TABLE 32.1 Gas Exchange Variables Used to Determine the Diffusing Capacity of the Inner Diffusion Barrier (Chorioallantoic Membrane and Capillary Blood) in Developing Chicken Embryos

Age (days)	10	12	14	16	18

Body mass (g); from Tazawa and Mochizuki (1976); PAO_2 (airspace PO_2, kPa), $PACO_2$ (airspace PCO_2, kPa), PvO_2 (mixed venous blood PO_2, kPa), $PvCO_2$ (mixed venous blood PCO_2, kPa); calculated from data in Tazawa (1973) and Wangensteen and Rahn (1970/71). Note: Unit of partial pressure is converted from 'mmHg' in original sources to 'kPa' in current text; P_aO_2 (arterialized PO_2 in the allantoic vein, kPa); from Tazawa (1973); pH_a (arterialized blood pH corresponding to the allantoic vein); from Tazawa et al. (1971a); S_aO_2 (oxygen saturation of arterialized blood, %); calculated by substituting P_aO_2 and pH_a into the modified Hill's equation of the O_2 dissociation curve (Tazawa et al., 1976a); S_vO_2 (oxygen saturation of mixed venous blood, %); determined by micro-photometer (Tazawa and Mochizuki, 1976); O_2 capacity (vol%); determined from Tazawa (1971) and Tazawa and Mochizuki (1977); $\dot{M}O_2$ (oxygen uptake, mL/min); from Tazawa (1973); $\dot{Q}_a$ (allantoic blood flow, mL/min); calculated by $\dot{M}O_2/[O_2$ capacity $(S_aO_2 - S_vO_2)]$; t_c (contact time, sec); determined by micro-photometer (Tazawa and Mochizuki, 1976); V_c (capillary volume, 10^{-3} mL), calculated by $\dot{Q}_a/60 \times t_c$; $F\bar{c}_{OX}$ (oxygenation velocity factor per s per kPa); from Tazawa et al. (1976b); Hct (hematocrit, %); from Tazawa et al. (1971a); DO_2 (diffusing capacity of inner diffusion barrier, mL/min/kPa); calculated by $60 \cdot V_c \cdot F\bar{c}_{OX} \cdot Hct$ or $\dot{Q}_a \cdot t_c \cdot F\bar{c}_{OX} \cdot Hct$.

probably because of shortening of the blood circulation time, as cardiac output increases more rapidly than total blood volume. Consequently, V_c increases even after the CAM spreads over the whole surface of the inner shell membrane on day 12 and reaches a maximum volume on days 14 and 15. Nevertheless, DO_2 increases further after day 14. This is largely due to the increase in $\dot{Q}_a$ and Hct, as both variables increase after the CAM spreads over the inner shell membrane. Towards the end of prenatal development, the increase in DO_2 slows down and $\dot{M}O_2$ reaches a plateau. This suggests an important contribution of the inner diffusion barrier to gas exchange, which contributes, along with the outer diffusion barrier (GO_2), to the plateau status of $\dot{M}O_2$. This results in the developmental pattern of $\dot{M}O_2$ paralleling the daily changes in DO_2 (Table 32.1).

In chicken eggs, the variability of shell GO_2 is large, higher than that of egg mass. Mass-specific $\dot{M}O_2$, measured on days 16 to 19 of incubation, is maximal at medium GO_2, decreasing at both lower and higher GO_2 (Visschedijk et al., 1985). The maximum $\dot{M}O_2$ at medium GO_2 values is considered to be optimal for embryo development, and the decrease in $\dot{M}O_2$ at both higher and lower GO_2 is a sign of compromised development. When GO_2 is decreased by partially covering the shell with impermeable material or increased by partially removing the shell over the air cell at the beginning of incubation, $\dot{M}O_2$ of day 16 embryos increases hyperbolically with increasing GO_2, reaching a maximum at the control GO_2 of intact eggs and decreasing with further increase in GO_2 (Okuda and Tazawa, 1988). When part of the shell is covered and the other is exposed to hyperoxia, $\dot{M}O_2$ and growth rate do not change, indicating uniform GO_2, and therefore uniform chorioallantoic perfusion is not required to maintain $\dot{M}O_2$ (Wagner-Amos and Seymour, 2002).

Because the oxygen diffusion coefficient (dO_2) affects shell conductance, GO_2 can be changed by replacing N_2 in air with an inert background gas whose density is different from that of N_2 (e.g., He or SF_6), thus changing dO_2 (Erasmus and Rahn, 1976; Ar et al., 1980; Tazawa, 1981a; Tazawa et al., 1981). Accordingly, the gas exchange of the egg can be manipulated by changing GO_2 with He or SF_6. The dO_2 is also inversely related to atmospheric pressure (P_B), and thus gas exchange of the egg is increased at high altitude because the shell GO_2 increases inversely with P_B. The reduction of GO_2 in eggs laid by birds incubating at high altitude occurs as a natural adaptation to altitude (Rahn et al., 1977).

As incubation proceeds, diffusive gas exchange governed by GO_2 and DO_2 is gradually replaced by convective gas exchange through the lungs during the perinatal period, beginning at IP (Figure 32.2). Breathing movements of perinatal embryos can be recorded as pressure changes using an optical system or pressure transducer (Romijn, 1948; Vince and Salter, 1967; Dawes, 1976). Conveniently, prenatal cardiac rhythms at the onset of IP and EP and the subsequent development of respiratory rhythms until hatching can be demonstrated by continuous measurements of cardiogenic, ventilatory and hatching activities in chickens by means of a condenser-microphone measuring

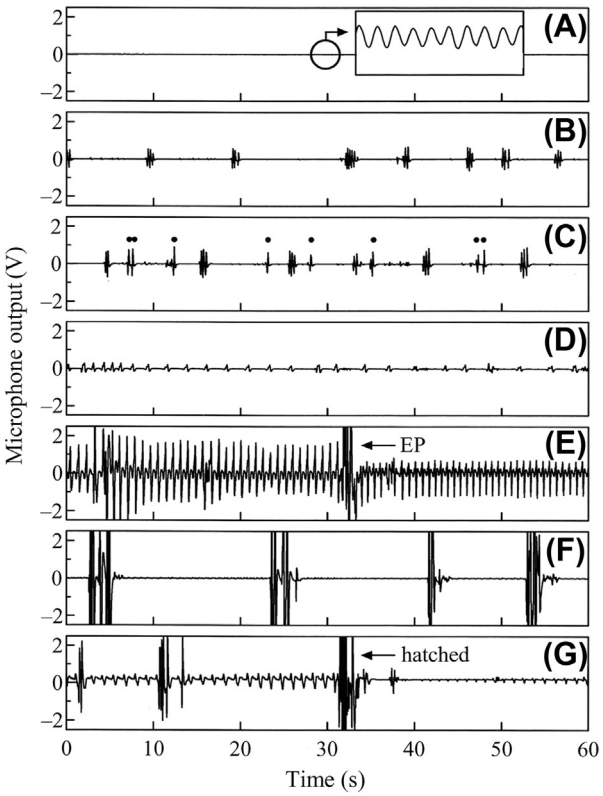

FIGURE 32.3 The cardiogenic and breathing activities of a chicken embryo from the prenatal through perinatal period to hatching, recorded by a condenser microphone attached hermetically on the shell. A 60 s recording is shown in each panel. (A) Cardiogenic signal (acoustocardiogram, ACG) during the final stages of the prenatal period; ACG is evident in the enlarged inset. (B) Beak-clapping signals just prior to IP (C) Onset of breathing signals occurring as single, irregular deflections (approximately once per 5 s) among beak clapping after IP (acoustorespirogram, ARG). (D) Rhythms become fast and somewhat irregular. (E) Breathing signals are more regular before and after EP. The onset of EP is evident by a sudden decrease in magnitude of ARG. (F) Approximately 1 h prior to hatching, large deflections due to hatching activities (e.g. climax) begin to occur and the breathing becomes intermittent. (G) The hatching activities continue before breathing regulates and finally the embryo hatches. Breathing signals are recorded after hatching, because the microphone is located close to the beak of hatchling. *From Chiba et al. (2002), with permission from Elsevier.*

system (Figure 32.3) (Chiba et al., 2002). Using the breathing patterns of chickens from the onset of IP through EP to hatching, the length of the IP, EP, and whole perinatal periods are determined as 14.1 ± 2.0 (SEM) h, 13.6 ± 1.3 h, and 27.6 ± 1.7 h long, respectively. The duration of climax (hatching) takes 48 ± 6 min. The instantaneous respiratory rate (IRR in breaths per min) is approximately 10 to 15 breaths/min at the beginning of IP; IRR baseline increases up to 80–100 breaths/min with large fluctuations of IRR of 60 to 180 breaths/min after the onset of EP.

Pulmonary ventilation and gas exchange during the perinatal period has been quantified using a barometric plethysmograph or pneumotachograph (Pettit and Whittow, 1982a; Menna and Mortola, 2003; Sbong and Dzialowski, 2007; Szdzuy and Mortola, 2007) and by measurement of gases in air cell and allantoic blood (Pettit and Whittow, 1982b; Tazawa et al., 1983b). The embryonic development of pulmonary ventilation and its regulation has been reviewed by Mortola (2009).

32.4.2 Acid–Base Regulation

While the embryo consumes O_2, it produces CO_2, which is partially dissolved and stored in the blood and body fluids, but mostly eliminated through the eggshell. As with O_2, CO_2 elimination $(\dot{M}CO_2)$ depends upon the eggshell CO_2 conductance (GCO_2) and CO_2 partial pressure difference between air cell ($PACO_2$) and atmosphere ($PICO_2$):

$$\dot{M}CO_2 = GCO_2 \cdot (PACO_2 - PICO_2) \qquad (32.11)$$

GCO_2 is a function of eggshell geometry (A_p and L), CO_2 diffusion coefficient (dCO_2), and the inverse product of R and T. $PICO_2$ is very close to zero when the egg is in air.

As embryos develop and their body mass increases, they produce more CO_2, which accumulates in the egg. $PACO_2$ increases, thus increasing arterialized blood PCO_2, P_aCO_2. Consequently, arterialized blood pH is lowered (Figure 32.4) or stays relatively constant in the allantoic vein during the last half of prenatal development (Dawes and Simkiss, 1969; Girard, 1971; Erasmus et al., 1970/71; Boutilier et al., 1977; Everaert et al., 2011). The rate of decrease in pH during embryonic development slows, however, late in incubation. Although the plasma bicarbonate concentration ($[HCO_3^-]$) increases with development, the increase is more than would be expected from changes in pH and the buffer value (−16 mmol/L, Burggren et al., 2012). The pH change due to CO_2 accumulation is mitigated by an increase in nonrespiratory HCO_3^- (Figure 32.4) (Tazawa, 1986, 1987). Hemoglobin (Hb), which serves as the noncarbonate buffer in blood, increases during the last half of incubation and thus is partly responsible for the mitigated change in pH. Reflecting the developmental increase in Hct and [Hb], the buffer value increases from ~−8 to −10 mmol/L on days 9 to 10 to ~−17 mmol/L on days 15 to 18 (Erasmus et al., 1970/1971; Tazawa and Piiper, 1984). In day 16 embryos, values ranging from −12.7 to −15 mmol/L are reported (Tazawa et al., 1981; Tazawa, 1980a, 1981b, 1982, 1986). Other studies have not found an increase in buffer value during development (Tazawa et al., 1983a; Andrewartha et al., 2011b; Burggren et al., 2012). The determination of the buffer value is a controversial issue, and clearly not all sources of variation have been identified. However, the value of −16 mmol/L reported recently (Burggren et al., 2012) is depicted in a pH-$[HCO_3^-]$ diagram (Davenport diagram, Figure 32.4) to show and estimate respiratory changes in acid–base balance.

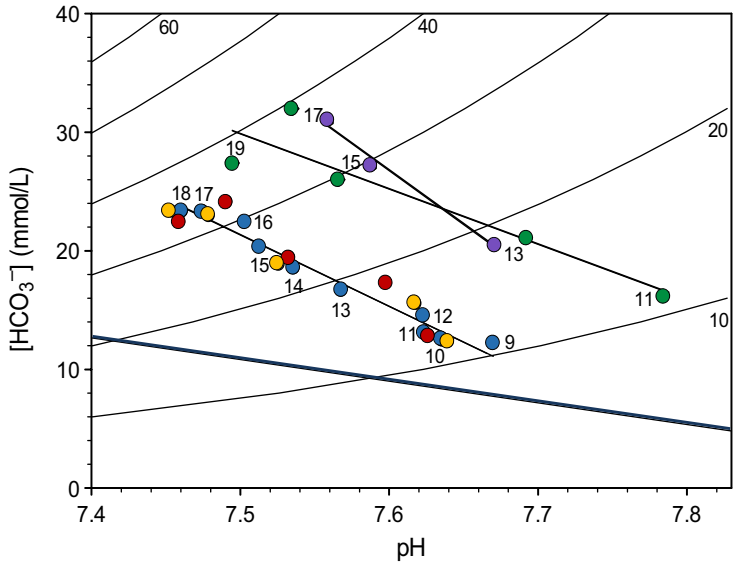

FIGURE 32.4 Davenport diagram illustrating the daily changes in control acid–base balance of arterialized blood in chicken embryos developing in air. The dark blue line is an arbitrary buffer line with the determined slope of −16 mmol/L pH/unit. Numbered curves are PCO_2 isopleths in mm Hg. The numbers near the data points represent the ages of the embryos. *Data are collected from the following studies; blue circles: Tazawa et al. (1971a), red circles: Tazawa et al. (1971b), yellow circles: Tazawa (1973), purple circles: Burggren et al. (2012), green circles: Tazawa et al. (2012). The solid line drawn through the data points corresponds to the following regression equation; (1) $[HCO_3^-] = -60.2\ pH + 472.6$ for combined data from Tazawa et al. (1971a, 1971b) and Tazawa (1973), (2) $[HCO_3^-] = -90.9\ pH + 717.4$ from Burggren et al. (2012), and (3) $[HCO_3^-] = -46.6\ pH + 379.1$ from Tazawa et al. (2012).*

Responses in acid–base balance to 1 day exposure to altered environmental gas mixtures differ depending on the gas mixture and age of chicken embryos (Figure 32.5) (Burggren et al., 2012). One day of hypercapnic exposure (5% CO_2, 20% O_2) increases P_aCO_2 and decreases pH_a, producing respiratory acidosis that is partially (~50%) compensated by metabolic alkalosis at all embryonic stages examined (days 13, 15, and 17) (Figure 32.5). Similar patterns of partially compensated respiratory acidosis have been reported in embryos exposed to 9% CO_2 in air for >3 days (Dawes and Simkiss, 1969). One day of exposure to hypercapnic hypoxia (5% CO_2, 15% O_2) abolishes compensatory metabolic alkalosis in day 15 and day 17 embryos, but a metabolic compensation of ~37% still occurs in day 13 embryos (Figure 32.5). This suggests that a relatively high O_2 level is required for metabolic compensation to occur. The lower $\dot{M}O_2$ and overall higher allantoic P_aO_2 in air (Tazawa, 1971, 1980a; Tazawa et al., 1971a,b) in day 13 embryos compared with more advanced embryos preserves the metabolic compensation during hypoxia. One day of hypoxic exposure (15% O_2) creates a metabolic acidosis in day 15 and day 17 embryos, but not in day 13 embryos (Figure 32.5). Hypoxia produces hypometabolism without anaerobic energy compensation (Bjønnes et al., 1987; Mortola and Besterman, 2007). However, once a lower threshold $\dot{M}O_2$ is reached, embryos turn to anaerobic glycolysis and blood lactate concentration ($[La^-]$) increases (Grabowski, 1961, 1966; Bjønnes et al., 1987). Therefore, embryos exposed to severe hypoxia (e.g., 10% O_2) encounter metabolic acidosis caused by glycolysis (Tazawa et al., 2012). However, metabolic acidosis occurring in moderate hypoxia is attributed only slightly to glycolysis and other unverified mechanisms, such as O_2 level influencing HCO_3^- transfer across the CAM. One day exposure to hyperoxia (40% O_2) causes respiratory acidosis that varies with embryonic age (Figure 32.5). Hyperoxia causes hypermetabolism (and a consequent increase in $\dot{M}CO_2$) (Visschedijk et al., 1980; Høiby et al., 1983; Stock et al., 1985; Tazawa et al., 1992b). Increased CO_2 is accumulated in the blood and hydrated to create H^+ and HCO_3^-. Coupled with a nearly fixed eggshell gas GCO_2, this results in respiratory acidosis. Age-specific differences in the magnitude of respiratory acidosis are due to hyperoxia causing a greater hypermetabolism in advanced embryos (Stock et al., 1985; Tazawa et al., 1992b).

Because eggshell GCO_2 is governed by dCO_2, respiratory acidosis also occurs in embryos exposed to a SF_6/O_2 gas mixture, which reduces GCO_2. Inversely, respiratory alkalosis occurs in embryos exposed to a He/O_2 atmosphere, which increases GCO_2 (Tazawa et al., 1981). Partially covering the eggshell with a gas-impermeable material or opening the eggshell over the air cell also produce respiratory acidosis and respiratory alkalosis, respectively. These respiratory disturbances to the acid–base balance occur rapidly and blood P_aCO_2 reaches a plateau ~10 min after changing GCO_2 (Tazawa, 1981a). Concurrently, blood pH changes to the value predicted by buffer capacity during the following 30–60 min (i.e., noncompensated respiratory

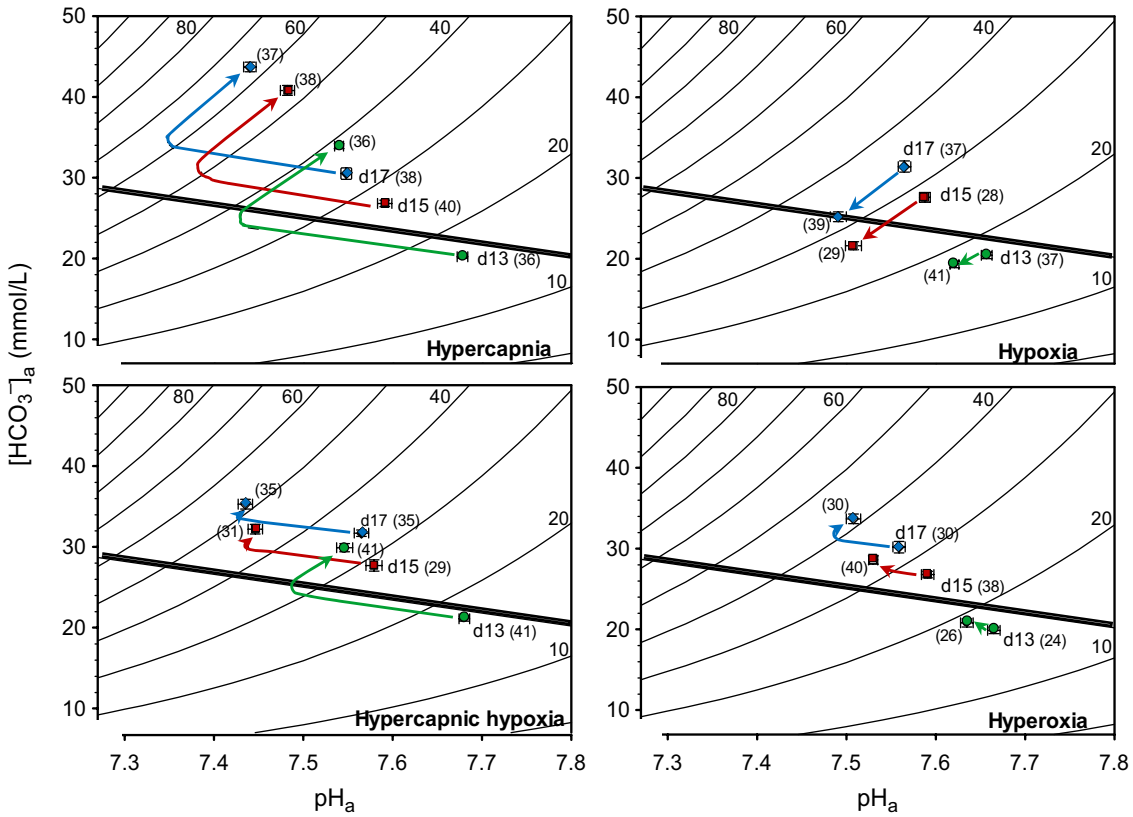

FIGURE 32.5 Regulation of arterialized blood acid–base balance of chicken embryos exposed to air (control) or altered [CO_2] and/or [O_2] for the last day of 13 (green), 15 (red), and 17 (blue) days of incubation. The colored arrows indicate changes in acid–base status from control. The dark blue line is the same as in Figure 32.4. *N* values are presented in parentheses. Mean values ±1 S.E.M. are shown. *Modified from Burggren et al. (2012), with permission from Elsevier.*

acidosis/alkalosis) with a subsequent (2–6 h), but incomplete, change toward the control level, while P_aCO_2 is maintained at a constant value. Once partial metabolic compensation is achieved at ~4–6 h, the state of acid–base disturbance remains constant over the next 24 h in normoxia or hyperoxia (e.g., 5% CO_2/20% O_2 or 5% CO_2/40% O_2), but metabolic compensation is not preserved after 24 h in hypoxia (5% CO_2/15% O_2) (Mueller et al., 2013b). Therefore, preservation of metabolic compensation requires an O_2 concentration above 20%.

Although partial metabolic compensation in response to hypercapnia or moderate hypoxia with hypercapnia (e.g., 15% O_2/5% CO_2) proceeds over the course of several hours, responses to severe hypoxia (10% O_2), with or without CO_2 (e.g., 5%), progress more quickly (Figure 32.6) (Tazawa et al., 2012). This is due to anaerobic glycolysis and the attendant rapid increase in [La^-] that creates severe metabolic acidosis. If hypoxic embryos can preserve [HCO_3^-] above ~10 mmol/L (in the case of day 15 embryos), which is generally reached beyond 2 h, embryos can survive and recover to the control state of acid–base balance in ~2 h after being returned in air (Figure 32.6) (Tazawa et al., 2012). Accordingly, hypoxia-induced acid–base disturbances are only transient and may not affect long-term survival.

In nature, the natural variations in eggshell conductance cause large differences in P_aCO_2 among eggs, but blood pH variations are kept to a minimum (Tazawa et al., 1983a). In eggs with low GCO_2, the Hct (and thus Hb) increases. In part, increased [Hb] may be responsible for the minimum change in pH.

The acid–base balance of chicken embryos also reacts promptly to metabolic disturbances, as shown by the time course changes in metabolic acid–base alterations created by infusion of electrolyte solution ($NaHCO_3$ and NH_4Cl) (see Figure 32.5 in Tazawa, 1982). For instance, the infusion of 15 µL 1 M $NaHCO_3$ increases plasma [HCO_3^-] and blood PCO_2. Because the embryo has no convective ventilation, the metabolic disturbance is not subjected to respiratory compensation. The increase in PCO_2 1 h after infusion indicates that the infused HCO_3^- is partly eliminated as dissolved CO_2. The acid–base status returns to control values 6 h after infusion. Besides elimination of CO_2 from the CAM, the increased fluid volume and hypertonicity of the infused $NaHCO_3$ solution may be partially responsible for the decrease in [HCO_3^-]. Additionally, penetration of HCO_3^- into the intracellular space and excretion of HCO_3^- into allantoic fluid through the CAM may contribute to the regulation (Tazawa, 1982, 1986).

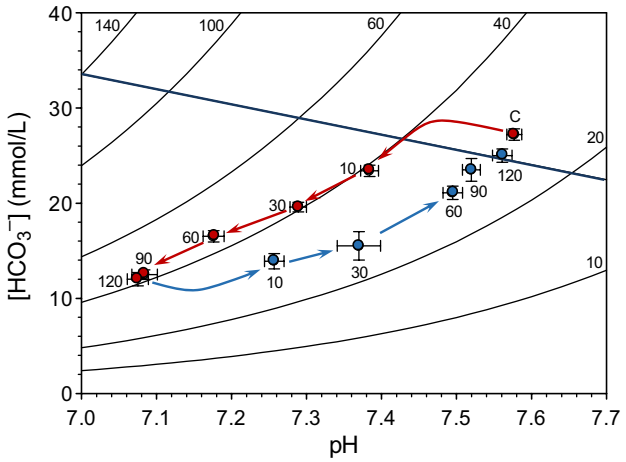

FIGURE 32.6 Time-course of acid–base disturbance in day 15 chicken embryos exposed to hypercapnic hypoxia (5% CO_2, 10% O_2) for 120 min (red circles) with recovery in air for 120 min (blue circles). Other details as in Figures 32.4 and 32.5. *Modified from Tazawa et al. (2012), with permission from Elsevier.*

In summary, acid–base regulation develops in concert with the increased CO_2 production as avian embryos grow. The ability of chicken embryos to tolerate and respond to acid–base disturbance, induced by environmental gas challenges, increases or decreases in GCO_2, or infusion of electrolytes, increases with development. Comparative approaches are required to examine species differences in acid–base regulation, and how tolerance to perturbations may be related to the incubation environment.

32.4.3 Cardiovascular System

32.4.3.1 Basic Cardiovascular Parameters

The primordial bird embryo's heart is a paired tubular structure that soon becomes a single tube. The heart begins to elongate more rapidly than the pericardial cavity containing it, and this space limitation forces the tubular heart to bend. Only the ventricle and bulbus are present on days 1.5 to 2 of chicken incubation. The impact of bloodstreams upon the inner surface of the contorted tube forms the external configuration and internal structure of the heart (Taber, 2001; Alford and Taber, 2003; Tobita et al., 2005) as well as contributing to blood vessel formation (le Noble et al., 2008; Burggren, 2013), although the specific role of pressure and flow fluctuations to the contribution of developing blood vessels remains somewhat enigmatic (Branum et al., 2013).

The structural alterations that separate atrium from ventricle, ventricle from aorta, and the left from the right chambers take place during days 3 to 8 of incubation, resulting in a four-chambered heart by days 8 to 9 (Pattern, 1951; see also multiple papers in Burggren and Keller, 1997). The mass of the heart increases as a power function of incubation day (I) (Romanoff, 1967; Clark et al., 1986):

$$\text{Heart mass } (\mu g) = 12.62 \cdot I^{3.26} \qquad (32.12)$$

The growth of the heart relative to the whole body is greatest early in development and declines during incubation. The ratio of the heart mass to the whole body mass falls from 1.8% on day 4 to 0.7% on day 18 of incubation.

The heart begins to beat at about 30 h of incubation and blood begins to circulate after about 40 h, when the connections between the dorsal aorta and the vessels of the yolk sac complete the circulation (Pattern, 1951). Despite the early generation of heartbeat and blood flow, heart rate is not initially required for convective blood flow to the tissues, but likely plays a role in angiogenesis (Burggren et al., 2000, 2004; Burggren, 2004, 2013; Branum et al., 2013).

Blood volume increases with incubation day (Figure 32.7(B)) (Yosphe-Purer et al., 1953; Barnes and Jensen, 1959; Lemez, 1972; Kind, 1975), and can be approximated by the following function (Tazawa and Hou, 1997):

$$\text{Blood volume } (\mu L) = 1.85 \cdot I^{2.64} \qquad (32.13)$$

The increase in blood volume during development is not as rapid as growth rate (Figure 32.7(A)), and therefore embryo mass-specific blood volume decreases during development from about 1 mL/g on day 4 to 0.15 mL/g on day 18.

As both the heart mass and blood volume increase, the stroke volume of the heart increases (Hughes, 1949; Faber et al., 1974; Hu and Clark, 1989). During early development, prior to the left and right separation of the heart, stroke volume depends on blood volume and increases in parallel with embryonic growth (Faber et al., 1974). The relationship between stroke volume and incubation day (I, days 2–6) (Hu and Clark, 1989) can be described as:

$$\text{Stroke volume } (\mu L) = 0.002 \cdot I^{3.46} \qquad (32.14)$$

Even after the second week of incubation, stroke volume seems to increase as a power function of incubation day (Figure 32.7(C)) (Hughes, 1949).

For early embryos, the dorsal aortic blood flow increases as a power function of incubation day during days 2 to 6 (Hu and Clark, 1989). The mass (embryo)-specific value is 0.5–1 mL/min/g. The mass-specific cardiac output of day 3 to 5 embryos, determined from the stroke volume, is similar at 1 mL/min/g (Faber et al., 1974). Cardiac output calculated from the stroke volume of young embryos and that of day 16 chicken embryos estimated by model analysis and blood O_2 measurement (White, 1974; Rahn et al., 1985; Tazawa and Johansen, 1987) indicate that the mass-specific cardiac output of young/late embryos is in the narrow range of 0.5–1.5 mL/min/g, and thus the cardiac output seems to increase as a power function of incubation day (Figure 32.7(D)). Eventually, cardiac output may increase almost in parallel with embryonic growth. If it is assumed that the

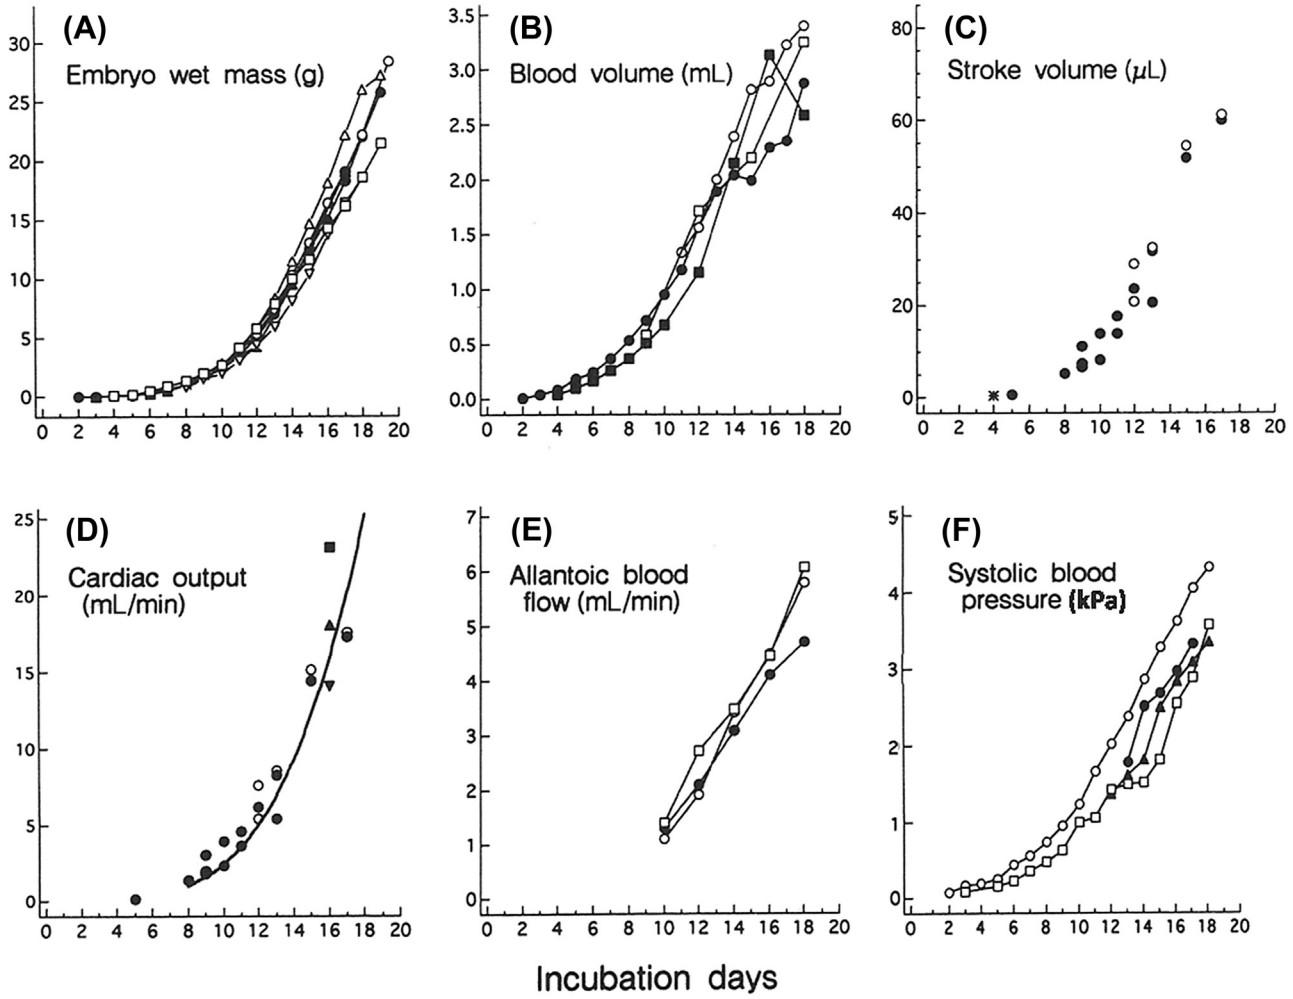

FIGURE 32.7 Developmental patterns of embryo wet mass (A), total blood volume (B), cardiac stroke volume (C), cardiac output (D), allantoic blood flow (E), and arterial systolic blood pressure (F) during the prenatal stage. Symbols connected by solid lines in (A), (B), (E), and (F) indicate the developmental patterns from the papers cited in the text.

mass-specific cardiac output during the last 2 weeks of prenatal development is 1 mL/min/g, the cardiac output of young embryos is related to incubation day (I) as follows,

$$\text{Cardiac output } (\mu\text{L/min}) = 0.24 \cdot I^4 \qquad (32.15)$$

which is the same expression as that relating body mass of developing embryos to incubation day (Eqn (32.5), Figure 32.7(A), (D)).

Blood flow through the CAM, determined from $\dot{M}O_2$, blood gas analysis, or via flow probe (Tazawa and Mochizuki, 1976, 1977; Bissonnette and Metcalfe, 1978; Van Golde et al., 1997), increases with embryonic growth (Figure 32.7(E)), but the mass-specific value decreases from ~0.5 mL/min/g on day 10 to ~0.25 mL/min/g on day 18. Although cardiac output increases in parallel with embryonic growth, its partition to the CAM decreases as embryos grow. On days 10 to 13, about half of the cardiac output goes to the CAM and this decreases to ~40% on days 17 to 19 (Mulder et al., 1997; Dzialowski et al., 2011 for review) or to ~17–20% on days 16 to 18 (Tazawa and Johansen, 1987). Consequently, the percentage of cardiac output to the organs and tissues increases as development proceeds.

Arterial pressure (P_a) is measured via a vitelline vessel in early embryonic chick development and an allantoic artery thereafter. Arterial systolic pressure (P_{sys}), measured by micropipette (Van Mierop and Bertuch, 1967; Girard, 1973) or needle-catheter techniques that maintain adequate gas exchange through the eggshell (Tazawa, 1981c; Tazawa and Nakagawa, 1985), increases with incubation day (I) in the following manner (Figure 32.7(F)):

$$P_{sys}\,(\text{kPa}) = 0.015 \cdot I^{1.86} \qquad (32.16)$$

P_a of the vitelline artery is pulsatile by day 2 of chicken incubation (Van Mierop and Bertuch, 1967; Hu and Clark, 1989; Taber, 2001). While the presence of a dicrotic notch is reported in early embryos (Hu and Clark, 1989; Yoshigi et al., 1996), a clear dicrotic notch is absent from allantoic P_a waves determined by others (Van Mierop and Bertuch,

1967; Tazawa and Nakagawa, 1985). However, the configuration of the P_a tracings and the ventricular pressure waves suggest that an arterial valve mechanism is present in early embryos, which lack true cardiac valves (Van Mierop and Vertuch, 1967; Faber, 1968).

32.4.3.2 Mean Heart Rate

According to the equations expressing the relationship between incubation day and body mass (Eqn (32.5)) or cardiac output (Eqn (32.15)), both body mass and cardiac output in day 16 chicken embryos are ~16 g and ~16 mL/min. Assuming a mean heart rate (MHR) of 280 beats per min (bpm), the stroke volume and mass-specific stroke volume are estimated as ~60 μL and ~4 μL/g. The cardiac contraction generating this amount of stroke volume physically moves the body of the embryo by an almost imperceptible amount, and these movements are transferred to the whole egg, producing cardiogenic ballistic movement of the egg, referred to as a ballistocardiogram (BCG) of the egg (Tazawa et al., 1989b). The egg movement determined by a laser displacement meter is ~1 μm (Sakamoto et al., 1995). The BCG measured by various means offers a convenient way to noninvasively determine MHR of avian embryos (Tazawa et al., 1999; Tazawa, 2005). Additionally, the heartbeat of the embryo inside the eggshell produces not only the ballistic movements of the egg, but also acoustic pressure changes outside the eggshell. A conventional condenser microphone hermetically fixed on the eggshell detects the cardiogenic acoustic pressure changes, designated as an acoustocardiogram (ACG) (Rahn et al., 1990), which can conveniently determine MHR of avian embryos.

In contrast to developmental patterns of the circulatory variables that increase steadily with embryonic growth, the embryonic MHR of chickens increases rapidly after the heart commences beating and then becomes asymptotic until early in the second week of incubation (Cain et al., 1967; Van Mierop and Bertuch, 1967; Girard, 1973; Hu and Clark, 1989; Tazawa et al., 1991a; Burggren and Warburton, 1994; Howe et al., 1995). During the last half of incubation, the daily change in MHR is small, with a temporal increase at 60–70% of incubation followed by a decrease toward IP and increase during hatching (Tazawa et al., 1991a). The change in MHR near the end of development in other precocial birds is shown in Table 32.2. Precocial species, from the smallest (king quail, *Coturnix chinensis*) to the largest (ostrich), show either a plateau or decrease in MHR prior to IP (Tazawa et al., 1991a, 1998a; 1998b, 2000; Pearson et al., 1998; Kato et al., 2002).

In comparison, HR increases rapidly toward hatching in small altricial embryos (Table 32.3) (Tazawa et al., 1994; Pearson et al., 1999). However, the increase in MHR during pre-pipping development slows in larger altricial eggs, such as those of crow (*Corvus corone*) and cattle egret (*Bubulcus ibis*), tending to remain unchanged during the last half of the prenatal period (Pearson and Tazawa, 1999; Tazawa et al., 2001b). The trend for MHR to remain unchanged during the end of prenatal development also occurs in semi-precocial seabirds such as the brown noddy (*Anous stolidus*) and laysan albatross (*Phoebastria immutabilis*) (Table 32.2) (Tazawa et al., 1991b; Tazawa and Whittow, 1994; Pearson et al., 2000). Hence, the pattern of change in MHR during development, particularly at the end of incubation, can be somewhat predicted by the degree of development at hatching. Precocial species tend to show a plateau or decrease in MHR near hatching, while MHR tends to increase in altricial species.

These determinations of embryonic MHR along with egg mass of various species (Tables 32.2 and 32.3) reveal a significant relationship between MHR at 80% of I and egg mass (Tazawa et al., 2001b). The allometric relationship derived for 20 species of altricial and semi-altricial (ASA) birds with egg mass ranging from 0.96 g of the zebra finch to ~41 g of the lanner falcon (*Falco biarmicus*) is:

$$\text{MHR at 80\% of } I = 371 \cdot (\text{Egg mass})^{-0.121} \quad (r = -0.846,\ P < 0.001) \tag{32.17}$$

The relationship for 13 species of precocial and semi-precocial (PSP) birds with egg mass ranging from 6 g of the king quail to ~1400 g of the ostrich is:

$$\text{MHR at 80\% of } I = 433 \cdot (\text{Egg mass})^{-0.121} \quad (r = -0.963,\ P < 0.001) \tag{32.18}$$

The slopes for MHR are parallel, but the MHR of ASA embryos is low compared with PSP embryos from the same egg mass. In ASA embryos, HR becomes maximal during the pipping period, and the maximum HR is significantly related to egg mass. Consequently, the allometric relationship of maximum HR and egg mass in ASA and that of 80% of I in PSP is statistically identical, expressed by a single allometric equation:

$$\text{MHR} = 437 \cdot (\text{Egg mass})^{-0.123} \quad (r = -0.948,\ P < 0.001,\ N = 33) \tag{32.19}$$

In addition, determination of MHR in embryos from the same clutch (siblings) in pigeons and bank swallows demonstrates that developmental patterns of MHR in siblings are more alike than those of embryos from other clutches of the same species (Burggren et al., 1994). These findings may be termed the "sibling effect," in which siblings are predisposed to show particular physiological patterns. Whether these effects are genetically based (i.e., resulting from the common genetic heritage of the F_1 offspring) or involve epigenetic influences is uncertain. Certainly, physiological process can be transferred across generations (see Ho and Burggren, 2010, 2012; Burggren, in press) through

TABLE 32.2 Egg Mass (g), Incubation Period (*I*, days), Heart Rate (HR, beats/min) at 80% of Incubation and Maximum Heart Rate (Max HR) during Prenatal Development in Precocial Birds and Heart Rate Prior to Internal Pipping (Pre-IP) and at the First Star Fracture of the Eggshell in Semi-Precocial Birds

epigenetic mechanisms. However, environmental effects on the mother may also cause siblings to undergo similar patterns of physiological development through a "maternal effect" or even direct effects on the gamete cells of the mother (Burggren et al., 1994; Dzialowski and Sotherland, 2004; Ho et al., 2011; Burggren, in press).

32.4.3.3 Instantaneous Heart Rate

In addition to daily changes in MHR during development, HR varies from beat to beat (i.e., instantaneous HR; IHR). At rest, the baseline IHR in chicken embryos is more or less constant before ~day 11, indicating that neither IHR accelerations of adrenergic origin nor IHR decelerations of cholinergic origin occurs during early development. The flat baseline of IHR begins to fluctuate with the appearance of rapid, transient decelerations on ~days 12 to 13, with a subsequent augmented frequency of appearance (Figure 32.8) (Höchel et al., 1998; Tazawa et al., 1999; Chiba et al., 2004). Thereafter, IHR becomes arrhythmic with the appearance of transient accelerations on ~days 15 to 16 and more arrhythmic with augmented decelerations and accelerations toward hatching (Höchel et al., 1998; Tazawa et al., 1999, 2002a; Moriya et al., 2000; Khandoker et al., 2003). These IHR decelerations are eliminated, and baseline HR is elevated, by intravenous administration of atropine (Figure 32.8). In late embryos whose IHR fluctuations consist of complicated decelerations and accelerations with augmented magnitude and frequency, atropine diminishes decelerations only but preserves accelerations, while the HR baseline is markedly elevated (e.g., Figure 32.3 of Chiba et al., 2004), indicating that IHR decelerations are mediated by the vagus nerve. Accordingly, vagal tone begins to appear on around days 12–13 of incubation in chickens, maturing with development, correcting previous reports on no vagal control of HR determined from blood pressure signals (Tazawa et al., 1992a). Furthermore, cholinergic chronotropic control of HR occurs on days 12 to 13 of incubation in both broiler and White Leghorn embryos (Yoneta et al., 2006c). These events coincide with the presence of a complete cholinergic effector pathway from 60% of chicken incubation (Pappano and Löffelholz, 1974).

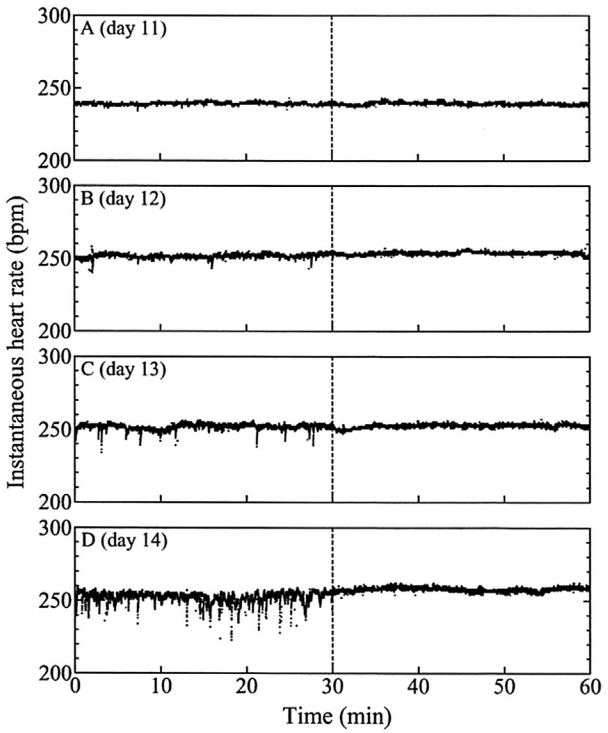

FIGURE 32.8 Instantaneous heart rate fluctuations before and after intravenous infusion of 20 µg atropine at 30 min in day 11 to day 14 chicken embryos. *From Chiba et al. (2004), with permission from Elsevier.*

Some controversy exists as to whether cholinergic tone is present at this developmental timepoint; blood pressure studies indicate no vagal tone on the heart during embryonic development (Crossley and Altimiras, 2000). Further, blood pressure studies using adrenoreceptor stimulation via pharmacological manipulation indicate that a positive β-adrenergic chronotropic tone can be induced from 60% of incubation (Crossley and Altimiras, 2000). The effect is enacted by circulating catecholamines, as ganglionic blockade with hexamethonium has no impact on HR. In comparison, pharmacological manipulation of blood pressure indicates that the emu heart is under both β-adrenergic and cholinergic control by 70% of incubation (Crossley et al., 2003).

Long-term measurement of IHR reveals the occurrence and development of various cardiac rhythms and irregularities. The developmental pattern of MHR (constructed from IHR measurement) of an embryo before and after hatching demonstrates the occurrence of infradian rhythm before and during IP, a gradual increase in HR baseline during IP, a sudden drop with a subsequent sudden increase in HR baseline during EP, and the first occurrence of circadian rhythm of HR after hatching (Figure 32.9) (Moriya et al., 2000). Recordings of IHR reveal respiratory arrhythmia associated with EP, together with three unique patterns of IHR during the final stage of EP (i.e., relatively long-lasting cyclic small accelerations, irregular intermittent large accelerations, and short-term repeated large accelerations) (Tazawa et al., 1999; Moriya et al., 2000). Short-term repeated large accelerations also occur in EP emu embryos, indicating imminent hatching (Figure 32.10) (Kato et al., 2002).

After hatching, three types of IHR fluctuations (Types I, II and III) are demonstrated in chickens (Moriya et al., 1999, 2000; Tazawa et al., 2002a). Type I is characterized as a widespread baseline HR (20–50 bpm) due to respiratory arrhythmia with a mean oscillatory frequency of ~0.7 Hz. Type II is evident by low-frequency oscillations of baseline HR at ~0.07 Hz, occurring at low T_a or when hatchlings are

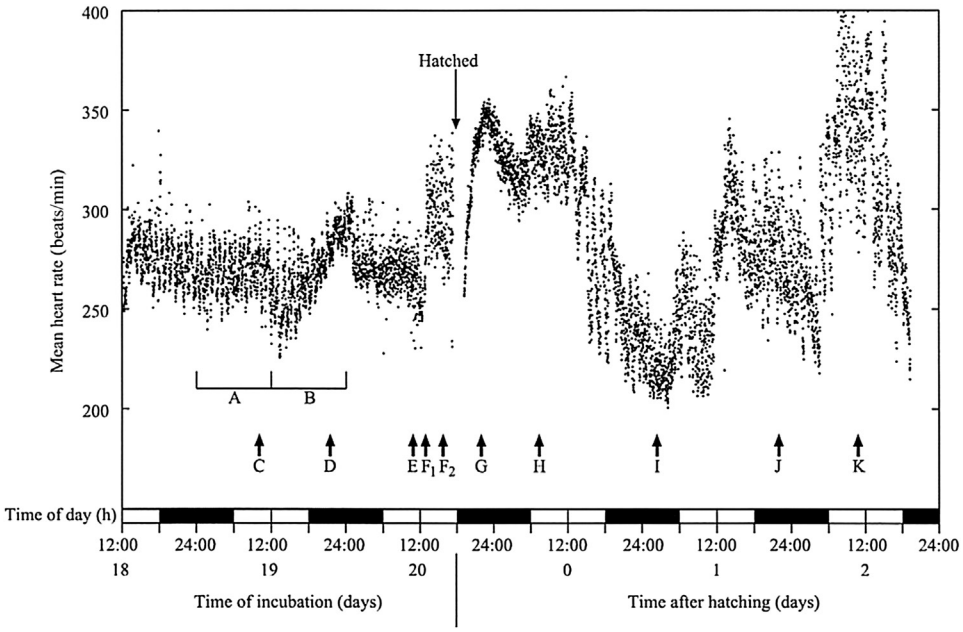

FIGURE 32.9 Typical developmental pattern of mean heart rate (MHR) of a chick, recorded from day 18 of incubation through hatching on day 20 to day 2 of post-hatching. Each point indicates the MHR over a 1 min period determined from the continuous recording of instantaneous heart rate (IHR). IP begins at around 12:00 on day 19 when MHR temporarily decreases with subsequent gradual increase during IP. The MHR oscillates with a period of about 42 min from the beginning of recording to middle of IP, i.e. infradian rhythm. EP begins at the start of day 20 when MHR suddenly drops. Following the drop, which lasts for the first half of day 20, MHR increases sharply at 12:00 and maintains high baseline until hatching. During the last period of EP, characteristic patterns of IHR occur, e.g., a sharp increase in MHR (pointed by F_1) consisting of relatively long-lasting cyclic small accelerations. The wide baseline of MHR during the last 1% of incubation is composed of repeated alternate occurrence of irregular intermittent large accelerations and short-term repeated large accelerations indicating imminent hatching (see Figure 32.10). After hatching, circadian rhythms occur on days one and 2. *Reproduced from Moriya et al. (2000), with permission from The Company of Biologists.*

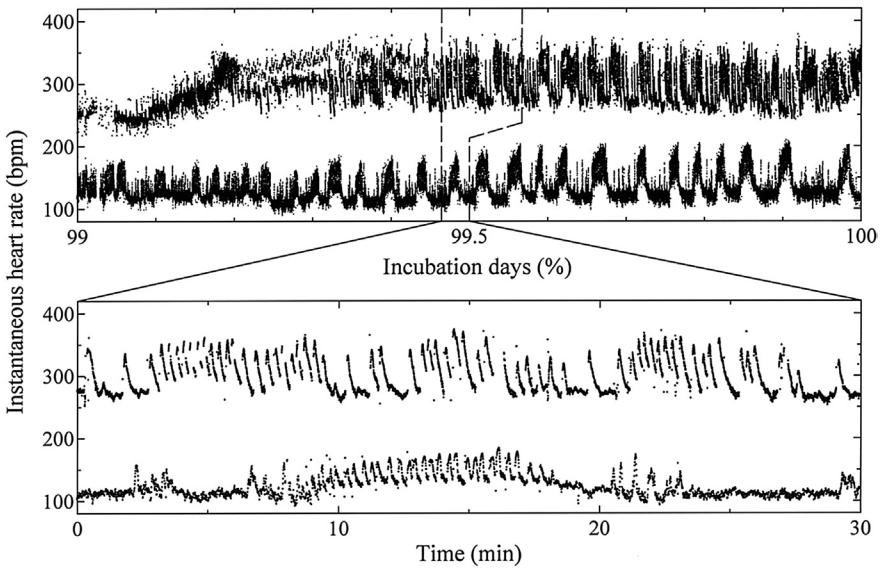

FIGURE 32.10 Instantaneous heart rate (IHR) during the last 1% of incubation of chicken (upper recording) and emu (lower recording) embryos (top panel) and the 60-min recordings taken from the middle of the last 1% of incubation indicated by broken lines (bottom panel). Short-term repeated large IHR accelerations with intermittent large accelerations continuously appear towards hatching in both embryos. HR of small chicken embryos is higher than that of large emu embryos (allometry). *From Kato et al. (2002), with permission from Elsevier.*

exposed to lowered T_a, and is thus related to thermoregulation. Type III is characterized as noncyclic irregularities, dominated by frequent transient accelerations. The image-processing system developed to capture the movements of wing or whole body of the hatchling reveals that Type I and Type II HR oscillations are related to the periodic movements of the wing and Type III HR irregularities occur simultaneously with spontaneous whole body movements (Yoneta et al., 2006a). Consequently, it is likely that the chick moves the body at the same frequencies as Type I and Type II oscillations and simultaneously with Type III HR irregularities, and these HR fluctuations and body movements are likely to be attributed to the same origins.

32.4.3.4 Blood Pressure Regulation

The sympathetic nervous system is heavily involved in regulation of avian embryonic blood pressure (Altimiras et al., 2009). Injection with the α-adrenereceptor antagonist phentolamine causes hypotension from 60% of chicken incubation, indicating α-adrenergic tone on the vasculature (Girard, 1973; Saint Petery and Van Mierop, 1974; Tazawa et al., 1992a; Crossley and Altimiras, 2000). Phentolamine also causes bradycardia, a likely indirect effect of vasodilation, and reduced venous return. β-adrenergic tone on the vasculature is also present from 60% of incubation, as evident by a P_a increase in response to the β-adrenereceptor antagonist propranolol (Girard, 1973; Saint Petery and Van Mierop, 1974; Tazawa et al., 1992a; Crossley and Altimiras, 2000). The magnitude of both α- and β-adrenergic tone is maximal at 90% of incubation, just prior to IP (Crossley and Altimiras, 2000). The increase in adrenergic tone is matched to the maximal plasma catecholamine release on day 19. Likewise, emu embryos show signs of increasing α- and β-adrenergic tone on the vasculature matched to increasing levels of catecholamines as incubation proceeds (Crossley et al., 2003).

In addition to regulation via catecholamines, other hormones may also influence baseline cardiovascular function of avian embryos. The most extensively studied in chicken embryos is angiotensin II (ANG II), a strong vasoconstrictor and the active peptide of the renin-angiotensin system (RAS). Components of the RAS, including renin, angiotensin-converting enzyme, ANG II and its receptors, are present early in chicken ontogeny (Nishimura et al., 2003; Savary et al., 2005; Crossley et al., 2010). ANG II levels are elevated in embryos compared to adults; the peptide produces hypertension from at least 60% of incubation (Crossley et al., 2010), and contributes to baseline P_a at 90% of incubation (Mueller et al., unpublished). Despite an increase in P_a, ANG II does not alter MHR as it instead attenuates the embryonic cardiac baroreflex. The baroreflex is an important compensatory mechanism that buffers short-term changes in P_a and is composed of a peripheral limb adjusting vascular resistance and a cardiac limb that changes HR. A functioning baroreflex is present in chicken embryos from 80% of incubation (Altimiras and Crossley, 2000; Elfwing et al., 2011). ANG II decreases the sensitivity of the cardiac baroreflex at 90% of incubation so that reflex changes in HR in response to P_a changes are blunted (Mueller et al., 2013a). ANG II also raises the operating P_a of embryos, and it is via these short-term changes that the hormone partly enacts some of its influence on long-term P_a.

Other potentially important moderators of cardiovascular function include endothelin-1 (ET-1), a potent vasoconstrictor produced primarily in the endothelium, and natriuretic peptides (NP), strong vasodilators excreted by heart muscle cells. Components necessary for functional ET-1, including mRNA and converting enzymes, are found in chicken embryos from 15% of incubation (Hall et al., 2004; Groenendijk et al., 2008) and ET-1 alters chicken embryo hemodynamics (Groenendijk et al., 2008; Moonen and Villamor, 2011). Likewise, NP is present in the chicken heart and most likely contributes to hemodynamics from at least day 14 (Maksimov and Korostyshevskaya, 2013). Further research from the molecular to whole-organism level is required to understand the contribution of these hormones to P_a and HR control, and therefore embryonic cardiovascular regulation.

32.4.4 Osmoregulation

During development, various avian embryos face one of two osmoregulatory challenges: water loss through the pores of the eggshell, in desiccating arid environments; or excess water gain from the metabolic production of water as part of metabolizing the yolk stores (Ar and Rahn, 1980). Irrespective of the species-specific challenge, the developing kidney and extra-embryonic structures, including the yolk, CAM, and allantoic and amniotic fluids work in concert to regulate ion and water balance. The embryonic kidney of chickens has three stages, actually comprising separate structures: the pronephros, mesonephros, and metanephros. The pronephros appears first and functions until day 5 to 6 of incubation (Abdel-Malek, 1950; Himura and Nakamura, 2003). Mesonephros function takes over from day 5, is maximal on days 10 to 15 (Romanoff, 1960), and then degrades between days 18 and 19 (Atwell and Hanan, 1926). The mesonephros functions simultaneously with the metanephros, which begins developing from day 4 (Abdel-Malek, 1950) and continues to develop post-hatching. The metanephros is the most complex of the three embryonic kidney structures, and comprises the functioning structure in adults. The allantoic sac first appears at about days 3 to 4 of incubation, and acts as a repository for kidney secretions, as evident by the increase in uric acid content throughout development (Romanoff, 1967). The allantoic

epithelium actively transports sodium across its membrane from days 12 to 19 (Stewart and Terepka, 1969; Graves et al., 1986; Gabrielli and Accili, 2010), thus maintaining the fluid hypo-osmotic to the blood and permitting reabsorption of water by the embryo (Hoyt, 1979).

Osmoregulation is strongly tied to cardiovascular function through the synergistic maintenance of blood pressure and osmotic homeostasis. Regulators of blood pressure, such as ANG II and NP (see above), may also contribute to ion and water balance in embryos. Chronic removal of ANG II from chicken eggs not only decreases P_a but also lowers osmolality, decreases Na^+, and increases K^+ concentration of the blood at 90% of incubation. These actions remove the osmolality gradient between the blood and allantoic fluid (Mueller et al., unpublished). Therefore, ANG II appears to influence osmotic balance and may do so by direct vasoconstrictive action or by stimulating the release of aldosterone and arginine vasotocin, which promote proximal tubular sodium reabsorption. Aldosterone is present in chicken embryo adrenal glands from day 15 (Pedernera and Lantos, 1973) and arginine vasotocin is present in the brain from day 6 and the plasma from days 14 to 16 (Klempt et al., 1992; Mühlbauer et al., 1993). Both aldosterone and arginine vasotocin alter allantoic fluid volume, allantoic salt content, and renal enzyme activity in chicken embryos (Doneen and Smith, 1982). Prolactin and growth hormone also have osmoregulatory effects in chicken embryos (Doneen and Smith, 1982; Murphy et al., 1986). The function of these hormones in osmoregulation requires further study, including how they may contribute to interactions between the developing cardiovascular and osmoregulatory systems and the maintenance of homeostasis.

32.4.5 Thermoregulation

Embryos produce metabolic heat, which increases as development progresses. Metabolic heat production of the chicken embryo increases from about 35 mW on day 12 to 130–140 mW on days 17 to 18 of incubation, and reaches 160–170 mW at EP (Tazawa et al., 1988b). Over the same developmental range, the egg's thermal conductance is ~70 mW/°C (Tazawa et al., 2001a). This means that metabolic heat production at 38 °C elevates egg temperature (T_{egg}) above ambient temperature (T_a) by ~0.5 °C on day 12 and ~2.5 °C in EP eggs. When eggs are cooled to 28 °C, a new quasi-equilibrium state is reached in 5 h (defined as a change in T_{egg} of less than 0.2 °C/h) (Tazawa and Rahn, 1987). The new difference between T_{egg} and T_a is lower, so that even in EP embryos T_{egg} is only 1.2 °C above T_a. In addition, during the quasi-equilibrium state at lowered T_a, embryos consume the amount of O_2 predicted by a temperature coefficient (Q_{10}) of 2. On the other hand, hatchlings, which are subjected to the same test, have body temperatures ~6 °C above T_a, even right after hatching, and consume much more O_2 than that predicted by Q_{10} of 2 (Tazawa and Rahn, 1987). These observations suggest that chickens are essentially poikilothermic during embryonic stages, even at EP, and rapidly develop the capacity to maintain body temperature upon cold exposure soon after hatching.

When eggs incubated at 38 °C are exposed to a T_a only 2 °C lower, the heat loss from the egg is greater than the heat produced by young embryos and comparable with the heat production in late embryos. If the eggs are exposed to air 10 °C cooler than the egg, the embryos would have to generate heat of about 800 mW to keep T_{egg} steady (Turner, 1986). Yet, even EP embryos can generate at most 170 mW. Consequently, heat loss during cooling exceeds the embryo's maximum rate of heat production. A feeble compensatory capacity, if any, may be overwhelmed by the much larger losses of heat. The egg cools and its metabolic rate decreases as a result of the van't Hoff-Arrhenius effect. The detection of homeothermic capacity thus requires a procedure in which the heat loss from the egg does not overwhelm the heat production of the embryo. The gradual cooling test fulfills this requirement, and it shows that prenatal chicken embryos near term respond to lowered T_a by maintaining $\dot{M}O_2$ until T_a falls below 35 °C (Tazawa et al., 1988b). This response in late embryos is evidently different from that in young embryos. In the prolonged cooling test, late chicken embryos are exposed to a slightly lowered T_a for a prolonged period, the $\dot{M}O_2$ is maintained at a level above that predicted by a Q_{10} of 2. This response also differs from that shown by young embryos (Tazawa et al., 1989a). Consequently, precocial chickens exhibit a feeble, incipient metabolic response to cooling, indicating endothermic homeothermy before hatching. This coincides with enhanced activity of the thyroid gland and increasing concentrations of peripheral thyroid hormones during the last stages of incubation (Decuypere et al., 1979; McNabb, 1987). In fact, while late prenatal embryos in eggs injected with saline show a feeble homeothermic metabolic response to gradual cooling, this response is absent in eggs treated with thiourea, which antagonizes the metabolic effect of thyroid hormones (Tazawa et al., 1989c). Additionally, while the compensatory metabolic response disappears in embryos exposed to hypoxia, it is augmented in perinatal embryos in hyperoxia or following improved oxygenation by opening the shell over the air cell (Tazawa et al., 1989c; Dzialowski et al., 2007; Szdzuy et al., 2008). These results indicate that the homeothermic metabolic response in late embryos is "O_2 conductance limited" in precocial chickens (Tazawa et al., 1988b).

The development of homeothermy in precocial and altricial birds has been modeled (Figure 32.11) (Tazawa et al., 1988b; Whittow and Tazawa, 1991; Tzschentke and Rumpf, 2011 for review). The transition for a precocial bird takes place in four stages; (1) an Arrhenius-limited stage in which $\dot{M}O_2$ is directly related to the temperature with a Q_{10} value

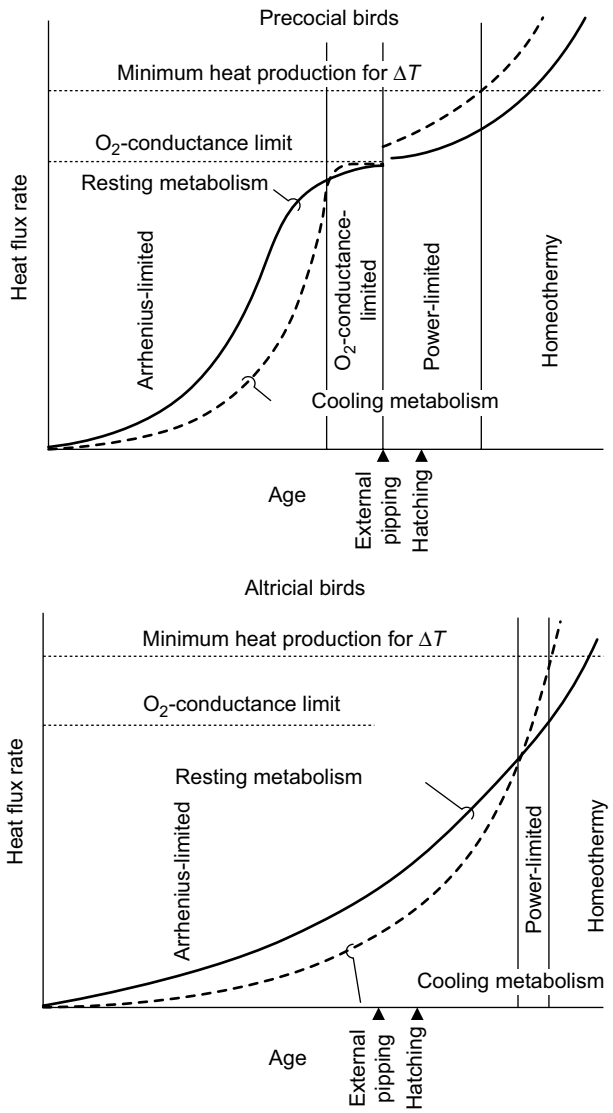

FIGURE 32.11 Models of the development of homeothermy in precocial and altricial birds. Minimum Heat Production for ΔT equals the amount of heat needed to keep the egg temperature warmer than ambient temperature by ΔT and homeothermy occurs when the embryo heat production reaches this level. *From Tazawa et al. (1988b), with permission from Elsevier.*

of approximately 2; (2) an O_2-conductance-limited stage in which $\dot{M}O_2$ is limited by the rate of diffusion of O_2 through the shell and CAM; (3) a power-limited stage in which the embryo has a limited capacity to generate heat in response to cooling, which is a function of the maturity of the tissues and development of thyroid activity; and (4) "full-blown" homeothermy. An altricial species never passes through the O_2-conductance-limited stage and is subject to the Arrhenius limitation until after it hatches.

The comparative metabolic responses to prolonged cooling have been examined in the precocial duck, semi-precocial brown noddy, and altricial pigeon (*Columba livia domestica*) (Matsunaga et al., 1989; Kuroda et al., 1990; Tazawa et al., 2001a). Incipient homeothermic ability appears in the duck during prenatal development, but it is not evident in the pigeon even after emergence from the shell. The precocial chicken and semi-precocial noddy are intermediate in their metabolic response between the duck and the pigeon.

The development and maturation of homeothermy is expected to occur and progress even during the prenatal period in the highly precocial emu. In addition to the precocial nature of the emu, its large egg with a smaller surface area-to-volume ratio and greater contribution of blood circulation compared to smaller eggs most likely enhances thermoregulatory capacity. For emus, a more apparent metabolic response test is used in which embryos and hatchlings are exposed for a prolonged period (e.g., 1.5 h) to T_a altered sequentially by 10 °C, for example, 35-25-35 °C for embryos or 25-35-25 °C for hatchlings (sequential cooling-warming test, with ΔT_a of ±10 °C) (Dzialowski et al., 2007). Hatchlings and EP embryos respond to ΔT_a with an endothermic change in $\dot{M}O_2$, showing an inverse metabolic response with marked increase and decrease in $\dot{M}O_2$ in response to sequential cooling and warming bouts. Late prenatal (day 45) and IP (day 49) embryos do not change $\dot{M}O_2$ in response to ΔT_a in air, but demonstrate partial (day 45) or apparent (IP) endothermic change in $\dot{M}O_2$ when the test is run in 40% O_2. This suggests that the late prenatal emu embryo already possesses homeothermic ability, but it is limited by the eggshell gas GO_2.

Changes in IHR, with apparent increases or decreases in HR baseline with oscillating pattern, in response to ΔT_a, are also effective in investigating endothermic capacity in precocial embryos and hatchlings (Tazawa et al., 2001a, 2004; Tamura et al., 2003; Khandoker et al., 2004). In the sequential cooling-warming test with ΔT_a of ±10 °C, the sequence of exposure (cooling-warming and vice versa) does not affect the endothermic HR response (Yoneta et al., 2006b). In chick hatchlings the endothermic HR response is demonstrated to be advanced by ~1 day in broiler compared with White Leghorn during 2 days of post-hatch life (Yoneta et al., 2007).

In the chicken embryo, the baseline of IHR shows a thermo-conformity pattern in response to a decrease in T_a during EP (day 20), but it changes little on day 21. IHR rises accompanying HR oscillation on day 22, when the embryo stays inside the egg (Tazawa et al., 2001a; Andrewartha et al., 2011b). Although the embryo fails to hatch after EP, it matures equivalently to a hatchling on day 21 and day 22. In newly hatched chicks, HR oscillations with a period of 10–25 s occur frequently in air, reported as Type II HR fluctuation (Moriya et al., 1999, 2000). In addition, IHR oscillates with lowering T_a, resulting in Type II low-frequency HR oscillation, which disappears when hatchlings are transferred to high T_a (Tazawa et al., 2002b; Khandoker et al., 2004). Consequently, chicken hatchlings

possess low-frequency HR oscillation (Type II HR fluctuation) in relation to their thermoregulation (Tazawa, 2005 for review).

In duck embryos (Figure 32.12 (A); day 24), the HR response during pre-IP stage indicates thermoconformity (Andrewartha et al., 2011b). However, the recovery of HR (and T_{egg}) at T_a of 38 °C is faster than chicken embryos (cf. Figure 32.1 of Tazawa et al., 2001a). By EP (Figure 32.12(C), (D); day 27), duck embryos demonstrate an endothermic HR response (increase during cold exposure) larger than chicken EP embryos. Immediately after hatching, the wet duckling cannot maintain the increased HR, succumbs to the cold, and HR decreases (E). However, the HR of ducklings blotted dry within 2 h is maintained at similar values at T_a of 35 °C (F), demonstrating incomplete endothermic capacity. By 2 and 13 h post-hatching (Figure 32.12(G), (H)), the plumage of the ducklings has naturally dried and their HR shows an apparent endothermic response with a small decrease in body temperature, T_b ($\Delta T_b = -1.9$ and -2.0 °C, respectively), close to full-blown homeothermy. Ducklings must attain thermoregulatory competence early (relative to the domestic chicken) during perinatal development to live in an aquatic environment soon after hatching.

In the more highly precocial emu, pre-IP and IP embryos exhibit thermoconformity and incomplete endothermic response of HR, respectively, but the apparent endothermic HR response occurs in EP embryos just like the endothermic metabolic response (Fukuoka et al., 2006; Dzialowski et al., 2007; Andrewartha et al., 2011b).

Assessment of $\dot{M}O_2$ and HR responses to various tests that alter incubation temperature have been successfully utilized to assess thermoregulatory ability of avian embryos. The timing of endothermic responses differs along the precocial to altricial continuum, with precocial species generally showing thermoregulatory ability earlier than altricial species. Examination of mitochondrial, cellular, and tissue-level mechanisms are now required to further our understanding of how thermoregulatory ability develops in embryos and hatchlings.

32.5 ARTIFICIAL INCUBATION

32.5.1 Preincubation Egg Storage

Many precocial birds laying multiple eggs in a clutch start their incubation with the penultimate or ultimate eggs. Consequently, first-laid eggs are stored in the nest until incubation starts, sometimes for many days. Egg storage is not just a phenomenon of nature, of course. Egg storage commonly occurs in commercial conditions of artificial incubation. If the storage temperature for freshly laid chicken eggs is kept below physiological zero (25–27 °C), dormancy of the embryo is maintained and fertile eggs can be stored for several days without a major loss of hatchability (Butler, 1991; Wilson, 1991). The optimal temperature for 3 to 7 days storage of chicken eggs is 16–17 °C and it drops to 10–12 °C for eggs stored for more than 7 days (Butler, 1991; Wilson, 1991). However, prolonged preincubation egg storage results in malformations and retarded growth of the embryos, decreased hatchability, and increased incubation period, and it even influences hatchling growth (Arora and Kosin, 1966; Mather and Laughlin, 1979). The hatchability of the northern bobwhite quail (*Colinus virginianus*) remains above 70% after 14 days of preincubation storage at 20–22 °C, but decreases to below 30% after 21 days of storage (Reyna, 2010). These deleterious effects are related to not only the length of storage but also the environmental and physical conditions such as temperature, relative humidity, atmospheric gas composition, orientation, and positional changes during storage (Brake et al., 1997).

Prolonged preincubation egg storage also affects the physiological function of developing chicken embryos (Haque et al., 1996; Fasenko, 2007). Albumen quality, an indicator of overall egg quality, decreases with storage (Scott and Silversides, 2000; Reyna, 2010). Furthermore, while the developmental patterns of $\dot{M}O_2$ are consistent among unstored (control) eggs, those stored for 20 and 30 days at 10–11 °C are varied and depressed among eggs; the depression of the $\dot{M}O_2$ increases in severity as the storage duration increases. The developmental trajectories of HR in stored eggs are flattened compared with those of control eggs. As a result, the O_2 pulse (O_2 uptake every heartbeat) is markedly lowered by preincubation storage, decreasing blood O_2 transport and retarding embryo growth in stored eggs, resulting in death during the last days of incubation (Haque et al., 1996).

32.5.2 Egg Turning

In many avian species, incubating adults actively move their eggs in the nest (egg-turning). The critical period for lack of egg-turning in artificial incubation of the chicken egg ranges from days 3 to 7 of artificial incubation (New, 1957; Deeming, 1989a). Chicken eggs should be turned minimally 3 times a day. Turning more than 24 times a day does not further enhance hatchability. Lack of egg-turning is detrimental not only to hatchability, but can slow incubation, the development of the CAM, and embryo growth (New, 1957; Tazawa, 1980b; Deeming et al., 1987; Tullet and Deeming, 1987; Deeming, 1989a,b).

Failure to turn eggs during incubation also produces adverse effects on gas exchange through the CAM (Tazawa, 1980b). The movement of albumen into the amnion is retarded, and the unabsorbed albumen, which becomes more viscid and heavy as it loses water early in incubation, sinks towards the lower end of the egg, where it remains. The chorioallantois fails to fold around the unabsorbed

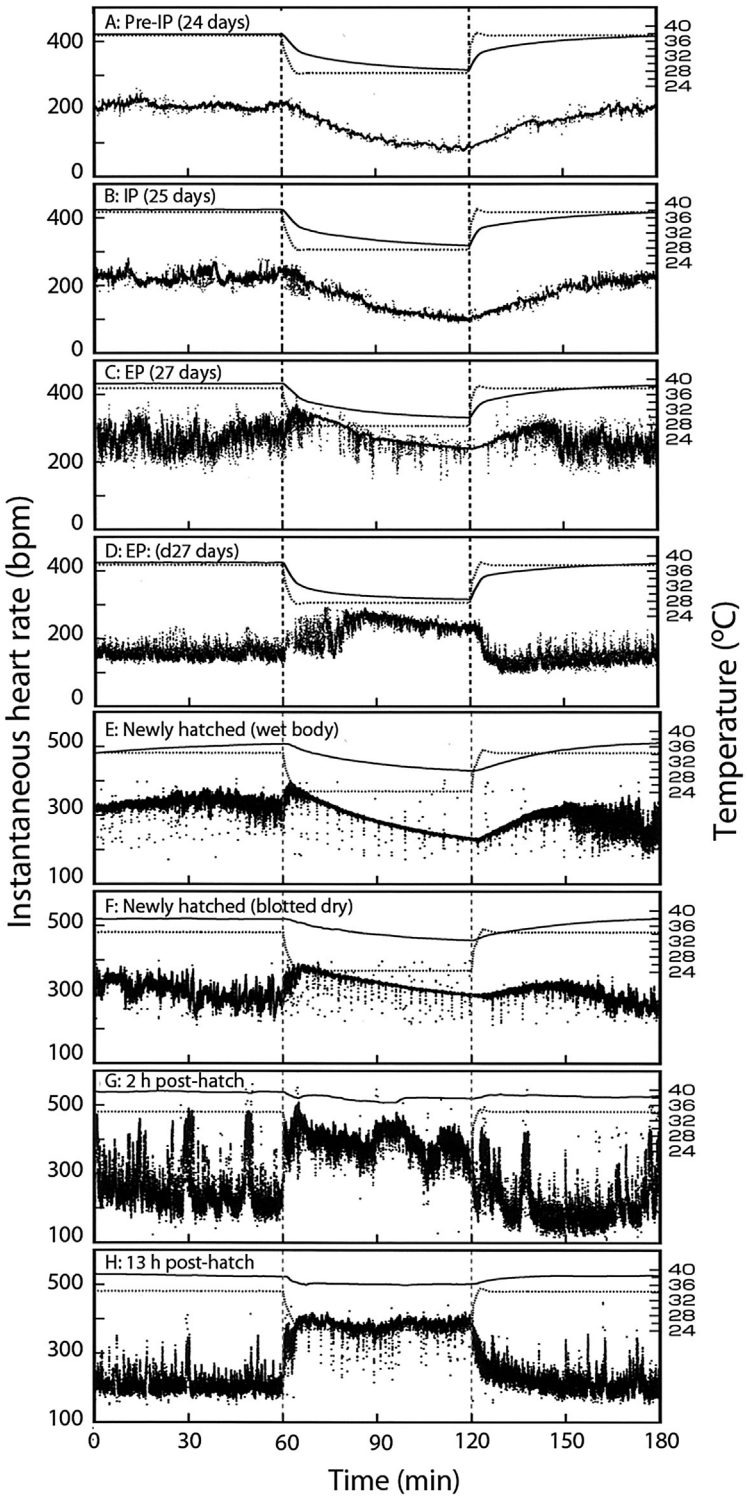

FIGURE 32.12 Responses of instantaneous heart rate (IHR) in duck embryos and hatchlings exposed sequentially to high ambient temperature (T_a = 38 °C for embryos and 35 °C for hatchlings; dotted line), low ambient temperature (T_a = 28 °C for embryos and 25 °C for ducklings), and high temperature again for 60 min, respectively. The solid line represents egg temperature or body temperature. *From Andrewartha et al. (2011a), with permission from Elsevier.*

albumen, and the interposition of the albumen between the CAM and inner shell membrane reduces gas exchange. These effects cause a pronounced fall in the arterialized blood PO_2 of late embryos, which is accompanied by an increase in Hct. The inhibition of gas exchange is reflected in the decreased $\dot{M}O_2$ of unturned eggs compared to turned eggs (Pearson et al., 1996).

32.5.3 Ambient Temperature and Incubation

Freshly laid eggs can be stored at a low temperature to maintain dormancy of embryos. However, once incubation starts, T_a must be kept within a certain range so that the embryo temperature is maintained and cell proliferation can proceed. In artificial incubation of chicken eggs at constant T_a, hatchability decreases when T_a is lowered to 35 °C or elevated to 40 °C from the optimal temperature of 37.5 °C. At 35 °C, incubation period and embryonic development of chickens are ~3 days longer than at 38 °C (Tazawa, 1973; Black and Burggren, 2004a). Survival during total incubation period is reduced at 35 °C (Black and Burggren, 2004a) and temperatures below this threshold are lethal. Hypothermal incubation decreases $\dot{M}O_2$ in proportion to retarded development of embryos and preserves the relative timing of IP and EP (Tazawa, 1973; Black and Burggren, 2004a). However, at the final stages of hypothermal incubation, hematological development and blood O_2-carrying capacity are retarded (Black and Burggren, 2004b), and eventually hypothermal incubation causes a significant delay of the relative timing of the onset of thermoregulatory ability (Tzschentke et al., 2001; Nichelmann, 2004; Black and Burggren, 2004b; Mortola, 2006).

The tolerance limits of developing embryos to acutely lowered and elevated T_a have been investigated in chickens in reference to their HR (Tazawa and Rahn, 1986; Ono et al., 1994). When day 10 embryos are exposed to a T_a of 28 °C or 18 °C, HR decreases in an exponential fashion to reach plateau values during 2–3 h of exposure. The plateau values are ~100 bpm at 28 °C and ~30 bpm at 18 °C, which are maintained until irreversible cardiac arrest occurs at ~100 and ~60 h after exposure to 28 °C and 18 °C, respectively. Accordingly, day 10 embryos survive exposure to 28 °C for no less than 4 days and to 18 °C for about 2.5 days. Reduction of T_a to 8 °C forces the heartbeat of day 10 embryos to cease after ~3 h. However, the cardiac arrest at this low T_a (8 °C) does not mean the death of embryos. Ten-day embryos survive the low T_a, without a heartbeat, for 18 h more, and the heart begins to beat again after rewarming at 38 °C. The survival time at 8 °C is reduced as the embryos grow. While the heart of day 6 embryos begins to beat even after 1 day exposure to 8 °C, the heart of day 20 embryos fails to beat after an 8 h exposure (Tazawa and Rahn, 1986).

Although chicken embryos can withstand a lowered T_a for a prolonged period without a heartbeat, at an increased T_a the cardiac arrest following arrhythmia is irreversible and the embryos cannot withstand exposure to an increased T_a for a prolonged period (Ono et al., 1994). The HR of embryos increases in an exponential fashion at increased T_a. When T_{egg} reaches 46–47 °C, regardless of the developmental stage of embryos, the HR becomes arrhythmic and irreversible cardiac arrest follows. The lethal T_a and tolerance time of chicken embryos depend upon the time T_{egg} takes to reach a lethal critical value of 46–47 °C. At a T_a of 48 °C, the tolerance time of day 12 embryos is ~100 min and that of day 20 embryos shortens by about half. The tolerance time to 48 °C exposure is shortened as the embryos grow. This may be in part due to the higher metabolic heat produced by late embryos compared to earlier embryos. The HR reaches ~450 bpm at the critical T_{egg} (46–47 °C) (Ono et al., 1994).

The embryos of ground-nesting birds in semiarid and arid areas, in particular, experience environmental temperatures well in excess of typical avian incubation temperatures. For example, the northern bobwhite quail can experience nest temperatures as high as 45 °C in the wild. Not surprisingly, this species shows remarkable tolerance to brief preincubation hyperthermia. Bobwhite quail embryos can survive 6 h exposure to 46 °C, 3 h exposure to 49 °C, and, remarkably, 1 h exposure to 50 °C (Reyna and Burggren, 2012). While these temperatures certainly increase mortality and decrease hatching rates, the high temperature tolerance of the bobwhite quail highlights the importance of a comparative approach to examining temperature tolerance. Extreme temperatures in the natural environment may result in increased tolerance in avian species, which warrants further investigation.

32.5.4 Humidity

Successful artificial incubation of chicken eggs occurs over a relative humidity (RH) range of 40–70% (Robertson, 1961). Within the successful incubation range, 53% RH is optimal for embryo survival and hatchability (Bruzual et al., 2000).

High (>85%) and low (<30%) humidity increases mortality in chicken embryos (Ar and Rahn, 1980; Bolin, 2009). Under low humidity, inadequate water content can result from increased water loss across the porous eggshell due to a high vapor pressure gradient between the inside of the egg and surrounding air. Under high humidity, water loss is reduced and this can exert its osmotic stress within the embryo. Allantoic fluid volume, which is a balance between renal filtrate production and water reabsorption into the embryo, is reduced under high water loss conditions, and conversely increased when water loss is low (Davis et al., 1988). Under high water loss, water is reabsorbed from the allantois, uric acid levels in the allantois increase, and sodium is actively transported to maintain the allantoic fluid hypotonic to the blood and aid water reabsorption (Hoyt, 1979; Davis et al., 1988). Plasma calcium, sodium, and potassium levels are elevated

in late-stage embryos, a sign of osmotic stress (Davis et al., 1988). After exposure to <30% RH, the kidneys of day 18 chicken embryos have additional glomeruli, more functioning glomeruli, and high cloacal fluid osmolality, illustrating an increased filtering capacity (Bolin, 2009).

Extremes in humidity or water loss reduce hatching success (Davis et al., 1988). Water balance appears to have the greatest effects on hatchability early in incubation, with hatchability related to water loss during the first half of incubation, rather than total water loss (Snyder and Birchard, 1982). Humidity extremes also affect late-stage embryo wet mass; that is, embryos from low-humidity or high water loss environments have smaller wet masses while those from high-humidity environments have higher wet masses (Bruzual et al., 2000). In low water loss environments, excess water is not always incorporated into wet mass but is instead left behind in the albumen (Davis et al., 1988). Growth and oxygen consumption can be retarded after exposure to extreme humidity (Bolin, 2009), but embryos that do hatch under extreme humidity reach normal weight within 7 to 10 days post hatch (Davis et al., 1988).

32.6 CONCLUSIONS AND FUTURE DIRECTIONS

Incubation is the first important process experienced by the embryonic life stages of any avian species. The characteristics of the egg itself and the surrounding environment determine the success and timing of embryonic development. As this chapter has demonstrated, the study of avian embryonic physiology has provided extensive information on the complex processes that occur during avian development. We examined the physical processes of incubation, including the transfer of water and heat between the egg and environment. We provided an overview of the development of the form and function of the major physiological systems, including the gas exchange, acid–base, cardiovascular, osmoregulatory, and thermoregulatory systems. The conditions for successful artificial incubation were discussed, as well as the effects of incubation extremes. However, numerous possibilities still exist to expand our knowledge of avian development by utilizing new physiological techniques and undertaking studies using a cross-discipline approach. Molecular and cellular studies will be important in revealing the mechanistic underpinnings of system- and organism-level observations. Furthermore, many fruitful areas of research at all levels, from genes to the whole organism, remain. These include the timing and control of important physiological events during development, how and when systems are perturbed during development and if recovery is possible, and how systems work together during development. Comparative approaches are also needed to place physiological processes in an ecological and evolutionary context. Addressing these research areas will allow us to further understand avian embryos for the complex, multisystem organisms that they are, while also contributing to the broader field of vertebrate development.

Chapter 33

Stress in Birds

Julio Blas
Estación Biológica de Doñana, Consejo Superior de Investigaciones Científicas (CSIC), Seville, Spain

33.1 INTRODUCTION

Birds undergo profound changes in physiology, morphology, and behavior across their lifecycles, and the endocrine system plays a fundamental role integrating external and internal signals and orchestrating adequate responses aimed at maximizing individual fitness. Some of these changes occur in response to *predictable fluctuations* in the environment like night–day and seasons, which allow year-round anticipatory organization of major life history stages in cyclic patterns. Superimposed on predictable components, *unpredictable perturbations* like severe weather, loss of social rank, habitat destruction, or human disturbance require emergency adjustments in physiology and behavior. The *adrenocortical response to "stress",* which results in a rapid elevation of circulating *glucocorticoid* levels (Figure 33.1; Chapter 26), provides a major physiological mechanism allowing birds to cope with environmental perturbations. *Glucocorticoids,* the *stress hormones,* allow mobilization of body energy, increase cardiovascular tone, regulate the immune system, and inhibit a variety of costly anabolic processes including digestion, energy storage, growth, and reproduction in response to "stress" (Sapolsky et al., 2000; Sapolsky, 2002). But these hormones are also fundamental for normal body functions and normal regulation of energy balance, physiology, morphology, and behavior under nonstress conditions (Landys et al., 2006). Unfortunately, it is relatively easy to find ornithology texts where the "stress of reproduction" or the "stress of migration" are invoked: authors are indeed referring to physiological demands of *normal, predictable life history stages* that *are not truly related to stress.* Even the common use of the word "stress" among comparative biologists and physiological ecologists often says *"virtually nothing about the underlying physiological or behavioral mechanisms"* (McEwen and Wingfield, 2003b). Therefore, before continuing this chapter dedicated to stress in birds, we should clarify (1) what we mean when using the term "stress", and (2) what alternative, unequivocal terms should be used to avoid confusion. Because the specific terminology is sometimes redundant and can be initially confusing, a final section (Section 33.6) provides concise definitions for many of the terms highlited in italics throughout this chapter.

33.2 UNDERSTANDING STRESS: FROM ENERGY TO GLUCOCORTICOIDS

"Stress" is a polysemous word that, depending on the context, may mean: (1) the *stimuli* that challenge homeostasis (i.e., *stressors, perturbations*), (2) the *emergency responses* to perturbations *(stress response),* or (3) the *chronic state of imbalance* that follows over-activation of the adrenocortical axis (*pathology, chronic stress*). This lack of specificity often implies that *"stress means whatever the author wants it to mean"* (Romero, 2012). In the biomedical literature this word remains ambiguous since it was first brought from the field of engineering by Cannon (1932) and Selye (1946). *Modern field endocrinologists* are making (ongoing) efforts to define and consolidate alternative and unequivocal terms, leading to the recent introduction of "*allostasis*" and an accompanying set of modern vocables to precisely define physiological responses to challenging and normal life history conditions, which are key aspects for this chapter.

Allostasis is the process of maintaining homeostasis through change. This concept was introduced decades ago to redefine stress (Sterling and Eyer, 1988), but it only started to reach ecological studies after McEwen and Wingfield proposed the *Allostasis Model* (McEwen and Wingfield, 2003a). Through the key concepts of *allostatic state, allostasis load,* and *allostatic overload,* the model incorporates classical *homeostasis* in the context of an organism's lifecycle and in relation to individual experience and how the individual responds to the ever-changing physical and social environments (Figure 33.2; McEwen and Wingfield, 2010). This model uses the balance between energy input and energy requirements to predict when an

Sturkie's Avian Physiology.

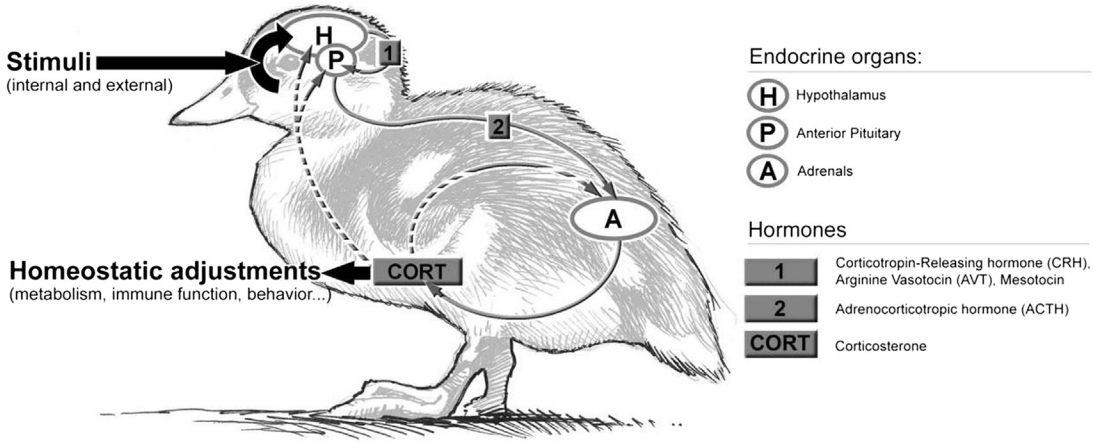

FIGURE 33.1 The adrenocortical response to stress in birds. Following exposure to perturbations of exogenous or endogenous origin (e.g., predation attempts, energy imbalances; see upper black arrows), the hypothalamus (H) releases a number of hormones including corticotropin-releasing hormone CRH. These, in turn, stimulate the anterior pituitary (P) to secrete adrenocorticotropic hormone ACTH into circulation. In birds, the adrenals (A) respond to increased ACTH levels secreting corticosterone (CORT). Within minutes to hours following exposure to stress, the resulting corticosterone elevations promote multiple changes in physiology and behavior (lower black arrow) including increased gluconeogenesis, suppression of reproductive behaviors, regulation of immune function, irruptive migration, and increased night restfulness. These adjustments promote the maintenance of homeostasis through change (i.e., allostasis). Corticosterone secretion is subjected to negative feedback mechanisms, as indicated with dashed arrows. In addition to stress-related fluctuations, baseline corticosterone levels show circadian and circannual rhythms in birds, allowing endogenous regulation of numerous physiological processes including body energy balance. *Figure from Baos and Blas, Adrenal toxicology, first edition, copyright © 2009, Informa Healthcare. Reproduced with permission of Informa Healthcare.*

animal should move away from the normal lifecycle into an emergency survival mode, and when a pathological imbalance would occur.

The *Reactive Scope Model* is an offshoot of the *Allostasis Model*, but presents a different terminology for contextualizing the impact of stress in the body and a new classification for the levels of the *mediators* (e.g., *corticosterone* in birds; see Figure 33.3) that allows the incorporation of a process known as *"wear and tear"*. Combining traditional notions of stress and homeostasis with the more recent terminology of *allostasis* and *allostatic load,* the *Reactive Scope Model* addresses the mechanisms of response to perturbations and the roles of different mediators, including glucocorticoids. It is critical to understand these two models and their associated terminology before we can understand the patterns of adrenocortical responses to stress and the underlying physiological mechanisms in birds, within a life history context.

- "Stress" is a misleading and highly unspecific term, which, depending on the context, may mean: (1) the *stimuli* that challenge homeostasis (i.e., stressors, perturbations), (2) the *emergency responses* to perturbations (stress response), or (3) the chronic *state of imbalance* that follows overactivation of the adrenocortical axis (pathology).
- Field endocrinologists are making ongoing efforts to define and consolidate alternative and unequivocal terms, leading to the recent introduction of the *Allostasis Model* and the *Reactive Scope Model*.

33.2.1 Allostasis

Homeostasis (as used in Cannon, 1932) *is the stability of physiological systems that are essential to life.* As discussed in McEwen and Wingfield (2010), the concept of homeostasis is *restricted to a few truly essential systems* (pH, body temperature, glucose levels, and oxygen tension): *those aspects of physiology that "keep us alive"* (McEwen and Wingfield, 2003a). *Allostasis is the process of achieving stability through change:* it maintains homeostasis even though the set points and other boundaries of control may change with environmental conditions. *Allostasis* thus refers to *those aspects of physiology that "help us adapt"* (McEwen and Wingfield, 2010). *Circulating glucocorticoids are major, but not the only allostasis mediators* (additional mediators include cathecolamines, cytokines, behavior, hearth rate, blood pressure, and antibody titers; see table 1 in Romero et al., 2009). Glucocorticoid levels can markedly *change to help the body maintain homeostasis* within narrow limits. To allow for this, glucocorticoids *levels fluctuate in daily and seasonal patterns* (i.e. not only in response to perturbations, despite being equivocally called "stress" hormones), *and also rise rapidly when a perturbation occurs.* Free-living birds respond to potentially noxious stimuli (like storms, social challenge, or human disturbance that reduce access to food and shelter) by increasing glucocorticoid secretion, which facilitates foraging and gluconeogenesis. In addition, elevated glucocorticoids inhibit

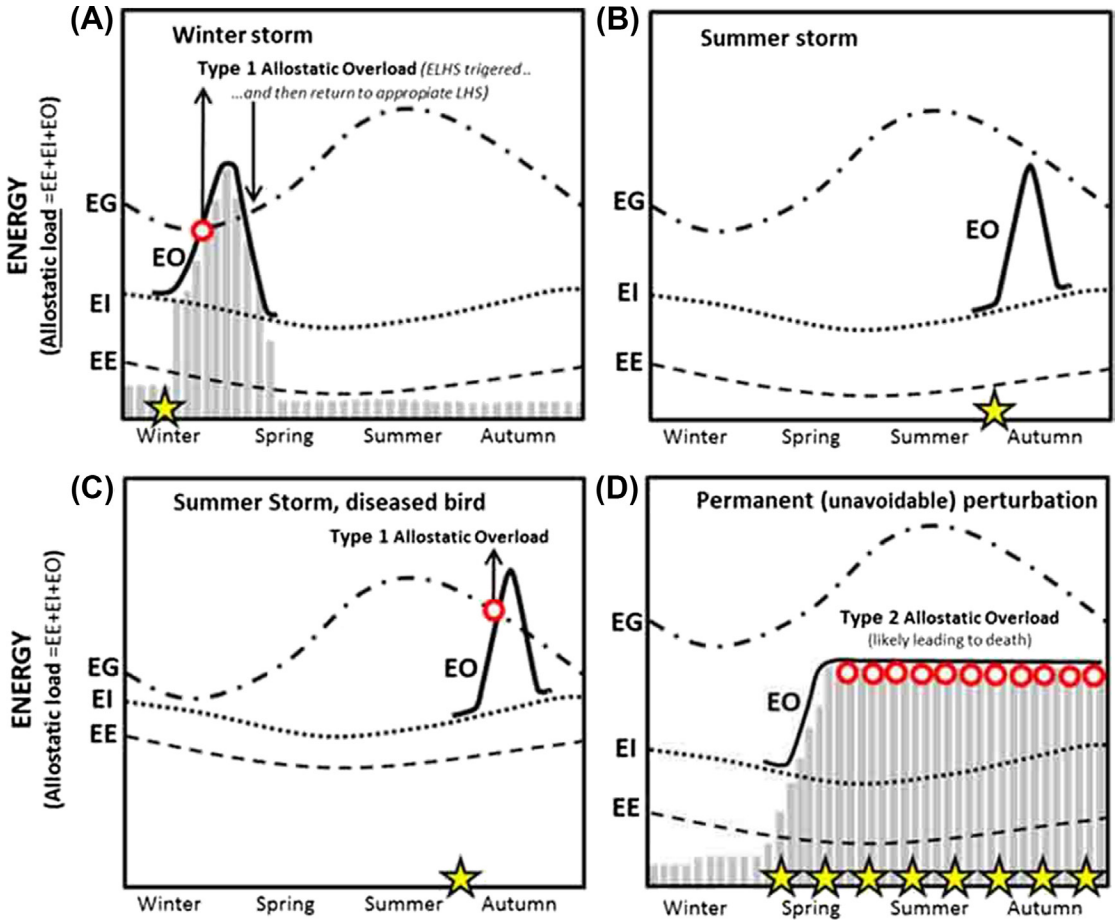

FIGURE 33.2 **The *Allostasis Model.*** The *Allostasis Model* provides a framework to understand the energetic requirements of organisms during their life, and predictions for when allostatic overload (red circles) occurs, under a range of environmental, social, and individual-based scenarios. The *y*-axis represents potential nutritional requirements (including energy *per se* and nutrients) during one year (seasons in *x*-axis). The lines represent several energy components: EG (energy to be gained) represents the amount of energy in food available in the environment. In temperate areas it is expected to rise dramatically in spring and summer and then decline through autumn and winter when primary productivity is low. EE (existence energy) is the minimum existence energy (resting metabolism) required for basic homeostasis in any life history stage. It may decline in spring and summer with ambient temperature. EI (ideal energy) is the extra energy required to go out, find food, process and assimilate it under ideal conditions (when there are no perturbations) while performing seasonal routines (breeding, molting, migrating). It likely changes seasonally and for clarity we assume that it varies in parallel with EE. EO-(energy following perturbation) is the additional energy required to go out, find food, process and assimilate it under non-ideal conditions (following a perturbation such as a storm). Allostatic load is the energy resulting from adding EE+EI+EO. In the figures, the star symbol defines when a perturbation (for example, severe weather) starts. Type 1 allostatic overload (panels A, and C) occurs when allostatic load surpasses the energy available in the environment EG, promoting corticosterone elevations (gray bars, only shown in panels A and D for clarity) that trigger an Emergency Life History Stage (ELHS). One result is suppressing the expression of another life history stages (LHS) like migration or breeding, and bring allostatic load below the level of EG (e.g., the bird may abandon spring migration to obtain more food and only continue migrating when the perturbation ends). The bird can now survive the perturbation in positive energy balance and glucocorticoid elevations subside, avoiding pathologies associated with chronic high levels. Note that the same perturbation (for example, a storm) can result in Type 1 overload during winter but not in summer (compare panels A and B) because there is more food available in the latter season (and EG>EE+EI+EO). However, an individual heavily infected by parasites or with a permanent injury or chronic disease (panel C) would enter Type 1 allostatic overload facing the same storm even in summer because its intrinsic (disease-related) EE and EI levels are higher compared to a healthy bird (compare panels B and C). A second type of overload (Type 2 overload; panel D) can take place in situations where energy from the environment EG is not a limiting factor but a long-term perturbation (for example climate change, captivity, permanent exposure to predators, permanent social challenge) triggers an allostatic state. The behavioral or physiological adjustments promoted by allostasis mediators (e.g. corticosterone) do not allow evading/copying with the noxious stimuli (the individual must be unable to escape the perturbation in order for Type 2 allostasis overload to occur). Corticosterone levels (gray bars) become chronically elevated, generating pathologies, and individuals likely die early. In the figures, the levels of allostasis mediators (for example, corticosterone) are only indicated as gray bars in the first and last panels (A and D) for simplicity, noting that their associations with energy levels (the metrics for *y*-axis in all the figures) are not necessarily linear. *Figures modified and expanded from McEwen and Wingfield, (2003a) with permission.*

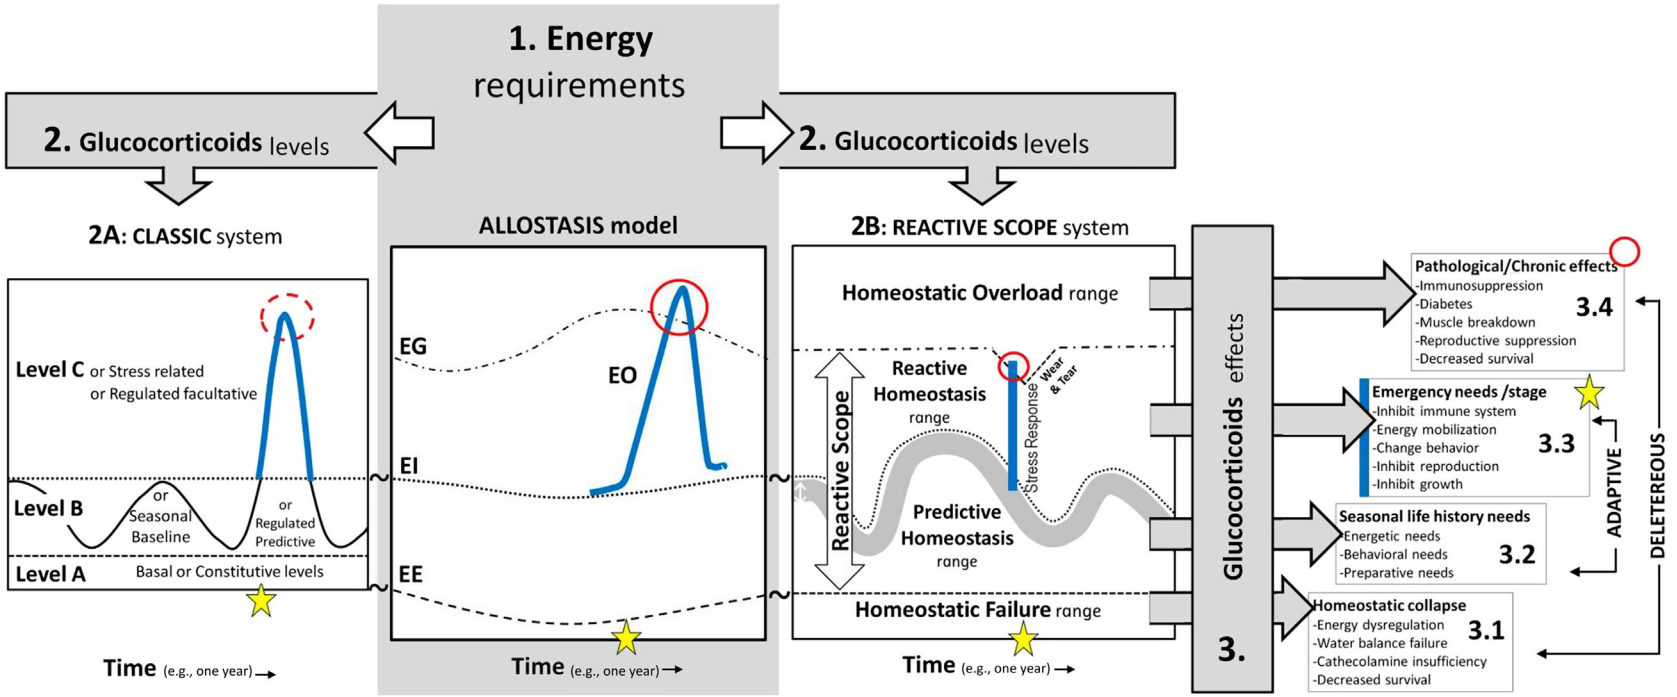

FIGURE 33.3 **Classification of corticosterone levels.** Classification of functional GC ranges according to the "Classic system" (**panel 2A**) and the "Reactive Scope system" (**panel 2B**). Both GC classification systems are presented in parallel to highlight the degree of overlapping and equivalence among system-specific terms (see main text and Section 33.6 for definitions), and in relation to the individual energy balance introduced by the *Allostasis Model* (energy requirements precede changes in GC levels, and thus the *Allostasis Model* is here presented as a central **panel 1**). Examples of GC effects on physiology and behavior are also presented in line with the corresponding GC ranges (**panel 3**). Within any given chart the *x*-axis represents the timeline (for example one year) and the star symbol indicates exposure to a perturbation, which first results in increased energy demands (depicted as a blue line in panel 1, implying increased allostatic load) and secondly in concomitant increases of GC levels reaching a range known as Level C or reactive homeostasis (blue lines in panels 2a and 2b respectively). The perturbation may eventually bring the individual into negative energy balance (depicted as a red circle in panel 1, implying allostatic overload type I), and GC elevations will reach an upper range (red circles in panels 2A and 2B) potentially causing deleterious effects on body systems (panel 3, box 3.4). To avoid the damage associated to both the energy imbalance and the high GC levels, a facultative emergency life history stage is typically triggered (panel 3, box 3.3). If the negative energy balance subsides (because the perturbation extinguishes, or the individual relocates) GC levels return to a normal seasonal baseline known as level B or predictive homeostasis (in panels 2A and 2B respectively) allowing resuming normal life history activities (panel 3, box 3.2). Note that the deleterious effects of GCs can occur both at very high and very low concentrations (panel 3, boxes 3.1 vs. 3.4). *Composite figure integrates graphs modified and expanded from several sources, including McEwen and Wingfield, 2003a; Landys et al., 2006 and Romero et al., 2009, with permission.*

processes that are not essential to immediate survival (e.g., reproduction, migration) and increase physical activity allowing an individual to move away from the perturbation or to find shelter as well as saving energy by increasing night restfulness (Wingfield, 1994; Wingfield and Ramenofsky, 1999; Wingfield et al., 1998). When the body experiences altered and sustained activity levels of *allostasis mediators* (e.g., *corticosterone,* the main avian glucocorticoid), it enters an *allostatic state,* which can only be maintained for limited periods before damaging the body.

The *Allostasis Model* (Figure 33.2) provides a framework to understand when and how emergency responses are activated (reaching an *allostatic state*) through modeling the energetic requirements of organisms during their life, and in relation to the energy available in the environment. In order to understand the model, the following energy components need to be considered:

EG (energy to be gained) represents the amount of energy in food available in the environment. In temperate areas it is expected to rise dramatically in spring and summer and then decline through autumn and winter when primary productivity is low.

EE (existence energy) is the minimum existence energy (resting metabolism) required for basic homeostasis in any life history stage. It may decline in spring and summer with increasing ambient temperature (if it becomes easier maintaining body functions).

EI (ideal energy) is the extra energy required to go out, find food, process and assimilate it under ideal conditions (when there are no perturbations) while performing seasonal routines (breeding, molting, migrating). It changes seasonally: it can follow EE and ambient temperature (for example, in a nonbreeding bird) or can increase during reproduction (spring-summer) and decrease during wintering. For clarity, in the Figure 33.2 (A) it varies in parallel with EE.

EO (energy following perturbation) is the additional energy required to go out, find food, and process and assimilate it under non-ideal conditions (following a perturbation such as a storm). It is always higher than EE+EI. In the Figure 33.2, the star symbol defines when the *perturbation* starts, setting the beginning point for elevations in EO energy demands.

Allostatic load can be now defined as the cumulative energetic requirements of the organism at a given time, and equals EE+EI+EO (although it is sometimes noted simply as EO). This concept relates to *all the energy requirements in a broad sense (encompassing nutrients and all other potentially limiting resources)*, and it can be interpreted as a cost: the cumulative cost of being there, responding to the current situations whether they are predictable or not; or the "workload" of a particular moment (at certain times, an animal has to work harder—expend more energy to maintain homeostasis). A detailed definition of *allostatic load* in McEwen and Wingfield (2010) is "*all of the energy and nutrients an organism needs to go about its daily and seasonal routines as the life cycle progresses, and to deal with unpredictable events from the physical and social environment that have the potential to be stressful.*" In the graphical representation, *allostatic load* fluctuates along a continuum with important transitional points (see red circles in Figure 33.2) that determine when the individual can cope with daily activities (when is the load affordable?) and when it needs to trigger facultative physiological and behavioral responses designed to reduce costs (when is the load unaffordable, becoming an overload?). In other words, transitional points determine when the individual enters *overload* and triggers an *allostatic state*.

There are two different outcomes. First, if energy demands exceed energy income and what can be mobilized from stores (i.e., if *allostatic load* surpasses EG), then *Type 1 allostatic overload* occurs. For example, breeding birds take advantage of the increasing food abundance in spring to raise their broods. If inclement weather then increases the cost of maintaining homeostasis in addition to the demands of breeding, and at the same time reduces the food available to fuel this *allostatic load,* then negative energy balance (*overload*) results in a loss of body mass and suppression of reproduction (Wingfield et al., 1983). This negative energy balance is *Type 1 allostatic overload*, which leads to an *allostatic state* (increased levels of glucocorticoids), which then triggers physiological changes (use of lipid stores resulting in body mass loss) and behavioral changes (brood desertion). This response has been classically referred to as the *emergency life-history stage (ELHS),* and will be discussed more in detail in Section 33.3.3. Note for now, however, that short-term elevations of glucocorticoids may promote rapid physiological and behavioral changes, allowing a decrease of *allostatic load* below the EG level, before it is required to abandon the present life history stage. Only above a certain threshold (likely variable among individuals) would corticosterone trigger *ELHS* (Wingfield and Romero, 2001). The final outcome of an *allostatic state* is normally survival because a positive energy balance can be reestablished: *allostatic load* will return to affordable levels when the individual relocates (or seeks refuge until the perturbations ends) and restores depleted condition through foraging. All of these actions are facilitated by the *allostasis mediators* (e.g., *corticosterone* levels, but also changes in behavior, hearth rate, blood pressure, cytokines, and antibody titers; see Romero et al., 2009), which are highly adaptive when elevated for a short period and then returned to normal (pre-perturbation) levels. Only in those circumstances when individuals are unable to avoid the perturbation even after entering the *ELHS*, elevated corticosterone can be maintained for long periods, resulting in serious pathological effects and eventually death.

The heuristic value of this *Allostasis Model* becomes clear when we incorporate individual variation due to habitat quality, body condition, disease and parasites, reproductive state, experience, genetics, social status, and many other additional parameters. For example, because the energy available in the environment (EG) fluctuates (e.g., food is more abundant in spring than in winter), a given perturbation will result in *Type 1 allostatic overload* faster at specific times of the year. This aspect is illustrated in Figure 33.2: the same storm (star symbol) promoting *Type 1 allostatic overload* in winter (panel (A)) fails to do so in summer (panel (B)) because there is sufficient energy in the environment to afford the increased *allostatic load*. However, an individual heavily affected by parasites or disease, or with a permanent injury (panel (C)), would enter *Type 1 allostatic overload* even in summer because its intrinsic (disease-related) energy requirement levels EE and EI are higher than average (in other words, its *allostatic load* was already elevated before the storm, and any additional EO load surpasses the energy available in the environment EG, rapidly resulting in *overload*). As an extreme example, habitats degraded by human transformation (not shown in graphics) often reduce food availability in the environment below the requirements for EE and EI. In the figures, the levels of *allostasis mediators* (for example, circulating corticosterone levels) are only indicated as gray bars in panels (A) and (D) for simplicity, but note that the metrics in the *Allostasis Model* refer to energy levels rather that the levels of any mediator. The relationships between energy requirement at a given moment and the level of a specific mediator are not necessarily linear because different *allostasis mediators* (e.g., glucocorticoids, cathecolamines, cytokines) act in concert and interact in complex physiological ways to meet allostatic demands (McEwen and Wingfield, 2010).

A second type of *allostatic overload* (qualitatively different from the Type 1 overload patterns described above) can take place in situations where energy from the environment EG is not limiting: then it is called *Type 2 allostatic overload* (see panel (D) in Figure 33.2). Here a long-term, rather than a short-term, perturbation (for example, climate change instead of weather inclemency, captivity or permanent exposure to predators instead of a single predation attempt, permanent social subordination instead of temporary social instability; see Section 33.3.3 for details) triggers an *allostatic state,* but concomitant elevations of glucocorticoids are unable to promote behavioral or physiological adjustments to cope with or to evade the noxious stimuli. For *Type 2 allostatic overload* to occur, the individual must be unable to evade the perturbation due to physical or social constraints. Corticosterone levels then become chronically elevated, generating pathologies despite adequate food resources (*Type 2 overload* occurs despite EE+EI+EO<EG; see Figure 33.2(D)). The effects on the body are similar to experimental exposure to exogenous corticosterone and metabolic pathologies arise (e.g., hyperinsulenemia, hyperphagia, obesity). This situation is most likely to occur in vertebrates living in complex hierarchical systems, where subordinate (or depending on the specific system, sometimes dominant) status imposes heavy *allostatic loads.* However, it can also affect birds under certain conditions, such as (1) natural populations exposed to permanent habitat disturbances or climate change, (2) avian social systems where dominance structure predominates over food and shelter as a source of *allostatic load* (see review in Goymann and Wingfield, 2004), and (3) captive settings. The hormonal imbalances and metabolic costs imposed by *Type 2 allostatic overload* are high and likely result in premature death and chronic disease (e.g., even birds with extreme fat stores are more likely predated due to decreased maneuverability; Lind et al., 1999; Gosler et al., 2002), providing strong selection for the mechanisms limiting *allostatic load.* But in captive animals (and human societies), the selection pressure is not there, and pathologies can persist long-term.

In summary, the concept of *allostasis* (maintaining *homeostasis through change*) combines the energetic costs or demands associated with daily rhythms and life history stages (predictable) with those costs accompanying environmental *perturbations* and social challenges (unpredictable and either short- or long-term, see Section 33.3.1) into a continuum named *allostatic load* (see figure 3 in Landys et al., 2006). Then *allostatic overload* is defined as either a short-term state in which the costs of the life history stage and accompanying challenges (=*allostatic load*) exceeds the food resources available to provide sufficient energy (*Type 1 allostatic overload*), or a long-term state in which deleterious challenges are chronic and lead to a sustained *allostatic state* independent of seasonal changes in the environment (*Type 2 allostatic overload*). The terminology introduced by the *Allostasis Model* allows physiologists to replace the overused word "stress" by a set of distinct, unambiguous, and precisely defined terms that are being gradually incorporated into modern ecological studies.

However, an acknowledged weakness of the *Allostasis Model* is the use of energy as both the underlying mechanism and the universal metric (for a discussion of this topic see Walsberg, 2003; McEwen and Wingfield, 2003b; Romero et al., 2009; McEwen and Wingfield, 2010). This becomes a problem that is mainly a consequence of our current inability to measure energy demand (*allostatic load*) and availability (EG) in free-living animals. Until we develop ways of measuring direct components of *allostatic load* (see Porter et al., 2002; Ricklefs and Wikelski, 2002 for research challenges and anticipating progress for the coming years), we will have to rely on the levels of *allostasis mediators* (e.g., circulating glucocorticoids) as best proxies to understand *allostasis*. The expected changes in *corticosterone* levels as a function of energy dynamics were only partially addressed

in the original presentation of the *Allostasis Model*, and this will be the subject of the following subsection.

- *Homeostasis* is the stability of physiological systems that are essential to life, including pH, body temperature, glucose levels, and oxygen tension (those aspects of physiology that "keep us alive"). In contrast, *allostasis* is the process of achieving homeostasis through change (those aspects of physiology that "help us adapt").
- The *Allostasis Model* provides a framework to understand the energetic requirements of organisms during their life, and in relation to the energy available. The model incorporates three concepts (*allostasis, allostatic load,* and *allostatic overload*) that allow replacing the overused and unambiguous word "stress".
  - *Allostatic load* is the cumulative energetic requirements of the organism in a broad sense (the "workload" in a particular moment), including predictable and unpredictable demands. *Allostatic load* fluctuates along a continuum, and transitional points determine when the individual can cope with daily activities and when it needs to trigger emergency responses aimed at reducing costs.
  - *Type 1 allostatic overload* is a short-term state of energy imbalance in which *allostatic load* exceeds the energy available from the environment plus the internal reserves.
  - *Type 2 allostatic overload* is a long-term state in which environmental or socially demanding challenges become chronic and exert deleterious effects on the individual, regardless of the energy available.
- The metric or "currency" for the *Allostasis Model* is energy. This represents a problem due to the difficulty of estimating energy demands and availability outside controlled conditions. However, energy management is achieved through changing levels of *allostasis mediators* (e.g., glucocorticoids, cathecolamines, cytokines, behavior, hearth rate, blood pressure, antibody titers) that can be measured accurately. The relationships between energy requirement at a given moment and the level of a specific mediator are not necessarily linear because different mediators act in concert and interact in complex ways.
- *Corticosterone* is the predominant *glucocorticoid* in birds and a major *allostasis mediator*. Circulating corticosterone levels *change in response to internal and external demands to manage energy balance*. When the body experiences altered and sustained corticosterone elevations, it enters an *allostatic state*, which can only be sustained for limited periods before damaging the body.
- The *Allostasis Model* is a largely theoretical paradigm requiring empirical tests. However, it provides a framework to understand when and how emergency responses are activated, and how individuals respond to changing physical and social environments.

33.2.2 Classification of Glucocorticoid Levels

Glucocorticoids (GCs) are major *allostatic mediators:* they allow lifetime modulation of avian energy balance throughout changing internal and external conditions. Their role in gluconeogenesis explains much of their relevance as mediators, but they also act facilitating morphological and behavioral changes and balancing the immune system in ways that are crucial for individual fitness (see details in Chapter 26). The year-round dynamics of avian energy requirements and constraints introduced with the *Allostasis Model* now provide a reference to describe expected changes in GC levels (Figure 33.3). It is critical to assimilate and properly use the range-descriptor terms provided below, because GCs can exert either housekeeping actions or devastating effects on the organism depending on what levels are involved: this requires specific terminology. The paradox affects most *allostasis mediators* (they are *"good and bad", "stress and antistress"* depending on the range), and an adequate term usage constitutes the only way to avoid confusion and to understand how opposing results regarding GC actions among studies are not necessarily a contradiction.

The nomenclature describing GC ranges and functional thresholds differ, however, between what we will here call the *Classic System* and the *Reactive Scope System.* The two classifications are graphically presented in Figure 33.3 as two parallel panels (2A and 2B) and in relation to the *Allostasis Model* (but note that the latter refers to energy balance and not GC levels) for ease of comparison. The *Classic System* combines three hormonal thresholds (levels A, B, and C) and a set of *corticosterone terms* traditionally used (*basal* versus *baseline*, *constitutive* versus *facultative,* seasonal versus stress related) as proposed by Wingfield et al. (1997) and further refined in Landys et al. (2006). The *Reactive Scope System* corresponds to a more recent classification given in the original proposal of a model (Romero et al., 2009) which will be explained in the following section (Section 33.2.3). Despite the possibility that parallel terminologies may initially add some confusion in understanding the complexity of GC actions (additional terms are not exempt from controversy, McEwen and Wingfield, 2010), it is relevant to become familiar with both systems. These ultimately agree that GC levels are presumed to exist in five ranges of increasing magnitude (Figure 33.3):

1. ***A pathological and physiologically unsustainable range where GC levels are too low*** for minimum homeostatic processes. This pathological range can be simulated by removing GCs through adrenalectomy (in mammals, Darlington et al., 1990) or chemical treatment (in birds, where adrenocortical cells are also located in the kidney tissue; see Chapter 26), and death rapidly occurs. In the *Allostasis Model* this would be equivalent to an

individual unable to meet the minimum energy requirements for existence (i.e., below EE level).
   a. In the Classic System, this range corresponds to GC concentrations *below level A* (this classification system does not have a specific place or level to represent a deadly physiological level or stage).
   b. In the Reactive Scope System, this is the GC range of *homeostatic failure*.
2. ***A minimum GC level allowing basic homeostatic processes*** (allowing meeting the existence energy demands EE in the *Allostasis Model*).
   a. In the Classic System, this range corresponds to GC concentrations *within level (range) A,* and corticosterone levels are termed *basal or constitutive*, (allowing "a physiological *state A* representative of undisturbed animals at rest, in which hormone action maintains internal systems at a basal operating level to support the most fundamental requirements of life"; Landys et al., 2006).
   b. In the Reactive Scope System this will be the lower end of (but already *inside) the predictive homeostasis range.*
3. ***A range where GC levels fluctuate according to predictable environmental changes,*** making it possible to cope with daily and seasonal routines of the life cycle (i.e., meeting ideal energy needs EI, in the *Allostasis Model*).
   a. In the Classic System, this range corresponds to GC concentrations *within levels (range) B* and corticosterone levels are termed *seasonal baseline* levels or *regulated predictive* level (allowing a physiological *state B* where "hormone action maintains systems within a heightened operated range to support increasing demands—*allostatic load,* especially in association with predictable changes in the environment or life history"; Landys et al., 2006).
   b. In the Reactive Scope System, this will be the *predictive homeostasis range*, where GCs encompass normal circadian, daily, and seasonal changes. In the graphical representation of the *Reactive Scope Model* (Figure 33.3, panel 2B), the width of the gray area represents circadian variation (driven by predictable daily changes in light and dark; see, e.g., Dallman et al., 1987), while the convolutions of this gray line along one year reflect seasonal variation (predictable changes normally driven by photoperiod), which allow anticipation and progression of life history stages such as breeding (see, e.g., Romero, 2002). The thin line above the gray line represents corticosterone fluctuations in response to normal, and still predictable daily activities like foraging (using other terminology, "the circadian peak within the gray line corresponds to resting metabolic rate, while the thin line marks the active metabolic rate for that time of the year"; Romero et al., 2009).
4. ***An upper, facultative range of GC levels*** (superimposed above the normal circadian, daily, and seasonal fluctuations), ***where short-term elevations allow counteracting unpredictable changes*** in the environment, and either maintain or return the body to homeostasis (i.e., meeting *allostatic load* EO: the increased energy demands that follow perturbations).
   a. In the Classic System, this range corresponds to GC concentrations *within level (range) C* and corticosterone levels are termed *stress-regulated* levels or *regulated facultative* levels (entering a physiological *state C* that "allow animals to survive threatening perturbations when *allostatic load* exceeds the immediate ability to cope, e.g. during encounters with a predator, infection, severe weather, energy storage and/or social instability"; Landys et al., 2006).
   b. In the Reactive Scope System, this will be the *reactive homeostasis range*.

Both classification systems agree to term these facultative GC elevations as the "***stress response***", and link the physiological, morphological, and behavioral changes to a distinct ***emergency life-history stage (ELHS)*** (Wingfield et al., 1998), which will be presented in detail in Section 33.3.3. In panels 2A and 2B of Figure 33.3, the occurrence of a *perturbation* is depicted by a star symbol in the time line (*x*-axis), and concomitant GC elevations (the GC stress response) are represented with a thicker blue line (the same perturbation is also depicted in the central panel dedicated to the *Allostasis Model* with the predicted changes in energy demand EO, *allostatic load,* represented with a thicker blue line). Note in the *Reactive Scope Model* (panel 2B), that the combination of *predictive* and *reactive homeostasis* ranges establishes the *normal reactive scope* for the individual, a concept that defines the upper and lower physiological constraints of a healthy animal and provides a name for the model, as we will explain shortly.

5. ***Finally, GC levels may reach a higher range where pathologies also develop.*** In the *Allostasis Model* this would be equivalent to reaching *Type 1 allostatic overload* (the demands exceed the energy available).
   a. The Classic System (panel 2A) does not have a specific graphical notation for this range, likely because the development of pathology also involves a prolonged duration (time) of the GC elevations in a range that could still be indicative of typical regulated facultative levels. Prolonged GC elevations in this range are termed *chronic GC levels*. For ease of interpretation, the red circle in panel 2A depicts the highest GC concentrations that would lead to pathology if maintained for days.
   b. In the Reactive Scope System, the upper GC levels would move into a *homeostasis overload* range (when corticosterone levels overpass the *normal*

reactive scope above the upper end of the *reactive homeostasis* range). A key aspect in the *Reactive Scope Model* (a conceptual novelty that was missing in the Classic System and in the *Allostasis Model*) is that, unlike the threshold for *homeostatic failure*, the actual threshold for *homeostatic overload* can change within and between individuals in response to certain stimuli through a mechanism known as *wear and tear.* Therefore the amplitude of the *reactive scope* is NOT a fixed trait in the individual. The effect of *wear and tear* is graphically represented in panel 2B, and its implications for *reactive scope* will be specifically discussed in the next section.

Because the absolute GC concentration defining each of the ranges described above varies between species (and even among populations within a given species, Wingfield and Romero, 2001), and GC actions on physiology and behavior are very different depending on the functional range (compare boxes 3.3 and 3.4 in Figure 33.3), a particular value or concentration of GC is generally meaningless *per se*, and unable to define the state of an individual. Unless it is close to zero or extremely high compared to the published records in other taxa (in both cases it would be indicative of serious body malfunction), a GC level or range presented in isolation says nothing about the physiological condition of that particular individual or population. As a consequence, the starting point for any field or laboratory study on avian adrenocortical function requires an initial assessment of the normal reactive scope (*predictive* and *reactive homeostasis* GC ranges) for the particular species or populations under research, and a simultaneous assessment of the conditions characterizing the same study subjects (e.g., health conditions, behavior, environmental conditions) that may affect *allostasis* and thus GC levels at a given time.

It is also important to remember that, for simplicity, we have been assuming a direct association between circulating GC levels and GC actions (panel 2 versus panel 3 in Figure 33.3). However, GC effects can be regulated at several levels (see the Chapter 26 and Wingfield, 2013b), including at least (1) regulation of secretion and clearance rates, (2) regulation of transport (over 90% of circulating GCs are bound to carrier proteins, and only the remaining 10% constitute free and biological active hormone; Malisch and Breuner, 2010), (3) regulation of receptors (there are three types of receptors differing in affinities and exerting different effects on the organism), and (4) regulation of steroidogenic enzymes.

- GCs can exert housekeeping actions or devastating effects on the organism depending on what levels are involved (they can be "*good and bad*", "*stress and antistress*"). The absolute GC concentrations defining these ranges are species-specific.
- Two nomenclature systems (the *Classic System* and the *Reactive Scope System*) propose *alternative terms* to name GC ranges within adaptive and nonadaptive (pathological) levels.
- Healthy individuals show circulating GC levels within two narrow ranges bellow and above which serious pathologies occur:
  - *Seasonal baseline* levels or *predictive homeostasis* range: GCs fluctuate according to *predictable* environmental changes, allowing the individual to cope with daily and seasonal routines.
  - *Regulated facultative* levels or *reactive homeostasis* range: short-term GC elevations (above *seasonal baseline*) allow counteracting *unpredictable* changes in the environment. Facultative elevations are also termed the "*stress response*", and allow rapid physiological and behavioral changes characteristic of a distinct *emergency life history stage* (ELHS).

33.2.3 "Wear and Tear" and the Reactive Scope

Allostatic load (the "workload" to maintain homeostasis) is recognized as one the most relevant conceptual advances of the *Allostasis Model* (McEwen and Wingfield, 2003a). However, this concept needed to be further refined and expanded to incorporate additional body costs that were not explicitly acknowledged in the original formulation of the model. In particular, *the elevation and maintenance of allostasis mediators incur a cost themselves*. For example, the long-term behavioral and cardiovascular responses that characterize *allostasis* result in cardiovascular disease (Sapolsky, 2001), and GC elevations are known to exert a negative impact on the immune system, leading to a greater susceptibility to infections (Spencer et al., 2001). These costs are directly related to the *allostasis mediators* themselves and not to *allostatic load per se*, leading to a recent proposal of the term "*wear and tear*": the cost of maintaining and using the physiological systems that mediate *allostasis* (Romero et al., 2009). The concept of *wear and tear* was originally introduced as a distinct attribute within a wider graphical interface, the *Reactive Scope Model* (Romero et al., 2009), which was proposed as a tool to characterize the physiological state of individuals across time, in response to *perturbations,* and according to the levels of *mediators* (not according to energy, which is the specific metric system of the *Allostasis Model* and generated ample criticism; Walsberg, 2003; Romero et al., 2009; McEwen and Wingfield, 2010). The *Reactive Scope Model* is therefore an extension (not a rebuttal) of the *Allostasis Model* and the seminal article leading to its formulation was supported by a thorough review of the potential *allostasis mediators* and their effects at different ranges, including immune factors, cardiovascular responses, behavior, the central nervous system, and

circulating GCs (Romero et al., 2009). For simplicity, only the later mediators (GCs; *corticosterone)* will be used here to explain *wear and tear* and the dynamics of the *Reactive Scope Model* across time and in response to *perturbations.*

As we detailed in the previous section, the *Reactive Scope Model* also proposed a specific nomenclature to characterize the functional GC ranges (Figure 33.3, panel 2B). This new classification was justified to avoid confusion with other terms previously defined (what we called the *Classic System* in Figure 33.3, panel 2A), and circulating GC levels were presumed to exist in four ranges of increasing magnitude: *homeostatic failure, predictive homeostasis, reactive homeostasis*, and *homeostatic overload*. The combination of *predictive* and *reactive homeostasis ranges* establishes the *normal reactive scope* for the individual (which lies in between the upper and lower physiological constraints of a healthy animal, *above and below which serious pathologies arise*) and provides a name for the model (Figure 33.4)

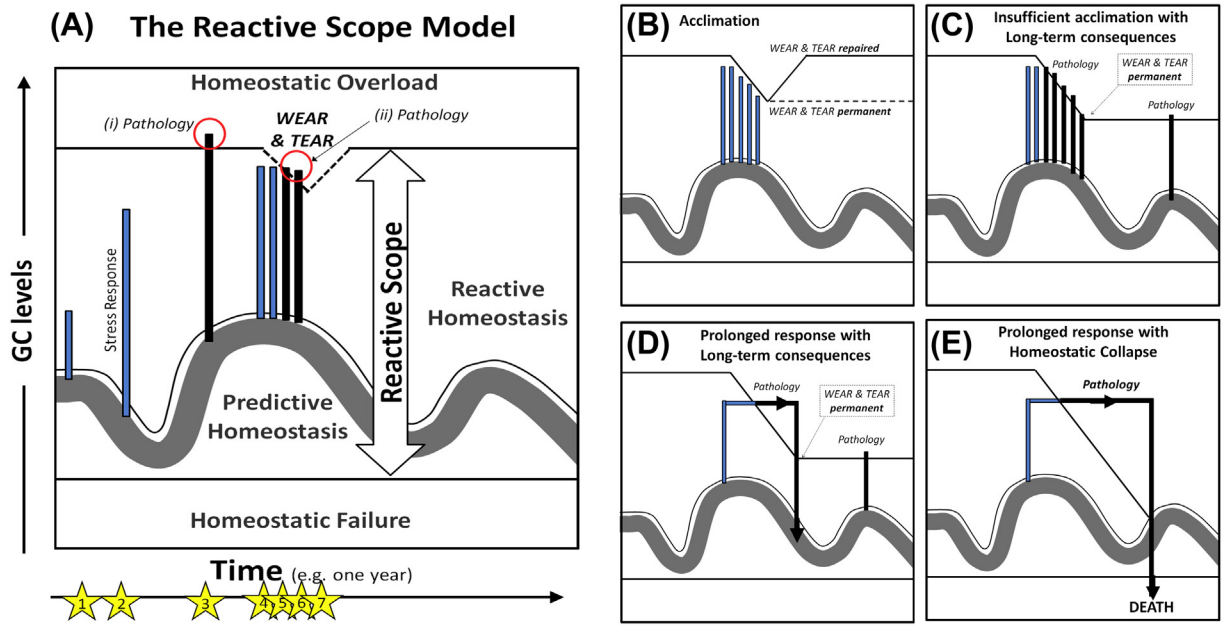

FIGURE 33.4 The Reactive Scope Model. Changes in circulating GC levels (*y*-axis) across time (*x*-axis) according to the Reactive Scope Model. ***Panel A:*** GC levels exist in four nominal ranges: the predictive homeostasis range varies according to seasons and life history stages, and the reactive homeostasis range represents the facultative range of GC elevations in response to unpredictable perturbations. Both ranges combined define the normal reactive scope of the individual. Below and above this range, GC levels result in pathology (homeostatic failure and homeostatic overload ranges, respectively). In response to perturbations (numbered stars in *x*-axis), each vertical line represents both a rapid GC spike in the reactive homeostasis range and a rapid decrease when the perturbation ends. In panel A, perturbation #2 is stronger than #1 and thus requires a stronger GC elevation to maintain homeostasis. Perturbations #2 and #3 are of similar strength, but occur at different times of year and only the latter results in GC levels extending inside the homeostatic *overload* range (depicted as black rather than blue bars) and cause pathology. Perturbations #4–5 do not cause pathology, but repeated GC elevations exert "wear and tear" as depicted by a progressive decrease in the threshold between reactive homeostasis and homeostasis overload (decreasing the reactive scope of the individual). Wear and tear implies that GC response to subsequent perturbations #6–7 will generate pathology. In this example, wear and tear is rapidly repaired and there are no long-term consequences on the ability to respond to future perturbations (the reactive scope becomes normal after the last perturbation #7). ***Panel B*** represents acclimation. Repeated responses to stressors exert wear and tear but the animal habituates or acclimates when GC elevations decrease over time. Since GC levels never cross the threshold of homeostatic overload, pathology does not develop (note that all the bars are blue). The accumulated wear and tear can be repaired once the stressor ends (upper continuum line), or alternatively remain permanent (lower dashed line). ***Panel C*** represents an insufficient acclimation with long-term consequences. Here the animal acclimates to a repeated perturbation but despite GC elevations progressively decrease, they enter the GC homeostatic overload range and pathology develops (denoted with black bars). The threshold of reactive homeostasis could be repaired, but in this example wear and tear exert permanent effects, increasing susceptibility to future perturbations. As a consequence, even a moderate GC elevation elicited to face the last perturbation in this panel (C), enters the homeostasis overload range and generates pathology. ***Panel D*** presents an example of long-term exposure to a perturbation (e.g., chronic social stress, habitat degradation). Long-term exposure elicits prolonged GC elevations (note that the light bars now indicate extended GC secretion), which also exert wear and tear. When the sustained increase in GC levels extends above the adjusted threshold (see blue color in bars turning to black color), pathology resulting from the elevated GCs themselves appears. Once the perturbation ends, GCs return to the predictive homeostasis range, but in this example wear and tear becomes permanent as it likely occurs under social stress. Consequently, a later response to perturbation pushes GCs immediately into the homeostatic overload range. ***Panel E*** presents an extreme example of long-term exposure to perturbations. It implies that GC elevations remain in the homeostatic overload range for long periods, generating long-term pathology and accumulating a continuous wear and tear. Once the threshold between GC reactive homeostasis and homeostatic overload ranges intersect with the predictive homeostasis range, GC levels collapse into the homeostatic failure range, turning pathology into death. *Figure modified and expanded from Romero et al. (2000) with permission.*

In response to unpredictable *perturbations,* GC levels rapidly elevate outside the *predictive* range into the *reactive homeostasis range*. These elevations are graphically represented as rapid GC spikes (blue vertical bars in Figure 33.4), which counteract the negative effects of *perturbations* (depicted as numbered star symbols along the time line) though physiological and behavioral changes and then quickly return to the *predictive homeostasis range*. This is the adrenocortical "*stress response*" aimed at maintaining *homeostasis* in the face of a *perturbation.* The sequence of perturbations experienced by a model avian individual in Figure 33.4 (A) indicate first that the magnitude of GC elevations depends of the type of perturbations. For example, the GC increase in response to perturbation 1 (e.g., a mild storm in winter) is significantly smaller than the elevations in response to perturbation 2 (a severe storm in winter). In these two examples, GC elevations remain within the *reactive homeostasis range*. In contrast, the same type of perturbation occurring at a different time of the year and even eliciting the exact same release of GCs can exert dramatically different effects on the individual. In Figure 33.4 (A), perturbations number 2 and 3 are two storms of similar quality (e.g., a severe storm occurring at the end of winter, and then again in early spring) eliciting similar GC elevations. However, only the latter causes *pathology* (red circle) as GC elevations reach the *homeostatic overload range* (GC spikes are represented now with a black, rather than a blue bar to indicate pathological effects). A similar feature was already suggested in the *Allostasis Model* with regards to an individual's likelihood of reaching states of negative energy balance at different times of the year, but some clarifications are needed. The *Allostasis Model* postulates that birds would be more resistant in winter because their energy requirements are lowest (winter perturbations should be stronger and demand more energy in order to reach *allostatic overload* Type 1; McEwen and Wingfield, 2003a), while the *Reactive Scope Model* postulates that birds are more resistant in winter because their GC *reactive homeostasis range* is wider (and thus reaching *homeostatic overload* would require a higher GC stress response, and likely a stronger *perturbation;* Romero et al., 2009). Energy demand (the *Allostasis Model* currency) and GC levels (the *Reactive Scope Model* currency) coincide in this example, as they both change in the same direction and result in deleterious effects, but this may not always be the case.

As we pointed out, the task of maintaining GC levels in the *reactive homeostasis* range during a *"stress response"* incurs a cost in itself known as *wear and tear. Wear and tear can be defined as the cumulative cost of maintaining GC levels within the reactive homeostasis range,* and this cost has a consequence: a decrease in the threshold level between the *reactive homeostasis* range and *homeostatic overload* (see decreased threshold after perturbations 4 and 5 in Figure 33.4 (A)). Note that the concept of *wear and tear* is different from the concept of *pathology*: in the latter, GCs themselves are causing damage, whereas in the former the likelihood of GCs causing damage increases. To illustrate this conceptual difference, compare the effect of perturbation 3 with the effects of perturbations number 4 and 5 in Figure 33.4 (A): only the former perturbation 3 positively generates pathology. *Wear and tear* can therefore be also interpreted as a *gradual decrease in the ability to cope with perturbations.* As the individual continues to respond to sequential or prolonged perturbations, GC elevations repeatedly enter the *reactive homeostasis* range, and the ability to counteract further stressors diminishes. At some point, the elevated GCs will cross a threshold and will start to create problems themselves. It is very important to note that, through *wear and tear,* GC levels can enter the *homeostatic overload* range even though their concentrations may not have changed. In other words the *Reactive Scope Model* proposes two ways of reaching *homeostatic overload*: either GC levels extend beyond the normal *reactive scope*, or GC levels remain in the *reactive homeostasis* range for an extended period, "shrinking" the *reactive scope* of the individual. Both scenarios are graphically depicted in Figure 33.4 (A). In response to perturbation 3, GC levels elevate above the *normal reactive scope* of the individual, entering the *homeostatic overload* range and generating *pathology.* Later on that year, the same individual is exposed to perturbations number 4 and 5, which trigger GC elevations within the *reactive homeostasis* range. These *perturbations* do not cause pathology *per se* because concomitant GC elevations do not reach the *homeostatic overload* range. However, they exerted *wear and tear* on the individual, increasing susceptibility to enter *homeostatic overload* in response to subsequent perturbations (in fact, perturbations number 6 and 7 trigger GC elevations similar in magnitude to perturbations 4 and 5, but only the former cause pathology as the *reactive scope* range "shrunk"; see Figure 33.4 (A)). In healthy individuals, *wear and tear* can be repaired after the perturbations end, but it could also remain for life, imposing a permanent decrease of the *reactive scope* of the individual and a permanent susceptibility to pathologies (the two options are represented within Figure 33.4 (B)). *Wear and tear* and its graphical representation is an alternative way to express the concepts encompassed by *allostatic load.* For examples and detailed explanations of the physiological mechanisms underlying *wear and tear,* see Romero et al. (2009).

Modeling *wear and tear* the way explained above illustrates why *equivalent GC responses might be adaptive early, but cause problems later*. It also illustrates why animals will be more resistant to stress-related pathologies during some life history stages compared to others. But in addition, the model suggests relevant evolutionary implications. For example, the authors propose that the slope of *wear and tear* in a specific individual could be determined empirically, because the threshold separating

reactive homeostasis from *homeostatic overload* is equivalent to the maximal GC secretion of the *normal reactive scope* (Romero et al., 2009). Maximum GC secretion in a young, healthy, naïve bird could be determined experimentally (for example, through exogenous adrenocorticotropin ACTH treatment; see Section 33.5.2), providing the actual limit of *reactive homeostasis*. Then, if a moderate *perturbation* is experimentally applied repeatedly to the animal for a short period, acclimation may occur (e.g., Walker et al., 2006) and the magnitude of the response will decrease (a visual example is provided as panel (B) in (Figure 33.4) As long as pathological symptoms do not appear, thereby revealing that the individual has entered the *homeostatic overload* range, the acclimation over time will occur and the slope of *wear and tear* will be manifested as a time-related decrease in GC secretion. As we already mentioned, there are situations where repeated GC elevations cause permanent changes to the individual's physiology, and this can be illustrated by a permanent decrease in the *reactive homeostasis range* (e.g., in Figure 33.4 (C), the decreased *reactive scope* implies that this individual will be lifelong susceptible to pathologies). Also, the examples above only depict scenarios of repeated, but short-term perturbations followed by episodic spikes of GC into the *reactive homeostasis* range. These scenarios would be equivalent to *Type 1 overload* in the *Allostasis Model* (McEwen and Wingfield, 2003a,b). However, a single but long-term *perturbation* may similarly cause prolonged GC elevations, a situation that was named *Type 2 overload* in the *Allostasis Model* and required separate conceptual explanations (McEwen and Wingfield, 2003a,b). With the graphical proposal of the *Reactive Scope Model* and the associated concept of *wear and tear,* the upper end of the *reactive homeostasis* range is simply expected to show a long-term (permanent) decrease in response to long-term perturbations, as depicted in panel (D). The graphical models for the response to both (1) repeated short-term perturbations (panels (A)–(C) in Figure 33.4) and (2) prolonged perturbations like subordinate social status or habitat degradation (panels (D) and (E)) are very similar under the *Reactive Scope Model* and the dichotomy between *Type 1* and *Type 2 overloads* is no longer necessary according to Romero et al. (2009). For example, low social status may impose a long-term cost to subordinate individuals compared with dominants (the reverse situation may also occur depending on the dynamics of the specific social system; Goyman and Wingfield, 2004), leading to what has been classically termed "*chronic social stress*". In the *Reactive Scope Model* this is depicted in Figure 33.4 (D) (social conflict elicits a prolonged *adrenocortical response*, likely "shrinking" the *reactive scope* of individuals).

In all of the examples above we represented scenarios where the repeated/prolonged GC responses eventually end. However, the model predicts that as long as a prolonged stress response remains in the *homeostatic overload* range, *wear and tear* should continue to occur (Figure 33.4 (E)). The threshold between *predictive homeostasis* range and *homeostatic overload* will decrease, until actually becoming lower than the *predictive homeostasis* range itself. In this situation, very low GC levels will fall into the *homeostatic failure* range, where normal *homeostasis* cannot be maintained and death should follow. *The Reactive Scope Model* further provides predictions for how long GC levels can remain in the *homeostatic overload* range until collapse will occur. Examples of chronic malnutrition, changes in social status, and lifelong allostatic changes resulting from early life experiences are provided in the original formulation of the *Reactive Scope Model* (Romero et al., 2009), establishing comparisons to the *Allostasis Model* and highlighting the benefits of an alternative interpretation for scenarios that generate enormous interest for both biomedical researchers and ecologists. The *Reactive Scope Model* provides, for example, a new framework to understand the concept of eustress (Selye, 1976), and those changes that occur during development and can reset an animal's *reactive scope* resulting in lower (rather than higher) vulnerability to enter *homeostatic overload* later in life, a concept that challenges traditional models (Saino et al., 2005).

Finally, note that despite the fact that considerable empirical grounds led to the formulation of both the *Allostasis Model* and the *Reactive Scope Model* these are still today largely theoretical paradigms. Experimental demonstration of the models and their predictions in free-living birds under diverse ecological scenarios are among the major current challenges for avian physiologists.

- The *Reactive Scope Model* is an extension of the *Allostasis Model* presented as a graphical tool for characterizing the physiological state of individuals according to the levels of mediators (e.g., circulating *corticosterone* titers) rather than energy levels.
- The combination of the two adaptive corticosterone ranges of a healthy animal (i.e., *predictive* and *reactive homeostasis* ranges) form the normal *reactive scope* of the individual. *Corticosterone levels above and below the reactive scope cause serious pathologies*. Therefore, the reactive scope defines the upper and lower physiological constraints of a healthy individual.
- In response to unpredictable perturbations, GC levels rapidly elevate into the *reactive homeostasis range* during a "*stress response*". Even when GC elevations do not reach *homeostatic overload* to cause pathology, as the individual continues to respond to sequential or prolonged perturbations GC levels will exert *wear and tear.*
- *Wear and tear* is defined as the cost of maintaining and using the physiological systems that mediate *allostasis,* and can be graphically depicted as a decreased threshold level between the *reactive homeostasis* range and *homeostatic overload* (and therefore a decreased *reactive scope*).

- *Wear and tear* implies a gradual decrease in the ability to cope with perturbations. This concept is different from pathology: GCs themselves are not causing damage, but increase the likelihood of damage due to a progressively decreased *reactive scope*. *Wear and tear* illustrates why equivalent GC responses might be adaptive early, but cause problems later.
- The *Reactive Scope Model* proposes two ways of reaching *homeostatic overload*: (1) either GC levels extend beyond the normal *reactive scope* and cause pathology; or (2) GC levels remain in the *reactive homeostasis range* for an extended period, "shrinking" the *reactive scope* of the individual and increasing the likelihood of pathology.
- The *Reactive Scope Model* is still a largely theoretical graphical tool requiring empirical demonstrations.

33.3 ADRENOCORTICAL RESPONSE TO ENVIRONMENTAL CHANGE

A cornerstone question for evolutionary biologists and field endocrinologists is: How do birds respond and adapt to an ever changing environment? There is large amount of evidence that *the mechanisms by which birds perceive potential challenges and transduce this information into neuronal and endocrine responses are fundamentally different when facing predictable versus unpredictable environmental events* (Wingfield, 2013a). In this section we will characterize the unpredictable events of the environment (the *perturbations*), especially those that disrupt the normal life cycle, and will summarize the adrenocortical responses that allow adaptive orchestration of facultative physiological and behavioral mechanisms aimed at maximizing fitness. This subject is critically relevant for basic and conservation-oriented research in the light of global change, because human-induced *perturbations* can generate similar adrenocortical responses to natural stressors and the individuals´ inability to cope inevitably precede all extinction processes.

33.3.1 Predictable versus Unpredictable Environmental Change

As we have previously pointed out, because some seasonality in climatic, biological, and social conditions exists to different degrees in all avian habitats, birds have evolved mechanisms to organize their life cycles in synchrony with other individuals and the predictable environment. Internal and external (temperature, photoperiod, rainfall, social interactions) environmental cues allow anticipatory adjustments of major life history events (Wingfield, 2008). Individuals can thus prepare for energy demanding times of year such as a rainy winter or a hot and dry season, and GC levels will fluctuate remaining within the *baseline, predictive homeostasis range*. Regardless of how stressful local conditions may appear to the human eye, GCs do not elevate into the *reactive homeostasis range* in response to the *predictable environment* (these are *not perturbations*). For example, American goldfinches (*Carduelis tristis*) do not elevate GC levels in winter despite exposure to severe weather and temperatures below −20 °C (Dawson et al., 1991), and adult king penguins (*Aptenodytes patagonica*) fast for weeks, relying on their fat stores during the austral winters without neccesarily increasing circulating GCs (Cherel et al., 1988). Extreme cold and lack of food constitute, within certain limits, the *normal environmental conditions* under which these two species evolved their life cycles. However, there is no habitat subjected to perfectly foreseeable changes. Sudden severe storms outside the expected season, attacks from predators or dominant individuals, human disturbance, and parasites/disease are generally not predictable and have the potential to disrupt the life cycle of the individual, potentially even causing death. *Unpredictable events* in the environment are generally termed *perturbations* or *stressors*. These could be characterized in the light of the *Allostasis Model* described earlier (Section 33.3.1), across a gradient of increased energy demands *(allostatic load),* and their effects *(allostasis)* in terms of GC secretion and subsequent adjustments of life history stages, which should depend on the energy available to each particular individual at each particular moment (see figure 3 in Landys et al., 2006). The fact than some types of *perturbations* eventually bring the individual into *allostatic overload* makes a qualitative difference for the role of circulating GCs in behavior and physiology, as will be discussed below. A widely accepted *classification for the types of perturbations* is provided by Wingfield (2013a,) (see also Wingfield and Romero, 2001), who proposes discriminating between *labile* (short-term, transient) and *permanent* (long-term, modifying factors). *Labile perturbation factors (LPFs)* are in turn roughly divided into two major groups: *indirect* LPF (lasting seconds to a few minutes) and *direct* LPF (lasting minutes to hours). The formulation for this accepted classification takes into account the duration of the unpredictable stimuli, the actual duration of the adrenocortical response, and its resulting effects on the normal progression of the individual's life cycle (all of these factors combined). Figure 33.5 synthetizes information about these parameters and provides examples for ease of interpretation of the text below.

- The mechanisms by which birds perceive potential environmental challenges and transduce this information into endocrine responses are fundamentally different when facing *predictable versus unpredictable* events.
- Regardless of how stressful local conditions may appear to the human eye, circulating corticosterone levels do not elevate into the *reactive homeostasis range* in response to birds' *predictable* environment.

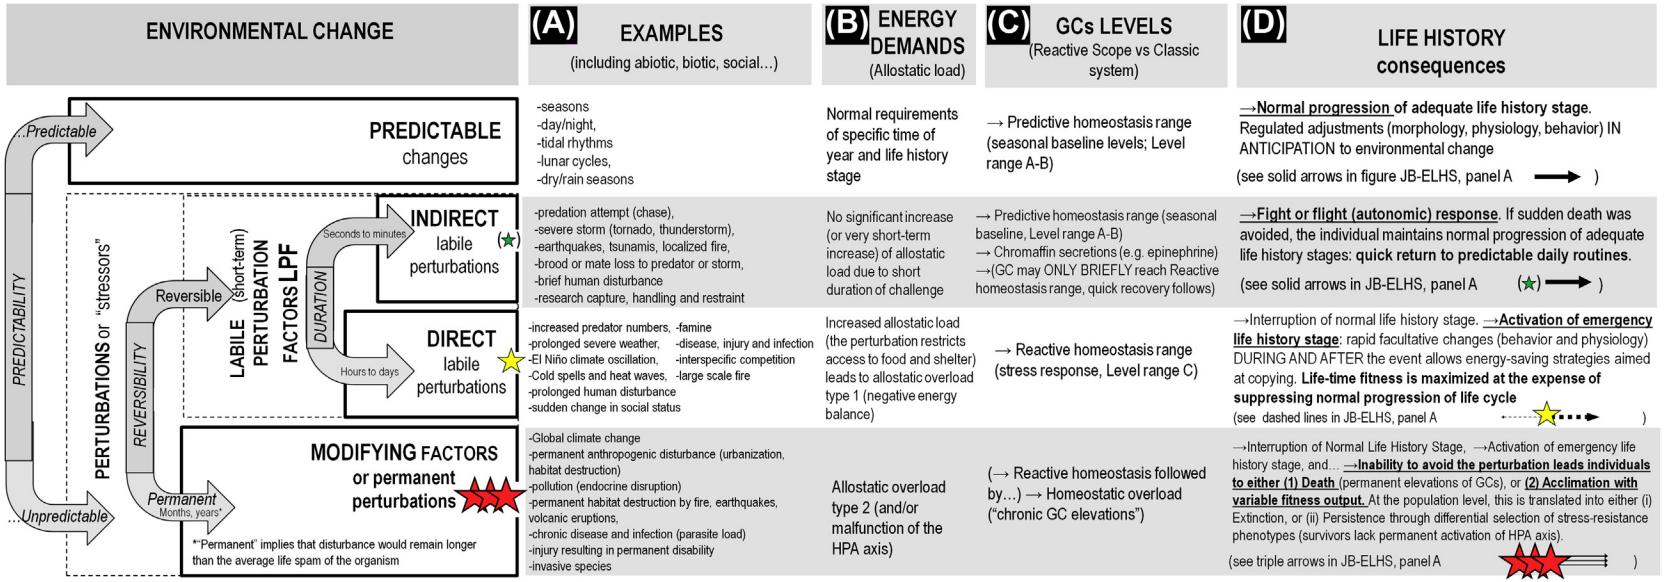

FIGURE 33.5 **Environmental change and adrenocortical responses.** Characterization of environmental change and its associated adrenocortical responses. Environmental changes can be predictable, or otherwise are termed "perturbations" or "stressors" (***column A*** lists potential examples). These can be classified as either labile (short-term, transient) or permanent (long-term, modifying factors). Labile perturbation factors (LPFs) are in turn roughly divided into two major groups: indirect LPF (lasting seconds to a few minutes) and direct LPF (lasting minutes to hours). The formulation for this accepted classification does not only take into account the duration of the unpredictable noxious stimuli, but also the energy demands (allostatic load) imposed on the individual ***(column B),*** the actual elevation of GC titers ***(column C)*** and its resulting effects on the normal progression of the individual's life cycle ***(column D).*** The fact than some types of perturbations may bring the individual into allostatic overload makes a qualitative difference for the actions of circulating GC, which may trigger an emergency life history stage (adaptive response) aimed at avoiding the perturbation, or create permanent damage (maladaptive response) if the individual cannot habituate to permanent stressors. *Figure created after Wingfield (2013a) and expanded to incorporate biotic and social examples from other sources and to implement the allostatic and reactive scope concepts.*

- *Unpredictable* and potentially noxious events in the environment are termed *perturbations* (or *stressors*), and elicit corticosterone elevations into the *reactive homeostasis range.*
- *Perturbations* can be classified as either (1) *labile perturbation factors* or *LPFs* (short-term, transient) or (2) *permanent perturbations* (long-term, also called *modifying factors*). *LPFs* can in turn be classified in two major groups: *indirect* LPFs (lasting seconds to a few minutes) and *direct* LPFs (lasting minutes to hours).
- This classification takes into account the duration of the unpredictable stimuli, the duration of the associated adrenocortical response, and the resulting effects on the normal progression of the individual's life cycle.

33.3.2 Indirect, Labile (Short-Term) Perturbations

Indirect LPFs are very short-lived perturbations, lasting seconds to a few minutes and have little or no long-term effects on an individual (as long as it manages to rapidly survive the sudden exposure to noxious stimuli). Examples may include a predation attempt/chase, a conspecific agonistic interaction, the loss of nest/offspring to a short severe storm, or a brief human disturbance. Here a "*flight or fight*" response is typically triggered with little or no elevation of GCs into the *reactive homeostasis range*, and resumption of normal activities (e.g,. social behavior, renesting) takes place within minutes to hours (Figure 33.5). The *flight or fight* response implies stimulation of the cholinergic sympathetic fibers that innervate the chromaffin tissue of the adrenal, causing the local release of acetylcholine, which triggers the release of predominately epinephrine in the blood. This rapid allostatic response promotes increased heart rate, vasodilation of arterioles in skeletal muscle, general venoconstriction, relaxation of bronchiolar muscles, pupilar dilation, piloerection, and (very importantly) mobilization of liver glycogen and free fatty acids (Axelrod and Reisine, 1984; Romero et al., 2009). Only if the perturbation persists beyond the first few minutes will the adrenocortical response be activated. Then an elevation of corticotropin (ACTH) secretion from the adenohypophysis will trigger the increase of circulating GC levels into the *reactive homeostasis range* (Figure 33.1; see details for the complete cascade of hormonal secretions in Chapter 26). Sustained elevation of GCs in the *reactive homeotasis range* mark the short-term response. At this point, the individual will require additional energy resources to cope with the noxious stimuli. Even though the perturbation is still *short-term or labile*, after a few minutes it will only be considered *indirect* if the individual readily resumes its normal life cycle when the perturbation is over. For example, the experimental *capture, restraint, and serial blood sampling protocol* that is routinely applied to quantify adrenocortical responses in wild birds (Section 33.5.1) typically lasts 30 to 60 min. Birds during this protocol elevate circulating GCs within the *reactive homeostasis range,* but they typically resume normal activities (e.g., nest attendance) within minutes following release. Capture and blood sampling would not be considered an *indirect LPF* according to its duration and associated GC elevations (allostatic responses need to go beyond the *flight or fight*, autonomic response), but this event does not qualify for a *direct perturbation* (see below) provided a fast resumption of normal life cycle activities and no apparent energy imbalance.

- *Indirect LPFs* are short-lived, lasting seconds to a few minutes and have little or no long-term effects on an individual. Examples include short predator chases, agonistic interactions, the loss of nest/offspring to a short severe storm, and brief human disturbance.
- *Indirect LPFs* elicit a *flight or fight* response largely mediated by the sympathetic nervous system, with little or no elevation of GCs into the *reactive homeostasis range*. Resumption of normal activities takes place within minutes to hours.

33.3.3 Direct, Labile (Short-Term) Perturbations and the "Emergency Life History Stage"

Direct LPFs are perturbations lasting hours or even days, when they impose high energetic demands upon the individual and result in a temporary disruption of the normal life cycle (for example breeding, resulting in brood desertion). Potential examples include exposure to prolonged severe weather, intra and interspecific competition for food or shelter, increased number of predators, reduced food resources, pollution, and prolonged human disturbance (Figure 33.5 (A)). The cumulative *allostatic load* imposed on the individual brings a negative energy balance (*allostatic overload Type 1*), and the individual redirects physiology and behavior into a facultative mode known as the *emergency life history stage (ELHS)* (Wingfield et al., 1998). Figure 33.6 illustrates a sequence of life history events of a model avian species (panel (A)) and empirical data from white-crowned sparrows *Zonotrichia leucophrys pugetensis* (panel (B)). Under normal conditions (in absence of perturbations), *the life cycle of a bird is composed of a finite number of life history stages LHS:* winter or nonbreeding, breeding and moult (depending on the species these could be more, and include for example, migration). The temporal sequence of LHS varies from species to species and each stage is expressed at a particular time of year for which it has evolved to maximize fitness (Jacobs and Wingfield, 2000). Each LHS has a varying number of unique substages (for example, the breeding stage involves gonadal maturation, courtship, ovulation, etc.) following a specific "one-way"

sequence as indicated with a solid thick arrow in Figure 33.6(A). The development of each stage and the sequential transitions between stages are regulated by endocrine secretions, which follow *predictable environmental cues* such as the annual photocycle and allow adequate stage-specific changes in physiology, morphology, and behavior in anticipation to energy demands (i.e., as dictated by the predictable portion of environmental change). In contrast, exposure to a *direct LPF* (represented with a yellow star symbol in the figure) can occur at any time and it will trigger a facultative "*emergency stage*" (the *ELHS*) at any point of the life cycle, as illustrated by dashed arrows in Figure 33.6(A). The substages within an ELHS are remarkably constant in all bird species studied to date, and serve first to redirect the individual into a survival mode and then to allow it returning to the normal LHS once the perturbation passes. The behavioral and physiological components that make up the substages of an ELHS (Wingfield and Kitaysky, 2002; Wingfield and Romero, 2001) are:

1. Disactivation of territorial behavior or social hierarchies in the home range of a group.
2. Adoption of one of the following alternative strategies: (1) "*leave it*" strategy: movement away from the direct LPFs; (2) "*take it*" strategy: switch to an alternate set of energy-conserving behavioral and physiological traits; or (3) "*take it at first, and then leave it*" strategy: switch to energy-conserving mode first, and then move away if conditions do not improve.
3. Once a strategy has been adopted, *mobilization of stored energy* (fat and protein) to fuel movement away, or finding refuge and endure while sheltering.
4. Finally, once the *direct LPF* passes (or the individual evades), the individual must *settle in an alternative habitat if an appropriate site is located or return* to the original site and resume the normal sequence of LHSs (returning to the most appropriate for that time of year, whether it is the same as before the LPF or any other; see thin dashed arrows in the figure).

FIGURE 33.6 **The emergency life history stage (ELHS).** ***Panel A*** presents a schematic representation of the adult life cycle in a model avian species (and concomitant hypothetic changes in circulating GC levels, depicted with different arrow line patterns), including a facultative emergency life history stage ELHS. The cycle is composed of a finite number of life history stages LHS (square boxes: winter or non-breeding, reproduction, moulting) occurring in a specific sequence. This sequence has evolved to maximize individual fitness, and each LHS occur at specific times of the year, when and where the environmental and social conditions are likely most adequate to use the energy available (e.g. food, fat stores) and invest it in performing specific life tasks. Each LHS is composed of a number of substages that also follow a pre-set sequence (for example, the breeding stage involves gonadal maturation, territory acquisition, courtship, laying etc). The external black arrow indicates the direction of the sequence and its width represent an hypothetical magnitude of the seasonal baseline GC levels, which fluctuate within a predictive homeostasis range, and allow regulation of the energy balance (allostasis) following predictable environmental cues (e.g. seasons, day/night rhythms). Superimposed on predictable environmental changes are unpredictable perturbations (star symbols), which may occur at any time of the year. Perturbations can be short-term and then they are termed labile perturbation factors LPF. When they require little energy investment to survive (for example, a short predator chase), they are termed *indirect labile perturbation factors* (green star symbol, within brackets), which trigger the autonomous "flight or fight" response, result in little or no elevations of circulating GC above seasonal baseline and allow the individual to continue its life cycle. However, labile perturbations may last hours and even days and require a larger energy investment to cope (for example, increased predator numbers). They are then termed *direct labile perturbations* (yellow star symbol), and trigger a facultative and considerable elevation of GC levels above the normal baseline, into the GC reactive homeostasis range or stress-induced levels (dashed arrows in the figure). These perturbations redirect individual´s life cycle into a facultative emergency life history stage (ELHS, central box), aimed at copying with the imposed extra energy demands (allostatic load) and survive at the expense of temporary suppression of normal LHS. Here reactive GC elevations (above seasonal baseline as depicted by the ticker width of the dashed arrows) promote dramatic changes in physiology and behavior, including the use of lipid and protein stores as energy to survive while sheltering or moving away (for example, during irruptive avian migrations). Once the direct LPF is over or the individual relocates, circulating GC levels decrease back to the predictive homeostasis range and the individual returns to the most appropriate LHS, which may or may not be the one when the perturbation occurred. Perturbations, however, may not always subside and eventually they may become long-term or permanent (for example, habitat destruction or climate change). These perturbations are then termed *modifying factors* (triple red star symbol). If the individual cannot avoid them, long-term or chronic GC elevations (triple arrow lines) can cause deleterious effects on the organism and eventually result in death. Alternatively, individuals may habituate to the perturbation and remain alive but fitness and normal progression of LHSs would only be achieved if GC function returns to normal levels. ***Panel B*** presents an empirical example of year-round changes in circulating GC levels (y-axis, average plasma corticosterone ± SE) across the life history stages and substages (x-axis) of adult male white-crowned sparrows *Zonotrichia leucophrys pugetensis*. The numbers indicates blood sample sizes. The solid black line connecting circles shows corticosterone levels in males breeding normally (i.e. GC levels within predictive homeostasis range or seasonal baseline levels). In contrast, the two vertical bars depict corticosterone levels following two separate perturbation events of severe weather, which occurred in a different year. A first severe storm resulted in birds abandoning their nests and territories and can be therefore considered a direct LPF (yellow star symbol). Note that corticosterone levels elevated well above the seasonal baseline, into a higher reactive homeostasis range allowing activation of an emergency life history stage ELHS (birds temporarily suspended breeding activities, ranging for days over a large area in loose flocks). After this perturbation subsided corticosterone levels returned to the predictive homeostasis range, the birds returned to their territories and renested. Then a second severe weather event occurred after renesting (during the parental phase II). However, because the second storm failed to elevate corticosterone levels above the predictive homeostasis range and no ELHS was activated, this labile perturbation is considered indirect (depicted with a green start symbol within brackets). *Panel A modified and expanded after Jacobs and Wingfield, (2000), with permission; panel B expanded from Wingfield and Kitaysky, (2002) by permission of Oxford University Press.*

These dramatic changes in behavior and physiology can occur within minutes to hours of exposure to *direct LPF,* and a combination of laboratory experiments and field studies indicates that the elevation and maintenance of GC levels *above seasonal baseline (predictive homeostasis) into the reactive homeostasis range (or stress-induced GC levels;* see Figure 33.3) underlies this facultative ELHS (Figure 33.6). A few examples follow, and additional examples can be found in other reviews (Wingfield and Romero, 2001; Wingfield and Kitaysky, 2002; Wingfield et al., 2011). Young but not adult European blackbirds (*Turdus merula*) migrated southwards when exposed to a severe weather event (*direct LPF*) in Germany that resulted in snow and ice covering their winter feeding grounds. The energy demanded by digging for food likely exceeded the energy to be gained, but only among unexperienced, first year individuals. As predicted, the group of young, unexperienced birds that left their regular winter areas showed concomitant elevations of circulating corticosterone levels compared with nonmigrating adults (Schwabl et al., 1985). There are similar studies linking unusually severe winter weather (a *direct LPF*) to elevated corticosterone levels and irruptive migrations (a "*leave it*" ELHS strategy) in ground-feeding birds because the snow covering food resources may impose an (unpredictable and) considerable increase to *allostatic load.* In North America, dark-eyed juncos (*Junco hyemalis*) showed significantly higher plasma corticosterone levels during a severe snowstorm compared with before or after it; circulating GC levels were highest when home ranges were abandoned and lower when the birds found refuge after the storm (Rogers et al., 1993). In contrast, Harris sparrows became inactive to ride out a severe winter storm (a "*take it*" strategy), but also showed concomitant elevations of circulating corticosterone (Rohwer and Wingfield, 1981). Note that the influences of inclement weather on the ELHS depend upon the severity of the storm and when it occurs.

If we now focus on the reproductive season, white-crowned sparrows (*Zonotrichia leucophris pugetensis*) delay the onset of breeding without elevating corticosterone levels if severe weather occurs before egg laying. This suggests that storms early in the season do not qualify as LPFs, and that they rather act as supplementary information (predictive environmental change) to fine-tune gonadal development. Alternatively, it is possible that the energy demands for that time of the year were low compared to the energy available in the environment plus the body reserves, allowing individuals to cope with a perturbation without triggering GC elevations above the *baseline, predictive homeostasis range*. However, during incubation and chick brooding, the additional energetic costs associated with these normal LHSs increases vulnerability to perturbations, and equivalent severe storms result in elevated corticosterone levels and the abandonment of nest and territory, which are typical examples of a "*leave it*" strategy within the ELHS (Wingfield, 1984).

Because sex roles during reproduction impose different *allostatic loads* for males and females in many bird species, we may also expect that a given LPF should differentially trigger corticosterone elevations and an ELHS depending on the energy invested by each sex in each substage. For example, territory acquisition is largely a male role in raptors. Male black kites *Milvus migrans* likely face higher *allostatic loads* compared to females at the start of the breeding season, and they showed higher corticosterone elevations in response to the experimental LPF of capture and restraint (Blas et al., 2011). *Allostatic load* should be even higher among young males because they rely on the competitive displacement of an older male to initiate breeding; and as expected, corticosterone levels following capture and restraint were higher in young compared to older males. This pattern was reversed among females, because young, floating individuals incur neither the *allostatic loads* of competition for territories nor the energy demands for egg formation: young females showed the lowest levels of corticosterone after exposure to capture, handling, and restraint and likely the lowest susceptibility to trigger an ELHS in response to perturbations (Blas et al., 2011). The effect of sex roles on the susceptibility to LPF has been also suggested in white-crowned sparrows. Severe weather may affect females more than males during the incubation period because males do not incubate, but a storm during the fledging phase would affect males more, as their parental effort is at its highest point (Wingfield, 1984; Wingfield et al., 1983). Here it is worth reminding readers that although some LHSs and substages (territory acquisition, incubation, and brooding) are energetically demanding, they are totally predictable and do not generate GC elevations into the *reactive homeostasis range per se*. However, because these life cycle activities increase *allostatic load,* they can generate a greater susceptibility to secrete GCs into the *reactive homeostasis range* after exposure to unpredictable perturbations (and therefore a greater susceptibility to enter ELHS).

The examples above strongly suggest that stress-induced GC elevations in the *reactive homeostasis range* underlie activation on the ELHS, but additional field and laboratory experiments (many of which include experimental manipulations of systemic GC titers) have allowed a more precise characterization of GC actions on the particular behavioral and physiological traits that make up the substages of an ELHS. We will briefly comment on some of these GC actions occurring within the *stress-induced* or *reactive homeostasis range* (i.e., those that accompany life-threatening perturbations). However, it is important to note that GC actions at the lower range that characterizes daily and seasonal life processes (that is, within the *predictive homeostasis range* or *baseline levels*) can modify the same traits in different and even opposite ways. These aspects are thoroughly reviewed elsewhere (Landys et al., 2006; Wingfield

and Romero, 2001). Major GC actions at *stress-induced* or *reactive* levels include:

1. ***Reactive GC levels increase protein catabolism and gluconeogenesis.*** Administration of exogenous GCs to mimic *reactive homeostasis levels* induces protein loss and muscle atrophy in a variety of avian species. For example, domestic fowls *Gallus gallus* respond to corticosterone treatment showing a rapid elevation of plasma uric acid, a byproduct of amino acid breakdown (Saadoun et al., 1987). In house sparrows (*Passer domesticus*), corticosterone implants decrease the mass of *pectoralis* muscles, but differentially promoting catabolism of the soluble (sarcoplasmatic) protein fraction rather than contractile (myofibrilar) components, which allows maintenance of flight capabilities (Honey, 1990). By making available amino acids, reactive GC levels support increased *allostatic load* through indirect provisioning of intermediates for the citric acid cycle and substrates for hepatic gluconeogenesis.
2. ***Reactive GC levels promote availability of lipid energy from adipose tissue stores*** (Dallman et al., 1993). Stored triglycerides may be released as free fatty acids, through either an increase of trygliceride breakdown or a decrease of in the rate of re-esterification. In addition, elevated GCs seem to support enzymatic mechanisms that allow delivery of fatty acids to working tissues (Mantha and Deshaies, 2000; Landys et al., 2006 and citations therein). Note that artificial elevation of GC levels may also result in increased fat depots when the experimental animals are in positive energy balance (Wingfield and Silverin, 1986).
3. ***Reactive GC levels decrease body mass.*** For example, exogenous corticosterone elevations inhibit weight gain in house sparrows and rufous hummingbirds *Selasphorus rufus* (Honey, 1990; Hiebert et al., 2000). Mass loss might be a consequence of the two metabolic effects described above (increased energy mobilization) plus a decreased maintenance of structural tissues.
4. ***Reactive GC levels modulate locomotor activity.*** For example, white-crowned sparrows *Z. leucophris* show a rapid increase in activity after corticosterone ingestion (Breuner et al., 1998). This effect likely depends of GC concentration: while moderate elevations promote intense activity (a "*leave it*" ELHS strategy), very high doses may actually stimulate inactivity (a "*take it*" strategy; Wingfield and Ramenofsky, 1999). In addition, energy availability seems to modulate this response: while corticosterone implants increase activity in fasting birds, they decrease activity when food is *ad libitum* (Astheimer et al., 1992). Both the dose- and the context-dependent effects of GC elevations match the expected behavioral responses under an ELHS: if the LPF does not reduce food resources it may be adaptive to "*take it*", but if the perturbation persists then a reduction of the available energy (food) would trigger higher GC elevations and a "*leave it*" strategy aimed at searching for energy somewhere else. GC effects on locomotor activity may be particularly relevant in avian species adapted to severe habitats such as deserts or high latitudes, which show irruptive movements in response to LPF (Wingfield and Ramenofsky, 1997). Note, however, that seasonal GC levels are typically elevated during those life history stages that demand high physical activity such as migration and dispersal (Landys-Ciannelli et al., 2002; Belthoff and Dufty, 1998), but these effects occur within the *predictive homeostasis range.*
5. ***Reactive GC levels may increase food intake.*** Although some studies propose that GCs regulate feeding rate in a permissive capacity (Dallman et al., 1993), recent research suggest that this effect is mediated through a threshold action of glucocorticoid receptors rather than by the extent of GC elevations above the *seasonal baseline* (see details in Landys et al., 2006). There is ample correlational evidence that foraging activities are normally highest during the times of day when baseline GC levels are maximal, and that feeding intensity can be shifted by *corticosterone* manipulations (Dallman et al., 1993), but again, these effects occur within the predictive homeostasis range.
6. ***Reactive GC levels suppress territorial and reproductive behavior.*** For example, male song-sparows (*Melospiza melodia*) reduce territorial aggression when treated with exogenous corticosterone (Wingfield and Silverin, 1986). Similarly, free-living pied flycatchers (*Ficedula hypoleuca*) decrease nestlings feeding rates when treated with exogenous corticosterone (bringing a concomitant decrease in nestlings' body condition and survival), and even cease all reproductive activities (abandoning the nest and the acquired territories) when given high-dose GC implants (Silverin, 1986).
7. ***Reactive GC levels increase night restfulness.*** Exogenous corticosterone elevations in captive white-crowned sparrows (*Z. leucophris*) and pine siskins (*Spinus spinus*) result in a uniformly low oxygen consumption pattern, with an estimated 20% energy savings overnight compared with controls (Buttemer et al., 1991). However, similar treatment applied to other species results in contradictory results (Palokangas and Hissa, 1971), likely because GC-induced gluconeogenesis also affects metabolic rate and thus oxygen consumption. Corticosterone administration to rufous hummingbirds (*S. rufus*) results in nocturnal torpor, a form of seeking *"refuge/take it"* strategy that these birds acquire through decreasing body temperature (Hiebert et al., 2000).

Summarizing, GC elevations into the *reactive homeostasis range*, which are typically several-fold higher than the

seasonal baseline or predictive range (Figure 33.6(B)), allow critical changes in physiology and behavior aimed at coping with LPFs and thus have a great adaptive value in maximizing survival and lifetime reproductive success, even at the cost of a temporary suppression of the life cycle. Once the direct LPF is over or the individual relocates, circulating GC levels normally decrease back to the *predictive homeostasis range* and the individual returns to the most appropriate LHS, which may or may not be the one when the perturbation occurred. Perturbations, however, may not always subside and eventually they may become *long-term or permanent* (for example, habitat destruction, climate change). Then, they are termed *modifying factors*.

- *Direct LPFs* last hours or days, impose high energetic demands *(allostatic load),* and result in a temporary disruption of the normal life cycle. Examples include exposure to prolonged severe weather, intraspecific competition, increased predators pressure, reduced food resources, and prolonged human disturbance.
- The cumulative *allostatic load* imposed on the individual brings a negative energy balance (*allostatic overload Type 1*), and the individual redirects physiology and behavior into a facultative life stage known as the *emergency life-history stage (ELHS)*. Such an emergency stage is largely driven by the elevation and maintenance of GC levels *above seasonal baseline (predictive homeostasis)* and into the *reactive homeostasis range* (or *stress-induced* levels).
- Corticosterone elevations in the *reactive homeostasis range* during an ELHS promote (1) increased protein metabolism and gluconeogenesis, (2) availability of lipid energy from adipose tissue stores, (3) decreased body mass, (4) changes in locomotor activity and foraging, (5) suppression of reproductive behavior, and (6) increased night restfulness. These corticosterone-mediated changes in physiology and behavior have a great adaptive value, maximizing individual fitness at the cost of a temporary suppression of the life cycle.
- Once the *direct LPF* is over or the individual relocates, circulating GC levels normally decrease back to the *predictive homeostasis range* and the individual returns to normal life history stages.

33.3.4 Permanent (Long-Term) Perturbations or "Modifying Factors"

Modifying factors are perturbations lasting months or years (they are termed "*permanent*" because the disturbance may remain longer than the average lifespan of the organism), when they impose high energetic demands upon the individual and result in a permanent disruption, even disintegration of the normal life cycle (Wingfield and Romero, 2001; Wingfield, 2013a). Potential examples include chronic disease and infection (e.g., high parasite load), injury resulting in permanent disability, global climate change, and sustained anthropogenic disturbance (Figure 33.5 (A)). The cumulative *allostatic load* imposed on the individual may bring a negative energy balance, leading to death if a prior activation of the ELHS did not allow evading the perturbation (for example, when relocation was not possible). Here the sustained long-term GC elevations exert *wear and tear* (see Section 33.2.3), reaching the *homeostatic overload range* and resulting in deleterious effects on critical body systems including inhibition of gonadotropin secretion and cessation of reproductive function (e.g., delay of puberty onset, gonadal involution); suppressed secretion of growth hormone (e.g., stress-induced dwarfism); complete breakdown of the skeletal muscle (e.g., suppressed flight and movement capabilities); suppression of T-lymphocyte response to infections (increasing susceptibility to disease); severe neuron loss in the hippocampus through impaired glutamate and calcium regulation; and decreased generation of arachidonic acid (for a review of effects, see Sapolsky, 1996; Wingfield and Romero, 2001; Romero et al., 2009). In contrast to the highly adaptive GC responses that characterize the ELHS, chronic GC elevations lack adaptive value. Note also that at a given point, chronic GC exposure will bring a disruption of the *hypothalamus-pituitary-adrenal (HPA)* axis, and the deleterious effects on the organism may occur even if the long-term perturbation subsides and the energy available in the environment becomes above the energy needs of a healthy individual (this will be equivalent to *allostatic overload Type 2,* to a critically reduced *reactive scope* generated by *wear and tear,* or to the ecological scenarios of social stress that we have already commented upon). Pollution is also considered a type of *modifying factor*, but its impact on avian adrenocortical function has been subjected to scarce research and there is a great need for field investigations (reviewed in Baos and Blas, 2009).

A critical point regarding to the effects of *modifying factors* is that not all the individuals within a population perceive and respond to perturbations in the same way. As a consequence, under particular scenarios (which should depend on the species and the type of perturbation) it is possible that even a drastic initial response to *modifying factors* (e.g. disappearance of a fraction of the population through death or emigration) is followed by a recovery through differential selection of stress-resistance phenotypes (Blas et al., 2007; Cockrem, 2007). In other words, perturbations may become selective pressures, potentially allowing adaptation, and population persistence could occur provided that (1) there exists some genetic variability in the response to stress, whereby specific genotypes do not activate adrenocortical responses to that specific perturbation; (2) individuals acclimatize to that particular perturbation, progressively reducing their adrenocortical responses and surviving without permanent activation of the HPA axis; or (3) epigenetic effects (e.g.,

maternal programming) reduce the impact of the perturbation through modifying the offspring's adrenocortical responses. Examples for these potential responses will be provided in the following section.

- *Permanent perturbations* (also called *modifying factors)* last months or years, imposing high energetic demands upon the individual and resulting in a permanent disruption of life cycles. Potential examples include chronic disease and infection, global climate change, and sustained anthropogenic disturbance (e.g., urbanization, habitat destruction)
- After the initial activation of the ELHS, inability to evade the perturbation implies that the cumulated *allostatic load* will bring the individuals into a negative energy balance, and death may follow.
- The sustained long-term GC elevations exert *wear and tear,* reaching the *homeostatic overload range* and resulting in deleterious effects on critical body systems, including (1) inhibition of gonadotropin secretion and cessation of reproductive function, (2) suppressed secretion of growth hormone, (3) complete breakdown of the skeletal muscle, (4) suppression of immune system, and (5) neuronal death.
- *Modifying factors* can lead to population extinctions. However, population persistence through local adaptations could also potentially occur if genetic variability and phenotypic plasticity in the response to stress allow a differential survival of stress-resistant individuals.

33.4 PHENOTYPIC PLASTICITY AND SELECTION ON THE STRESS RESPONSE

Avian speciation has taken place under contrasting environmental scenarios (e.g., from deserts to poles), and *adrenocortical responses* have evolved in parallel, shaped by the prevailing *perturbation* factors and likely explaining the strong interspecies variability. Within a given species, different subspecies, races, morphs, and even populations have been reported to differ in the patterns of adrenocortical secretion (Wingfield and Romero, 2001). On the one hand, such variability reveals a genetic basis that controls HPA function and, for example, has allowed humans to domesticate wild animals and generate stress-resistant phenotypes through artificial selection (Keith et al., 1973; Satterlee et al., 2000). In addition to such genetically determined patterns, the adrenocortical response to stress shows a strong phenotypic plasticity. For example, the environmental conditions experienced early in life can prime lifelong differences in the patterns of adrenocortical responses, revealing adaptive epigenetic patterns (Love et al., 2013). Furthermore, individuals often show the ability to modulate their adrenocortical response according to the specific requirements characterizing different life history stages, thereby maximizing the cost-benefit balance associated with the actions of corticosterone on behavior and physiology (Lendvai et al., 2007). Phenotypic plasticity is also manifested when repeated exposure to the same perturbations provoke gradual changes in adrenocortical function, revealing that experience-related patterns occur through acclimation, and highlighting the close connection between cognition (i.e., an individual's perception of a potential threat) and the adrenal response (Cyr and Romero, 2009). Overall, the HPA axis shows all the features of a trait subjected to natural selection (Love et al., 2013; Cockrem, 2013): large individual variation (Williams, 2008; Cockrem, 2013), repeatability under consistent conditions (Ouyang et al., 2011), heritability (Bartels et al., 2003; Evans et al., 2006; Solberg et al., 2006), and actual response to artificial selection (Satterlee and Johnson, 1988; Evans et al., 2006).

- The HPA axis shows all the features of a trait subjected to natural selection: large individual variation, repeatability under consistent conditions, heritability and response to artificial selection.
- Superimposed on genetically determined patterns, individuals show phenotypic plasticity in their responses to stress

33.4.1 The Stress Response during Development

Young birds display highly variable HPA responses during development (reviewed in Blas and Baos, 2008). On one hand, interspecies differences reflect the wealth of variability in developmental strategies within the altricial-precocial spectrum (Figure 33.7(A); Starck and Ricklefs, 1998). Although precocial species such as mallards (*Anas platyrhynchos,* which hatch with sight, covered with down, and can thermoregulate, locomote, and feed independently from parents) can elevate circulating corticosterone in response to human handling one day after hatching (Holmes et al., 1990), altricial species such as northern mockinbirds (*Mimus polyglottos*, hatching blind, almost naked, unable to thermoregulate and locomote) show little HPA response to the same stimuli during the first few days post-hatch (Sims and Holberton, 2000), indicating a *"stress hyporesponsive period"*. On the other hand, within a given developmental mode and species, HPA responses gradually increase as the individual grows and develops. For example, white storks (*Ciconia ciconia*) a semi-altricial species, show very moderate GC responses to capture and handling until 20 days post-hatching (Figure 33.7(B)), but the same type of experimental stimuli gradually elicit more robust corticosterone secretions as birds grow older, reaching maximal corticosterone secretion (resembling typical adult-like responses) near fledging (Blas et al., 2006a).

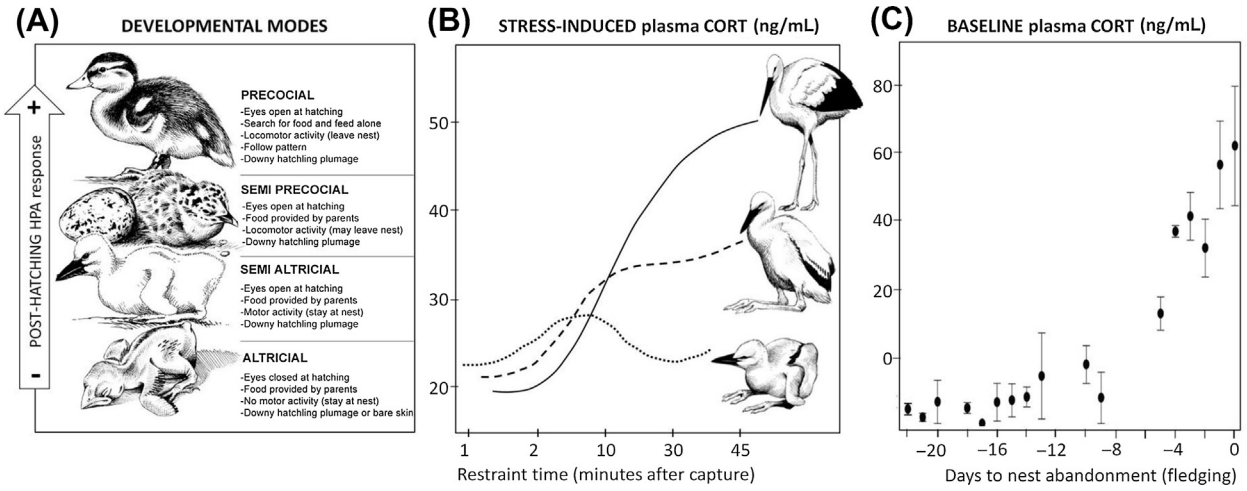

FIGURE 33.7 **The stress response during development.** ***Panel A.*** *Avian developmental modes* range across a gradient defined by two extremes: precocial and altricial species. Altricial species (e.g., Passeriforms, a house sparrow *Passer domesticus* in the drawing) hatch with closed eyes, lack of feather coat, have reduced motor capabilities, and are unable to thermoregulate or forage without parental care. Precocial species (e.g., Galliforms, a mallard *Anas platyrhynchos* in the drawing) hatch in an advanced developmental stage, with open eyes, feather coat, and independing foraging and locomotor capabilities. Intermediate developmental modes include semi-altricial (e.g., a white stork *Ciconia ciconia*) and semi-precocial species (e.g., a yellow-legged gull, *Larus michahellis*). The ability of responding to environmental and social perturbations through HPA function (e.g., ability to elevate corticosterone in response to capture and handling) increases across the developmental gradient of hatchlings: altricial species show a *stress hyporesponsive period* characterized by inability to show Glucocorticoid elevations until days following hatching, while altricial species show robust HPA responses within one day post-hatch. ***Panel B.*** *Developmental changes in HPA function.* Within a given species (e.g., white storks, *Ciconia ciconia*) HPA function progressively increases during ontogenic development. The figure shows circulating corticosterone levels (*y*-axis) during the 45 min following capture and restraint (reactive homeostasis range) for three nestlings aged 24, 40, and 60 days old. ***Panel C.*** *Transition from nestling to fledging stages*. Circulating baseline corticosterone levels typically elevate shortly before hatching, fledging, and during dispersal, allowing birds to meet the increasing energy demands associated to ontogenic transitions. The figure shows baseline circulating corticosterone (predictive homeostasis range) in thin-billed prion *Pachyptila belcheri* chicks, relative to the observed time of fledging. Note maximum corticosterone levels during the day prior to departure. *Panel A modified from Blas and Baos (2008), with permission; panel B redrawn from Blas et al. (2006a), with permission; panel C from Quillfeldt et al. (2007) with kind permission from Springer Science + Business Media.*

The *Developmental Hypothesis* proposes that the patterns of maturation of HPA responses within and across species evolved to balance the costs and benefits of GC actions with the individual's progressive ability to overcome environmental perturbations (Blas and Baos, 2008). Inability to show robust responses during initial developmental stages avoids exposure to high and prolonged GC levels, which reduces growth and impairs thyroid function and cognitive and competitive abilities (Schwabl, 1999; Kitaysky et al., 2003; Hayward and Wingfield, 2004). However, as the individual grows, its ability to show *stress-induced* responses (i.e., GC elevations within the *reactive homeostasis* range) acquires a critical adaptive value. For example, corticosterone elevations in nestling black-legged kittiwakes *Rissa tridactyla* at mid-developmental stages (15–20 days old) facilitate begging and aggression (Kitaysky et al., 2001, 2003), two behavioral responses highly advantageous to cope with food shortages early in life despite being still dependent on parental care. In addition to a progressive, developmental increase in the ability to trigger robust HPA responses, circulating GCs in the *predictive homeostasis* range (i.e., *baseline* levels) typically show age-related changes that serve to regulate ontogenic transitions across vertebrate taxa (reviewed in Wada, 2008). *Baseline* (*predictive*) GC elevations promote maturation of critical organs and possibly control both the ability to hatch and the timing of fledging. For example, *baseline* corticosterone levels peaks around hatchling in domestic fowls *Gallus domesticus* (Carsia et al., 1987) and graylag geese *Anser anser* (Frigerio et al., 2001), and exogenous corticosterone administration in turkey *Meleagris gallopavo* embryos 2 days before hatching significantly increases hatching success (Wentworth and Hussein, 1985). In white storks *C. ciconia*, *baseline* corticosterone levels increase prior to fledging (Corbel and Groscolas, 2008), and similar patterns have been found in American kestrels *Falco sparverius* (Heath, 1997), pied flycatchers *F. hypoleuca* (Kern et al., 2001), canaries *Serinus canaria* (Schwabl, 1999), thin-billed prions *Pachyptila belcheri* (Quillfeldt et al., 2007), and Laysan albatross *Phoebastria immutabilis* (Seabury and Breuner, 2005). Interestingly, *baseline* corticosterone elevations at the time of nest departure may be related to the species requirements to perform the first flights, and thus nest location. Avian species nesting on the ground (e.g., snowy owls, *Nyctea scandiaca*) or in low brush (e.g., northen mockingbirds) do not perform their first flights until a few days following nest departure, and the later transition is not associated

to *baseline* corticosterone elevations (Romero et al., 2006; Sims and Holberton, 2000). In contrast, avian species nesting in cavities or higher substrates (high trees, cliffs) perform their first flights as they abandon the nest, and typically show increased *baseline* corticosterone levels (e.g., cavity-nesting American kestrels, Heath, 1997; screech-owls *Otus* sp, Belthoff and Dufty, 1998; or burrow-nestling thin-billed prions, Quillfeldt et al., 2007; see Figure 33.7(C)). Furthermore, corticosterone levels elevate before and during the activity periods in fledging screech-owls (Belthoff and Dufty, 1998), suggesting a role of this hormone in natal dispersal. Corticosterone elevations during avian development may thus serve to meet with the increasing energy demands *(allostatic load)* associated with ontogenic transitions including hatching, fledging, and dispersal (Wada, 2008).

- Avian developmental modes range across a gradient defined by two extremes: altricial and precocial.
  - The *stress response* of hatchlings increases across the developmental gradient: while altricial species show a "*stress hyporesponsive period*" characterized by an early inability to show GC elevations, altricial species show robust HPA responses soon after hatch.
  - Inability to show robust responses early during development allows avoiding exposure to high and prolonged GC levels, which reduce growth and impair thyroid function, cognitive and competitive abilities.
  - The *Developmental Hypothesis* proposes that the patterns of maturation of HPA responses evolved to match the costs and benefits of GC actions with the individual's progressive ability to cope with *perturbations* (e.g., increased behavioral performance and parental independence).
  - *Baseline* corticosterone levels (*predictive homeostasis* range) increase prior to hatching, fledging, and during dispersal, making it possible to meet the increased energy demands *(allostatic load)* associated with ontogenic transitions.

33.4.2 Maternal Effects

Studies in humans and laboratory models indicate a profound effect of parental care early in life on offspring's HPA function and associated behavioral responses (McGowan and Szyf, 2010; McGowan et al., 2011). GC actions during development exert permanent *organizational effects* on the individual, with a stronger impact on performance (fitness: reproduction and survival), compared to reversible *activational effects* of the same hormones when the endocrine systems are already developed (Williams, 2008). In birds, developmental exposure to high GC levels can occur prenatally (i.e., maternally mediated changes or *in ovo* composition, e.g., Almasi et al., 2012) and also postnatally or *ex ovo* (e.g., according to the amount of offspring care: food provisioning, shelter, social competition; see Blas and Boas, 2008 for a review), and has the potential to translate ecological and environmental conditions into permanent offspring responses through a process termed *maternal programming* (Figure 33.8(A–B), reviewed in Love et al., 2013). As a consequence, mothers can "*prime*" lifelong responses in offspring through exposure to high or low levels of GCs, resulting in a permanent modification of HPA function (Hayward and Wingfield, 2004; Love et al., 2005; Saino et al., 2005; Love and Williams, 2008) that will likely affect the ability to cope with ecological perturbations. Such priming can be highly adaptive and allow animals to adjust to changing environments, because exposure to a low level of perturbations early in life often result in individuals that are better able to cope with exposure to higher levels of perturbations on subsequent occasions (a process known as *hormesis*; Constantini et al., 2010). Note that these adaptations occur *epigenetically*: the genetic composition in the offspring can be the same, but the expression of different genes in response to perturbations and GCs during development will result in different phenotypes. For example, cross-fostering the biological offspring between high and low caring mothers can permanently reverse offspring's HPA response in laboratory animals (Francis et al., 1999). The fitness of the modified phenotypes through *maternal programming* is expected to be context-specific, and determined by the environmental conditions encountered after development, and how much they resemble natal conditions (*Maternal-Match Hypothesis*; Love et al., 2013). In those situations when the early priming was a reliable predictor of the offspring's future environment, *maternal programming* is expected to increase offspring and even maternal fitness (Figure 33.8(B)). However, if maternal signaling was a poor predictor of offspring's future environment, the programming would exert negative (maladaptive) effects on the offspring ("*thrifty phenotypes*"; Hales and Baker, 1992). The *Maternal-Match Hypothesis* (Love et al., 2013) is a recently proposed paradigm refining the broader *Environmental-Match Hypothesis* (Sheriff et al., 2009, 2010, 2011a). Although these hypotheses require testing in wild birds, there is evidence for a number of environment-maternal-offspring connections mediated through corticosterone, which constitute the pillars for *maternal programming* summarized in Figure 33.8:

1. ***Environmental and social conditions affect circulating GC levels in adult birds, including reproducing females.***

   For example, increased risk of predation (Hawlena and Schmitz, 2010; see Clinchy et al., 2013 for a review on the "*ecology of fear*"), unpredictable changes in food availability (Kitaysky et al., 1999a,b, 2007; Shultz and

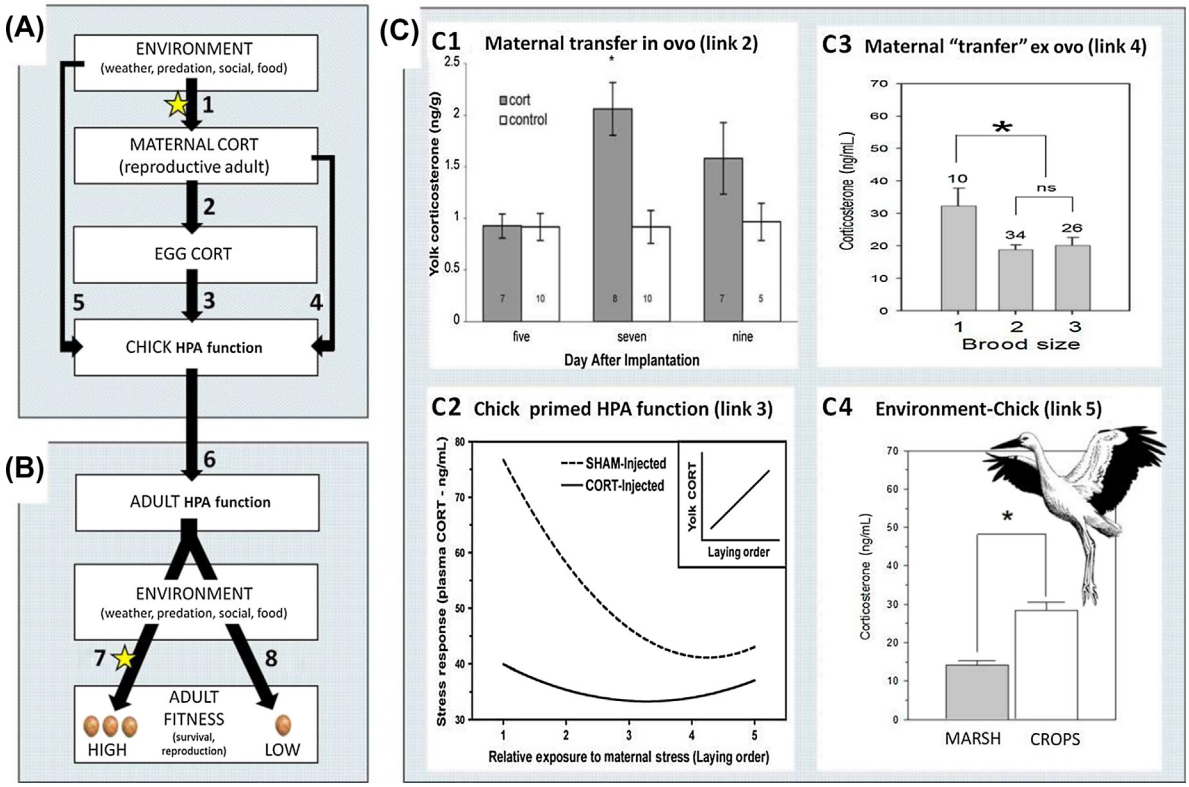

FIGURE 33.8 Maternal effects. ***Panel A.*** Summary of the proposed mechanisms whereby environmental perturbations transduce into permanent changes of the HPA-axis function in developing birds, through maternal effects (maternal programming). Environmental perturbations (star symbols) activate the HPA axis of reproducing, adult female birds (#1). High circulating corticosterone levels in pre-laying and laying females result in high corticosterone levels being deposited in the eggs (#2), and these will hatch nestlings developing a "primed", permanent modification of their HPA response (#3). In addition, variability in maternal care such as reduced nestlings´ attendance and food provisioning or increased within-brood social conflicts, can elicit further corticosterone elevations in the nestlings (#4). Because parental care cannot completely buffer environmental perturbations, these may also exert a direct effect on nestlings´ corticosterone levels (#5) and contribute to permanent modifications of the HPA-axis. The "priming" of HPA responses experienced by growing birds during development can be long-lasting, and the resulting adult phenotypes will show a permanent epi-genetic modification of their response (#6). ***Panel B.*** *The Maternal-Match Hypothesis.* Depending on the GC exposure that birds received during development (a function of maternal care and natal environmental conditions) different phenotypes regarding HPA function will result. For example, high- vs. low-HPA responders could be the offspring of the same couple of birds in different years. Phenotypes may differ in the amount of corticosterone secreted in response to standardized perturbations, and therefore in the ability to cope with environmental challenge later in life. The maternal-match hypothesis proposes that the fitness of each phenotype will be determined by the environmental conditions encountered after development. In those situations when the early "priming" was a reliable predictor of the offspring´s future environment (#7; note the same star as #1 in Panel A) offspring fitness will increase. However, if maternal signaling was a poor predictor of offspring´s future environment, offspring fitness will be reduced (#8). ***Panel C.*** *Examples illustrating maternal effects.* Corticosterone implants in female Japanese quail (*Coturnix coturnix japonica*) significantly increased the concentrations of corticosterone in the yolk of eggs laid seven and nine days after implantation. This figure illustrates arrow #2 in panel A. *C2*: Relative responsiveness of the stress axis (reactive corticosterone levels in plasma) in fledging, free-living European starling (*Sturnus vulgaris*) in relation to natural variation in exposure to maternal stress (note that yolk corticosterone naturally increases across laying order; see insert and Love et al., 2008). The stress response of nestlings was further decreased when the eggs had been previously treated with exogenous corticosterone (continuous line) compared to controls (discontinuous line). This figure illustrates arrow #3 in panel A. *C3*: Nestling white storks (*Ciconia ciconia*) showed higher baseline corticosterone (predictive plasma levels) when they were singletons, reared in nests that suffered a strong brood reduction (insufficient parental care), compared to nestlings from two- and three-chick broods. This figure illustrates arrow #4 in panel A. *C4*: Baseline corticosterone (predictive plasma levels) in nestling white storks (*Ciconia ciconia*) were higher when reared in the less productive environment (crop fields) compared to nestlings reared beside wetlands (marsh), where food availability is higher. This figure illustrates arrow #5 in panel A. *Panel C1 from Hayward and Wingfield 2004; panel C2: from Love et al. 2013; panels C3–C4 modified from Blas et al. 2005; and Blas and Baos, 2008, all with permission.*

Kitaysky, 2008), human disturbance (Thiel et al., 2008; Zhang et al., 2011), and social competition consistently promote plasma GC elevations in females that may be forming eggs, laying, or brooding offspring. Therefore, the potential for GC transfer into eggs and developing young exists.

2. *Environmental and social conditions affect offspring GC levels (in ovo and developing birds).*

Although the precise mechanism whereby circulating GCs are transferred from the mother to the eggs requires additional research (Groothuis et al., 2005), positive correlations between maternal (plasma) and egg (yolk)

levels have been shown in European starlings *Sturnus vulgaris* (Love et al., 2005) and barn owls *Tyto alba* (Almasi et al., 2012). Additional studies have reported a concomitant increase in egg GC levels in response to maternal exposure to environmental challenge (barn swallows *Hirundo rustica,* Saino et al., 2005; European starlings *S. vulgaris,* Love et al., 2008; song sparrows *M. melodia,* Travers et al., 2010), including predation pressure and social conditions. For example, solitary breeding females of the semicolonial European starling deposit higher egg GC levels (Love and Williams, 2008), and reduced female condition often results in decreased food provisioning rates to nestlings, elevating post-hatching GC levels (Love et al., 2004; see Angelier et al., 2007b, 2009 for seabirds). Single chicks in white storks nests are the result of partial hatching failure and brood reduction (indicating insufficient parental care), and show higher circulating GC levels (*baseline* or *predictive homeostasis* range) compared to nestlings from two- and three-chick broods (Figure 33.8, panel C3; Blas et al., 2005).

3. ***Environmental challenge and elevated GC levels in developing offspring (in ovo, and post-hatch) generate long-term differences in HPA function, behavior, and performance.***

For example, in nestling black-legged kittiwakes *R. tridactyla*, experimental food restriction during development results in sustained elevations in 30 day old chicks (Kitaysky et al., 1999a,b), and experimentally elevated corticosterone levels promote begging and aggression (Kitaysky et al., 2001) but result in long-term impairment of cognitive abilities persisting at least 8 months later (Kitaysky et al., 2003). In European starlings *S. vulgaris,* reduced maternal provisioning rates increase fledglings' adrenocortical responsiveness (Love and Williams, 2008). Within a given clutch, maternal GC levels (deposited in egg yolks) sequentially increase (Love et al., 2008) and the subsequent HPA responses of nestlings are negatively correlated with *in ovo* GC exposure (Figure 33.8, panel C2). The latter association can be further enhanced by exogenous administration of GC in the eggs, which results in fledgings showing the lowest HPA responses (Love and Williams, unpublished data in Love et al., 2013). Somehow opposing results have been reported in Japanese quail *Coturnix coturnix japonica*, where experimentally elevated plasma corticosterone in laying females is transferred to egg yolk (Figure 33.8, panel C1), but the hatched chicks (which grow at a slower rate) display higher, rather than lower responsiveness of the HPA axis as adults (Hayward and Wingfield, 2004). Unfortunately there is a lack of studies in wild birds monitoring whether such changes in HPA function, behavior, and performance persist in the phenotypes after fledging, but a negative relationship between stress-induced corticosterone levels in nestlings and survival into adulthood was found in wild, unmanipulated white storks *C. ciconia* (Blas et al., 2007).

Maternal programming has been proved to be an adaptive (GC-mediated, epigenetic) mechanism bridging maternal and offspring environment to explain, for example, the cyclic population dynamics of wild mammals (see Sheriff et al., 2009, 2010, 2011a). Whether this mechanism also applies to wild birds urgently requires additional field research under contrasting environmental scenarios and in association with long-term monitoring of the individual's performance and HPA function.

- Glucocorticoids actions during development exert *permanent organizational effects* on the individuals.
- Developmental exposure to glucocorticoids occur prehatch (*in ovo*; during egg formation), and post-hatch (*ex ovo*: according to the amount of maternal and paternal care).
- Glucocorticoid transfer from mothers to offspring has the potential to translate ecological and environmental conditions into permanent offspring responses through a process termed "*maternal programming*".
- Such "*priming*" can be highly adaptive and allow animals to adjust to changing environments.
- The fitness of the modified phenotypes is likely context-specific, and determined by the environmental conditions encountered after development (*Maternal-Match Hypothesis*).

33.4.3 Modulation of the Stress Response

The *emergency life history stage ELHS* (Figure 33.6 and Section 33.3.3) redirects energy investment away from normal activities into a survival mode. Such energy shift (mediated through corticosterone elevations into the *reactive homeostasis* range) can be highly adaptive in most circumstances, but the individual also incurs important costs. In fact, life history theory postulates that organisms are continually facing trade-offs in the allocation of a limited quantity of resources/energy between competing functions (Stearns, 1992). For example, breeding birds have to trade off energy and resources between current reproductive investment and survival (which determines future reproduction). Whether an individual should allocate more resources to one or the other life history trait depends on the relative importance in maximizing lifetime fitness, and natural selection has likely filtered optimal decisions. This is a core argument for widely accepted models on the cost of reproduction (Williams, 1966), leading to a recently proposed *"Brood Value Hypothesis* (Heidinger et al., 2006; Lendvai et al., 2007; Lendvai and Chastel, 2008). The *Brood Value Hypothesis* proposes that the stress response should be modulated as a function of the relative

importance of the current reproductive attempt: when the value of the current reproduction is relatively high, the stress response should be mitigated to ensure that the current breeding attempt is not compromised. This hypothesis has found empirical support in numerous field studies, within and across species. For example, maximum corticosterone in response to capture and restraint (*reactive homeostasis*, plasma levels) in red-legged partridges *Alectoris rufa* declines from the pre-laying to the laying stage, suggesting an adaptive down-modulation of adrenocortical responses as the value of reproduction increases (Figure 33.9(A); Blas and Marchant, unpublished data). The first experimental demonstration that individuals can flexibly modulate their stress response with respect to the reproductive value of their brood was performed in free-living house sparrows *P. domesticus*. By means of an experimental increase or reduction of clutch size during the nestling period, Lendvai et al. (2007) found that parents tending enlarged clutches responded less strongly to a stressor than those tending reduced clutches (Figure 33.9(B)). In addition, they examined whether individuals responded less strongly to a stressor as the breeding season progressed and future reproductive opportunities declined. The stress response decreased with breeding date during the birds' first breeding attempt, but it remained constant during their second breeding attempt. The same line of hypothesis applies to interspecies comparisons: avian species breeding in northern latitudes have limited opportunities to renest due to a short breeding season, and as predicted by the *Brood Value Hypothesis*, they show attenuated stress responses compared to southern populations/species (having a wider reproductive season, and more possibilities to breed within the same year; Silverin et al., 1997; O'Reilly and Wingfield, 2001; Breuner et al., 2003; but see Wingfield et al., 1995a). Similarly, older individuals have progressively reduced breeding opportunities, making it adaptive to increase reproductive effort as they age ("*Terminal Investment Hypothesis*": Clutton-Brock, 1984; Velando et al., 2006). Consistent with the *Brood Value Hypothesis*, older birds show attenuated secretion of GCs in response to challenges (Heidinger et al., 2006), although this pattern may not always occur (Angelier et al., 2007a). The response to stress have been shown to be reduced in the sex providing the most parental care (Wingfield et al., 1995b; O'Reilly and Wingfield, 2001; Holberton and Wingfield, 2003), during the specific breeding substages requiring higher parental investment (Meddle et al., 2003; see Figure 33.9(A)), and even within a given substage (e.g., brooding) as offspring quality or quantity increases (Lendvai et al., 2007; Lendvai and Chastel, 2008). A recent phylogenetic comparative analysis on 34 wild avian species found that those with a higher value of the current brood relative to future breeding mounted weaker corticosterone responses during acute stress (Figure 33.9(C)), and that females in the species with more female-biased parental care had weaker corticosterone responses (Bókony et al., 2009). Collectively, correlational, experimental, and comparative evidence suggest that modulation of the stress response functions as a physiological mediator for the adaptive allocation of energy and resources between current and future reproduction. Also very important, these studies point to a particular hormonal mechanism, the HPA axis function, as the physiological bases for life history trade-offs, indicating that HPA

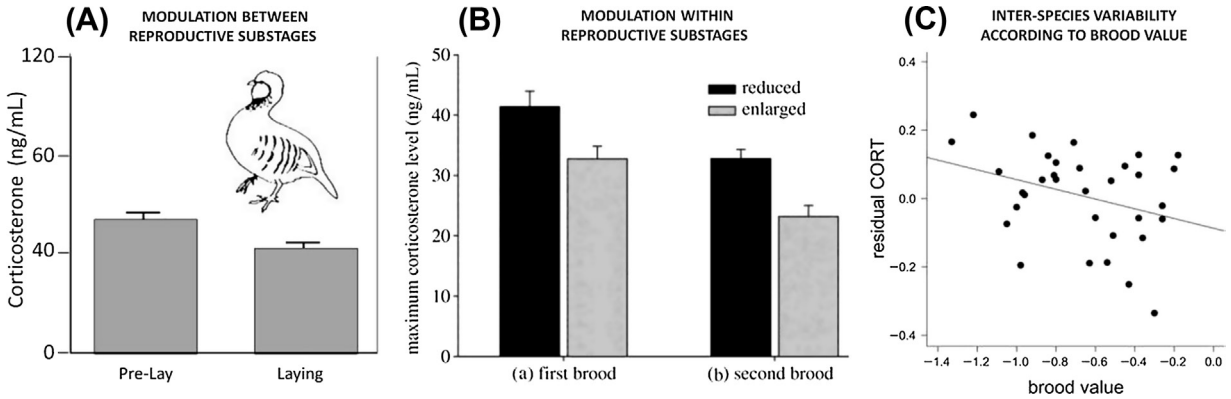

FIGURE 33.9 Modulation of the stress response during reproduction. ***Panel A.*** Maximum corticosterone (reactive, plasma levels) in response to capture and restraint in captive red-legged partridges (*Alectoris rufa*), across breeding sub-stages. Stress-induced corticosterone declined as birds started laying eggs, suggesting an adaptive down-modulation of HPA responses. ***Panel B.*** Maximum corticosterone titers (reactive, plasma levels) in free-living house sparrows (*Passer domesticus*) as a function of a manipulation of brood size (number of nestlings) performed in the (a) first and (b) second breeding attempt of a year. Experimentally increased broods elevated the brood value to adult birds, which down-modulated their HPA responses. ***Panel C.*** Residual, maximum corticosterone titers (peak plasma level controlled for baseline and breeding latitude) in relation to brood value in 34 wild avian species. Brood value expresses the putative importance of current reproduction as LOG(clutch size/[clutch size × broods per year × average reproductive life span]). *Panel A from J. Blas and T.A. Marchant, unpublished data; panel B reproduced from Lendvai et al. 2007 with permission from the Royal Society; panel C reproduced from Bókony et al. 2009 with permission from the University of Chicago Press.*

function and GC secretion may be a target of selection just like other traits (Bókony et al., 2009).

- Individuals can flexibly modulate their stress response with respect to the reproductive value of their brood (*Brood Value Hypothesis*).
- The intra-individual patterns of modulation are consistent with interspecies differences in stress responses, suggesting similar underlying ecological constraints. Avian species breeding in northern latitudes have limited opportunities to re-nest due to short breeding seasons, and show attenuated stress responses. Females in avian species showing female-biased parental care have weaker corticosterone responses.
- Modulation of corticosterone secretions makes it possible to trade off energy and resources between current reproductive investment and survival, providing a proximate mechanism for life-history evolution.

33.5 FIELD METHODS TO STUDY ADRENOCORTICAL FUNCTION

Our current understanding of avian adrenocortical function is to a large extent based on experimental studies performed in laboratory conditions using captive birds. This allows researchers to control a considerable number of variables known to affect *hypothalamus-pituitary-adrenal (HPA)* function (e.g., photoperiod, temperature, food and water, social interactions, status, age, sex, and life history stage). Captive birds are easily accessible for repeated sampling and trait manipulations, and most lab facilities have readily available infrastructure to obtain, process, and store the collected samples in repeatable conditions.

However, laboratory settings impose a considerable bias when extrapolating results to the real world (Fusani et al., 2005). To start with, only a few avian species can be kept in captivity for experimentation, limiting research conclusions to specific species or phylogenetic groups (e.g., poultry species), and even to specific breeds whose HPA system has been voluntarily or involuntarily modified through artificial selection (Keith et al., 1973; Satterlee et al., 2000). Furthermore, when a wild avian species is brought to captivity for experimentation, the artificial settings are unable to replicate the richness of natural stimuli and their complex interactions, and the recorded physiological and behavioral responses likely represent a minimum diversity compared to what occurs in natural habitats, when birds are exposed to real ecological scenarios (Fusani et al., 2005; Fusani, 2008). For example, wild *Passerine* species show reduced hippocampal volume, lower levels of circulating testosterone, and contrasting responses to pharmacological treatment when brought to captivity (Wingfield et al., 1990; Smulders et al., 2000; Canoine and Gwinner, 2002), strongly indicating that deprivation of environmental and social cues can dramatically modify neuroendocrinological and behavioral responses.

The last four decades have witnessed an increasing number of behavioral endocrinologists focusing their research on wild species under natural settings, largely following the pioneering work of John Wingfield (Wingfield and Farner, 1975, 1993) who implemented methods to quantify hormones in small blood samples, avoiding the need for killing the study subjects and establishing the discipline of *Field Endocrinology*. Working in the field imposes at least five important challenges compared to laboratory settings (Fusani et al., 2005; Fusani, 2008) and has led to the use of alternative, noninvasive tools to monitor endocrine function (Bortolotti et al., 2008; Sheriff et al., 2011b). First, wild specimens inevitably differ in nutritional condition, social status, life history stage, and many other factors whose variability should be taken into account during the design of a field experiment, the collection of samples, and the subsequent statistical treatment of data. Second, catching wild birds may take a considerable amount of effort, and the trapping method should be carefully chosen to avoid additional interferences on adrenocortical function. For example, the use of visual decoys and playbacks may facilitate capture, but using social stimulation as "bait" also stimulates rapid hormone secretions (e.g., elevating testosterone levels, Wingfield and Wada, 1989), potentially effecting GC levels (Charlier et al., 2009). Even the use of passive trapping methods like mist nets should be carefully supervised because the capture event itself is stressful, and the time elapsed until sampling need to be standardized, controlled for, or at least meticulously recorded (see Section 33.5.1). Third, sample sizes are often reduced compared to laboratory studies ($N \leq 10$ are not uncommon) due to the difficulty of capturing wild birds and also to minimize the impact on wild populations. Whenever possible, repeated-measures designs are advisable to increase the statistical power, although recapturing the same individuals may not be always possible as individuals learn avoidance behaviors. Fourth, because conditions can be primitive when working in field or remote locations, specific logistics may be required for sample processing and transportation. For example, the separation of plasma from blood samples for subsequent determination of corticosterone levels may require using a battery- or manually-operated centrifuge, while plasma preservation, storage, and transport in frozen conditions may require handling dry ice or liquid nitrogen in specific containers adapted for field and travel (details are in Fusani et al., 2005). Finally, special care should be taken regarding the ethical and legal considerations associated with the manipulation of wild birds (Fair et al., 2010), aimed and minimizing potential impacts on the well-being of study subjects and the viability of natural populations.

All the constraints and the special considerations above imply that a first step for any field study of avian

adrenocortical function requires a carefully planned experimental design. Environmental stochasticity (unpredictable events) occur frequently during field studies, and this may actually result in "natural experiments" that provide unique opportunities to understand the role of adrenocortical function in birds, for example, during inclement weather (Wingfield et al., 1983), social conflict (Goymann and Wingfield, 2004), famine conditions (Kitaysky et al., 1999a,b) and pollution accidents (Baos et al., 2006; Baos and Blas, 2009). Below we will summarize common field techniques that are frequently used for assessing adrenocortical function in wild birds, some of which have been developed or largely implemented in recent years (laboratory techniques aimed at quantifying GC levels have been reviewed elsewhere; see e.g., Sheriff et al., 2011b).

- Deprivation of environmental and social cues can modify avian neuroendocrinological and behavioral responses, preventing the extrapolation of results from laboratory studies to the real world.
- Field endocrinologists focus their research on wild species under natural settings, but face important challenges during sample collection, processing, and transportation. These have led to the development of alternative and noninvasive tools to monitor endocrine function.
- Field research requires carefully planned experimental designs and special care to minimize impacts on the well-being of individuals and the viability of natural populations.
- Environmental stochasticity often results in "natural experiments" that provide unique opportunities to understand the role of the stress response in avian ecology and evolution.

33.5.1 Obtaining Adequate Blood Samples: Capture and Restraint Protocols and the "Stress Series"

Field endocrinologists face an obvious methodological difficulty when collecting samples aimed at assessing HPA function in wild animals: an adequate "*baseline*" blood sample containing GC levels truly indicative of the individual's *predictive homeostasis* range should not be affected by the investigator disturbance. However, the trapping and capturing activities that necessarily precede blood sampling are perceived by wild birds as real predation attempts (Scheuerlein et al., 2001; Canoine et al., 2002). Although many behavioral and neuroendocrine components of the "*fight or flight*" response occur within seconds (e.g., epinephrine/norepinephrine elevations accompanied by escape behaviors and alarm calls; see details in Chapter 26) the elevation of circulating corticosterone levels typically shows a 2–3 min delay (Romero and Reed, 2005). This short timeframe constitutes, in many field situations, a feasible period for obtaining a first blood sample *in situ*. This can be done through venipuncture of the wing (brachial) vein using a sterilized needle and collecting blood drops in heparinized microhematocrit tubes (e.g., one or several 50 µL tubes) or using heparinized syringes that also allow accessing the leg or jugular veins. These procedures are generally harmless provided adequate training and observing the recommended blood sampling volume limitations according to body size (Fair et al., 2010; though see Brown and Brown, 2009). Following capture and initial collection of a baseline blood sample, birds should be kept in cloth bags or immobilized with cloth corsets, allowing adequate ventilation but preventing injury if the bird struggles. Birds should also be placed in a safe place, sheltered from direct negative effects of weather, and their vision deprived (large birds may require using falconry hoods, Blas et al., 2010). It is very important to follow a strict capture, handling, and restraint protocol, because subsequent collection of additional blood samples at predefined intervals of time (for example, 10, 30, and 45 min postcapture, Blas et al., 2006a) will allow the characterization of GC elevations at the individual level during a "*stress series*" (Figure 33.10(A)). Researchers can therefore transform/adapt their normal capture and sampling activities into standardized experimental protocols that will allow establishing formal group comparisons in a repeatable manner within and across studies (for example, in relation to age, sex, and body condition). In some field situations it may not be possible to obtain rapid samples from all the individuals in unstressed/*baseline* conditions (for example, when the trapping method involves simultaneous capture of many birds; Blas et al., 2011) or repeated samples from the same individuals (for example, in small species or during early developmental stages, when blood volume is highly limited; Fairhurst et al., 2013b). In all the cases it is still critical to keep accurate records of the times elapsed from capture to blood sampling each individual, and GC responses can be subjected to group comparisons through regression analyses (Figure 33.10(B)).

- Capturing wild birds stimulates their stress response. As a consequence, *baseline* corticosterone levels (representative of the individuals' *predictive homeostasis range*) can only be accurately assessed in blood samples obtained within 2–3 min postcapture. Additional blood samples will allow characterizing the *adrenocortical response to stress* at the individual level ("*stress series*").
- Blood sampling requires keeping meticulous records of the times elapsed from capture to blood sampling for each individual. Samples can be collected at predefined intervals of time or along a continuum, but a standardized *capture, handling, and restraint protocol* is required to establish group comparisons.

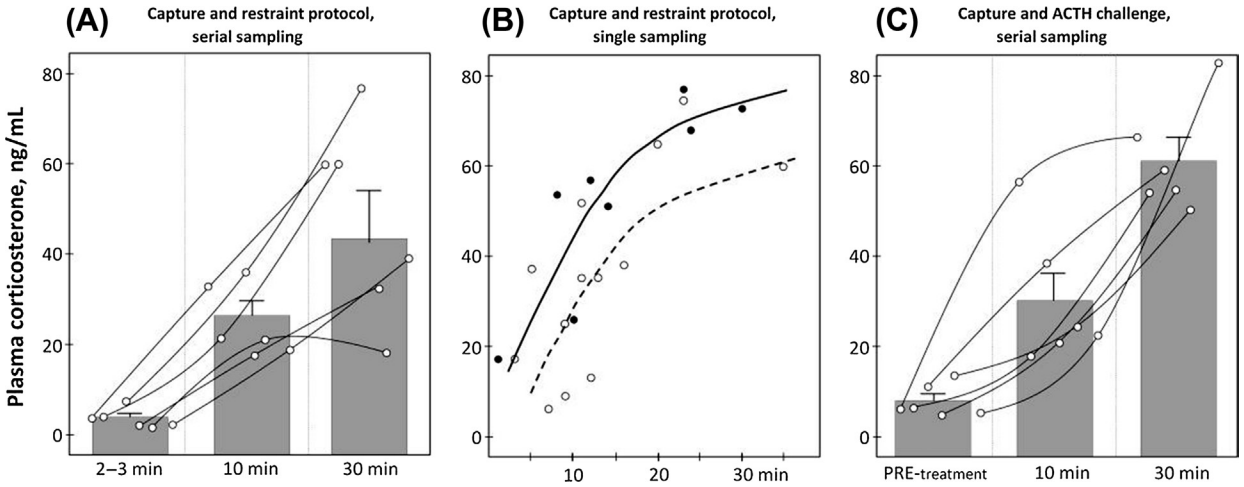

FIGURE 33.10 **Protocols for assessing the "stress response".** ***Panel A.*** *Capture and restraint with repeated blood sampling*. Plasma corticosterone levels in nestlings black kites (*Milvus migrans*) after standardized capture, restraint and serial bleeding of the same individuals (one line per individual, $N=6$ birds) at three fixed times (X-axis). The bars in the background represent mean and S.E. per sampling episode. ***Panel B.*** *Capture and restraint with single blood sampling*. Plasma corticosterone levels in adult male black kites (*Milvus migrans*) after standardized capture, restraint and collection of one single sample per individual (single dots are independent individuals). The solid and dashed lines indicate logistic regression estimates for non-breeding (black dots) and adult breeding birds (white dots). ***Panel C.*** *Capture and restraint with ACTH challenge and serial blood sampling*. Plasma corticosterone levels in nestlings black kites (*Milvus migrans*) after standardized capture, restraint and intravenous injection of ACTH. Serial bleeding was performed before and after (10 and 30 minutes) treatment (one line per individual, $N=6$ birds). ACTH injections were performed within 2 minutes from capture for ease of comparison with the corticosterone responses shown in Panel A. The bars in the background represent mean and S.E. per sampling episode. *Panel A and C from L. López et al., unpublished data; panel B redrawn from Blas et al. (2011).*

33.5.2 Quantifying Adrenocortical Sensitivity and Robustness

Although the *handling and restraint protocol* accompanied by serial collection of blood samples is a widely used method for assessing adrenocortical function in wild birds, the resulting GC elevations may be affected by perception differences among and within individuals. For example, wild penguins exposed to human presence show moderate GC elevations following the same capture and restraint protocol that triggers strong adrenocortical responses in unexposed conspecifics (Walker et al., 2006), suggesting habituation to human presence (Cyr and Romero, 2009). The reverse outcome may also occur when predator-naïve species learn that humans can be a potential danger, resulting in gradually stronger GC responses (Rödl et al., 2007). For these reasons, field studies may benefit by incorporating additional research methods to characterize adrenocortical function regardless of perceptional biases (see Canoine et al., 2002). For example, the sensitivity and the robustness of an individual's adrenocortical response can be estimated by means of administration of two commercially available drugs followed by the collection of blood samples to monitor concomitant, short-term (e.g., within 30–90 min) changes in endogenous GC levels (Figure 33.10(C)). The adrenals' *maximal ability or capacity* to secrete GC can be experimentally assessed through intravenous, intramuscular, or intraperitoneal administration of exogenous adrenocorticotropin (ATCH). Porcine ACTH is commercially available for research purposes, and it is known to elicit corticosterone release in the avian adrenals (Astheimer et al., 1994; Wasser et al., 1997; Rich and Romero, 2005). The commercial product is normally provided lyophilized, requiring suspension in an injectable isotonic solution (Ringer's solution). Dosage choice and injection volumes can be assessed according to previous references, and a pilot study using a small sample size (e.g., four to six birds) would allow selecting the minimal dose eliciting maximal response (*adrenal saturation*) and the optimal postinjection time for the subsequent collection of blood samples. Unfortunately, ACTH degrades at room temperature or following thaw–freeze cycles, requiring the preparation of aliquots maintained frozen until a few minutes before injection. The *robustness* of an individual's adrenocortical response can be characterized through exogenous (intravenous, intramuscular, or intraperitoneal) administration of *dexamethasone* (DEX). DEX is a synthetic GC that competes with endogenous corticosterone for binding receptors in the brain, and artificially stimulates negative feedback (Dallman et al., 1992). Because DEX does not bind to the antibodies commonly used in radioimmunoassays, a decrease of endogenous GC levels can be monitored by performing serial collection of blood samples within a relatively short period (e.g., 30, 60, and 90 min) after chemical challenge, allowing standardized comparisons among experimental groups. Negative feedback is a critical component of HPA function, as a failure in this system can lead to persistent elevated corticosterone levels that lengthen and strengthen the overall

stress response (Romero, 2004), potentially resulting in stress-related disease (Sapolsky, 1992; Romero and Wikelski, 2010). Contrary to ACTH, commercial DEX solutions are generally stable at room temperature, and because it is a common antiinflammatory drug the product is easily accessible in veterinary clinics.

- The individual's *maximal capacity* to secrete GCs can be experimentally assessed through ACTH injections, followed by serial collection of blood samples and quantification of corticosterone elevations.
- The *robustness* of an individual's adrenocortical response can be characterized through exogenous administration of dexamethasone (DEX), a synthetic GC that competes with endogenous corticosterone and stimulates negative feedback.

33.5.3 Phenotypic Engineering

One of the best ways to explore whether and how traits of organisms are currently adaptive is to manipulate them experimentally and compare the relative fitness of altered and unaltered individuals. This method has been termed *phenotypic engineering*, and it is a powerful tool in *field endocrinology* studies (Ketterson et al., 1996). For example, one could manipulate body condition and monitor the effects on circulating hormones (Figure 33.11(A)). More often, field endocrinologists are interested in a continuous manipulation of the individual's hormone levels (over the course of a few days or weeks) in order to assess the effects on physiology, morphology, behavior, and performance (Figure 33.11(B–C)). Repeated administration of a substance (e.g., daily injections) is impossible in most field conditions because focal individuals avoid being regularly recaptured. As a consequence, field researchers rely on subcutaneous implant devices to deliver the target substance (e.g., corticosterone, dexamethasone) more or less continuously. Depending on the chemical properties of the target substance and other considerations (including the researcher's budget), this can be achieved through three alternative subcutaneous implant devices (described below; see also Fusani, 2008). With the required training, the associated surgical procedures are simple, fast, and minimally invasive: after applying local anesthesia (e.g., external or subcutaneous lidocaine solution between the wings, the lower neck, or the upper leg area where the implant will be placed) and superficially cleaning the area with a cotton swab impregnated in povidone-iodine solution (alcohol should be avoided), a small incision using a sterile scalpel allows subsequent insertion of the implant device with forceps. The skin is subsequently closed using a small dab of tissue adhesive (Fairhurst et al., 2013b) or surgical stitches (Blas et al., 2006b).

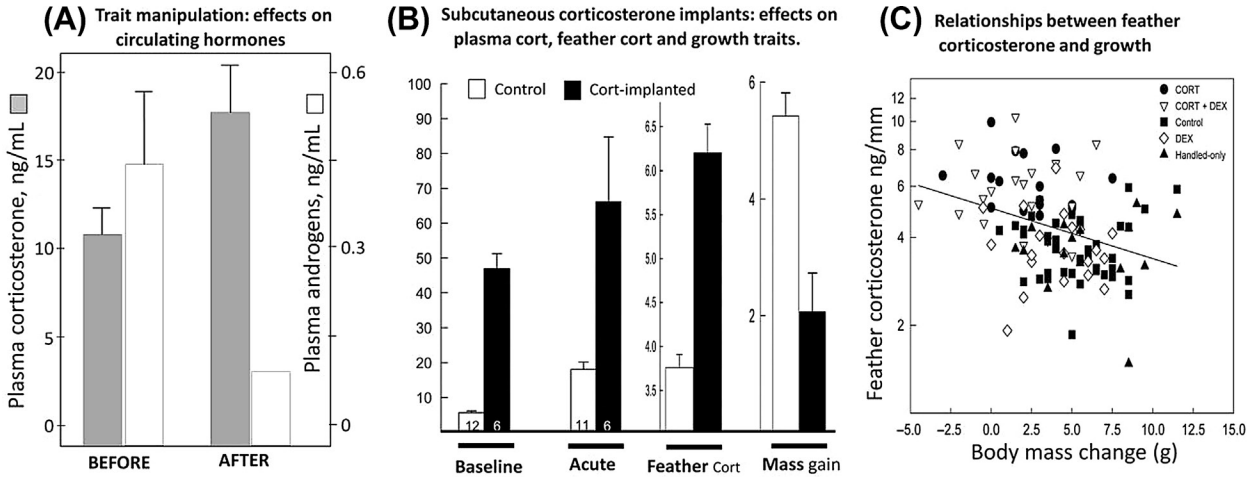

FIGURE 33.11 **Phenotypic engineering and feather corticosterone.** ***Panel A.*** *Effects of trait manipulations on circulating hormones.* Plasma levels of baseline corticosterone (left axis, gray bars) and androgens (right axis, white bars) before and after an experimental food restriction that caused a decrease in the body condition of adult male red-legged partridges (*Alectoris rufa*). Bars indicate means and S.E. All plasma samples were collected 3 minutes post-capture. ***Panel B.*** *Effects of sustained corticosterone manipulations on plasma cort, feather cort and body mass.* Plasma corticosterone levels (ng/mL), feather corticosterone levels (pg/mm) and body mass gain (g) in nestling tree swallows (*Tachycineta bicolor*) subcutaneously implanted time-release corticosterone pellets or drug-free pellets (black and white bars respectively) on day 7th post-hatch. Baseline blood samples were collected within 2–3 minutes following capture, and acute (stress-induced) blood samples were collected after 30 minutes of restraint (all samples collected 3 days after implanting). The feathers were growing during the experimental period, and were collected on day 15 post-hatch. Body mass change was estimated between days 7 and 11 post-hatch. All bars indicate means and S.E. ***Panel C.*** *Relationships between feather corticosterone and growth.* Negative association between feather corticosterone and body mass gain during development in nestling tree swallows (*Tachycineta bicolor*) subjected to systemic manipulations of hormone levels through time-release pellets. *Panel A redrawn from Pérez-Rodriguez et al. (2006) with permission; panels B and C adapted from Fairhurst et al., (2013b), with permission.*

1. ***Silicone implants.*** Silastic Medical Grade silicone tubing (Dow Corning, Inc.) can be filled with crystalline hormone and the two ends closed with silicon glue. After subcutaneous insertion, the substance diffuses thought the semipermeable walls for a variable period determined by the length of the tube, the thickness of the walls, the amount of drug, and its lipophilic nature. Although this inexpensive technique can be useful for highly lipophilic hormones such as testosterone (Blas et al., 2006b), silastic implants have low permeability for hydrophilic substances such as corticosterone (Kinel et al., 1968). In addition, *continuous* release does not mean *consistent* release (see Fusani, 2008). The choice of perforating the tube or leaving one end open causes a fast release of the hormone and thus inability to maintain a sustained elevation within or between individuals (Newman et al., 2010), which may confound experimental results.
2. ***Osmotic pumps.*** Osmotic minipumps (Alzet, Durect Corporation, Cupertino, CA, USA) allow for up to four weeks of *continuous and consistent* hormone release independent of its solubility (e.g., Soma et al., 2000; Fusani et al., 2001). This method is relatively expensive but provides high repeatability (Fusani, 2008).
3. ***Time-release pellets.*** Innovative Research of America (Sarasota, Florida, USA) manufactures pellets for the most common hormones and antihormone drugs as well as placebo (vehicle only) pellets (Figure 33.11(B–C)). The hormone is included in a cholesterol matrix that is slowly reabsorbed when placed subcutaneously. Although commercial pellets are relatively expensive, it is not necessary to recapture the animal to remove any experimental device after the study, providing a considerable advantage compared to silicone implants and osmotic pumps. Caution should be taken regarding dosages and expected release times despite manufacturer specifications. These estimations result from studies performed in laboratory rodents, and a number of studies have pointed out that systemic elevation of corticosterone and dexamethasone from subcutaneous pellets lasts for shorter times in a range of avian species (Muller et al., 2009; Fairhurst et al., 2013b), likely due to the higher metabolic rates of birds.

Note that continuing hormonal treatment for longer than a few days or one week can bring endogenous readjustment of the individual's endocrine system (evolved to maintain homeostasis). Therefore, long-term administration of an exogenous hormone may result in reduced endogenous production through negative feedback, and eventually in a regression of endocrine glands. These effects may last longer and be opposite to the intended initial manipulation (Fusani, 2008), potentially confounding the interpretation of results.

- One method to explore how endocrine traits are adaptive is to alter them experimentally and compare the fitness of altered and unaltered individuals ("*phenotypic engineering*").
- Field endocrinologists rely on subcutaneous implant devices to deliver the target substances (e.g., corticosterone) more or less continuously. Depending on the chemical properties of the target substance this can be achieved through silicone implants, osmotic pumps, or time-release pellets.
- Hormonal treatment for longer than a few days may result in a reduced endogenous production and caution should be taken to avoid potentially confounding results.

33.5.4 Corticosterone in Feathers

Quantifying circulating (plasma) corticosterone levels is the best way to characterize individual adrenocortical status at a particular moment and to understand how the HPA system works mechanistically and in relation to the environment. However, blood levels are instantaneous measurements, and the circulating GC titers within a given individual show dramatic fluctuations according to the immediate internal and external circumstances (e.g., social, environmental, daily rhythms). Field avian researchers face a challenge when trying to establish associations between long-term metrics (for example, fitness) and individual adrenocortical function, because GCs at a particular instant in time (a blood sample) hardly represent the long-term allostatic responses of an individual. Establishing robust eco-physiological associations would require repeatedly sampling the same individuals across time and/or large samples sizes. Such tasks are difficult to accomplish in field scenarios, explaining, for example, why GC-fitness associations are rarely reported and remain generally elusive to ecological studies (Breuner et al., 2008; Bonier et al., 2009; Crespi et al., 2013). In addition, obtaining blood samples requires capturing wild birds, with a potential artifact of the investigator disturbance on the results (Table 33.1) and concerns related to the well-being of the individuals and the conservation of wild populations (Sheriff et al., 2011b). For this and other methodological and logistical reasons summarized in Table 33.1, field researchers may chose alternative biological samples to study adrenocortical function in wild birds.

Recently it has been discovered (Bortolotti et al., 2008, 2009a) and independently confirmed (Lattin et al., 2011; Koren et al., 2012; Fairhurst et al., 2013b) that corticosterone is also present in feathers, and adequate laboratory protocols for its quantitative determination have been provided (Bortolotti et al., 2008, 2009a). Although the precise

TABLE 33.1 Monitoring Adrenocortical Function in Blood, Feathers, and Excreta

	Blood Samples (Corticosterone, CORT)	Feather Samples (Corticosterone, CORT)	Excreta Samples (Corticosterone metabolites, CM)
Trapping and capture required	**Yes**	**No** Capturing is optional. Feathers can be collected after natural molt (e.g., near nest site) or from dead/museum specimens.	**No** Capturing is optional. Direct field observation may be required to collect fresh samples and assign bird identity.
Potential researcher's interference on results	**High** Blood GC levels increase 2–3 min postcapture. Variability in handling and restraint affects circulating CORT in the collected samples.	**Neglegible** Even if capture is applied for sampling, the potential effect would only affect currently growing feathers (and even there it will be negligible on the overall feather CORT levels). Only longer-term perturbations (such as captivity) would affect CORT levels in growing feathers.	**Low** If capture is applied, time until defecation may elevate excreta CM levels (the extent of interference depends on the frequency of defecations and the species' metabolism).
Training required to obtain samples	**Yes** Proper blood sampling techniques require initial training	**No** Training not required. Fresh feathers can be collected during natural molt in the field, or be plucked/clipped from research specimens.	**No** Training not required. Fresh excreta can be collected in the field, or after restraining captured birds in cloth bags.
Time scale (of adrenocortical activity) reflected in samples	**Short** Minutes (possibility of accurate, short-term characterization of adrenocortical responses).	**Medium-long** Days to weeks or months (depending on feather growth duration). Adult birds may have feathers grown at different times and in different locations. Feather morphology allows discrimination of different portions grown across consecutive days.	**Medium-short** Minutes to hours (timeframes depend on the actual delay between feeding and excretion in any given sample).
Logistics for sample collection and initial processing	**High** Venipuncture and blood sampling require using syringes or sterilized needles and microhematocrit tubes (preferably heparinized). Plasma should be separated from whole blood through centrifugation (field centrifuge, pipettes, tubes, etc. required).	**Low** Plastic or paper bags.	**Medium-low** Excreta samples can be collected in vials or plastic bags.
Logistics for sample preservation, storage, and transport	**High** Coolers are required to preserve blood samples fresh until centrifugation within the same day. Storage and transport requires freezing (freezer, dry ice, or liquid nitrogen and specific containers).	**Low** Feathers can be stored in paper envelopes or plastic bags at room temperature.	**Medium-high** Considerable microbial degradation requires freezing samples immediately. Alternatively, samples can be preserved in alcohol, dried in an oven or lyophilized.
Possibility of subsampling to characterize timeframes	**No** Repeated blood sampling is required to analyze time-related patterns (e.g., capture and restraint series).	**Yes** Feathers can be clipped and subsampled to select portions grown across different days.	**No** Subsampling should be avoided. CM are not uniformly distributed within a sample. Undigested materials can cause interference with final results.

TABLE 33.1 Monitoring Adrenocortical Function in Blood, Feathers, and Excreta—cont'd

	Blood Samples (Corticosterone, CORT)	Feather Samples (Corticosterone, CORT)	Excreta Samples (Corticosterone metabolites, CM)
Retrospective potential	**No** Circulating CORT reflects current adrenal activity and therefore has very little retrospective potential.	**High** GCs are incorporated in the feather structure during growth, but birds maintain the same feathers for months or years (depending on the feather tract and the species' molt patterns), allowing retrospective analyses (for example, feathers collected this year can reflect circulating CORT levels of a previous year when they were grown).	**Low** Excreted CM reflects secretion, metabolism, and excretion during a variable period (minutes to hours) prior to deposition, allowing for short-term retrospective analyses (for example, researchers may decide to collect samples minutes to hours after a storm or a bout of aggressive interactions, and focal individuals can be chosen *posthoc*).
Discrimination between predictive and reactive homeostasis GC levels (i.e., baseline *versus* stress-induced levels)	**High** Capture and restraint (and serial blood sampling) allows assessing baseline and stress-induced CORT levels in the individual. An evaluation of the internal (e.g., nutritional), environmental, and social conditions is required to determine whether baseline blood samples represent predictive versus reactive homeostasis CORT levels.	**Low** Feather CORT integrates the amplitude and duration of circulating CORT levels during a growth period. Interpretation of results should take into account the potential variation in both predictive and reactive homeostasis ranges within and between feather samples.	**Low** Excreta CMs integrate the amplitude and duration of circulating CORT levels between food ingestion and excreta deposition. Interpretation of results should take into account the potential variation in both predictive and predictive homeostasis ranges within and between excreta samples.

Summary of methodological advantages and disadvantages associated with the use of blood, feathers, and excreta samples for assessing adrenocortical function in wild birds. Differences in laboratory assay methods required for the quantification of corticosterone or corticosterone metabolites levels in each type of sample should also be taken into account.

proximate mechanism remains largely unknown, there is solid evidence that circulating (systemic) corticosterone is gradually deposited in the feather structure as it grows from dermal follicles (likely through diffusion), and remains sequestered within the feather keratin structure rather than being externally deposited (for example, through preen oils; Bortolotti et al., 2008; Lattin et al., 2011). In a recent study manipulating systemic corticoterone levels in wild tree swallows (*Tachycineta bicolor*), Fairhurst and colleagues provide robust experimental evidence that feather corticosterone can correlate with both baseline and stress-induced measurements of plasma GC levels, but they emphasize that such a relationship likely occurs only when the latter reflect sustained HPA activity (Figure 33.11(C); Fairhurst et al., 2013b).

The slow growth rate of feathers implies that the period over which researchers can assess an individual's GC levels is days or weeks, rather than minutes or hours. This represents a considerable methodological advantage for field studies, as feather corticosterone levels likely reflect a more representative and ecological meaningful time scale of individual allostatic responses, including exposure and response to environmental perturbations. Despite the novelty of the discovery, feather corticosterone levels have already been shown to correlate with individual fitness and performance (Figure 33.11(B–C); Bortolotti et al., 2008; Koren et al., 2012; Fairhurst et al., 2012b, 2013a; Kouwenberg et al., 2013), quality-dependent traits (Bortolotti et al., 2009b; Mougeot et al., 2010; Kennedy et al., 2013), and environmental conditions (Fairhurst et al., 2011, 2012a, 2013a; Carrete et al., 2013).

Feather corticosterone levels are best expressed as pg/mm because length reflects time during feather growth (Bortolotti et al., 2008, 2009a; Bortolotti, 2010). Depending on the researcher interest, feathers can be used to assess changes in HPA activity across short- or long-term scales. For example, because daily feather growth can be determined through visual examination of growth bands (one pair of dark/light bands is typically grown every 24 h; Jovani et al., 2010), by clipping and subsampling different feather portions it is possible to assess changes in GC levels across the few days or weeks required to complete feather formation. Alternatively, a complete feather could be used to assess GC activity over a longer period of days or weeks, depending on the total amount of time required to grow each feather type. Because birds regularly replace all body feathers in a species-specific molting sequence, different feathers from

the same individuals allow assessing HPA activity at different times of the year and at different locations (Carrete et al., 2013). The analysis of GC levels can be combined with stable isotopes in the same samples to establish the detailed spatial-temporal dynamics of adrenocortical function (Fairhurst et al., 2013a). Sample storage, transport, and preservation does not require freezing, and feathers can be stored in plastic bags or paper envelopes at room temperature. The analysis of feather hormones has the unique advantages of allowing for experimentation and sampling at any time of the year with minimal investigator-induced impacts and offering a large retrospective potential (Table 33.1). For example, molted feathers can be collected without disturbing wild birds, and also from museum specimens. Considering these benefits, feather corticosterone may well provide the ultimate noninvasive physiological measure of adrenocortical function in birds (Bortolotti et al., 2009a).

- Circulating corticosterone is deposited in growing feathers, remaining sequestered within the keratin structure and allowing a retrospective assessment of adrenocortical activity.
- Feather corticosterone levels are best expressed as pg/mm because length reflects time during feather growth. The slow growth rate allows inferring an individual's exposure and response to environmental perturbations across days or weeks (rather than minutes or hours).
- Feather plucking induces regrowth, allowing for experimentation with minimal investigator-induced artifacts. In addition, feathers are naturally replaced in a specific molt sequence, allowing noninvasive, long-term monitoring of adrenocortical function.
- Different feathers from a captured individual or a museum specimen allow inferring adrenocortical activity at different times of the year and at different locations.
- Feather corticosterone provides the ultimate noninvasive physiological measure of adrenocortical function.

33.5.5 Corticosterone Metabolites in Droppings (Excreta)

Circulating corticosterone levels can be also traced using bird "droppings", the excretory products including urine and feces (both are normally mixed in the cloaca prior to excretion; Klasing, 2005). This can be done using either a homogenate of the entre dropping (Washburn et al., 2003) or collecting only the fecal portion (Hirschenhauser et al., 2005). However, it is very important to point out that there are no native GCs in excreta samples (Touma and Palme, 2005): GCs are extensively metabolized in the liver and excreted into urine (via the kidneys), or into the guts (via the bile ducts), undergoing further chemical modifications by the intestinal flora (Palme, 2005; Palme et al., 2005). This process results in complex and varied excreted ***glucocorticoid metabolites*** (GCMs) whose proportion and structure depends on the species and its metabolism at the time of dropping production (Goymann et al., 2006). Importantly, this requires a proper validation study to ensure that the final levels of the analyzed byproduct (GCMs) reliably reflects the original GC levels (e.g., corticosterone) in the circulatory system of the research model (Millspaugh and Washburn, 2004; Goymann, 2005; Palme et al., 2005). Because excreta samples are also subjected to considerable microbial degradation after defecation (Möstl et al., 1999, 2005), samples should be collected fresh and preserved frozen immediately. Alternatively, they can be preserved in alcohol or dried in an oven (Wasser et al., 1997; Khan et al., 2002; Terio et al., 2002): the choice of method will determine whether GCMs are expressed as per wet or dry mass (these two values may correlate; Wasser et al., 2000). It is also important to avoid excreta subsampling (GCM may not be uniformly distributed with a sample) and remove undigested materials if differences in diet among samples are observed, because both factors may introduce considerable interference with final results.

Excreta sample collection in the field is noninvasive (see Table 33.1), but obtaining fresh samples implies the need to perform observations of marked/controlled individuals to monitor defecation events either visually (Wasser et al., 1997) or through remote spatial tracking (Thiel et al., 2008). Alternatively, birds can be trapped and restrained until defecation occurs (Garamszegi et al., 2012). Whether the stress caused by capture and manipulation affects excreta GCM levels depends on the frequency of defecations and the species' metabolism (Palme et al., 2005), making it advisable to keep detailed records of the times from capture to sample collection and preservation, and restrict the analyses to those samples collected within a short time after capture (for example, within 5 min: Garamszegi et al., 2012). GCM levels in droppings are assumed to reflect an integrated average of three processes: GC secretion, metabolism, and excretion. Although it is debated whether GCMs best represent baseline or stress-induced GCs, it is more likely that they reflect overall GC levels in circulation within a variable period of time (Sheriff et al., 2011b). The noninvasive nature of excreta sampling procedures make it a very suitable substrate for the study of avian adrenocortical function in relation to behavior (Lucas et al., 2006; Carere et al., 2003), habitat quality (Wasser et al., 1997), and to monitor the effects of human-related perturbations in natural environments (Thiel et al., 2008), having a wide array of applications in animal welfare and conservation biology (for reviews, see Busch and Hayward, 2009; Millspaugh and Washburn, 2004).

- Adrenocortical activity can be monitored analyzing avian excretory products (bird "dropings"). However, ***native corticosterone does not exist in excreta samples***.

- Before excretion, circulating glucocorticoids are chemically transformed into ***glucocorticoid metabolites*** (GCMs), whose proportion and structure depends on the avian species. As a consequence, proper validation studies are required before assuming a direct association between circulating corticosterone titers and excreted GCM levels.
- Excreta sample collection in the field is noninvasive and provides a suitable substrate for the study of avian adrenocortical activity. Because bird "droppings" are subjected to microbial degradation, it is important to control the times from defecation to sample collection and to preserve samples adequately.

33.6 GLOSARY OF TERMS AND ABBREVIATIONS

ACTH: *corticotropin; adrenocorticotropic hormone*.

Acute levels *(of corticosterone)*: [also termed *stress-regulated* levels or *regulated facultative* levels]. Corticosterone levels within the *reactive homeostasis* range.

Adrenocortical response: physiological response to stress involving the hypothalamic–pituitary–adrenal (HPA) axis and culminating with the release of glucocorticoids (e.g. *corticosterone*) from the adrenal glands [33.5.1]; [Fig. 33.1].

Allostasis: process of maintaining stability (i.e. *homeostasis*) through change. It refers to those aspects of physiology that "*help us adapt*". This concept is gradually replacing one of the meanings of the ambiguous term "*stress*" [33.2.1]; [Fig. 33.2]; [Fig. 33.3].

Allostasis mediators: processes and body systems allowing allostasis (e.g. *glucocorticoids*, corticosterone, cytokines, cathecolamines, hearth rate, blood pressure, antibody titers) [33.2.3].

Allostasis Model: theoretical paradigm and framework to understand when and how animals activate emergency ("*stress* related") responses through modeling their energetic requirements across life and in relation to the energy available. Using energy as study metrics, the model introduces the key concepts of *allostasis*, *allostatic state*, *allostatic load* and *allostatic overload* [33.2.1]; [Fig. 33.2]; [Fig. 33.3].

Allostatic overload type 1: short-term, deleterious state of energy imbalance in which *allostatic load* exceeds the energy available from the environment plus the internal energy reserves. As a response, individuals typically acquire an *allostatic state* (e.g. sustained *corticosterone* elevations) leading to *the emergency life history stage ELHS* [33.2.1]; [33.3.3]; [Fig. 33.2]; [Fig. 33.3].

Allostatic overload type 2: long-term, deleterious state in which environmental or socially demanding challenges become *chronic* (e.g. social stress, captivity) and the sustained *corticosterone* elevations generate pathologies, regardless of the energy available [33.2.1]; [33.3.4]; [Fig. 33.2].

Allostatic load: cumulative energetic requirements of the organism in a broad sense (the "*workload*" to maintain *homeostasis* in a particular moment), including predictable and unpredictable demands [33.2.1]; [Fig. 33.2]; [Fig. 33.3].

Allostatic state: altered and sustained activity levels of allostasis mediators (e.g., elevated *corticosterone*), which can only be maintained for limited periods before damaging the body [33.2.1]; [Fig. 33.2].

Basal levels *(of corticosterone)*: [also termed *constitutive levels*]. Minimum levels allowing basic homeostatic processes. Minimum levels allowing a *physiological "state A"* representative of undisturbed animals at rest [33.2.2]; [Fig. 33.3].

Baseline levels *(of corticosterone)*: [also termed *seasonal baseline* levels, *regulated predictive* levels or *predictive homeostasis* range]. A range where *corticosterone* levels fluctuate according to *predictable environmental changes*, allowing copying with daily and seasonal routines of the life cycle but being insufficient to cope with *unpredictable perturbations*. *Baseline levels* allow a *physiological "state B"* where hormone actions maintain systems within a heightened operated range to support *allostatic load* [33.2.2]; [Fig. 33.3].

Brood Value Hypothesis: hypothesis proposing that birds can flexibly modulate their adrenocortical response according to the value of their brood (as the brood value increases, the adrenocortical response decreases) [33.4.3]; [Fig. 33.9].

Capture, handling and restraint protocol: standardized method for capturing, handling and restraining wild birds in repeatable conditions, required to establish adequate comparisons of their *adrenocortical response*. This protocol is frequently accompanied by the collection of a *stress series* [33.5.1]; [Fig. 33.10].

Chronic stress: pathological state characterized by a malfunctioning of critical body systems as a consequence of prolonged or repeated exposure to *perturbations*. *Allostatic overload type 2* [Fig. 33.3].

Classic System: traditional nomenclature describing corticosterone ranges and functional thresholds. This classification system combines three hormonal thresholds (*levels A, B, and C*) and a set of contrasting terms including *basal* and *baseline*, *constitutive* and *facultative*, *seasonal* and *stress-related* [33.2.2]; [Fig. 33.3].

Constitutive levels *(of glucocorticoids)*: *basal levels*.

Corticosterone (CORT): predominant *glucocorticoid* in birds, and a major *allostasis mediator*. Circulating corticosterone levels change in response to internal and external demands (both predictable and unpredictable) to manage energy balance [Fig. 33.1]; [Fig. 33.3].

Corticotropin (ACTH): *adrenocorticotropic hormone*. Hormone produced by the anterior pituitary (in response to hypothalamic signals) that stimulates the release *glucocorticoids* in the adrenal glands [33.5.2]; [Fig. 33.1]; [Fig. 33.10].

Developmental Hypothesis: hypothesis proposing that the patterns of maturation of *adrenocortical responses* within and between avian species evolved to match the costs and benefits of *glucocorticoid* actions with the individual's progressive ability to cope with *perturbations* (e.g., increased behavioral performance and parental independence) [33.4.1]; [Fig. 33.7].

DEX: dexamethasone.

Dexamethasone (DEX): synthetic glucocorticoid that competes with corticosterone for binding sites and stimulates *negative feedback* [33.5.2]; [Fig. 33.11].

Direct LPF *(direct labile perturbation factors)*: short-lived *perturbations* lasting hours or days, imposing high energetic demands and resulting in activation of the *emergency life history stage* (*ELHS*) temporary disrupting the normal lifecycle [33.3.3]; [Fig. 33.5]; [Fig. 33.6].

ELHS: *emergency life history stage*.

Emergency life history stage (ELHS): facultative life stage activated in response to *direct labile perturbations*, and driven by the elevation and maintenance of *glucocorticoid* levels above *baseline* titers (i.e. into the *reactive homeostasis range* or *stress regulated levels*). During an *ELHS*, birds change their behavior and physiology to

maximize survival at the cost of temporary suppressing their normal lifecycle [33.3.3]; [Fig. 33.2]; [Fig. 33.6].

Field Endocrinology: emerging scientific discipline aimed at studying the interplay between the endocrine system and the environment, using wild animals in their natural habitats as study models [33.5].

Flight or fight *response*: physiological and behavioral responses to short-term perturbations, mediated by the *sympathetic nervous system* with little or no elevation of *glucocorticoids* [33.3.2]; [Fig. 33.6].

GCM: glucocorticoid metabolites [33.5.5]; [Table 33.1].

GCs: *glucocorticoids* [Fig. 33.1].

Glucocorticoids (GCs): [also termed *stress hormones*] steroid hormones produced in the adrenals and released in response to ACTH. GCs are major *allostasis mediators* in vertebrates, control carbohydrate, fat and protein metabolism and their circulating levels change in response to internal and external demands to manage energy balance. The predominant GC in birds is *corticosterone* [Fig. 33.1]; [Fig. 33.3].

Homeostasis: stability of the physiological systems essential to life. This concept is often restricted to a few truly essential systems such as *pH, body temperature, glucose levels,* and *oxygen tension*. Homeostasis refers to those aspects of physiology that "*keep us alive*" [33.2.1]; [Fig. 33.1]; [Fig. 33.4].

Homeostatic failure: pathological state characterized by unsustainably low levels of *corticosterone*, insufficient to maintain *homeostasis* and resulting in death. Term associated to the *Reactive Scope Model* [33.2.2]; [33.2.3]; [Fig. 33.3]; [Fig. 33.4].

Homeostatic overload: pathological state characterized by abnormally elevated levels of *corticosterone* that disrupt normal body functions. The actual threshold for *homeostatic overload* can change within and between individuals in response to certain stimuli through a mechanism known as *wear and tear* [33.2.2]; [33.2.3]; [Fig. 33.2]; [Fig. 33.4].

HPA axis: hypothalamic–pituitary–adrenal axis [Fig. 33.1].

Indirect LPF (*indirect labile perturbation factors*): short-lived perturbations lasting seconds to a few minutes and inducing a *flight or fight* response with little or no elevation of glucocorticoids into the *reactive homeostasis range* [33.3.2]; [Fig. 33.5]; [Fig. 33.6].

Labile perturbation factor (LPF): short-term *perturbation*. According to their duration, *labile perturbations* can be classified as either direct (direct LPF) or indirect (indirect LPF) [33.3.2]; [Fig. 33.5].

LHS: life history stage (e.g. migration, moult, breeding) [Fig. 33.6].

LPF: *labile perturbation factor*.

Maternal Programming Hypothesis: hypothesis proposing that the transfer of *glucocorticoids* from mothers to offspring is an adaptation, evolved to translate ecological and environmental conditions into permanent offspring responses [33.4.2]; [Fig. 33.8].

Maternal-Match Hypothesis: offset from the Maternal Programming Hypothesis, proposing that the fitness of the modified offspring phenotypes (through *maternal programming*) is context specific, and highest when the environmental conditions experienced during adulthood are similar to those experienced during development [33.4.2]; [Fig. 33.8].

Modifying factor: [also termed *long-term* or *permanent perturbation*] perturbation lasting months or years, imposing high energetic demands and resulting in a permanent disruption of lifecycles, potentially leading to populations extinction [33.3.4]; [Fig. 33.5]; [Fig. 33.6].

Permanent perturbation: *modifying factor*.

Perturbation: [also termed *stressor*] unpredictable and potentially noxious environmental stimulus. Perturbations can be classified as either *labile* (*LPF*; and these can be direct or indirect) or *permanent* (also known as *modifying factors*) [33.3]; [Fig. 33.2]; [Fig. 33.4]; [Fig. 33.5].

Phenotypic engineering: experimental method consisting in altering a trait (e.g. elevating systemic hormone levels through subcutaneous implants) to explore whether and how such trait is adaptive. This method is a powerful tool in field endocrinology studies [33.5.3]; [Fig. 33.11].

Predictive homeostasis range *(corticosterone levels)*: intermediate levels of *corticosterone* allowing circadian and seasonal adjustments in response to *predictable environmental changes*. [Equivalent terms: *baseline* levels, *seasonal baseline* levels and *regulated predictive* levels] [33.2.2]; [Fig. 33.3]; [Fig. 33.4].

Reactive homeostasis range *(corticosterone levels)*: elevated levels of *corticosterone* needed to reestablish *homeostasis* after a *perturbation*. Upper, facultative range of *corticosterone* levels required to cope with unpredictable challenges. The elevations of *corticosterone* levels within this range are known as the *stress response*, and can trigger an *emergency life history stage ELHS*. [Equivalent terms: *acute* levels, *stress-regulated* levels, *regulated facultative* levels] [33.2.2]; [33.2.3]; [Fig. 33.3]; [Fig. 33.4].

Reactive scope: range of *corticosterone* levels defining the upper and lower physiological constraints of a healthy animal, according to the *Reactive Scope Model*. Combination of the *predictive* and the *reactive homeostasis ranges* above and below which serious pathologies arise. The amplitude of the *reactive scope* can be reduced through *wear and tear* [33.2.3]; [Fig. 33.3]; [Fig. 33.4].

Reactive Scope Model: graphical tool for characterizing the physiological state of animals across time, in response to *perturbations*, and according to the levels of allostasis mediators such as circulating *corticosterone*. Offshoot of the *Allostasis Model*, presenting a different terminology for contextualizing the impact of stress in the body, a new classification of corticosterone levels (see *Reactive Scope System*) and introducing the concept of *wear and tear* [33.2.3]; [Fig. 33.3]; [Fig. 33.4].

Reactive Scope System: recently proposed nomenclature describing *corticosterone* ranges and functional thresholds within the framework of the *Reactive Scope Model*. *Corticosterone* levels are presumed to exist in four ranges of increasing magnitude: *homeostatic failure, predictive homeostasis, reactive homeostasis,* and *homeostatic overload* [33.2.2]; [33.2.3]; [Fig. 33.3]; [Fig. 33.4].

Regulated facultative levels *(of corticosterone)*: *acute* levels, *stress-regulated* levels, corticosterone levels within the *reactive homeostasis range*.

Regulated predictive levels *(of corticosterone)*: *baseline* levels, *seasonal baseline* levels, corticosterone levels within the *predictive homeostasis range*.

Seasonal baseline levels *(of corticosterone)*: *baseline* levels, *regulated predictive baseline* levels, corticosterone levels within the *predictive homeostasis range*.

Stress: polysemous term that depending on the context may mean: (1) the stimuli that challenges homeostasis (i.e., *stressor*, *perturbation*), (2) the emergency responses to perturbations (*stress response*), or (3) the chronic state of imbalance that follows over-activation of the *adrenocortical axis* (*pathology*; *chronic stress*). Modern field

endocrinologists are making efforts to define and consolidate alternative and unequivocal terms, leading to the recent introduction of the word *allostasis* [33.2].

Stress hormones: *glucocorticoids* [Fig. 33.1].

Stress hyporesponsive period: temporary inability to elevate circulating *glucocorticoids* in response to *perturbations* [33.4.1]; [Fig. 33.7].

Stress regulated levels *(of corticosterone)*: *acute* levels, *regulated facultative* levels, corticosterone levels within the *reactive homeostasis* range.

Stress response: facultative and short-term elevations of *corticosterone* levels in response to *perturbations*, allowing rapid physiological and behavioral changes aimed at maximizing survival [33.2.2]; [33.2.3]; [Fig. 33.3]; [Fig. 33.4].

Stress series: serial collection of blood samples at predefined intervals of time following capture, aimed at characterizing the adrenocortical response of the individual through subsequent determination of *glucocorticoids* levels [33.5.1]; [Fig. 33.10].

Stressor: perturbation.

Wear and tear: the cost of maintaining *corticosterone* elevations during a *stress response*, as proposed in the *Reactive Scope Model*. Cost of maintaining and using the physiological systems that mediate *allostasis*. *Wear and tear* can be graphically represented as a decrease in the threshold level between the *reactive homeostasis range* and *homeostasis overload* which results in a decreased ability to cope with *perturbations* and increased likelihood of pathology [33.2.3]; [Fig. 33.3]; [Fig. 33.4].

ACKNOWLEDGMENTS

I am grateful to R. Carsia for proposing me for this contribution. R. Carsia C. Scannes and P. González provided valuable assistance during the preparation of this chapter. G. Fairhurst, T.A. Marchant, and S. Cabezas reviewed a previous manuscript. J.A. Sencianes made the bird drawings for Figures 33.1, 33.7, and 33.8. S. Palacios provided invaluable logistic assistance. L. López, F. Sergio, A. Tanferna, S. Cabezas, and T. Marchant kindly provided unpublished data for Figures 33.9 and 33.10. J. Blas was supported by a Ramon y Cajal contract from the CSIC, a research project CGL2012-32544 (Spanish Ministry of Economy and Competitiveness and FEDER funds), and grant 511/2012 (Organismo Autónomo de Parques Nacionales) from the Spanish Ministry of Agriculture, Food and the Environment.
