Dedication

**To all who have inspired me—my wife,
my parents, my children, my mentors, my colleagues,
and my students and to Paul Sturkie,
who I had the privilege of knowing.**

Part I
Undergirding Themes

1. Avian Genomics

Jerry B. Dodgson

1.1 Introduction 3
1.2 Genome Size 3
1.3 Chromosomes 3
1.3.1 Karyotypes 3
1.3.2 Sex Chromosomes 4
1.3.3 Telomeres and Centromeres 4
1.4 Genome Sequences 4
1.4.1 Approach 4
1.4.2 Coverage 4
1.5 Annotation 7
1.6 Genome Browsers 7
1.7 Genes 7
1.8 Transposons 8
1.9 Genome Diversity 8
1.9.1 SNP Discovery 8
1.9.2 SNP Diversity 9
1.9.3 Recombination 9
1.10 Connecting Sequence to Phenotype 9
1.10.1 Avian-Specific Genes 9
1.10.2 Mapping Mutations and QTL 10
1.10.3 Resequencing 10
1.11 Conclusions and Summary 10
References 11

2. Transcriptomics of Physiological Systems

Tom E. Porter

Abbreviations 15
2.1 Introduction 15
2.2 Early Efforts 15
2.3 Nervous System 17
2.4 Endocrine System 17
2.5 Reproductive System 18
2.6 Immune System 18
2.7 Muscle, Liver, Adipose, and Gastrointestinal Tissues 19
2.8 Cardiovascular System 20
2.9 Hurdles and Future Developments 20
References 21

3. Avian Proteomics

Dusan Kunec and Shane C. Burgess

3.1 Introduction 25
3.2 Protein Identification and Analysis 26
3.2.1 Two-Dimensional Gel Electrophoresis-Based Proteomics 26
3.2.2 Gel-Free Based Proteomics 27
3.3 Quantitative Proteomics 28
3.4 Structural Proteomics 28
3.5 Application of Proteomics in Avian Research 29
3.5.1 Organ and Tissue Proteomics 29
3.5.2 Proteomics of Cell Metabolism 30
3.5.3 Production Proteomics 31
3.5.4 Proteomics of Disease and Infection 32
3.6 Conclusions 34
References 34

4. Mitochondrial Physiology

Walter Bottje

4.1 Mitochondria: An Introduction 39
4.1.1 Overview 39
4.1.2 Physical Description 39
4.1.3 Mitochondrial and Nuclear DNA Interaction for Assembly and Function 39
4.1.4 Mitochondrial Fusion and Fission 41
4.1.5 The Respiratory Chain and ATP Synthesis 41
4.1.6 Assessing Mitochondrial Function 42
4.1.7 Mitochondrial Role in Apoptosis 42
4.2 Mitochondrial Inefficiencies 43
4.2.1 Electron Transport Defects and Oxidative Stress 43
4.2.2 Antioxidants 45
4.2.3 Mitochondrial Uncoupling and Attenuation of Oxidative Stress 45

4.3 Matching Energy Production to Energy Need 46
4.3.1 Mitochondrial Biogenesis 46
4.3.2 AMP-Activated Protein Kinase 47
4.3.3 Sirtuins 47
References 47

Part II
Sensory Biology and Nervous System Theme

5. The Avian Somatosensory System: A Comparative View

J. Martin Wild

Abbreviations 55
5.1 Introduction 55
5.2 Body Somatosensory Primary Afferent Projections in Different Species 56
5.2.1 Spinal Cord 56
5.2.2 Brainstem 57
5.3 Ascending Projections of the Dorsal Column Nuclei 58
5.4 Telencephalic Projections of Thalamic Nuclei Receiving Somatosensory Input 60
5.5 Somatosensory Primary Afferent Projections from the Beak and Tongue to the Trigeminal Column 61
5.5.1 Principal Sensory Trigeminal Nucleus 61
5.5.2 Nucleus of the Descending Trigeminal Tract (nTTD) 62
5.6 Nucleus Basorostralis 63
5.7 The Meeting of the Spinal and Trigeminal Systems 64
5.8 The Somatosensorimotor System in Birds 64
5.9 Somatosensory Projections to the Cerebellum 65
5.10 Magnetoreception and the Trigeminal System 65
5.11 Summary and Conclusions 66
References 66

6. Avian Hearing

Christine Köppl

Abbreviations 71
6.1 Introduction: What Do Birds Hear? 71
6.2 Outer and Middle Ear 72
6.2.1 No Specialized Outer Ear Structures, Except in Owls 72
6.2.2 The Single-Ossicle Middle Ear 72
6.2.3 Coupled Middle Ears? 73
6.3 Basilar Papilla (Cochlea) 73
6.3.1 General Morphology and Physiology 73
6.3.2 Hair-Cell Types: A Remarkable Example of Evolutionary Convergence in Birds and Mammals 76
6.3.3 Hair-Cell Regeneration: Birds Never Lose Their Hearing 76
6.3.4 Cochlear Specializations: Auditory Foveae, Infrasound Hearing 77
6.3.5 Auditory Nerve: What the Ear Conveys to the Brain 77
6.4 The Auditory Brain 78
6.4.1 Basic Organization of Auditory Pathways 78
6.4.2 The Generation of an Auditory Space Map in the Barn Owl 81
6.4.3 Developmental Plasticity: Auditory Space is Calibrated by Vision 82
6.4.4 The Special Processing of Birdsong 82
6.4.5 Echolocating Birds 83
6.5 Summary 84
References 84

7. The Chemical Senses in Birds

Larry Clark, Julie Hagelin and Scott Werner

7.1 Chemical Senses 89
7.2 Chemesthesis 89
7.2.1 Trigeminal and Somatosensory Nerves 89
7.2.2 Performance Characteristics of Nociceptors 90
7.2.3 Receptor Mechanisms 90
7.2.4 Chemical Structure–Activity Relationships to Irritants 92
7.2.5 Responses to Respiratory Stimuli 93
7.2.6 Nasal and Respiratory Irritation and Interaction of Olfaction and Chemesthesis 93
7.2.7 Behavioral Responses to Irritants 94
7.2.8 Applications 94
7.3 Olfaction 94
7.3.1 Morphology of Olfactory System 94
7.3.2 Innervation of Olfactory Receptors 94
7.3.3 Olfactory Neuronal Response 96
7.3.4 Laboratory Detection Thresholds, Discrimination, and Seasonal Change 96
7.3.5 Development 98
7.3.6 Field Studies and Behavioral Ecology 98
7.3.7 Summary 99
7.4 Gustation 100
7.4.1 Taste Receptors 100
7.4.2 Response to Sweet 100
7.4.3 Response to Salt 102
7.4.4 Response to Sour 102

7.4.5 Response to Bitter 102
7.4.6 Response to Umami 103
7.4.7 Response to Calcium 103
7.4.8 Taste Behavior and Applications 103
7.4.9 Summary 104
References 104

8. Magnetoreception in Birds and Its Use for Long-Distance Migration

Henrik Mouritsen

8.1 Introduction 113
8.2 Magnetic Fields 113
8.3 The Earth's Magnetic Field 114
8.4 Changing Magnetic Fields for Experimental Purposes 115
8.5 Birds Use Information from the Earth's Magnetic Field for Orientation and Navigation 115
8.6 The Magnetic Compass of Birds 118
8.7 Do Birds Possess a Magnetic Map? 119
8.8 Interactions with Other Cues 120
8.9 How Do Birds Sense the Earth's Magnetic Field? 121
8.10 The Induction Hypothesis 121
8.11 The Iron-Mineral-Based Hypothesis 121
8.12 The Light-Dependent Hypothesis 125
8.13 Irreproducible Results and the Urgent Need for Independent Replication 129
8.14 Where Do We Go from Here? 129
References 129

9. The Avian Subpallium and Autonomic Nervous System

Wayne J. Kuenzel

9.1 Introduction 135
9.2 Components of the Subpallium 136
9.2.1 Dorsal Somatomotor Basal Ganglia 136
9.2.2 Ventral Viscerolimbic Basal Ganglia 139
9.2.3 Extended Amygdaloid Complex: Central Extended Amygdala and Medial Extended Amygdala 142
9.2.4 Basal Telencephalic Cholinergic and Noncholinergic Corticopetal System 144
9.2.5 Septum and Septal Neuroendocrine Systems 145
9.3 Components of the Autonomic Nervous System 149
9.3.1 Sympathetic Nervous System 149
9.3.2 Parasympathetic Nervous System 150
9.4 Functional Neural Pathways Involving the Subpallium and ANS 150
9.4.1 Regulation of the Reproductive System 150
9.4.2 Regulation of Food Intake 151
9.5 Summary and Conclusions 154
Acknowledgments 154
References 155

Part III
Organ Systems Theme

10. Blood

Colin G. Scanes

10.1 Introduction 167
10.2 Plasma 167
10.2.1 Circulating Electrolytes 167
10.2.2 Circulating Nutrients and Other Small Organic Molecules 167
10.2.3 Plasma Proteins 168
10.3 Erythrocytes 171
10.3.1 Structure of the Erythrocyte 171
10.3.2 Erythrocyte Chromatin and Transcription 171
10.3.3 Metabolism of Erythrocytes 172
10.3.4 Number of Erythrocytes and Packed Cell Volume (Hematocrit) 173
10.3.5 Production of Erythrocytes 173
10.3.6 Lifespan of Erythrocytes 174
10.3.7 Hemoglobin 174
10.3.8 Carbonic Anhydrase 175
10.3.9 Transporters 176
10.3.10 Hormonal Effects on Erythrocytes 176
10.3.11 Effect of Stressors 176
10.3.12 Other Roles for the Avian Erythrocyte 177
10.4 Blood Gases 177
10.5 Leukocytes 177
10.5.1 Populations 177
10.5.2 Heterophils 179
10.5.3 Lymphocytes 181
10.5.4 Eosinophils 181
10.5.5 Monocytes 182
10.5.6 Basophils 182
10.6 Thrombocytes 182
10.6.1 Structure 183
10.6.2 Function 183
10.6.3 Number 183
10.6.4 Production 183
10.7 Clotting 184
10.8 Avian Blood Models 184

10.8.1 β-adrenergic Receptors 184
10.8.2 Transgenic Chickens 185
10.8.3 Avian IgY Antibodies 185
10.8.4 Nutritional Models 185
References 185

11. The Cardiovascular System

Edward M. Dzialowski and Dane A. Crossley II

11.1 Introduction 193
11.2 Heart 193
11.2.1 Gross Structure and Function 193
11.2.2 Cardiac Variables 197
11.2.3 Fine Structure and Cardiac Electrophysiology 198
11.3 General Circulatory Hemodynamics 205
11.4 The Vascular Tree 206
11.4.1 Arterial System 206
11.4.2 Capillary Beds 215
11.4.3 Venous System 218
11.4.4 Embryonic Shunts 221
11.5 Control of the Cardiovascular System 222
11.5.1 Control Systems 222
11.5.2 Control of Peripheral Blood Flow 223
11.5.3 Control of the Heart 231
11.5.4 Reflexes Controlling the Circulation 253
11.5.5 Integrative Neural Control 258
11.5.6 Development of Cardiovascular Control 259
11.6 Environmental Cardiovascular Physiology 266
11.6.1 Flight 266
11.6.2 Swimming and Diving 269
Acknowledgments 271
References 271

12. Osmoregulatory Systems of Birds

Eldon J. Braun

12.1 Introduction 285
12.1.1 Organs of Osmoregulation in Vertebrates 285
12.1.2 Osmoregulation by Birds 285
12.2 The Avian Kidney 286
12.2.1 Vascular Anatomy of the Kidney 287
12.2.2 Glomerular Filtration 289
12.2.3 Ion Transport by Renal Tubules 290
12.2.4 The Renal Medulla 291
12.2.5 Concentration and Dilution of Urine 292
12.2.6 Nitrogen Excretion 294
12.2.7 Form of Uric Acid in Avian Urine 295
12.3 The Avian Lower Gastrointestinal Tract 297
12.4 The Avian Salt Gland 298
12.4.1 Structure of the Salt Glands 298
12.4.2 Product of Salt Gland Secretion 299
12.4.3 Control of Salt Gland Secretion 299
References 299

13. Respiration

Frank L. Powell

13.1 Overview 301
13.1.1 Oxygen Cascade **301**
13.1.2 Symbols and Units **301**
13.2 Anatomy of the Avian Respiratory System 301
13.2.1 Upper Airways 302
13.2.2 Lungs 303
13.2.3 Air Sacs 305
13.2.4 Respiratory System Volumes 306
13.3 Ventilation and Respiratory Mechanics 307
13.3.1 Respiratory Muscles 307
13.3.2 Mechanical Properties 307
13.3.3 Ventilatory Flow Patterns 309
13.4 Pulmonary Circulation 312
13.4.1 Anatomy of the Pulmonary Circulation 312
13.4.2 Pulmonary Capillary Volume 312
13.4.3 Pulmonary Vascular Pressures, Resistance, and Flow 312
13.4.4 Fluid Balance 313
13.5 Gas Transport by Blood 314
13.5.1 Oxygen 314
13.5.2 Carbon Dioxide 317
13.5.3 Acid–Base 318
13.5.4 Blood Gas Measurements 318
13.6 Pulmonary Gas Exchange 318
13.6.1 Basic Principles of Oxygen Transport 319
13.6.2 Cross-Current Gas Exchange 320
13.6.3 Lung Diffusing Capacity 321
13.6.4 Heterogeneity in the Lung 322
13.6.5 Frontiers: Gas Exchange during High-Altitude Flight 323
13.7 Tissue Gas Exchange 324
13.7.1 Microcirculation 324
13.7.2 Myoglobin 325
13.7.3 Effects of Hypoxia and Exercise 325
13.8 Control of Breathing 325
13.8.1 Respiratory Rhythm Generation 326
13.8.2 Sensory Inputs 327
13.8.3 Ventilatory Reflexes 328
13.8.4 Ventilatory Response to Exercise 330
13.8.5 Frontiers: Extreme Hyperventilation at High Altitude 330
References 330

14. Gastrointestinal Anatomy and Physiology

D. Michael Denbow

14.1 Anatomy of the Digestive Tract 337
14.1.1 Beak, Mouth, and Pharynx 337
14.1.2 Esophagus and Crop 338
14.1.3 Stomach 340
14.1.4 Small Intestine 341
14.1.5 Ceca 341
14.1.6 Colon (Rectum) and Cloaca 342
14.2 Anatomy of the Accessory Organs 342
14.2.1 Pancreas 342
14.2.2 Liver 342
14.3 Motility 342
14.3.1 Esophagus 342
14.3.2 Gastrointestinal Cycle 343
14.3.3 Small Intestine 345
14.3.4 Ceca 345
14.3.5 Colon 346
14.3.6 Other Influences on Motility 347
14.4 Neural and Hormonal Control of Motility 347
14.4.1 Rate of Passage 351
14.5 Secretions and Digestion 351
14.5.1 Mouth 352
14.5.2 Esophagus and Crop 352
14.5.3 Stomach 352
14.5.4 Intestines 354
14.5.5 Colon 355
14.5.6 Pancreas 355
14.5.7 Bile 355
14.6 Absorption 356
14.6.1 Carbohydrates 356
14.6.2 Amino Acids and Peptides 357
14.6.3 Fatty Acids and Bile Acids 359
14.6.4 Volatile Fatty Acids 359
14.6.5 Electrolytes 359
14.6.6 Water, Sodium, and Chloride 359
14.6.7 Vitamins 360
14.7 Age-Related Effects on Gastrointestinal Function 360
14.7.1 Microflora 361
References 361
Further Reading 366

15. Poultry Bone Development and Bone Disorders

M. Pines and R. Reshef

15.1 Introduction 367
15.2 Bone Development 367
15.2.1 Somitogenesis and Sclerotome Formation 367
15.2.2 Signaling Molecules Influence Sclerotome Formation 368
15.2.3 Tissue Interactions and Gene Activity in Limb Development 368
15.2.4 Molecular Mechanisms Controlling Chondrogenesis 369
15.3 Bone Disorders 370
15.3.1 Inherited and Rare Bone Disorders 370
15.3.2 Bone Disorders of the Spine 370
15.3.3 Bone Disorders due to Mycoplasma Infection 371
15.3.4 Bacterial Chondronecrosis with Ostemyelitis—Femoral Head Necrosis 372
15.3.5 Angular Limb Deformities 372
15.3.6 Vitamin and Mineral Deficiencies 372
15.3.7 Tibial Dyschondroplasia 373
15.4 Conclusions 373
References 374

16. Skeletal Muscle

Sandra G. Velleman and Douglas C. McFarland

16.1 Introduction 379
16.2 Diversity of Avian Skeletal Muscle 379
16.3 Embryonic Origins of Skeletal Muscle 380
16.4 Postnatal or Posthatch Skeletal Muscle Development 381
16.5 Skeletal Muscle Growth 381
16.6 Skeletal Muscle Fiber Types 384
16.7 Muscle Structure and Contraction 384
16.8 Muscle Development: Function of Myogenic Regulatory Factors 386
16.9 Satellite Cell and Myoblast Heterogeneity 386
16.10 Maternal Inheritance and Growth Selection on Breast Muscle Morphology 387
16.11 Effect of Selection for Increased Growth Rate on Muscle Damage 389
16.12 Extracellular Matrix Regulation of Muscle Development and Growth 390
16.13 Regulation of Muscle Growth Properties by Cell-Membrane Associated Extracellular Matrix Macromolecules 395
16.14 Regulation of the Myogenic Regulatory Factors by the Extracellular Matrix 396
16.15 Novel Genes Involved in Avian Myogenesis 396
16.16 Summary 396
Acknowledgment 396
References 396

17. The Avian Immune System

Pete Kaiser and Adam Balic

17.1 Introduction **403**
17.2 The Organs and Cells of the Avian Immune Response **403**
17.2.1 Primary Lymphoid Tissues 403
17.2.2 Secondary Lymphoid Tissues 406
17.3 Regulation of the Immune Response **410**
17.3.1 Molecules and Cells of the Innate Immune Response 410
17.3.2 The Major Histocompatibility Complex 411
17.3.3 Cytokines and Chemokines 411
17.4 Summary and Conclusions **414**
References **415**

Part IV
Metabolism Theme

18. Carbohydrate Metabolism

Colin G. Scanes

18.1 Overview of Carbohydrate Metabolism in Birds **421**
18.2 Circulating Concentrations of Carbohydrates **421**
18.2.1 Introduction: Circulating Concentrations of Glucose across Avian Species 421
18.2.2 Domestication and Circulating Concentrations of Glucose 422
18.2.3 Fasting and Circulating Concentrations of Glucose 422
18.2.4 Influence of Feeding 423
18.2.5 Shifts in Circulating Concentration with Age, Reproductive State, and Migration 423
18.2.6 Shifts in Circulating Concentrations of Glucose due to Disease, Toxicants, and Husbandry Practices 425
18.2.7 Temperature and Circulating Concentrations of Glucose 425
18.3 Glucose Utilization **425**
18.3.1 Developmental Changes 425
18.3.2 Fasting and Glucose Utilization 425
18.4 Glucose Transport **426**
18.5 Intermediary Metabolism **428**
18.5.1 Glucose Phosphorylation and Dephosphorylation 428
18.5.2 Glycolysis 428
18.5.3 Citric Acid or Tricarboxylic Acid Cycle 429
18.6 Gluconeogenesis **430**
18.6.1 Gluconeogenesis and Fasting 430
18.6.2 Relative Importance of the Liver and the Kidney 431
18.7 Glycogen **431**
18.7.1 Overview 431
18.7.2 Synthesis and Breakdown 431
18.7.3 *In ovo* Feeding 433
18.7.4 Glycogen Body 433
18.8 Carbohydrate Digestion and Absorption **434**
18.8.1 Starch Digestion 434
18.8.2 Disaccharide Digestion 434
18.8.3 Glucose Absorption 434
18.8.4 Gastrointestinal Storage of Ingesta 435
18.8.5 Intestinal Fermentation 435
18.9 Conclusions **436**
18.9.1 In starvation and metabolism 437
References **437**

19. Adipose Tissue and Lipid Metabolism

Johan Buyse and Eddy Decuypere

Abbreviations **443**
19.1 Introduction **443**
19.2 Development of Adipose Tissue **443**
19.3 Adipocyte Proliferation and Differentiation **444**
19.4 Distribution of Body Fat **444**
19.5 Lipid Metabolism **445**
19.5.1 Lipoprotein Metabolism 445
19.5.2 Hormonal Control of Lipid Metabolism 446
19.6 Functions of Adipose Tissue **448**
19.7 Factors Affecting Fat Metabolism and Deposition **450**
19.8 Summary and Conclusions **451**
References **451**

20. Protein Metabolism

Colin G. Scanes

20.1 Introduction **455**
20.1.1 Protein Metabolism: Overview 455
20.1.2 Muscle 455
20.1.3 Feathers 456
20.2 Digestion of Proteins **456**
20.2.1 Protein Digestion in the Gizzard and Proventriculus 456

20.2.2 Protein Digestion in the Small Intestine 457
20.2.3 Amino Acid Absorption in the Small Intestine 457
20.2.4 Large Intestine and Protein Digestion 458
20.3 Protein Synthesis and Degradation 458
20.3.1 Whole-Body Synthesis and Degradation 458
20.3.2 Muscle Protein Synthesis and Degradation 458
20.3.3 Liver and Gastrointestinal Tract 461
20.3.4 Protein Metabolism in Immune Tissues 462
20.3.5 Proteins and Reproduction 462
20.4 Amino Acids and Metabolism 463
20.4.1 Amino Acid Transfer into Muscle and Other Cells 463
20.4.2 Nitrogenous Waste 463
20.4.3 Amino Acids as Energy Sources 464
20.4.4 Amino Acid Derivatives 464
20.5 Extranutritional Effects of Amino Acids 465
20.5.1 Amino Acids in the Control of Metabolism 465
References 465

21. Food Intake Regulation

D. Michael Denbow and Mark A. Cline

21.1 Introduction 469
21.2 Peripheral Regulation of Food Intake 469
21.3 CNS Control of Food Intake 470
21.4 Classical Neurotransmitters 470
21.5 Peptides 472
21.5.1 Neuropeptide Y 472
21.5.2 Melanocortins 475
21.5.3 Corticotrophin-Releasing Hormone 476
21.5.4 Obestatin 476
21.5.5 AMP-Activated Protein Kinase 476
21.5.6 Opioids 476
21.5.7 FMRFamides 477
21.5.8 Galanin 477
21.5.9 Visfatin 477
21.5.10 Somatostatin 478
21.5.11 Cannabinoids 478
21.5.12 Glucagon-like Peptide 478
21.5.13 Cholecystokinin 478
21.5.14 Glucagon Superfamily 478
21.5.15 Insulin 479
21.5.16 Bombesin 479
21.6 Selection for Body Weight Alters Food Intake Control Mechanisms 479
21.7 Differences between Birds and Mammals 480
References 480
Further Reading 485

Part V
Endocrine Theme

22. Avian Endocrine System

Colin G. Scanes

22.1 Introduction 489
22.2 Avian Phylogeny 489
22.3 Peptides and Other Chemical Messengers Controlling Physiology 490
22.4 Chemical Messengers Found in Birds but Not Mammals 490
22.5 Hormones Produced by Nontraditional Endocrine Organs 490
22.5.1 Adiponectin 490
22.6 Unique Aspects of Birds 490
22.6.1 Song 490
22.6.2 Salt Glands 490
22.6.3 Unique Aspects of Metabolism 494
22.6.4 Reproduction 494
22.6.5 Opportunities for Transgenic Poultry 495
22.7 The Enigma of Leptin 495

23. Pituitary Gland

Colin G. Scanes

23.1 Introduction 497
23.2 Anatomy of the Hypothalamic–Hypophyseal Complex 497
23.2.1 The Anterior Pituitary Gland or Pars Distalis 497
23.2.2 Pars Tuberalis 498
23.2.3 Posterior Pituitary Gland or Pars Nervosa 498
23.3 Gonadotropins 500
23.3.1 Structure 500
23.3.2 Action of Gonadotropins 500
23.3.3 Control of Gonadotropin Release 501
23.3.4 Control of Expression of Gonadotropin Subunits 504
23.3.5 Pituitary Origin of Gonadotropins 505
23.3.6 Ontogeny of Gonadotropins 505

23.4 Thyrotropin 505
23.4.1 Structure 505
23.4.2 Actions of TSH 505
23.4.3 Control of Thyrotropin Release 505
23.4.4 Control of TSH β-Subunit Expression (in the Pars Distalis) 506
23.4.5 Origin of Thyrotropin 506
23.4.6 Ontogeny of Thyrotropin 506
23.5 Growth Hormone 507
23.5.1 Chemistry 507
23.5.2 Growth Hormone Variants 507
23.5.3 Actions of Growth Hormone 507
23.5.4 Control of GH Secretion 508
23.5.5 GH Gene and Control of GH Expression 510
23.5.6 Pituitary Origin of Growth Hormone 510
23.5.7 Extrapituitary Production of GH 510
23.5.8 Ontogeny of GH 511
23.6 Prolactin 511
23.6.1 Chemistry 511
23.6.2 Variants 511
23.6.3 Actions of PRL 511
23.6.4 Control of PRL Release 512
23.6.5 PRL Expression 513
23.6.6 Origin of PRL 514
23.6.7 Extrapituitary Production of Prolactin 514
23.6.8 Ontogeny of PRL 514
23.7 Adrenocorticotropic Hormone 514
23.7.1 Chemistry of ACTH and Other POMC-Derived Peptides 514
23.7.2 Actions of ACTH 514
23.7.3 Control of ACTH Release 515
23.7.4 Control of POMC Expression 515
23.7.5 Origin of ACTH 515
23.7.6 Extrapituitary Production 516
23.7.7 Ontogeny of ACTH 516
23.8 Other Anterior Pituitary Peptides 516
23.8.1 Adiponectin 516
23.8.2 Calcitonin 516
23.8.3 Chromogranin A 516
23.8.4 Glucagon Receptor 516
23.8.5 Ovoinhibitor 516
23.8.6 Parathyroid-Related Peptide 516
23.8.7 Peptides 517
23.8.8 Steroidogenic Enzymes 517
23.9 Functioning of the Pars Tuberalis 517
23.9.1 Pars Tuberalis and Photoperiodism 517
23.9.2 Pineal Effects on the Pars Tuberalis 517
23.9.3 Circadian Rhythms and the Pars Tuberalis 517
23.10 Neurohypophysis 517
23.10.1 Introduction 517
23.10.2 Actions of AVT 518
23.10.3 Actions of MT 518
23.10.4 Behavioral Effects of Mesotocin and AVT 519
23.10.5 Control of AVT and MT Release 519
23.10.6 AVT and MT Expression 519

24. Thyroids

F.M. Anne McNabb and Veerle M. Darras

24.1 Anatomy, Embryology, and Histology of Thyroid Glands 535
24.2 Thyroid Hormones 535
24.2.1 Synthesis, Release, and Circulating Concentrations of Thyroid Hormones 535
24.2.2 Mechanism of Action of Thyroid Hormones 537
24.2.3 Cellular Uptake of Thyroid Hormones 538
24.2.4 Thyroid Hormone Activation and Degradation 539
24.3 Hypothalamic–Pituitary–Thyroid Axis 539
24.4 Effects of Thyroid Hormones 540
24.4.1 Thyroid Hormone Effects on Development 540
24.4.2 Thyroid Hormone Effects on Metabolism and Thermoregulation 541
24.4.3 Thyroid Hormone Effects on Reproduction and Maternal Influences on Developing Young 541
24.5 Thyroid Interactions with Other Hormones 542
24.6 Environmental Influences on Thyroid Function 543
24.7 Conclusions and Summary 544
References 544

25. The Role of Hormones in the Regulation of Bone Turnover and Eggshell Calcification

Christopher G. Dacke, Toshie Sugiyama and Carol V. Gay

Abbreviations 549
25.1 Introduction 549
25.2 Evolutionary Aspects of Egglay and Medullary Bone 550
25.2.1 Egglay and Evolution of Calcium Reservoirs 550

25.2.2 Evolution of Medullary Bone 551
25.2.3 Bone Formation and Resorption during the Egg-Laying Cycle 551
25.2.4 Specific Calcium Metabolism for Eggshell Formation 553
25.3 Chemistry and Secretion of Calcium-Regulating Hormones 554
25.3.1 Parathyroid Hormone and Related Peptides 554
25.3.2 Calcitonin and Related Peptides 556
25.3.3 The Vitamin D System 556
25.4 Actions of Parathyroid Hormone, Calcitonin, and Vitamin D on Target Organs 558
25.4.1 Actions on Skeleton (Bone and Cartilage) 558
25.4.2 Renal Actions 563
25.4.3 Actions on Intestine and Oviduct 564
25.4.4 Actions on Smooth Muscle 565
25.5 Parathyroid Hormone Related Peptides 565
25.6 Calcitonin Gene-Related Peptide and Amylin 566
25.7 Prostaglandins and Other Factors 567
25.8 Conclusions 568

26. Adrenals

Rocco V. Carsia

26.1 Anatomy 577
26.1.1 Gross Anatomy, Blood Supply, and Innervation 577
26.1.2 Microanatomy 577
26.2 Adrenocortical Hormones 582
26.2.1 Corticosteroid Secretory Products 582
26.2.2 Other Secretory Products 583
26.2.3 Synthesis and Intraadrenal Degradation of Corticosteroids 583
26.2.4 Transport of Corticosteroids 586
26.2.5 Circulating Concentrations of Corticosterone and Aldosterone 587
26.2.6 Secretion, Clearance, and Metabolism of Corticosterone and Aldosterone 587
26.2.7 General Regulation of Adrenocortical Function 589
26.2.8 Regulation of Aldosterone Secretion 591
26.2.9 Overview of the HPA Axis 593
26.2.10 Adrenocortical Function in Development, Maturation, and Senescence 594
26.3 Physiology of Adrenocortical Hormones 595
26.3.1 Corticosteroid Receptors and Their Action in Target Cells 595
26.3.2 Corticosteroids and Intermediary Metabolism 597
26.3.3 Corticosteroids and Electrolyte Balance 598
26.3.4 Corticosteroids and Immune Function 599
26.3.5 Corticosteroids and Behavior 599
26.4 Adrenal Chromaffin Tissue Hormones 600
26.4.1 Catecholamine Synthesis and Secretion 600
26.4.2 Circulating Catecholamines and Stress Response 600
26.4.3 Some Physiological Actions of Norepinephrine and Epinephrine 601
26.4.4 Changes in Development, Maturation, and Senescence 602
Acknowledgments 602

27. Endocrine Pancreas

Joëlle Dupont, Nicole Rideau and Jean Simon

27.1 Introduction 613
27.2 Pancreas Embryogenesis and Development 614
27.2.1 Morphology of Avian Pancreas 614
27.2.2 Distribution of Avian Pancreatic Endocrine Cells between the Different Pancreatic Lobes 614
27.2.3 Development of Avian Pancreas 615
27.3 Insulin and Glucagon Peptides 615
27.3.1 Insulin and Pre-pro-insulin, Pro-insulin, and C-Peptides 615
27.3.2 Glucagon and Glucagon-like Peptides 617
27.4 Insulin and Glucagon Release 618
27.4.1 Pancreatic Hormone Levels During Development and After Hatching 618
27.4.2 Insulin Release 618
27.4.3 Glucagon Release 619
27.4.4 Somatostatin 619
27.4.5 Avian Pancreatic Polypeptide 620
27.5 Glucagon and Insulin Receptors 620
27.5.1 Glucagon Receptors 620
27.5.2 Insulin Receptor 621
27.6 General Effects of Glucagon and Insulin 624
27.6.1 Insulin and Embryonic or Posthatch Development 624
27.6.2 Insulin–Glucagon and Food Intake 625

27.6.3 Insulin and the Endocrine System 625
27.6.4 Insulin and Glucose Metabolism 625
27.6.5 Insulin–Glucagon and Lipid Metabolism 626
27.6.6 Insulin and Protein Metabolism 626
27.6.7 Insulin and Gene Expression 627
27.7 Experimental or Genetical Models 627
27.8 Summary and Conclusion 627

Part VI
Reproductive Theme

28. Reproduction in the Female

Alan L. Johnson

28.1 Introduction 635
28.2 Development and Function of the Female Reproductive System 635
28.2.1 Late-Embryonic and Posthatch Ovary 636
28.2.2 Sexually Mature Ovary 637
28.2.3 Follicle Selection and Establishment of the Preovulatory Hierarchy 639
28.2.4 Follicle Atresia 640
28.2.5 Ovulation and Postovulatory Follicles 640
28.2.6 Domesticated Hen Ovary as a Model for Human Ovarian Cancer 641
28.2.7 Reproductive Tract and Sperm Storage Glands 641
28.3 Ovarian Hormones 643
28.3.1 Embryo and Posthatch Ovary 643
28.3.2 Mature Ovary 643
28.4 Endocrine and Physiologic Factors Affecting Ovulation and Oviposition 646
28.4.1 Ovulation 646
28.4.2 Oviposition 648
28.5 Reproductive Seasonality, Breeding, and Ovulation–Oviposition Cycles 648
28.5.1 Ovulation–Oviposition Cycle and Rate of Lay 649
28.5.2 Parthenogenesis 650
28.5.3 Maternal and Environmental Effects on the Embryo 651
28.5.4 Photorefractoriness, Broodiness, Molt, and Reproductive Senescence 651
28.6 Composition and Formation of the Yolk, Albumen, Organic Matrix, and Shell 653
28.6.1 Yolk 653
28.6.2 Albumen 653
28.6.3 Organic Matrix 654
28.6.4 Layers of Crystallization 655
28.6.5 Calcium Availability 656

29. Reproduction in Male Birds

Jorge Vizcarra, Rebecca Alan and John Kirby

29.1 Introduction 667
29.2 Reproductive Tract Anatomy 667
29.2.1 Testis 667
29.2.2 Excurrent Ducts 669
29.2.3 Accessory Organs 670
29.3 Ontogeny of the Reproductive Tract 671
29.3.1 Overview 671
29.3.2 Formation of the Undifferentiated Gonad 672
29.3.3 Gonadal Differentiation and Müllerian Duct Regression 673
29.3.4 Formation of the Excurrent Ducts 673
29.4 Development and Growth of the Testis 674
29.4.1 Proliferation of Somatic and Stem Cells in the Testis 674
29.4.2 Differentiation of Somatic Cells within the Testis 674
29.4.3 Initiation of Meiosis 676
29.4.4 Altering the Pattern of Testis Growth and Maturation 676
29.5 Hormonal Control of Testicular Function 676
29.5.1 Central Control of Testicular Function 676
29.5.2 Control of Adenohypophyseal Function in Males 677
29.5.3 Effects of Gonadotropins on Testicular Function 681
29.6 Spermatogenesis and Extragonadal Sperm Maturation 681
29.6.1 Spermatogenesis 681
29.6.2 Extragonadal Sperm Transport and Maturation 683
29.7 Seasonal Gonadal Recrudescence and Regression 686
29.7.1 Photoperiodic Control of Gonadal Regression and Recrudescence 686
29.7.2 Other Factors Affecting Gonadal Maturation and Regression 686

Index 1003

Preface

The new edition is staying true to the vision of Paul Sturkie with the two foci of avian physiology—domesticated birds (mainly chickens) and wild birds. The volume has a cohort of returning authors who have extensively revised their chapters. In addition, there are multiple new chapters and new authors. Some of the more recent research approaches (e.g., genomics, transcriptomics, and proteomics) are covered in the initial chapters. Moreover, new chapters address recent work including the control of feed intake, endocrine disruptors, the metabolic challenges of migration together with magnetoreception, and other senses in birds. The volume also returns to its roots in earlier editions with chapters on blood, as well as carbohydrate, lipid, and protein metabolism.

The professionalism and support of Pat Gonzalez at Elsevier are gratefully acknowledged.

Chapter 1

Avian Genomics

Jerry B. Dodgson
Department of Microbiology and Molecular Genetics, Michigan State University, East Lansing, MI, USA

1.1 INTRODUCTION

The fifth edition of *Sturkie's* contained neither an avian genomics chapter, nor any of the subsequent three chapters in this edition. Their inclusion here reflects the fact that all aspects of physiology have become intertwined with our understanding of genes and genomes. The early history of this transition is discussed elsewhere (Siegel et al., 2006), but the keystone event was the sequencing of the chicken genome (International Chicken Genome Sequencing Consortium, 2004). Soon, we will have genome sequences for thousands of avian species (Genome 10K Community of Scientists, 2009), but the fundamental challenge will remain: learning how to read the fascinating stories of avian physiological adaptations and evolution from a long string of a billion or so A, T, G, and C nucleotides per bird.

1.2 GENOME SIZE

Haploid avian genomes are generally the smallest among amniotes (www.genomesize.com), averaging 1.35 Gb (billion base pairs). A narrow range separates the smallest (black-chinned hummingbird, 0.9 Gb) and largest (ostrich, 2.1 Gb) species. Their compactness reflects the low frequency of repetitive elements that derive from transposons and their descendent sequences (International Chicken Genome Sequencing Consortium, 2004). Avian genome size correlates with physiological measures, such as with red cell size and (inversely) with metabolic rate (Gregory, 2002). It was proposed that small genomes were selected during the evolution of flight (Hughes and Hughes, 1995). However, Organ et al. (2007) suggested that contraction in genome size preceded the acquisition of flight, and nonadaptive and neutral explanations for small bird genomes also have support (Lynch and Conery, 2003; Nam and Ellegren, 2012).

1.3 CHROMOSOMES

1.3.1 Karyotypes

Avian karyotypes have been unusually stable during evolution (Burt et al., 1999; Ellegren, 2010). The ancestral avian karyotype is predicted to have $2n = 80$ chromosomes, with the only subsequent change in chicken ($2n = 78$) being a fusion between ancestral chromosomes 4 and 10 (Shibusawa et al., 2004; Griffin et al., 2007). However, there are exceptions, with avian chromosome numbers ranging from 40 to 126 (Griffin et al., 2007). A particular feature of avian karyotypes is that most species have numerous "microchromosomes", a trait they share with some, but not all, nonavian reptiles (Janes et al., 2010). The definition of a microchromosome is somewhat arbitrary (Masabanda et al., 2004), but, generally, microchromosomes are too small to discriminate by size in standard karyotypes.

In those birds with fewer chromosomes (falcons, Nishida et al., 2008; hawks and eagles, de Oliveira et al., 2005; stone curlew, Nie et al., 2009), some, but not all, microchromosomes have fused to ancestral macrochromosomes or to each other. It remains difficult to determine orthologous relationships because sequences derived from one species' microchromosomes often fail to hybridize to those of another species (e.g., Nie et al., 2009), suggestive of high content of rapidly evolving repetitive DNA. However, in general, translocations appear to have been very rare during avian evolution (Griffin et al., 2007), in comparison to the somewhat more common frequency of chromosome inversions (Warren et al., 2010; Zhang et al., 2011; Skinner and Griffin, 2012). Interestingly, in turkeys there appears to be a predominance of acrocentric (centromere at or near one telomere) chromosomes (Zhang et al., 2011), whereas in falcons and hawks the trend is towards metacentric (centromere near the middle) chromosomes (Nishida et al., 2008).

1.3.2 Sex Chromosomes

Another characteristic that all birds share with some non-avian reptiles is the use of a ZW sex chromosome arrangement in which males are homogametic (ZZ) and females are heterogametic (ZW). However, sex determination has evolved independently several times within the vertebrates, although common genes or a common set of autosomes may be reused (Marshall Graves and Peichel, 2010; Ellegren, 2010). The ratite W is minimally diverged from the Z (and presumably the ancestral autosome), whereas in other birds, W is smaller, gene-poor, and repeat rich (Marshall Graves and Shetty, 2001). The Z-specific gene, *DMRT1*, appears to play a major role in masculinization (Smith et al., 2009), although it appears that both cell autonomous and hormonal sex determination pathways exist, with the interplay between the two yet to be fully elucidated (Zhao et al., 2010). Further aspects of sexual differentiation are discussed in later chapters.

1.3.3 Telomeres and Centromeres

Birds share the canonical TTAGGG telomere repeat with all other vertebrates. However, chickens, turkeys, and other birds possess variable numbers of unusually large telomere repeat blocks, even up to 3–4 Mb (million base pairs) in length (Delany et al., 2000; O'Hare and Delany, 2009). Although the purpose of these mega-telomeres remains unknown, they map preferentially, but not obligatorily, to specific chromosomes (Delany et al., 2007; O'Hare and Delany, 2009). Chicken centromeres also merit special mention. Although most contain typical long (>100 kb pairs) arrays of chromosome-specific simple repeats, the centromeres of GGA5, GGA27, and GGAZ are remarkably short (~30 kb) and lack the usual repeat structure (Shang et al., 2010). Being able to clone and manipulate these centromeres by homologous recombination (Shang et al., 2013) promises to make the chicken the primary model system for the study of vertebrate centromeres. A final point is that the zebra finch and probably other birds possess a germline restricted chromosome, with a function that remains obscure (Itoh et al., 2009).

1.4 GENOME SEQUENCES

1.4.1 Approach

All bird genomes sequenced to date have employed a whole genome shotgun method, in which overlaps between millions of random reads are used to assemble contiguous blocks of sequence (i.e., contigs) along the genome. Due to their relatively low repeat content, avian genomes are ideal for shotgun sequencing. Contigs are then assembled into scaffolds (i.e., aligned groups of contigs containing size-calibrated gaps), using mate-pair reads in which both ends are sequenced from DNA fragments within a selected size range. Even for genomes with deep coverage, this generates hundreds to thousands of scaffolds that, ideally, are ordered and aligned using physical (based on mapping of recombinant clones in bacterial artificial chromosome (BAC) vectors) and/or linkage maps (Table 1.1).

The chicken (International Chicken Genome Sequencing Consortium, 2004) and zebra finch (Warren et al., 2010) were sequenced by the Sanger method, in which reads are derived one-by-one from recombinant clone libraries. This currently remains the gold standard for genome sequencing but no longer is cost-effective with the advent of next-generation sequencing (NGS) methods, which directly sequence collections of (uncloned) DNA fragments in a multiparallel manner. NGS read lengths often are shorter and sometimes more error-prone than Sanger reads, but NGS compensates by much higher coverage, such that the consensus sequence is at least as accurate. Various NGS methods have been developed (Metzker, 2010). The first avian genome to be sequenced via NGS was that of the turkey (Table 1.1), and we can anticipate an onslaught of new bird genomes soon (Genome 10K Community of Scientists, 2009).

1.4.2 Coverage

Most current avian genome sequence assemblies contain about 90–95% of their respective euchromatic genomes (typically 1.1–1.2 Gb; Table 1.1). Coverage is usually estimated by the fraction of different mRNA transcripts that can be found within the assembly. Highly repetitive heterochromatic sequences, especially when repeated in tandem, are nearly impossible to assemble and are missing from all vertebrate genomes, but these contain few genes. For example, centromeres (however, see Shang et al., 2010), telomeres, and rDNA (tandem repeats that encode ribosomal RNA, on GGA16) are generally missing altogether or shown as gaps, and very little of the repeat-rich/gene-poor W chromosome is usually assembled. Sequence scaffolds are ordered and aligned along chromosomes for birds that have dense linkage maps and/or BAC contig physical maps, sometimes assuming a common local order with closely related genomes (comparative maps); however, most NGS-derived avian genomes currently are unordered (Table 1.1). Sequence scaffolds that cannot be placed are arbitrarily clustered on chrUn (chromosome unknown) or, for example, chr1_random if the chromosome but not the location is known, or simply provided as a list of unplaced scaffolds. Even for the chicken, it has been impossible to align sequence scaffolds with specific smaller microchromosomes (GGA29–31, GGA33–38, and most of GGA16 and 32), so any such sequence is on chrUn. In part, this is due to a paucity of aligning markers; however, more generally, microchromosomal DNA is poorly represented in sequence reads. The reasons remain unclear, but they likely relate to microchromosomes being rich in

[1]Whole Genome Shotgun (WGS) project numbers and assembly names and dates from National Center for Biotechnology Information (NCBI) Assembly (http://www.ncbi.nlm.nih.gov/assembly, accessed May 14, 2013). The most recent builds and dates are listed. In some cases, these are more recent updates of those described in references. References are listed for those assemblies not curated in NCBI Assembly.
[2]Initial method employed (see Metzker, 2010), although supplemented later by alternative approaches in some cases.
[3]Sequenced base total generally includes gaps within scaffolds. Aligned to chromosome indicates whether scaffolds were ordered and aligned to chromosomes, typically using linkage maps (all indicated), bacterial artificial chromosome contig physical maps (chicken, turkey, zebra finch), comparative maps (turkey, flycatcher, duck), and/or radiation hybrid maps (chicken).
[4]N50 is the size of a scaffold or contig such that half the sequenced genome is contained in scaffolds or contigs that size or larger.
[5]Approximate genome coverage estimates are calculated relative to the euchromatic genome. NR=not reported. Falcon coverage shown is likely an overestimate (see text).

repetitive sequences and high in GC content. It was initially thought that this made microchromosomal DNA refractile to recombinant DNA cloning (and, indeed, it is rare in clone libraries), but these reads remain underrepresented even in uncloned NGS sequences. The smallest chicken chromosome with reasonable sequence representation is GGA25 (~2.2 Mb), but the sequence assembly is problematic for this and at least two other small chromosomes (GGA28, Gordon et al., 2007; GGA16, Shiina et al., 2007), in part due to repeated sequences. Even though they may be rich in repeats, for the most part, microchromosomes are also gene-rich (International Chicken Genome Sequencing Consortium, 2004), although one cannot be certain about GGA29–38. It seems likely that much of the missing 5–10% of current assemblies (Table 1.1) lies on microchromosomes and W chromosomes. (Falcon assemblies claim 97–99% coverage (Zhan et al., 2013), but this probably is not due to the fact that these genomes contain fewer microchromosomes, but rather because the authors measured coverage by the frequency with which cloned sequences are found, so their test set is biased away from microchromosomes.)

1.5 ANNOTATION

Much of the value of the reference genome sequence depends on annotation (Yandell and Ence, 2012), which links the DNA sequence to all the information available on component genes, mRNAs, proteins, etc. Once the genome is sequenced, there are two broad classes of annotation: (1) evidenced-based, which uses RNA or proteomic data (see Chapters 3 and 4), as well as homology to genes in other species; and (2) ab initio annotation, employing computer searches for open reading frames, likely initiation and stop codons, splice junctions, and other sequence-based characteristics to predict the existence of genes for which experimental evidence is lacking. Transposable elements are annotated based on their repetition in the genome, relatedness to transposons in other species, and their characteristic end structures (Jurka et al., 2005). Annotating regulatory sequences (such as transcription factor binding sites) is more problematic; it also relies on both comparisons to other genomes and evidence from genome-wide DNA methylation and chromatin immunoprecipitation (ChIP) analyses (see Chapter 2). This is exemplified by the human ENCODE project (The ENCODE Project Consortium, 2012), but it will be some time before that level of data is available for any bird. Much of the annotation of avian genome sequences has relied on comparisons to other genomes and has not been manually curated. Thus, the annotations are frequently inaccurate, especially for those genes and other elements whose functions are lineage-specific (i.e., only found in a given species or only in birds). Thus, one should be hesitant to accept conclusions based solely on computer analysis of avian genome sequences in their current state.

1.6 GENOME BROWSERS

Most of the user community depends on one or more genome browsers to utilize sequence data. There are three major browsers: University of California at Santa Cruz (UCSC) Genome Bioinformatics (www.genome.ucsc.edu), Ensembl (www.ensembl.org), and the National Center for Biotechnology Information (NCBI) Map Viewer (www.ncbi.nlm.nih.gov/genome); there are also avian-focused sites such as Avian Genomes (aviangenomes.org) and Bird Base (birdbase.arizona.edu/birdbase). The browsers all employ the same reference sequence information as a series of chromosomes, scaffolds, or both. Any property that is sequence-specific (genes, ChIP binding sites, RNA sequences, homology with other sequences, etc.) can be displayed as a track on the genome (Figure 1.1). Genome browsers are only as good as the underlying sequence assembly and annotation. Not all avian genomes are available at every browser site, and not all annotation tracks are available for each build (i.e., updated assemblies based on new data). The various options are in constant flux.

1.7 GENES

All bird genomes evolved via two whole genome duplication events that preceded the ancestral vertebrate genome (Van de Peer et al., 2009). A commonly cited outcome are the four clusters of *HOX* homeobox developmental transcription factor genes found in most vertebrates (e.g., chicken *HOXA* cluster on GGA2; *HOXB* on GGA27, Figure 1.1; *HOXD* on GGA7; and *HOXC* on chrUn, probably on a microchromosome). In most instances, one or more of the potential four ancestral genes or clusters has been lost during subsequent evolution or, as in the case of the *HOX* clusters, has diverged to perform different functions, thereby providing a selective force leading to its retention. Another major force in gene evolution has been the (usually local) expansion and contraction of gene families. For example, the γ-c clade of olfactory receptor genes (always among the most rapidly diverging gene families) is highly expanded in the chicken and zebra finch, but falcon genomes have only one or two copies (Zhan et al., 2013).

Depending on the methods employed and the available evidence, avian genomes are estimated to contain 15–20,000 protein-coding genes, but keep in mind that each gene locus may generate multiple transcripts and proteins due to alternative splicing, transcriptional start sites, and polyadenylation sites. This number may end up being slightly low once additional transcriptome and proteome data accumulate (Chapters 3 and 4). There is some evidence of a greater rate of gene loss versus gene gain during avian evolution (International Chicken Genome Sequencing Consortium, 2004), but this must be viewed cautiously, given the less fully annotated state of bird genomes. The most reliably identified genes are

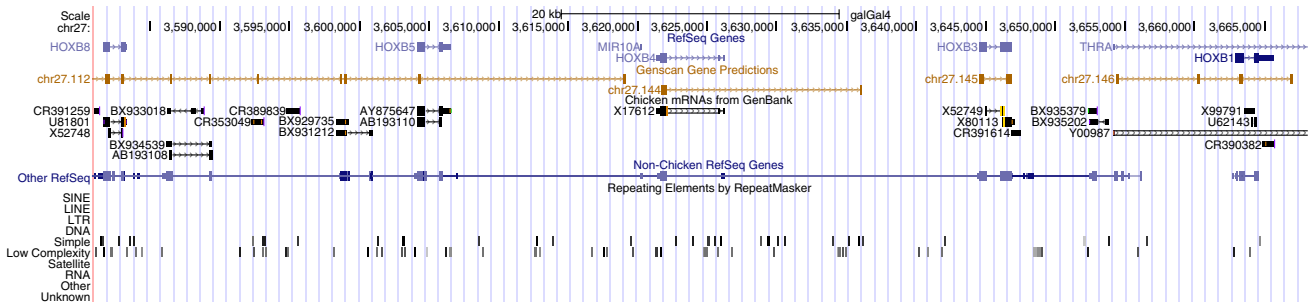

FIGURE 1.1 UCSC genome browser view of the chicken *HOXB* cluster on GGA27. Sequence coordinates chr27:3,581,000–3,668,000 (shown at top) from the November 2011 International Chicken Genome Sequencing Consortium Gallus_gallus-4.0 assembly are shown. In descending order, tracks are appended for the following: (1) RefSeq genes (blue): five *HOXB* genes, a microRNA *MIR10A* locus, and part of the overlapping *THRA* gene; (2) Genscan ab initio gene models (light brown, note numerous incorrect exons); (3) sequences mapping to chicken mRNAs (black); (4) homology to RefSeq genes from other species (blue); and (5) repeated sequences (gray-black boxes) of classes designated at left (interestingly, long interspersed nuclear transposable elements, which are common in most of the genome, are absent here). In the first three tracks, exons are shown as filled boxes with coding regions thicker than untranslated regions, and introns are depicted as narrow lines with arrowheads in the direction of transcription. Chicken mRNAs are complementary DNA clone sequences estimated to be full length, but often (as shown) they are not, and those lacking introns should be considered as likely artifacts (genomic DNA fragments contaminating mRNA). This view was generated with the following track settings: Base Position and RepeatMasker set to full; RefSeq Genes, Genscan Genes, and Chicken mRNAs set to pack; Other RefSeq genes set to dense; and all other tracks set to hide. Although only five *HOXB* genes are shown as RefSeq annotated, using the chicken mRNAs (BX931212, BX934539, BX935202) and homology to Other RefSeq genes (shown only in dense mode here for sake of scale) and expanding the initial coordinate to chr27:3,530,000 also reveals homologues to *HOXB2, HOXB6, HOXB7, HOXB9* and *HOXB13*. The UCSC Genome Browser Gateway at http://genome.ucsc.edu was accessed on May 28, 2013 (Kent et al., 2002).

the RefSeq (http://www.ncbi.nlm.nih.gov/projects/RefSeq/) genes that have been manually annotated, but the RefSeq set is conservative (low false-positive rate and higher false-negative rate). For example, only five of at least 10 likely *HOXB* genes are official chicken RefSeq genes (Figure 1.1). However, by using mRNA information and sequence homology to genes and/or proteins in other species, it often is straightforward to identify a gene of interest, even when it is not a RefSeq gene. This is particularly critical for birds other than chickens, whose genomes are less well annotated.

1.8 TRANSPOSONS

As noted previously, avian genomes contain comparatively low levels of transposable element-derived repeats (less than 10% of the assembled sequence), although these numbers also can diverge widely depending on the estimation methods employed (compare Zhan et al., 2013 to Warren et al., 2010; Dalloul et al., 2010 for chicken, zebra finch, and turkey). The predominant avian transposon is the chicken repeat 1 long interspersed nuclear transposable element, although it appears these comprise a smaller portion of passerine genomes (Warren et al., 2010; Ellegren et al., 2012), and the zebra finch genome is comparatively rich in long terminal repeat transposons. Short interspersed nuclear element (SINE) transposons are extremely rare (less than 0.1% of all avian genome sequences), suggesting that the ability to transpose SINEs died out long ago (International Chicken Genome Sequencing Consortium, 2004). DNA transposons constitute close to 1% of the turkey and chicken genomes but appear quite rarely in other avians. For most of these transposon families, there appear to be few, if any, copies that are still active (Wicker et al., 2005), with the caveat that ~5–10% of the genome remains missing, especially in repeat-rich regions. Overall, it appears that transposon copies are being deleted 3–5 times faster than new ones are being created in avian evolution (Nam and Ellegren, 2012).

1.9 GENOME DIVERSITY

1.9.1 SNP Discovery

At least for chickens and turkeys, genome maps, especially linkage maps, predated the genome sequence (Siegel et al., 2006) and were important complements in aligning sequence scaffolds to chromosomes. However, NGS allows one to sequence a genome first and then use that sequence for high-resolution mapping, both to improve the assembly and to locate trait-encoding loci. Sequencing provides the critical component for linkage analysis: DNA polymorphisms, mostly single-nucleotide polymorphisms (SNPs) and copy number variations. Polymorphism is an enemy of accurate reference genome assembly, so the ideal is to sequence a single (preferentially inbred and genetically monomorphic) individual. This was feasible for chickens, but parallel sample sequencing of three other chickens generated nearly 3 million SNPs, which provided the initial basis for high-density genotyping (International Chicken Polymorphism Map Consortium, 2004). For most other birds, the sequenced individual was, at best, only slightly inbred, thus immediately providing extensive SNP variation between the two copies of each chromosome (usually a ZZ male was sequenced). Additional SNPs can be obtained by NGS sequencing of other individuals (resequencing) or by NGS RNA sequencing (RNA-seq).

1.9.2 SNP Diversity

Avian genomes exhibit high levels of diversity with typical average pairwise heterozygosity rates (π) of 2–10 SNPs per kilobase (International Chicken Polymorphism Map Consortium, 2004; Balakrishnan and Edwards, 2009; Ellegren et al., 2012; Shapiro et al., 2013). These considerably exceed the rate in humans (except for falcons; Zhan et al., 2013), which is presumably a reflection of larger effective population sizes during the evolution of the respective birds. NCBI dbSNP (www.ncbi.nlm.nih.gov/snp) currently lists over 9.4 million reference chicken SNPs. Although commercial breeding has reduced SNP numbers in chickens (Muir et al., 2008), both broilers and (to a lesser extent) layers retain relatively high genetic diversity. This explains why commercial breeders continue to make progress in enhancing economically desirable traits even after 50 years of intense selection; it also testifies to their ability to avoid excessive inbreeding. It should be noted that large populations have not been deeply sequenced from any bird, so the above discussion considers relatively common (and therefore ancient, having had time to spread through the population) SNPs. Indeed, given the enormous worldwide numbers of commercial chickens, one expects that extremely rare SNPs exist at nearly every base pair, but these have extremely low likelihoods of long-term persistence.

1.9.3 Recombination

High-density SNP genotyping arrays have been developed for chickens (Kranis et al., 2013), which allow for both linkage mapping and association analysis. The former relies on meiotic recombination in genotyped family pedigrees, whereas the latter relies on historical linkage disequilibrium (LD, the nonrandom correlation in the co-segregation or association of linked alleles) within a broader population. The greater the local recombination rate, the lower the level of LD, so high recombination rates increase map resolution but require denser marker panels. The chicken genome exhibits a high average recombination rate per Mb of DNA compared to mammals (International Chicken Genome Sequencing Consortium, 2004), along with much greater variation in that rate between chromosomes. This is to be expected, given that proper segregation of microchromosomes should require at least one crossover per meiosis, therefore making them >50 cM. Thus, a 4 Mb microchromosome (e.g., GGA22) should average >12.5 cM/Mb, which is more than 10 times the typical mammalian rate. This should allow for higher resolution in mapping the microchromosomes (which is good because they typically are gene rich), but they need to be much more densely sampled in genotyping panels. The same trend occurs in the zebra finch (and presumably most, if not all, birds), but, interestingly, recombination along the length of individual chromosomes is more variable (Backström et al., 2010). Although there is a clear tendency for higher crossover density within 10 Mb of a chicken telomere, this is much more dramatic in zebra finch (the difference can only be observed on macrochromosomes >20 Mb). As a result, LD should be much greater near the center of larger zebra finch chromosomes, making identification of the specific genes/alleles involved in traits more difficult. (See Ellegren, 2005 and Backström et al., 2010 for more discussion of recombination effects on avian genomes.)

1.10 CONNECTING SEQUENCE TO PHENOTYPE

1.10.1 Avian-Specific Genes

Beyond generating lists of SNPs, genes, transcripts, noncoding RNAs, etc., a major goal for sequence analysis is to increase the understanding of avian phenotypes. For agricultural species, traits that have economic impact tend to receive the greatest attention, and many of these trait alleles have been selected in the last 6000 years since domestication or during commercial breeding. For wild birds, ecological and evolutionary questions predominate, and some of the traits of interest date back millions of years to the time of speciation (Ellegren et al., 2012).

In general, little is known about what genes or alleles make avian physiology unique. As noted above, it is much more difficult to annotate and identify functions for lineage-specific genes/alleles unique to birds. It is known that birds have greatly expanded their repertoire of keratin genes (feather, scale, and claw keratins), and, of course, they retain genes used in egg production in common with most nonavian reptiles (International Chicken Genome Sequencing Consortium, 2004; Warren et al., 2010), but there is obviously much more to learn. In addition to the presence or absence of certain genes, conclusions are also derived from rates of gene evolution, often by comparing the rates of amino acid altering nucleotide substitutions to synonymous changes (K_A/K_S ratios). High ratios suggest positive/diversifying selection of derived alleles that enhance fitness, whereas low ratios imply negative/purifying selection that eliminates diverse alleles in evolutionarily conserved genes. For example, Warren et al. (2010) found evidence for positive selection within zebra finch genes that exhibit differential expression in the auditory forebrain, suggesting a possible role in the evolution of singing behavior. Similar evidence of positive selection (as well as gene duplication) identified candidate genes involved in beak morphology in both Darwin's finches (Rands et al., 2013) and falcons (Zhan et al., 2013).

1.10.2 Mapping Mutations and QTL

The availability of a reference chicken sequence, along with dense SNP maps and genotyping arrays, has facilitated identification of causal alleles for several Mendelian (monogenic) traits (Davey et al., 2006; Gunnarsson et al., 2007; Eriksson et al., 2008; Wright et al., 2009; Dorshorst et al., 2010; Hellström et al., 2010; Dorshorst et al., 2011; Robb et al., 2011; Imsland et al., 2012; Ng et al., 2012; Wang et al., 2012; Wells et al., 2012). A host of chicken lines exist with specific mutant, physiological, or immunological characteristics (Delany, 2004; Robb et al., 2011) that remain open to this sort of analysis. Chickens have also been widely employed for the mapping of numerous quantitative trait loci (QTL). Currently, there are over 3800 QTL in ChickenQTLdb (www.animalgenome.org/cgi-bin/QTLdb/GG/index). Recently, QTL analysis also has been performed in turkey and zebra finch (Aslam et al., 2011; Schielzeth et al., 2012a,b).

1.10.3 Resequencing

With the decreasing costs of NGS, it is now feasible to resequence rather than use SNP genotypes at least for reasonably small numbers of individual birds. In this case, one chooses (1) to sequence whole genomes (often along with parents and/or siblings as controls) or (2) to hope that the allele(s) of interest is coding, therefore sequencing the "exome" (i.e., DNA enriched for exons by hybridization to a synthetic array designed for this purpose; Ng et al., 2009). The challenge then becomes to identify potential candidate causal mutations in a background of unrelated polymorphisms and sequencing errors. Various filters can be applied to reduce the background due to errors, and common polymorphisms can be eliminated from consideration because these are unlikely to generate a typically deleterious mutant trait. The remaining candidate alleles can be searched for those most likely to result in a dramatic phenotype based on evolutionary conservation and predicted effect on the protein product (for coding mutations). As one example, resequencing of pigeon genomes (Shapiro et al., 2013) demonstrated an *EphB2* allele that gives rise to a derived head crest trait. At a broader level of resolution, resequencing can identify genome segments, such as selection signatures, that show unusual absence of diversification in the selected populations. Because the signal detected derives from many SNPs across an LD block, it can be more readily identified relative to the background. In the first application of this approach in birds, Rubin et al. (2010) resequenced nine pooled samples from domestic broiler, layer, and red jungle fowl breeds to identify more than 70 genome regions likely to have been involved in domestication and/or subsequent commercial selection. More recently, Ellegren et al. (2012) resequenced collared and pied flycatchers and found approximately 50 large (~400 kb) divergence islands characterized by high interspecies (and low intraspecies) diversity, at least some of which were likely involved in the split of the two species over the last 2 million years. We are just beginning to see the first of many fascinating stories linking genome sequence to avian physiology, behavior, and evolution. Additional powerful tools relating gene expression to phenotypic traits derive from transcriptomic and proteomic analyses, which are discussed in Chapters 3 and 4.

1.11 CONCLUSIONS AND SUMMARY

The sequencing of the chicken genome was a watershed moment in avian biology. Zebra finch and turkey genome sequences were completed in 2010, and we now stand at the leading edge of a wave of avian genomes. Beyond being a table of contents of genes, transposons, and other elements, the genome sequence is the central foundation for transcriptomics, proteomics, linkage maps, and other tools. In particular, avian genome sequences form the foundation upon which tools such as resequencing and SNP arrays (above), ChIP-seq and methyl-seq (Chapter 2), RNA-seq and microarrays (Chapter 3), and proteomics (Chapter 4) depend. Together, these domains provide a critical genetic reference text for all aspects of avian physiology.

All avian genomes currently are incomplete drafts, with particular deficiencies on microchromosomes. A major challenge remains to fill the gaps in these assemblies and properly align them along chromosomes. An even greater challenge is to accurately annotate all the components that contribute to gene expression and its regulation. To date, most annotation of avian genomes derives from information from other species, and this necessarily misses lineage-specific characteristics that define what it is to be a bird. The coming era of avian genomics will focus on elucidating the function of the various sequence elements. This is where genomics and physiology must join forces to ultimately marry genotype to phenotype.

Although the reference genome sequence is a critical first step, next-generation methods allow for the sequencing of many individuals within any species. This also provides an avenue to address questions of ecology and evolution, such as diversity and speciation, as well as traits of commercial interest in domestic species such as muscle growth, disease resistance, and reproduction. We will soon have genome sequences from thousands of different birds and, at least for some of these, the sequences of hundreds to thousands of individuals. We will also be hearing about the epigenomes, transcriptomes, and proteomes of many of these species. How will we integrate all this data and derive a more thorough understanding of the nearly 200 million years of separate avian evolution and the approximately 10,000 extant birds? This is the challenge for the next generation of avian physiologists.

Chapter 2

Transcriptomics of Physiological Systems

Tom E. Porter

Department of Animal and Avian Sciences, University of Maryland, College Park, MD, USA

ABBREVIATIONS

ACTH Adrenocorticotropic hormone gene
ADRB2 Beta 2 adrenergic receptor gene
ALD Anterior latissimus dorsi
cDNA Complementary DNA
DIO2 Thyroid hormone deiodinase 2 gene
DNA Deoxyribonucleic acid
CGA Alpha subunit of thyroid-stimulating hormone gene
ESTs Expressed sequence tags
GLUT1 Glucose transporter 1 gene
GRM8 Type 8 glutamate receptor gene
LPS Lipopolysacharide
MAPK Mitogen-activated protein kinase
miRNA Micro-RNA
mRNA Messenger RNA
NFκB Nuclear factor kappa B gene
NPYR5 Neuropeptide Y receptor type 5 gene
PLD Posterior latissimus dorsi
POMC Pro-opiomelanocortin gene
PPARγ Peroxisome proliferator-activated receptor gamma gene
RNA Ribonucleic acid
RNAseq Massively parallel sequencing of RNA
TTR Transthyretin gene

2.1 INTRODUCTION

How does the brain integrate environmental cues to control behavior, vocalization, and reproduction? How do the endocrine tissues respond to internal and external signals to coordinate physiological responses? What governs immune cell responses to pathogens? What are the mechanisms underlying muscle differentiation and development? How do hepatic, gastrointestinal, and adipose tissues mediate nutrient uptake and metabolism? How does the cardiovascular system respond to systemic and environmental needs? These questions have been asked by physiologists for decades. Multiple approaches have been taken to advance our knowledge in these areas. With the sequencing of the genome for multiple avian species discussed in Chapter 1 and the development of genome-wide tools for analysis of mRNA levels, physiologists have begun to address these still-open questions on a genomic scale. Transcriptomics, also known as transcriptional profiling and functional genomics, involves large-scale and in many cases genome-wide analysis of mRNA levels in samples using DNA microarrays and, more recently, massively parallel sequencing of RNA (RNAseq). The discussion in this chapter highlights some of the efforts by avian physiologists to apply transcriptomics to the open questions noted in this introduction.

2.2 EARLY EFFORTS

The first major efforts in transcriptional profiling in avian species occurred with the chicken. A dramatic increase in the number of expressed sequence tags (ESTs) for the chicken submitted to GenBank occurred between 1999 and 2002, prior to the release of the chicken genome sequence in 2004. During that 4-year period, the number of ESTs for the chicken increased from a few hundred to more than 400,000. Currently, 688,203 ESTs have been deposited in GenBank. Assembly of these ESTs allowed for the production of more than a dozen microarray platforms. Details on the production of these microarrays have been reviewed in detail (Cogburn et al., 2007; Gheyas and Burt, 2013). In 2001, three papers were published that marked the beginning of transcriptomics in birds (Liu et al., 2001; Morgan et al., 2001; Neiman et al., 2001). These first avian cDNA microarrays contained cDNAs representing approximately 2000 genes expressed in lymphoid tissues that were printed on nylon membranes. Several other tissue-specific cDNA microarrays were developed in the following few years (Bailey et al., 2003; Carre et al., 2006; Cogburn et al., 2003, 2004; Ellestad et al., 2006), and two groups produced cDNA microarrays representing more than half the expressed genes in the chicken (Burnside et al., 2005; Cogburn et al., 2004). These system-wide cDNA microarrays were followed by oligonucleotide arrays representing the majority of expressed genes in the chicken (Affymetrix, ARK-Genomics/Operon, Agilent). Within 5 years of the foundation of functional genomics in the chicken and

Sturkie's Avian Physiology.

shortly after the release of the chicken genome sequence, tools were established for near genome-wide analysis of mRNA levels in chicken samples. Subsequent to these early efforts in the chicken, similar projects established resources for genomics studies in the zebra finch (Li et al., 2007) and Northern bobwhite quail (Rawat et al., 2010). These genomics tools were rapidly put to use in studies of physiological systems, which will be discussed in this chapter.

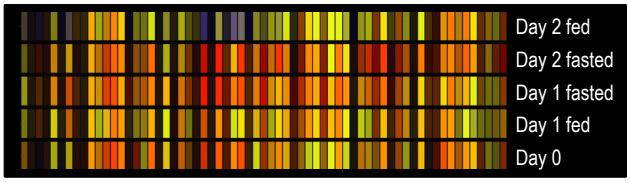

FIGURE 2.1 Heat map illustrating the effects of fasting or feeding of newly hatched chickens on mRNA levels in the hypothalamus. Hypothalamic mRNA samples were analyzed using cDNA microarrays, and the results were clustered. Shown is a cluster of genes for which mRNA levels were increased (red) in response to fasting. Among these were *DIO2* and neuropeptide Y receptor type 5. *The data presented have been published previously (Higgins et al., 2010), but not in this format.*

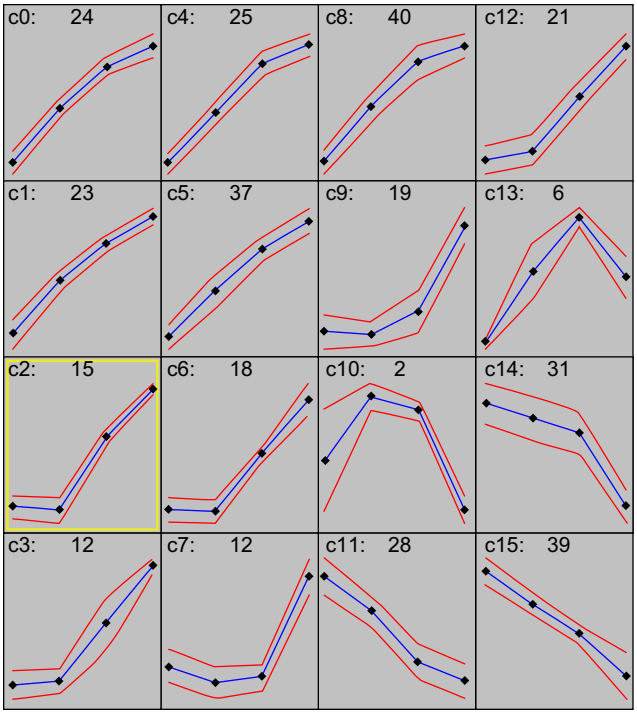

FIGURE 2.2 Self-organizing maps (SOMS) clustering of mRNA levels in the anterior pituitary gland during embryonic development. Pituitary gland mRNA samples from embryonic days 12, 14, 16, and 18 were analyzed using cDNA microarrays, and the results were clustered into SOMS based on mRNA level profiles during development. Cluster 2 (C2, outlined in yellow) contains 15 genes whose expression increased on embryonic day 16. Growth hormone was among the genes in this cluster. *These results have been published previously in a different format (Ellestad et al., 2006).*

Early studies on transcriptomics in birds frequently resulted in long lists of genes that were either upregulated or downregulated in one set of samples relative to another. Although these lists represented candidate genes for potential involvement in physiological responses, they did not add substantially to our comprehensive understanding of the gene interactions mediating those responses. Many studies used hierarchical clustering, heat maps, or self-organizing maps to group genes based on their expression patterns in responses to treatments or during time-course studies. Examples of heat map and SOMS clustering are presented in Figures 2.1 and 2.2, respectively. The rationale used was that genes that respond with similar patterns are likely to be regulated by shared mechanisms or even common transcription factors. More recent transcriptomics studies have placed differentially expressed genes into known or predicted gene networks and pathways based on reports in the literature (see example in Figure 2.3). One commonly used pathway analysis software is Ingenuity Pathway Analysis. Taking multiple approaches to analyze transcriptomics results can lead to a broader understanding of the cellular pathways, gene networks, and transcriptional regulation of gene expression involved in physiological processes.

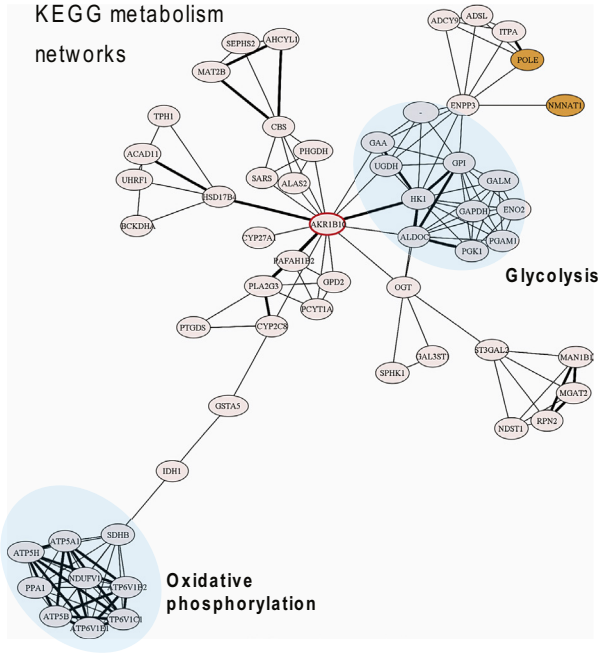

FIGURE 2.3 Network of genes that were differentially expressed in the hypothalamus of chickens genetically selected for high or low body fat. Hypothalamic RNA samples from the two genetic lines were analyzed using cDNA microarrays, and the results were further analyzed using Ingenuity Pathway Analysis software. Genes involved in glycolysis and oxidative phosphorylation were among those that were differentially expressed in the hypothalamus of the fat and lean chickens. Additional details on these findings can be found in Byerly et al. (2010).

2.3 NERVOUS SYSTEM

Vocalization in songbirds is part of the courtship ritual and an important neuroscience model for speech in humans and for sexual dimorphism in the central nervous system. However, the genes involved in establishing differences in vocalization between male and female songbirds were not known. Using microarray technology, differences in hypothalamic gene expression in response to territorial intrusion were found between the spring and autumn in free-living song sparrows (Mukai et al., 2009). Among the genes that were differentially expressed between the seasons were genes involved in thyroid hormone regulation and action, including genes encoding for the alpha subunit of thyroid-stimulating hormone (*CGA*) and transthyretin (*TTR*), supporting a role for thyroid hormones in modulating hypothalamic control of territorial aggression during seasonal reproduction. Gene expression in the high vocal center (HVC) of zebra finches and canaries was similarly characterized (Li et al., 2007). Relative to a whole-brain reference RNA sample, expression of 190 genes was greater in the HVC of both zebra finch and canaries, suggesting that these genes might function in controlling vocalization. Genes expressed specifically within the song control nucleus HVC were also identified in the Bengalese finch using microarrays (Kato and Okanoya, 2010).

In a more comprehensive study, microarray analysis of the basal ganglia identified thousands of genes differentially expressed in area X of singing zebra finches (Hilliard et al., 2012). Microarray analysis was also used to identify genes located on the Z chromosome that are expressed within the song control nucleus of the male zebra finch that are involved in cell survival (Tomaszycki et al., 2009), supporting their role in formation of the sexually dimorphic nucleus involved in masculinization of song. A similar microarray analysis of gene expression in the telencephalon of zebra finch and whitethroat indicated that most of the genes differentially expressed in males were linked to the Z chromosome (Naurin et al., 2011). However, only half of these were differentially expressed in males of both passerine species. Transcriptional profiling of the auditory lobe of zebra finches identified genes whose expression changes with the introduction of a novel song and reverts upon habituation of the birds to the introduced song (Dong et al., 2009; London et al., 2009). Interestingly, RNAseq revealed micro-RNAs (miRNA) in the auditory forebrain responsive to song that target genes whose expression changes with song (Gunaratne et al., 2011), indicating that expression of miRNAs likely contributes to song in birds.

The central nervous system plays an essential role in regulating metabolism, growth, and body composition. However, the full complement of genes expressed within the central nervous system that function in regulating these processes is not known. Transcriptomics has been used to identify genes and gene networks involved in these processes. Transcriptional profiling of the telencephalon of the white-crowned sparrow during the migratory and nonmigratory seasons revealed differences in expression of genes involved in glucose transport, including glucose transporter 1 (Jones et al., 2008). These findings support an increased need by the nervous system for glucose during the migratory season. In a study in which the metabolism of newly hatched chickens was perturbed by fasting, microarray analysis revealed that fasting altered expression in the hypothalamus of genes involved in the regulation of metabolic rate, including thyroid hormone deiodinase 2 (*DIO2*) and pro-opiomelanocortin (*POMC*; Figure 2.1), suggesting hypothalamic modulation of metabolic rate in order to compensate for decreased feed intake (Higgins et al., 2010). Genes not previously associated with hypothalamic regulation of feed intake and metabolism were also identified, including the beta 2 adrenergic receptor (*ADRB2*) and the type 8 glutamate receptor (*GRM8*). Functional relationships between *ADRB2*, *GRM8*, and *POMC* were confirmed in cultures of hypothalamic neurons, and effects were dependent on whether the neurons were derived from chicks that were previously fed or fasted.

In two other reports, hypothalamic gene expression was profiled in genetic lines of chickens divergently selected for high or low body fat (Byerly et al., 2010) or high or low body weight (Ka et al., 2011). Differences in expression of genes associated with glucose sensing, transport, and metabolism were detected in the hypothalamus of birds selected for low or high body fat, suggesting that differences in hypothalamic regulation of body fat in birds might involve the capacity of the hypothalamus to sense and metabolize glucose (Figure 2.3). In contrast, selection for body weight did not affect hypothalamic expression of genes known to regulate feed intake and metabolism, even though the high body weight birds are hyperphagic. These studies demonstrated how involvement of novel gene pathways within the central nervous system in physiological processes can be identified using transcriptomics.

2.4 ENDOCRINE SYSTEM

Transcriptomics has been used to characterize gene expression within endocrine tissues and the responses to hormonal treatments in birds. In one of the first microarray analyses in birds reported, transcriptional profiles were defined within the pineal gland of chicks during a light–dark circadian cycle (Bailey et al., 2003). Expression of hundreds of genes in the pineal gland was found to oscillate during the light–dark cycle, including genes involved in melatonin synthesis. Importantly, this transcriptomics analysis revealed many genes associated with immune responses, stress responses, and hormone binding, suggesting other roles for these genes within the pineal gland or for the pineal gland within these

other physiological systems. A similar analysis was subsequently performed in the chick retina (Bailey et al., 2004). Although some overlap in oscillating gene expression was found between the retina and the pineal gland, distinct differences were also noted, suggesting that differences might exist in circadian regulation within the two tissues. Effects of thyroid hormone and growth hormone on hepatic gene expression have been characterized in the chicken using microarrays (Wang et al., 2007b). Dozens of thyroid hormone- and growth hormone-regulated genes were identified. Interestingly, crosstalk between the two systems was noted, as thyroid hormone status affected levels mRNA levels for growth hormone receptor and insulin-like growth factor binding protein 1.

Microarrays have been used to characterize the response of the avian adrenal gland to adrenocorticotropic hormone (ACTH). Injection of ACTH increased mRNA levels for several steroidogenic genes as well as genes with other functions, such as transcription, cell division, and electron transfer (Bureau et al., 2009). The effects of insulin immunoneutralization through administration of antiserum to insulin were evaluated in the chicken (Simon et al., 2012). Microarray analysis of mRNA samples from liver and muscle revealed that expression levels for more than 1000 genes were affected by decreased insulin levels or the elevated glucose levels associated with insulin immunoneutralization. The results demonstrated the wide range of the effects of insulin on the two target tissues. Microarrays were used to characterize changes in gene expression in the pituitary gland during chicken embryonic development (Ellestad et al., 2006). Numerous genes were identified with expression profiles that suggested involvement in differentiation of pituitary thyrotrophs, somatotrophs, and lactotrophs (Figure 2.2). Effects of glucocorticoids on pituitary gene expression were also identified using cDNA microarrays. Treatment with corticosterone of chicken embryonic pituitary cells affected mRNA levels for hundreds of genes, and these were placed into networks of affected genes (Jenkins et al., 2013). The results were also used to identify putative glucocorticoid receptor targets in the chicken, demonstrating the power of pathway and network analysis of transcriptional profiles.

2.5 REPRODUCTIVE SYSTEM

Development and function of the reproductive system involves gonadal differentiation and hormonal effects on reproductive tissues, including the testes, ovary, and oviduct. However, the full extent of the genetic mechanisms underlying these processes is not known. A number of studies have been reported in which investigators used transcriptomics to shed light on the underlying mechanisms controlling development and function of the reproductive system in birds. A comparison of gene expression in the shell glands of juvenile and laying chicken hens using cDNA microarrays identified hundreds of genes that are differentially expressed in the mature shell gland (Dunn et al., 2009). Similar transcriptional profiling of the uterus of the chicken using cDNA microarrays revealed genes expressed specifically in the magnum or the isthmus (Jonchère et al., 2010). Among these were genes encoding for antimicrobial proteins and ion transporters, respectively, supporting their role in antibacterial properties of the egg albumen and for egg shell formation. An analysis of the effects of a synthetic estrogen on gene expression in the oviduct demonstrated that estrogen affects expression of genes associated with epithelial differentiation and tissue remodeling (Song et al., 2011), consistent with the dramatic effects of estrogens on oviduct size and glandular development.

Microarrays were used to identify genes expressed specifically within the germinal disk of the developing oocyte (Elis et al., 2008). These genes are likely to play a role in oocyte maturation or early embryonic development. Other genes found to be expressed in the granulosa cells are more likely involved in follicular maturation. Within the developing gonad of the chicken, miRNAs that were specific to the testes or ovary were identified using microarrays (Bannister et al., 2009), suggesting a role for miRNA expression in gonadal differentiation. One reproductive organ that is often overlooked is the pigeon crop, which produces a "milk" for the nutritional supply of lactating parents' offspring. A comparison of gene expression in nonlactating and lactating pigeon crop using oligonucleotide arrays identified genes that are differentially expressed in the lactating crop (Gillespie et al., 2011). Genes associated with extracellular matrix receptors, adherens tight junctions, and Wnt signaling were found. This finding supported hyperplasia and cellular release into the crop lumen in the formation of pigeon crop milk.

2.6 IMMUNE SYSTEM

Differences exist in immunological responses to pathogens among individuals in a species. However, the genes expressed within cells of the immune system that account for responses to pathogens and differences in responses among individuals are not entirely known. Microarray analysis was used to study gene expression in one lymphoid organ—the spleen—of susceptible and resistant lines of chickens in response to *Campylobacter jejuni* infection (Li et al., 2012b). Not surprisingly, expression of genes for lymphocyte activation and humoral responses, including immunoglobulin heavy and light chains, was increased following infection in the resistant line. Surprisingly, expression of genes related to erythropoiesis and apoptosis was affected in the susceptible line. These differences in genetic responses within the spleen to *C. jejuni* infection could contribute to susceptibility or resistance of individual birds to infection.

In a similar study, transcriptional responses of the spleen to *Escherichia coli* infection were profiled (Sandford et al., 2011). Immunological pathways including cytokine signaling and Toll-like receptors were affected by *E. coli* challenge, and the magnitude of transcriptional changes was correlated with the severity of infection. Surprisingly, immunization prior to *E. coli* challenge had no significant effects on transcriptional profiles in response to *E. coli*. Similarly, transcriptional profiling of macrophage responses to *Salmonella*-derived endotoxins revealed effects on expression of genes for multiple cytokines and Toll-like receptors (Ciraci et al., 2010). In an earlier study of macrophage responses to lipopolysaccharide or *E. coli*, downstream targets of the Toll-like receptor pathway were affected (Bliss et al., 2005). Transcriptional profiling of cecal gene expression in *Salmonella*-challenged neonatal chicks followed by pathway analysis revealed that expression of genes associated with the nuclear factor kappa B complex and apoptosis were affected by *Salmonella* administration (Higgins et al., 2011). In each of these studies, other genes not previously associated with immune responses were identified, which might play a role in immunological responses to pathogens. In an analysis of miRNA expression within the spleen and the bursa of Fabricius of embryonic chicks, divergent expression of numerous miRNAs was noted, suggesting that these miRNAs might play diverse roles in the functions of the various tissues of the immune system (Hicks et al., 2009).

2.7 MUSCLE, LIVER, ADIPOSE, AND GASTROINTESTINAL TISSUES

Multiple tissues are involved in nutrient absorption, metabolism, and partitioning into tissues for animal growth or energy storage. Among these are the intestine, liver, skeletal muscle, and adipose tissues. However, all of the genes expressed in these tissues to regulate growth and nutrient partitioning are not known. In a comparison of skeletal muscle from slow-growing layer and fast-growing broiler chickens, transcriptional profiling using microarrays revealed differences in expression of genes encoding for muscle fiber proteins and regulators of satellite cell proliferation and differentiation (Zheng et al., 2009). Genes associated with slow muscle fibers were expressed at a greater level in the breast muscle of layer chickens than in broiler chickens, whereas mRNA levels for genes associated with satellite cell growth were greater in muscle of broiler chickens than in layer chickens.

In a similar analysis of gene expression in muscle types, microarray analysis was used to identify differentially expressed genes between the anterior latissimus dorsi (ALD) and posterior latissimus dorsi (PLD) muscles of turkeys (Nierobisz et al., 2011). Expression of genes encoding for extracellular matrix proteins was greater in the slow-twitch, red ALD muscle than in the fast-twitch, white PLD. In contrast, expression of genes involved in glycolysis was greater in the PLD than in the ALD. In a comparison of a random-bred turkey line with a line selected for increased body weight, microarray analysis of mRNA levels in breast muscle revealed alterations in expression of genes associated with extracellular matrix, apoptosis, Ca^{2+} signaling, and muscle function.

Transcriptomics has been used to identify genes associated with meat quality of chicken breast muscle. Genes associated with lipid and carbohydrate metabolism were associated with meat quality (Sibut et al., 2011). In a similar study aimed at identifying genes involved in deposition of intramuscular fat in chickens, transcriptional profiling of breast muscle from broiler chickens and a slow-growing Chinese breed using DNA microarrays revealed differential expression of genes involved in lipid metabolism and muscle development (Cui et al., 2012). DNA microarrays for chicken were also used to study pectoralis gene expression in juvenile and sea acclimated king penguins (Teulier et al., 2012). Genes associated with lipid metabolism were upregulated, whereas genes associated with carbohydrate metabolism were downregulated, in older, sea-acclimated penguins. High environmental temperatures impair growth performance in chickens, but the mechanisms involved have not been elucidated. Microarray analysis of gene expression in breast muscle of chickens exposed to chronic heat stress revealed changes in expression of genes involved in protein turnover, tumor necrosis factor signaling, and mitogen-activated protein kinase signaling (Li et al., 2011). In studies aimed at identifying mechanisms responsible for differences in feed efficiency in broiler chickens, transcriptional profiling of breast muscle mRNA levels using microarrays indicated that an upregulation of genes involved in anabolic processes and energy sensing and a downregulation of genes involved in muscle fiber development and function are associated with high feed efficiency (Bottje et al., 2012; Kong et al., 2011).

Excessive deposition of body fat in commercial poultry leads to decreased conversion of feed into muscle for meat. However, the genetic mechanisms involved in accumulation of body fat in poultry are not known. Transcriptional profiling of adipose tissue from chicken lines divergently selected for low or high body fat revealed that genes involved in lipid metabolism and endocrine function were differentially expressed between the genetic lines (Wang et al., 2007a). Genes identified included lipoprotein lipase (*LPL*), fatty acid binding protein, thyroid hormone-responsive protein (*Spot14*), and leptin receptor. In a more comprehensive study of a different pair of chicken lines genetically selected for low or high abdominal fat, microarray analysis of adipose tissue was used to identify genes and gene networks involved in the observed differences in adiposity (Resnyk et al., 2013). Many genes involved in

adipogenesis and lipogenesis were upregulated in the fat line. Again, many genes involved in endocrine signaling were also differentially expressed between the two genetic lines, including *TTR*, *DIO1*, *DIO3*, *Spot14*, and chemerin. These findings suggest that differences in adiposity among individual birds might be related to differences in endocrine regulation of adipocyte differentiation and growth and lipid metabolism.

Lipogenesis in birds occurs primarily in the liver, and this process is regulated by the energy needs of the animal. Transcriptional profiling of newly hatched chicks that were fed or fasted revealed that the metabolic perturbation of fasting delayed the upregulation of lipogenic genes in the liver (Richards et al., 2010). Expression of one gene that encodes for a transcription factor that regulates expression of the lipogenic genes, peroxisome proliferator-activated receptor gamma (*PPARγ*), was also delayed, supporting coordinated regulation of lipogenesis. A similar analysis of transcriptional responses of the liver to fasting of older chickens has also been reported (Désert et al., 2008). In this study, fasting resulted in upregulation of genes involved in ketogenesis, gluconeogenesis, and fatty acid beta-oxidation, whereas genes involved in fatty acid synthesis were downregulated. These findings demonstrated the coordinated regulation of genes involved in nutrient partitioning by the liver in response to the metabolic perturbance of fasting.

Development of the intestine has also been studied using transcriptomics. Transcriptional profiles of the duodenum during embryonic development of the turkey were characterized using microarrays (de Oliveira et al., 2009). Results indicated that expression of peptidase and lipase genes (*LPL*) decreased toward hatch, whereas expression of genes encoding for peptide and glucose transporters (e.g., *PEPT1* and *SLC5AP*) increased toward hatch. Transcriptional profiles of the chicken jejunum were characterized during the first 3 weeks after hatch (Schokker et al., 2009). Microarray analysis indicated that genes involved in morphological and functional development were highly expressed immediately after hatch, while expression declined during later juvenile development.

2.8 CARDIOVASCULAR SYSTEM

Chicken embryos are a widely used model for studies of cardiac development. As such, much is known about development of the heart in chickens. However, the complex relationships among genes necessary for cardiac development are not known. Gene expression profiling of early embryonic heart tissues was used to identify genes associated with cardiac development (Buermans et al., 2010). Results from this analysis included components of Wnt signaling. In another microarray analysis of heart development, differences in gene expression between the left and right ventricle were defined (Krejčí et al., 2012). Not surprisingly, the set of differentially expressed genes included genes associated with cardiac cell differentiation, heart development, and morphogenesis. However, many other genes not associated with these processes were also identified, providing a novel list of candidate genes for future research on the mechanisms underlying cardiac development. The cardiovascular system acclimates to life at higher altitudes and the associated hypoxia. However, the genes involved in cardiac acclimation in birds are not known. Microarray analysis of gene expression in the heart of the Tibetan chicken and chickens not adapted to life at high altitudes has been performed (Li and Zhao, 2009). Results provided a list of candidate genes that might function in chronic acclimation to high altitudes. Although not part of the cardiovascular system, microarray analysis of pectoral muscle was performed on rufous-collared sparrows sampled at 2000 and 4000 m above sea level in the Andes Mountains (Cheviron et al., 2008). Differentially expressed genes included those involved in oxidative phosphorylation and oxidative stress. Interestingly, none of the genes identified remained differentially expressed when high-altitude and low-altitude birds were allowed to acclimate to life at sea level, supporting functional involvement of the candidate genes identified in acclimation of the birds to high altitudes.

2.9 HURDLES AND FUTURE DEVELOPMENTS

One hurdle facing comparative physiologists in performing transcriptomics on nonmodel species is a lack of genomics resources. These include an assembled and annotated genome sequence and genomics tools such as DNA microarrays. However, the number of avian genomes sequenced continues to grow, making functional genomics possible for investigators who are interested in nonmodel and wild species. Furthermore, the advent of RNAseq makes it possible to perform transcriptional profiling in species for which no DNA microarrays exist. With declining costs of RNA-seq, this transcriptomics approach is now preferred over microarray analysis for most studies of gene expression in physiological systems. A number of investigators have used RNAseq for characterization of mRNA and miRNA levels in the chicken (Goher et al., 2013; Hicks et al., 2010; Kang et al., 2013; Nie et al., 2012; Wang et al., 2011). Importantly, RNAseq has been used in nonmodel species to sequence and annotate the transcriptome in the dark-eyed junco (Peterson et al., 2012) and song sparrow (Srivastava et al., 2012), identify genes involved plumage coloring in ducks (Li et al., 2012a), study gene dosage compensation in the European crow (Wolf and Bryk, 2011), compare gene expression between the black carrion crow and the gray coated crow (Wolf et al., 2010), and identify genes

differentially expressed between the ovaries of laying and broody geese (Xu et al., 2013). These studies using RNA-seq are among the first transcriptomics studies in nonmodel avian species, and they demonstrate the utility of RNAseq for transcriptional profiling in physiological systems of any avian species.

3.1 INTRODUCTION

Whereas genomics provides and analyzes the entire set of functional elements encoded in a genome, and transcriptomics studies gene expression by measuring RNA levels, proteomics analyzes protein expression, modification, structure, localization, interaction, and function. Having a completed genome sequence of an organism is a key step towards understanding how that organism is built and maintained, and thus its complex biology. This information is stored in the genome in the form of genes, which are transcribed into RNA, and RNA is translated into proteins. The entire set of RNA transcripts and proteins encoded by the genome is called transcriptome and proteome, respectively (Velculescu et al., 1997; Wilkins et al., 1996). Although genes provide instructions, proteins are the functional units of almost all biological processes and the principal structural building blocks of all living organisms. Systems-level understanding of cell physiology is thus inevitably based on understanding the multifaceted interplay of gene expression and protein functional networks.

An individual's genome sequence (with the exception of some regions dedicated to the adaptive immune system) is static, its epigenome (the methylation patterns on DNA) less so, and the transcriptome and proteome are extremely dynamic. These latter two differ from cell to cell, and change dramatically according to conditions that cells are exposed to. The transcriptome is more complicated than the genome because of both frame-shifting and alternative splicing. The proteome is even more complex, because most proteins are co- and posttranslationally modified (Walsh, 2006). More than 200 different types of protein modifications are documented in vertebrates, and more than one of these modifications routinely occurs on most proteins (Walsh, 2006). Measurement of the proteome is also more challenging than that of the transcriptome because the dynamic range of proteins in tissues is higher than of transcripts, and can span over 11 orders of magnitude in body fluids (Anderson and Anderson, 2002), and most importantly from a technical perspective, there is no equivalent of the polymerase chain reaction (PCR) for proteins—we must use very expensive machinery to directly identify proteins.

Although mRNA quantities measured by quantitative (q)PCR, microarrays, or sequencing are often used as surrogates for protein quantities, and indirectly, protein activity, there is no or little correlation between mRNA and levels of its corresponding protein (Gygi et al., 1999a; Cullen et al., 2004; Nagaraj et al., 2011; Marguerat et al., 2012). This means that the presence or quantities of proteins in biological samples cannot be satisfactorily estimated solely through their mRNA levels. In addition, posttranslational modifications often profoundly affect protein activities. Though arguably less sensitive, proteomics methods are more specific for determining what is happening at the protein level—they can identify and quantify protein amounts and posttranslational modifications. Proteomics thus provides a direct measure of the predominant functional units responsible for cellular behavior.

Although not absolutely essential, a sequenced and structurally annotated genome greatly facilitates proteomics. The more accurate the genome assembly and annotation, the more accurate the proteomics methodologies can be; this extends to the individual—the most accurate proteomics experiments will be done using the individual's own genome sequence and, to be more accurate still, the transcriptome that corresponds to the proteome. Conversely,

proteomics can be used to improve the structural annotation of genomes (Nanduri et al., 2010; Jaffe et al., 2004).

Red junglefowl (*Gallus gallus*), the major wild ancestor of the domestic chicken, was the first avian and nonmammalian amniote to have its genome sequenced (International Chicken Genome Sequencing C, 2004). The chicken is the principal nonmamamlian vertebrate animal model for studying development, infectious disease, immunology, oncogenesis, and behavior. It is also one of the most important agricultural species for production of meat and eggs. Until additional avian complete genomes became available, the chicken genome served as de facto model bird genome, and most of the proteomics studies have utilized this model to study various aspects of bird biology.

Recently, complete or draft genomes of several other avian species have become available, including several lines of domestic chicken (*Gallus gallus domesticus*), zebra finch (*Taeniopygia guttata*), domestic turkey (*Meleagris gallopavo*), collared flycatcher (*Ficedula albicollis*), pied flycatcher (*Ficedula hypoleuca*), large ground finch (*Geospiza magnirostris*), scarlet macaw (*Ara macao*), mallard duck (*Anas platyrhynchos*), ground tit (*Pseudopodoces humilis*), Puerto Rican parrot (*Amazona vittata*), and budgerigar (*Melopsittacus undulatus*) (Ellegren et al., 2012; Warren et al., 2010; Oleksyk et al., 2012; Dalloul et al., 2010; Rands et al., 2013; Rubin et al., 2010; Huang et al., 2013; Cai et al., 2013; http://aviangenomes.org/, 2013). The turkey, duck, and domestic chicken were sequenced because they are economically important (Dalloul et al., 2010; Rubin et al., 2010; Rao et al., 2012). These species are also used as biomedical models, which is the reason that the zebra finch, scarlet macaw, and Puerto Rican amazon were sequenced—they are important in neuroscience for studying their behavioral, cognitive, and speech abilities (Warren et al., 2010; Oleksyk et al., 2012; Seabury et al., 2013). Darwin's finches are model organisms to study of various aspects of evolution and development (Rands et al., 2013). Flycatchers are important models for speciation (Ellegren et al., 2012), and the genome of the ground tit provides new opportunities to study adaptation mechanisms to extreme conditions (Cai et al., 2013). Collectively, the availability of these additional genomes is opening up the avenues for genome-wide studies of various aspects of bird biology both on the RNA and protein levels. It is expected that large-scale analysis of the avian genome, transcriptome, and proteome will increase our understanding of complex molecular processes that determine phenotype.

3.2 PROTEIN IDENTIFICATION AND ANALYSIS

Although traditional protein biochemistry focuses on studying properties of individual proteins, proteomics encompasses nearly any type of technology that enables studying proteins on a large scale. Among the most commonly used tools are two-hybrid systems (Fields and Song, 1989), protein/peptide microarrays (Haab, 2003; Panse et al., 2004), and mass spectrometry (MS)-based approaches (Fenn et al., 1989). Although the two-hybrid systems and protein/peptide microarrays have only limited applicability—identification of protein–protein interactions—the analytical capabilities of MS make it an ideal tool for a broad range of applications. In addition to its versatility, MS has also the ability to handle the difficulties associated with the complex and dynamic nature of proteomes (Han et al., 2008). MS simplifies and accelerates the analysis and characterization of proteins. Thus, not surprisingly, MS plays a prime and increasingly indispensable role in current large-scale proteomic research. MS-based proteomics refers to approaches that use MS for identifying, characterizing, and/or quantifying proteins in biological samples (Figure 3.1).

Mass spectrometers are used to detect, identify, and quantify small molecules based on their mass and charge (m/z) ratios with high precision, sensitivity, and speed. Many excellent reviews have been written that cover instrumentation and principles of protein identification by MS (Yates et al., 2009; Yates, 1998; Steen and Mann, 2004), and we will not replicate this information. Rather, we will introduce the key methods.

A typical biological sample contains extremely complex proteomes. Because mass spectrometers can analyze only a limited number of different peptides at a time, the sample complexity must be reduced before MS. This is usually done on the protein level by gel electrophoresis, or on the peptide level by various chromatography techniques. Also mass spectrometry-based approaches are often divided into two major groups depending whether sample fractionation includes gel electrophoresis (gel-based approaches) or not (gel-free approaches).

3.2.1 Two-Dimensional Gel Electrophoresis-Based Proteomics

Two-dimensional (2-D) polyacrylamide gel electrophoresis (PAGE) was the first technique that allowed truly complex proteomic analysis and was instrumental for the development of proteomics (O'Farrell, 1975; Rabilloud et al., 2010). 2-D PAGE is the most widely used technique in gel-based proteomics; it simply deconvolutes a protein mixture in two dimensions. Proteins are first separated in the first dimension by their isoelectric point (pI), and then in the second dimension according to their electrophoretic mobility (which is a function of molecular weight and charge of a protein) in a polyacrylamide gel. Separated proteins are then stained and appear as spots in the gel. The amount of protein in a spot is determined by measuring the spot volume.

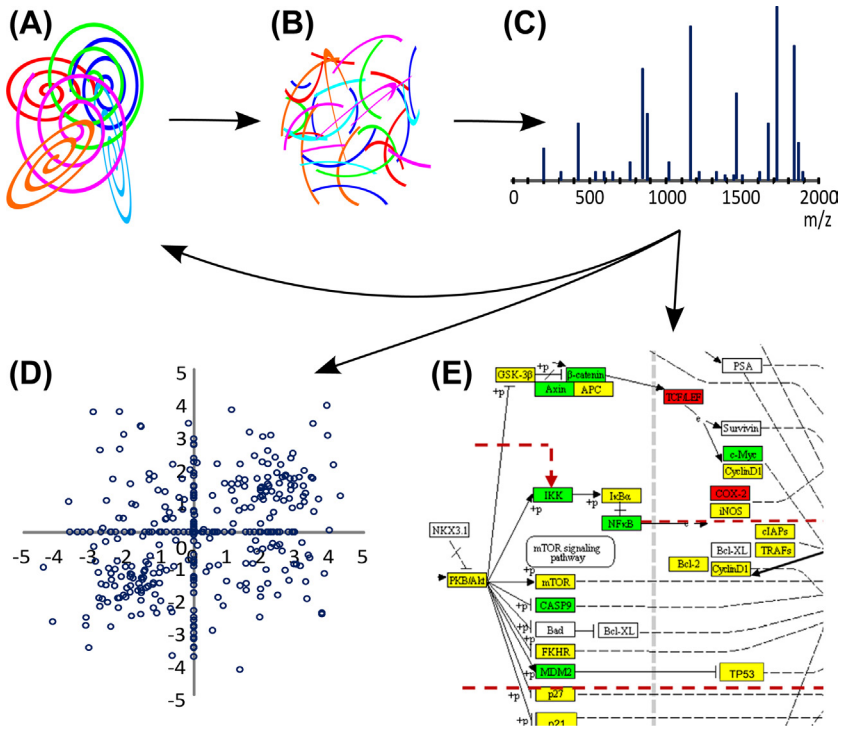

FIGURE 3.1 The workflow of mass spectrometry-based proteomics. The goal of proteomics is physical (protein identity, modifications, structure, localization) and functional (protein interactions, composition of protein complexes) characterization of the proteome. Proteomics denotes the collection of diverse technologies that enable the study of proteins on a large scale. In current proteomic research mass spectrometry (MS) plays prime and indispensable role, because several thousand proteins can be rapidly analyzed, correctly identified and accurately quantified in a single MS-based experiment. Proteins (A) are typically too large for accurate mass determination by mass spectrometry, therefore, they are first digested into peptides (B), which are then analyzed by a mass spectrometer. The obtained peptide masses, peptide (tandem) mass spectra (C), are then searched against predicted peptide masses derived from DNA or protein sequence databases by using one or several different mass spectral search algorithms and their amino acid sequence is determined. The amino acid sequence of an identified peptide is often unique to its parental protein, and such peptides are used for unambiguous identification of proteins that were present in the analyzed sample. In addition to protein identification, MS enables accurate relative or absolute quantification of proteins. As a result, MS is commonly used to identify proteins that are qualitatively and/or quantitatively differentially expressed between studied conditions. The obtained proteomic information is integrated with existing knowledge and/or data from other large-scale studies (mRNA profiling, siRNA screens) to better understand cell or tissue biology at the system level. For example, protein expression levels are compared with mRNA levels (D), and differences in protein expression are analyzed in the context of biological pathways or interaction networks (E) in effort to identify the underlying causalities and mechanistic principles that give rise to a studied phenomenon or phenotype.

This quantification is used as a screening process to select a limited number of corresponding spots that contain different amounts of protein on related gels. The identity of the protein(s) in a selected spot is next identified by MS.

This technique is very useful for comparing two samples that have similar protein expression profiles in order to find proteins that differ between the samples in their expression levels or posttranslational modifications (Rabilloud et al., 2010). The major advantage of this method is that it is intrinsically quantitative. The major drawbacks are the limited capacity of protein separation; poor reproducibility of 2-D gels; and low sensitivity, dynamic range, and throughput. Although efforts to overcome some of the shortcomings inherent to gel-based approaches resulted in the development of improved 2-D gel methods, such as 2-D fluorescence gel electrophoresis (2-D DIGE) (Unlu et al., 1997), gel-free chromatographic approaches, which offer a number of advantages over gel-based ones, now completely dominate the field of proteomics.

3.2.2 Gel-Free Based Proteomics

Experimentation with various gel-free separation techniques resulted in the emergence of multidimensional high-performance liquid chromatography (HPLC) as a viable alternative to gel-based separation techniques. Multidimensional HPLC quickly became the technique of choice for large-scale proteomic studies. Here, in contrast to gel-based approaches, the entire analyzed proteome is first digested and the resulting peptides are then separated by multidimensional HPLC and further analyzed by MS. Digestion of a protein mixture generates a highly complex mixture of peptides, in which the connection between the peptide and the originating protein is lost. Peptides detected and identified by MS are then used

to infer the presence of all original proteins in the sample, which is the principle of the "shotgun" proteomics named by an analogy to shotgun DNA sequencing.

Multidimensional HPLC combines several separation steps to improve resolution of complex mixtures of peptides. One of the most popular multidimensional separation methods utilizes strong cation exchange (SCX) and reversed-phase (RP) chromatography to separate peptides in two dimensions: first peptides are separated based on charge, and then on hydrophobicity (Washburn et al., 2001). This separation method is the basis of the shotgun proteomic strategy known as multidimensional protein identification technology (MudPIT) (Washburn et al., 2001).

Another important chromatographic technique that is often used in gel-free approaches is affinity purification. Selective enrichment affinity materials are either used to enrich for peptides that contain certain posttranslational modifications, such as phosphorylation (Ficarro et al., 2002; Cao and Stults, 1999) or glycosylation (Geng et al., 2000; Durham and Regnier, 2006), or peptides that contain a specific selectable amino acid residue, such as cysteine (Wang and Regnier, 2001) or histidine (Wang et al., 2002). Affinity-enriched peptide mixtures are usually directly (online) or offline transferred to RP HPLC columns and further analyzed by MS.

Gel-free approaches overcome many of the drawbacks that are inherent to gel-based methods (for example, proteins with extreme size, pI, or hydrophobicity are amenable for analysis); but more importantly, they allow a large number of proteins to be identified and quantified in a high throughput manner and short time. The major disadvantage of shotgun proteomics is that peptides derived from very low abundance proteins are often undetected (Yates et al., 2009). An additional drawback relates to the loss of link between a peptide and a parental protein after digestion, which can lead to the incorrect identification of parental proteins.

3.3 QUANTITATIVE PROTEOMICS

In addition to protein identification, mass spectrometry can quantify proteins in complex biological samples. The proteome of a cell is highly dynamic and expressed proteins often change their locations, interactions, and modifications in response to different stimuli. The goal of quantitative proteomics is to obtain a snapshot of a proteome at a particular time. Accurate quantification of proteins is important for understanding of physiological or pathological phenomena, and for identification and modeling of functional networks.

Traditionally, protein quantification has been based on the 2-D PAGE approaches, but several gel-free methods allow accurate protein quantification solely by MS. Methods of quantitative proteomics are classified into two major categories: those that use stable isotopes and those that do not. The most popular stable isotope-labeling techniques either label peptides with isobaric tags for relative and absolute quantitation (iTRAQ) (Ross et al., 2004), or label proteins metabolically by incorporation of stable isotope labels with amino acids in cell culture (SILAC) (Ong et al., 2002) or enzymatically with isotope-coded affinity tags (ICATs) (Gygi et al., 1999b).

Protein quantification by label-free approaches is based on the observation that the chromatographic peak area for any given peptide in an LC run (Bondarenko et al., 2002; Chelius and Bondarenko, 2002) and the number of tandem MS spectra of a given peptide (Liu et al., 2004) are proportional to peptide concentration in the analyzed sample. Thus, relative quantification by label-free approaches can be done by measuring and comparing the intensities of precursor ions, or by counting and comparing the number of tandem MS spectra derived from a particular protein in different experiments.

3.4 STRUCTURAL PROTEOMICS

A protein's function is determined by its structure. The major goals of structural proteomics are to elucidate the three-dimensional (3-D) protein structures and to determine the relationship between protein structure and function. Traditionally, static 3-D protein structures are determined by X-ray crystallography (Sherwood et al., 2011) or nuclear magnetic resonance spectroscopy (Wuthrich, 1990). However, experimental determination of protein structure by these methods remains a difficult and laborious task (Sherwood et al., 2011; Hyung and Ruotolo, 2012). Alternatively, protein structures can be predicted computationally by homology modeling, or *ab initio* (Flock et al., 2012). However, and despite decades of intensive research, these approaches do not always produce reliable models (Flock et al., 2012).

Recently, hydrogen-deuterium exchange (Wales and Engen, 2006), covalent labeling (Chance, 2001), or chemical cross-linking (Young et al., 2000; Petrotchenko and Borchers, 2010) have been coupled with MS to emerge as viable methods to probe 3-D protein structure. Protein footprinting methods modify the surface of the protein that is exposed to the solvent by exchanging amide protons with heavier deuterium atoms (Wales and Engen, 2006), or by different covalent modifications (Stocks and Konermann, 2009). The labeling changes the molecular weight of a protein, and this enables MS to identify the modified sites. Protein footprinting methods are used to investigate protein conformation in solution. Chemical cross-linking covalently couples parts of a protein(s) that are close in space under native conditions. Subsequent MS analysis identifies the location and identity of the cross-linked sites, which provides important clues about the structural topology

of the protein or protein complexes (Young et al., 2000; Petrotchenko and Borchers, 2010).

3.5 APPLICATION OF PROTEOMICS IN AVIAN RESEARCH

Until recently, red junglefowl, the ancestor of domestic chickens, was the only avian species with a sequenced genome (2004) (International Chicken Genome Sequencing C, 2004). Because proteomics greatly depends on a complete and well-annotated genome sequence, most of the proteomics studies in birds have been done on this animal model. Since then, the complete genomes of zebra finch (2010) (Warren et al., 2010), turkey (2011) (Dalloul et al., 2010), and two flycatchers (2012) (Ellegren et al., 2012) have been sequenced and assembled and many more are underway (Oleksyk et al., 2012; Rands et al., 2013; Rubin et al., 2010; Huang et al., 2013; Cai et al., 2013; Seabury et al., 2013). The increasing number of sequenced avian genomes expands the range of unique bird phenomena that can be studied on a global protein level, but more importantly, makes it possible to study avian proteomes directly through their genomes, obviating the need for cross-species peptide matching.

A number of proteomic studies have been done to study various aspects of bird biology including egg production, embryogenesis, development, metabolism, behavior, cognition, immunity, cancer, disease, and infection.

3.5.1 Organ and Tissue Proteomics

A number of studies have focused on initial description and functional characterization of proteomes of different avian tissues, anatomical structures, or entire organs.

The avian egg is a reproductive cell and a highly elaborate biological structure that protects and nourishes the developing embryo. The major components of the egg—the crystalline shell (Mann et al., 2006, 2007), albumen (egg white) (Mann and Mann, 2011; D'Ambrosio et al., 2008; Mann, 2007), yolk (Farinazzo et al., 2009; Mann and Mann, 2008), and the vitelline membrane (Mann, 2008)—have been extensively characterized by various proteomic approaches.

McCarthy et al. (2006) analyzed the proteomes of the supporting stromal and B cells isolated from the chicken bursa of Fabricius, a unique bird organ and a common experimental system for B-cell development (McCarthy et al., 2006). Proteins were isolated from the two major functional cell types of bursa by a sequential detergent extraction procedure that increased proteome coverage and helped to localize known and previously unknown proteins to different cellular compartments. The analysis identified 5198 proteins in bursa, and of these, 1753 were B-cell specific, 1972 were stroma specific, and 1473 proteins were identified in both cell types. Functional modeling of the identified proteins provided insights about signaling pathways involved in programmed cell death, proliferation, and differentiation. In a similar study, van den Berg et al. (2007) applied whole organ proteomics to study frozen spleen (van den Berg et al., 2007).

To gain a better understanding of B-cell development in the bursa of Fabricius, Korte et al. used a quantitative 2D PAGE approach to study bursal proteomes from the embryonic and posthatch developmental stages. They showed that enzymes of the retinoic acid metabolism play a crucial role in the early development of the primary avian B-cell organ (Korte et al., 2013). Similar observations were done in mammals, where vitamin A plays a similarly important role in the development of secondary lymphoid organs (van de Pavert et al., 2009).

Proteomic analysis of the Harderian gland showed that Harderian gland is a site of active mucosal immunity also due to expression of hematopoietic prostaglandin D synthase (Scott et al., 2005), which is necessary for production of prostaglandin D_2, the potent activator of inflammatory responses (Serhan et al., 2008).

The chicken embryo is one of the most useful and investigated comparative and biomedical models for studying development, physiology, and pathogenesis. Several proteomic studies have used chicken embryos to study embryonic development of retina (Lam et al., 2006; Mizukami et al., 2008; Finnegan et al., 2008, 2010), face (Mangum et al., 2005), cerebrospinal fluid (Parada et al., 2005, 2006), liver (Jianzhen et al., 2007), cardiovascular system (Bon et al., 2010), and vasculature (Soulet et al., 2013).

Lam et al. (2006), Mizukami et al. (2008), and Finnegan et al. (2008) used 2D PAGE to catalog the most abundant proteins in young chicken retina and to identify those that were differentially expressed between different stages of retina development (Lam et al., 2006; Mizukami et al., 2008; Finnegan et al., 2008). These studies identified known and novel proteins that play roles in early ocular growth and neural development. The retinal dysplasia and degeneration (rdd) chick was used as a model to identify proteins that are differentially expressed during the onset of degeneration of retina (Finnegan et al., 2010).

Mangum et al. (2005) studied the development of the first pharyngeal arch, an embryonic structure that is crucial for the formation of the face, as a model for the craniofacial defects in humans (Mangum et al., 2005). This study showed that expression of molecular chaperones, cytoskeletal proteins and plasma proteins associated with vascularization, was altered the most between the different stages of craniofacial development.

Proteomics has been used to characterize the proteome of a chicken embryonic cerebrospinal fluid (CSF) (Parada et al., 2006). This study identified, among others, 14

proteins that are also present in human CSF, and 12 of them are altered in neurodegenerative diseases and/or neurological disorders.

Bon et al. (2010) identified and quantified selected proteomes of three different heart tissues and studied them at three different developmental stages (Bon et al., 2010). By comparing the identified proteomes, it was possible study the changes in proteome expression and to identify proteins that were specific for particular heart structures or developmental stages. Grey et al. (2010) used an alternative approach, based on MALDI tissue imaging MS, to study spatial distribution of proteins in chicken heart structures such as vessels, valves, endocardium, myocardium, and septa.

Initial characterization of the zebra finch retina and optic tectum, a major structure of the midbrain, proteomes have been done using the 1D PAGE approach coupled with MS (Sloley et al., 2007a, 2007b). Because these studies were done before the complete zebra finch genome was available, potential zebra finch proteins had to be identified by cross-species matching using the nonredundant NCBI, Ensemble, and Swissprot protein databases.

3.5.2 Proteomics of Cell Metabolism

Biomineralization is a complex and not well understood process, which starts with the release of matrix vesicles by mineralization competent cells, such as osteoblasts or odontoblasts, into the extracellular matrix (Golub, 2009). Matrix vesicles are essential for the formation of hydroxyapatite, the main primary inorganic component of bones, but their exact role in this process is unknown. To better understand embryonic chicken bone formation, Balcerzak et al. (2008) applied proteomics to identify protein machinery of matrix vesicles, which is essential for the formation of hydroxyapatite (Balcerzak et al., 2008). Functional analysis of the matrix vesicle constituents suggested what roles these protein might have in the mineralization process.

2D PAGE MS was used to compare expression profiles of proteins in the oviduct in chicken hens of different ages during the egg-laying period (Kim et al., 2007). The analysis reveled that anterior gradient homolog 2 (AGR2) protein was among the most differentially expressed proteins. Analysis of the mRNA showed that expression of AGR-2 was limited to the magnum and isthmus of the oviduct, and that this expression was approximately 900-fold higher in the mature oviduct in comparison to the premature one. Because AGR-2 is a secreted protein that shows estrogen-dependent expression, and egg laying is strongly affected by estrogen, it was suggested that AGR-2 might be important for the development of the epithelial cells in the oviduct during the egg-laying period in chickens.

To better understand how birds are prepared for transition from a fat-rich diet *in ovo* to saccharide- and protein-based diet after hatch, Gilbert et al. (2010) analyzed the proteome of chicken small intestine at hatch and during the early posthatch period in two different broiler lines (Gilbert et al., 2010). This study identified differences in expression of digestion and absorption-related proteins between different genetic lines.

Recently, 2D PAGE and MudPIT have been used to discover genetic and molecular mechanisms that compromise sperm mobility in chickens (Froman et al., 2011). Analysis of the sperm proteome from chicken lines of low or high sperm mobility allowed deduction of a proteome-based model that explained well the differences in sperm mobility between lines, and confirmed the initial hypothesis that defects in ATP metabolism and glycolysis are responsible for premature mitochondrial failure, which results in sperm immobility.

The zebra finch is the dominant animal model for studying molecular mechanisms underlying learning, memory, vocalization, and social behavior. A natural perceptual experience, such as a sound of another bird singing, triggers rapid changes in expression of specific genes in the auditory region of the zebra finch brain (Mello et al., 1992). Repeated exposure to the same song leads to stimulus-specific habituation of the original response (Petrinovich and Patterson, 1979). To understand the process of habituation better, Dong et al. (2009) used DNA microarrays and 2D PAGE MS approaches to analyze global changes of gene expression at different stages in the development of habituation. This study showed that exposure to a song induces massive changes in gene expression, and that song response habituation is not a simple loss of the original responses but rather a change of neuronal responses underpinned by a novel and different gene expression profile. Analysis of protein expression showed that habituation is accompanied by a decrease in expression of cellular and mitochondrial proteins that are involved in biosynthesis and energy metabolism.

Neuropeptides are signaling peptides found in neural tissue that modulate a wide range of physiological and behavioral processes including metabolism, reproduction, learning, and memory. Xie et al. (2010) used a combination of bioinformatics, MS, and biochemistry for prediction, identification, and localization of neuropeptidome of the zebra finch. Computational analysis of the zebra finch genome predicted 70 putative pro-hormones and 90 peptides derived from 24 putative pheromones identified in the zebra finch brain by two different MS approaches. The power of MS was further used for localization of a subset of peptides in the major song control nuclei of the zebra finch brain. Furthermore, gene expression of a subset of pheromone genes was anatomically mapped in selected zebra finch brain sections by in situ hybridization.

Birds display an enormous range of plumage colors, and this diversity rivals or exceeds that of plants (Stoddard and Prum, 2011). Still, bird plumage occupies only about 30% of the possible colors that birds can see (Stoddard and Prum, 2011). The molecular mechanisms that determine and drive the development of this diversity are largely unknown. The breeding plumage of male pied flycatchers varies from a brown to dark black. Leskinen et al. (2012) characterized and quantified the proteome of developing pied flycatcher feathers to advance understanding of physiological processes that underlay the variation in pigmentation. In total, 294 proteins were identified in the developing feathers. Sixty-five proteins were linked with epidermal development and/or pigmentation in the developing feathers, and 23 proteins were associated with pigment-containing organelles—melanosomes. The comparison of the brown- and black-specific proteomes revealed several proteins and functional networks that differed in expression between the two phenotypes and that are candidates for further studies. The most pronounced differences were detected in immunological signaling, oxidative stress, energy balance, and protein synthesis networks, and these differences might be responsible for differential feather growth and color pigmentation.

3.5.3 Production Proteomics

Food products derived from farm animals, birds, and fish represent a significant part of the human diet. Understanding the nutrient metabolism, muscle accretion, and fat deposition in food birds provides practical knowledge that can be used to improve feed conversion efficiency, food quality, and the health and welfare of animals.

Animal feed represents the major cost of poultry production. A balanced poultry diet is reflected in optimal growth and production at minimal nutrient expense. Because of the composition of poultry diet, where corn and soybeans are used as major sources of energy and proteins, respectively, some amino acids become more limited than others. Corzo et al. (2005) utilized the power of MS to understand amino acid requirements in chickens. Blood plasma proteome from chickens fed an adequate or lysine-deficient diet was analyzed to identify potential biomarkers of dietary lysine deficiency. The analysis revealed that lysine deficiency might not result in a simple overall reduction of protein synthesis in chickens fed with a lysine-deficient diet, but rather in reduced anabolism of specific proteins. Corzo et al. (2006) and Zhai et al. (2012) also evaluated the effect of dietary methionine on breast muscle accretion in broiler chickens (Corzo et al., 2006; Zhai et al., 2012). This study showed that four canonical pathways related to muscle development (citrate cycle, calcium signaling, actin cytoskeleton signaling, and clathrin-mediated endocytosis signaling) were differentially regulated between chickens that were fed with low- and high-methionine diets (Zhai et al., 2012). In addition, this study suggested that a methionine-rich diet preferably induced muscle accretion by sarcoplasmic over myofibrillar hypertrophy.

The blood plasma is an extremely complex tissue that contains thousands of distinct proteins. It is also the most common tissue used in diagnosis of disease and nutritional status. Several authors analyzed blood plasma protein composition to gain better understanding of protein dynamics during chicken development (Huang et al., 2006), or for discovery of plasma biomarkers that reflect nutritional conditions (Corzo et al., 2004, 2006).

Muscle meat food products derived from birds, and in particular chickens, are important sources of essential nutrients and energy intake in the human diet. Proteomics has an obvious potential to study a broad range of aspects related to the meat production including nutrition, muscle formation, breed differentiation, meat quality, and meat contamination (Paredi et al., 2013).

Chicken strains selected for meat production show dramatic growth rates and accelerated accretion of the pectoralis (breast) major and minor muscles. The proteome of the chicken pectoralis muscle has been extensively profiled (Corzo et al., 2006; Zhai et al., 2012; Doherty et al., 2004; Teltathum and Mekchay, 2009), and the most recent study identified over 5000 unique proteins in the pectoralis muscle of studied birds (Zhai et al., 2012).

A complementary study identified the proteome of the pipping muscle, which is primarily used for breaking the egg's surface during hatching (Sokale et al., 2011). The identified proteins, 676 in all, were analyzed using the assigned Gene Ontology categories for molecular function, biological process, or cellular component. This analysis revealed which protein functions and cellular activities are important for rapid development of pipping muscle during embryogenesis.

A proteomic approach was also used to identify hypothalamic biomarkers associated with high egg production in chickens (Kuo et al., 2005). Comparison of the hypothalamic proteomes from two related chicken lines selected for meat and high egg production resulted in identification of six proteins that differed in their expression between the lines, and some of these proteins are involved in regulation of gene expression, signal transduction, and lipid metabolism. The heterogeneous nuclear ribonucleoprotein H3 was suggested as novel biomarker for high egg production.

A global analysis of the chicken embryo liver proteome resulted in identification of proteins that were differentially expressed between two chicken lines that differed in hepatic lipid metabolism and fat deposition (Huang et al., 2010). Comparative analysis of the identified liver proteins showed that proteins involved in gluconeogenesis, cholesterol metabolism, and fatty acid oxidation were expressed earlier and more abundantly in the liver of lean-line of chickens. In a similar study, to better understand duck liver physiology at the protein level, liver proteome of a domesticated lean

Pekin duck (*Anas platyrhynchos domestica*) was analyzed at different developmental stages (Zheng et al., 2012). Comparison of the identified proteomes showed that proteins involved in transportation were more abundantly expressed in newborn ducks, whereas adult duck liver proteome contained more abundantly expressed proteins associated with carbohydrate and protein metabolism, immune defense, and antioxidation.

3.5.4 Proteomics of Disease and Infection

The recent explosion of animal and pathogen genomes has not only enabled identification of genes involved in the etiology and pathology of diseases (such as mutant gene variants or virulence factors), but also has opened up the door for proteomics to probe the pathogenesis and pathogen–host interactions on a global protein level. Proteomics has greatly improved understanding of diseases; it has been very valuable in diagnostic marker discovery and it has a great potential in drug discovery. Despite its great value, disease proteomics remains to be one of the least-developed areas in avian research. Nevertheless, proteomics has been used to study the pathogenesis, etiology, and pathology of several avian (infectious) diseases. In addition, proteomics has been used to study various human diseases on chicken experimental models (Andrews Kingon et al., 2013).

3.5.4.1 Disease Proteomics

The chicken is an ideal and unique animal model to probe the etiology and progression of spontaneous human epithelial ovarian cancer (EOC), largely because the domestic chicken has a high prevalence of spontaneous ovarian carcinomas. EOC remains the most lethal gynecologic malignancy in part because early detection and therapeutic strategies have been largely unsuccessful (Kurman and Shih, 2010). Hawkridge et al. (2010) used this model to study the onset and progression of EOC by a large-scale biomarker discovery effort involving longitudinal sample collection and protein analysis by MS. Inter- and intra-individual measurement of proteins identified ovomacroglobulin (ovostatin) as a potential EOC biomarker because its levels in plasma were undetected in a healthy individual and significantly higher during later stages in an EOC bird.

Pulmonary hypertension syndrome, or ascites syndrome, is a metabolic pathogenesis in meat-type chickens that is manifested by the formation of ascites. Ascites syndrome is one of the major problems in the chicken industry, and is caused by cardiopulmonary insufficiency during high oxygen demands spurred by a rapid tissue growth (Currie, 1999). Proteomic analysis of the cardiac mitochondrial matrix proteomes of the ascites-resistant and ascites-susceptible line broilers suggested that the mitochondria of susceptible chickens may respond inappropriately to hypoxia (Cisar et al., 2005). A complementary proteomic analysis of the hepatic proteomes of healthy birds and those with ascites suggested that insufficient energy generation in the liver is responsible for development of pulmonary hypertension syndrome (Wang et al., 2012).

3.5.4.2 Proteomics of Infections

Some strains of the highly pathogenic avian influenza A subtype H5N1 cause severe acute encephalopathy and neurodegeneration in poultry and migratory birds. To reveal the mechanisms that cause the observed neuropathogenesis, Zou et al. (2010) used comparative proteomics to identify the proteins that were expressed differently in the brains of healthy and H5N1-infected chickens (Zou et al., 2010). Among the differentially expressed proteins were septin 5 and collapsin response mediator protein 2 (CRMP2). Septin 5 is dysregulated in Parkinson's disease and CRMP2 in Alzheimer's disease, Down syndrome, and human T-cell lymphotropic virus type I associated myelopathy (Vincent et al., 2005; Lubec et al., 1999; Son et al., 2005). This suggests that these proteins might also have a role in neurodegenerative pathologies associated with influenza H5N1 infection.

Gallid herpesvirus 2 (GaHV-2) is an avian oncogenic herpesvirus that causes a highly infectious and rapidly progressive lymphomatous disease of chickens, Marek's disease (MD). GaHV-2 infects and transforms cells in all chicken genotypes, but some chickens are genetically resistant to gross lymphoma formation (Burgess and Davison, 2002). To better understand the molecular mechanisms of differential susceptibility to MD, spleen proteomes of MD-susceptible and MD-resistant chickens were analyzed using the 2D PAGE MS approach (Thanthrige-Don et al., 2010). Among the differentially expressed proteins identified in this study were antioxidants; molecular chaperones; and proteins involved in the activation and migration of T lymphocytes, formation of cytoskeleton, protein degradation, and antigen presentation; and some of these were implicated as potential factors in MD resistance.

In a similar study, analysis of the changes in the chicken spleen proteome induced by the GaHV-2 infections revealed that protein expression was the most altered during early stages of infection. Comparative analysis showed that proteins that were differentially expressed at different time-points postinfection were involved in a variety of cellular processes that are crucial for the host response to GaHV-2 infection and pathogenesis (Thanthrige-Don et al., 2009).

To better understand how GaHV-2 infection changes the host protein expression, several proteomic profiling studies have been done to determine the proteome of GaHV-2-lytically infected chicken embryo cells (CECs) (Liu et al., 2006; Chien et al., 2011; Ramaroson et al.,

2008; Chien et al., 2012) compare the phosphoproteomes of mock- and GaHV-2-infected CECs (Chien et al., 2011; Ramaroson et al., 2008); and quantify protein expression changes caused by GaHV-2 infection (Chien et al., 2012). Collectively, these studies revealed GaHV-2 infection dramatically changes the protein expression profile of infected cells. Overlaying quantitative and phosphorylation data revealed that GaHV-2 infection altered both protein expression and phosphorylation of proteins from several cellular pathways, and among the most affected processes were RNA transport, signal transduction, initiation of translation, and protein degradation. Perhaps the most interesting discovery of these studies is that GaHV-2 causes unique phosphorylation of the translation initiation factor 4E-binding protein 1 (4E BP1), which is important for the assembly of the protein translation initiation complex after virus infection.

In a complementary study Buza and Burgess (2007) used MudPIT to profile the proteome of the GaHV-2-transformed lymphoblastoid cell line UA01. Functional modeling the UA01 proteome showed that cells had a typical cancer phenotype. UA01 cells were activated, differentiated, and proliferative, but antagonistic to apoptosis, anergy, quiescence, and senescence. Identified cytokines, cytokine receptors, and related proteins suggested that the UA01 proteome had a T-cell regulatory (T-reg) rather than T-helper (Th)-2 phenotype.

Marek's disease, a CD4+ T cell lymphoma of chickens, and many human lymphomas overexpress the Hodgkin's disease antigen CD30 ($CD30^{hi}$). Marek's disease lymphomas, like its human homologs, are formed by a minority of transformed ($CD30^{hi}$) and a majority of non-transformed ($CD30^{lo}$) cells (Burgess and Davison, 2002; Shack et al., 2008). Although the GaHV-2 gene meq is the principal oncogene, which acts as a transcription factor and transforms via the Jun pathway (Levy et al., 2005), the exact mechanism of neoplastic transformation and transition from $CD30^{lo}$ to $CD30^{hi}$ neoplastic phenotype is unknown. As described in this review, most of the proteomics work that has been done in aves has been descriptive, based on differential expression. Kumar et al. (2012), though, compared microRNA, mRNA and protein levels and from this data imputed functional models. As described by many others in many different systems, there was poor overall correlation between mRNA and protein expression (Gygi et al., 1999; Cullen et al., 2004). However, to identify the key regulatory proteins responsible for neoplastic transformation, all gene products which were differentially expressed in the same direction at both mRNA and protein levels (i.e. concordant) were selected for further analysis and these did have an overall positive correlation. Those gene products with the greatest mRNA and protein correlation are known to be involved in human CD30-over expressing lymphomas. When ranked into pentiles based on protein expression levels, the Gene Ontology Biological Processes of cell cycle and proliferation to programmed cell death ratios were greatest in pentile 1. The authors then identified the numbers of putative canonical MDV Meq (the virus oncogene) binding sites in each of the 88 concordantly-expressed genes' promoters; and genes in pentile 1 had the most Meq binding sites. Of the five concordant genes previously implicated in lymphomagenesis in other species most were in pentile 1 suggesting direct transcriptional regulation by Meq. In contrast, one gene product, CST3 was likely regulated by a micro-RNA.

Plasmodium gallinaceum is a protozoal avian malaria parasite and the most relevant animal model of the human parasite *Plasmodium falciparum* sexual stages zygote and ookinete. The early stages of the *P. gallinaceum* life-cycle occur in its definitive host, the mosquito, but this process is largely unknown. To better understand the initial molecular mechanisms of *P. falciparum* vector interaction, Patra et al. (2008) used high-throughput proteomics to identify 966 orthologous proteins of *P. falciparum* present in the zygote and ookinete proteomes (Patra et al., 2008). Forty percent of the identified proteins had hypothetical status and the majority of these were transmembrane or secreted proteins. This suggests that these proteins might play important roles in parasite–host interactions.

Coccidiosis of fowl, an intestinal disease caused by a protozoal parasite Eimeria, causes significant losses for the poultry industry. Recently, plasma proteome profiles of two different chicken lines infected with one of three common Eimeria species were compared by the 2D PAGE MS (Gilbert et al., 2011). Fourty-six proteins displayed significantly changed expression in response to Eimeria infection. The differentially expressed proteins were found to participate in innate immunity, blood clotting, and iron and mitochondrial metabolism, and these processes fit well within the host acute-phase responses that are initiated when a tissue is invaded by a microorganism. Some of the identified proteins were suggested as candidate biomarkers for early diagnosis of Eimeria infection.

Salmonella enterica subspecies enterica is a Gram-negative enterobacterium and an important pathogen that infects a broad range of vertebrate species including chicken and man. The subspecies is routinely divided into more than 2500 serotypes (serovars) based on antigenic epitopes (Franklin et al., 2011). *Salmonella* serovars differ in host range and pathogenic potential, but molecular mechanisms underlying these differences are not well understood. Several proteomic studies compared proteomes of different avian *Salmonella* serovars and discovered possible molecular mechanisms responsible for the observed phenotypic differences (Encheva et al., 2005; Osman et al., 2009; Sun and Hahn, 2012).

3.6 CONCLUSIONS

One of the primary goals of biology is to understand how organisms function on a molecular level. Because proteins are the "makers of life", understanding their functions is central to understanding biology. During the last decade, proteomics has emerged as an extremely versatile and comprehensive platform to study proteins on a large scale. It offers a broad range of tools that can be used to determine the identity, structure, quantity, and quality of expressed proteins in biological systems. Thus, while scientific questions in avian research remain essentially the same, proteomics has the potential to transform the form of biological inquiry.

Chapter 4

Mitochondrial Physiology

Walter Bottje
Department of Poultry Science, Division of Agriculture, University of Arkansas, Fayetteville, AR, USA

4.1 MITOCHONDRIA: AN INTRODUCTION

4.1.1 Overview

Mitochondria generate 90% of the energy within a cell in the form of adenosine triphosphate (ATP) by oxidative phosphorylation, thus earning them the title of "powerhouse of the cell." The process of oxidative phosphorylation from the respiratory or electron transport chain (ETC) activity was first reported by Kennedy and Lehninger (1949). Energy production, however, is just one of many roles orchestrated by mitochondria. Mitochondria are the only organelle outside the nucleus with a discrete pool of DNA (mitochondrial DNA, or mtDNA). This distinction lead to the accepted theory of an endosymbiotic origin of mitochondria, in which an α-proteobacteria took up a commensal residence within a eukaryotic cell, with more recent evidence of co-evolution of an extant eukaryotic cell (Gray et al., 1999).

According to Lehninger (1965), Rudolf Albert van Kolliker, a Swiss cytologist, first described mitochondria in 1857 and gave them the name of sarcosomes, as they have a distinct granular structure surrounded by a membrane. Later, Benda (1898) renamed the structure mitochondrion—a derivation from Greek for thread (*mitos*) and grain (*chondrion*); this has been the standard name for the organelle since the 1930s (Lehninger, 1965). The synthesis and import of nuclear (n) encoded proteins, which represent 98% of all mitochondrial protein, is tightly coordinated with the synthesis of mtDNA-encoded proteins; this is followed by the coordinated assembly needed for a fully functional mitochondria. Mitochondria play a vital role in programmed cell death (apoptosis), and mitochondrial-generated reactive oxygen species (ROS) make it a major site of endogenous oxidative stress. Mitochondria are dynamic organelles that change morphology and composition in response to physiological signals, such as variations in nutrition, oxygen levels, and metabolic demand (Aw and Jones, 1989). Mitochondria also undergo fission processes associated with mitochondrial biogenesis when additional energy is needed.

4.1.2 Physical Description

Under electron microscopy, mitochondria appear bean-shaped with striations that are visible due to folding of the inner mitochondrial membrane, called cristae, which is where the ETC is located. Electron tomography revealed mitochondria as long tube-like structures that weave throughout the cytosol (Mannella, 2000). Parts of the mitochondrial membrane are contiguous with the endoplasmic and sarcoplasmic reticula, that facilitate the shuttling of molecules such as ATP and adenosine diphosphate (ADP) between the mitochondria and cytosol (Scheffler, 1999; Sharma et al., 2000). Mitochondria have an inner membrane that surrounds the mitochondrial matrix and an outer membrane that encloses an intramembranous space (Figures 4.1 and 4.2). Cytochrome *c*, located in the intramembranous space, is critical for cellular respiration and for initiating normal cell turnover (apoptosis). Most mitochondrial proteins are found in the matrix and are associated with the Krebs cycle, β-oxidation of fats, synthesis of heme proteins, and the iron-sulfur proteins prevalent in the ETC. Mitochondrial DNA is also present in the matrix. The outer mitochondrial membrane is a simple phospholipid bilayer, whereas the inner mitochondrial membrane is highly convoluted, forming cristae that greatly increase its surface area. Due to the presence of the multiprotein complexes of the ETC, the inner mitochondrial membrane contains 70% protein and 30% lipid, compared to the equal ratio of proteins to lipids that is typically found in membranes. The inner mitochondrial membrane also contains cardiolipin, a unique lipid found primarily in mitochondria (Hatefi, 1985).

4.1.3 Mitochondrial and Nuclear DNA Interaction for Assembly and Function

Mitochondrial DNA, a circular molecule with over 16,000 base pairs, contains roughly 37 genes that code for two ribosomal RNAs, 22 transfer RNAs, and 13 proteins, that combine with over 70 other n-encoded proteins to form the respiratory chain (Anderson et al., 1981). Transcription, translation, and mtDNA replication, including synthesis of ribosomal proteins,

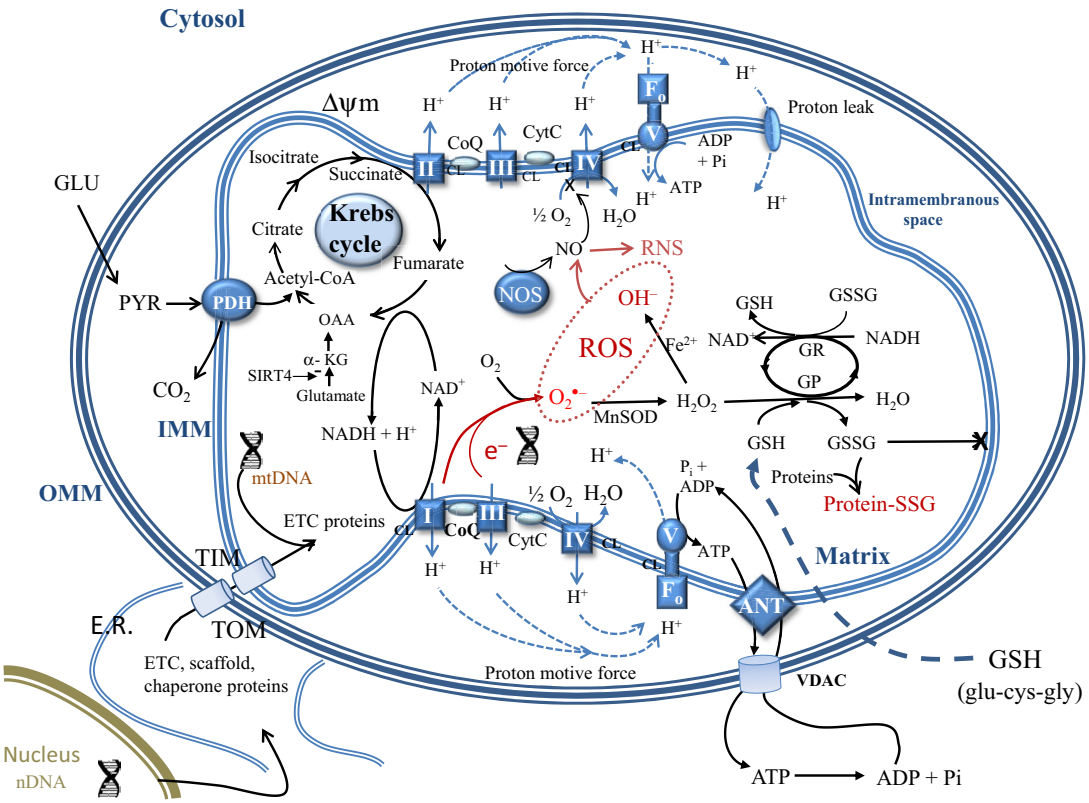

FIGURE 4.1 Overview of mitochondria. A stylized mitochondria showing some mitochondrial processes discussed in the text. The mitochondria have both an outer (OMM) and inner (IMM) mitochondrial membrane with the electron transport chain (ETC) (I, II, III, IV, V) located on the IMM. The ETC towards the top shows electrons moving from succinate, an intermediate of the Krebs cycle, to complexes II–IV. The ETC on the bottom shows NADH-linked energy substrates with electrons entering the ETC at complex I. Electrons are passed between complex II and III, and complex I and III, by coenzyme Q (CoQ). Cytochrome *c* (cyt *c*) shuttles electrons from complex III to complex IV. The movement of electrons down the respiratory chain is accompanied by pumping of protons (H^+) in the intramembranous space, sets up a proton motive force that drives adenosine triphosphate (ATP) synthesis when protons flow through ATP synthase (complex V). ATP is transported out of the mitochondria for use by the cell through the adenine nucleotide translocase (ANT) on the inner membrane and the voltage-dependent anion channel (VDAC) on the outer membrane. A mitochondrial nitric oxide synthase (NOS) produces nitric oxide (NO), that competes with oxygen for the active site on cytochrome *c* oxidase. Protons may also move through the membrane at sites other than the ATP synthase in a process called proton leak. Proton leak dissipates the proton motive force without synthesis of ATP but can also attenuate formation of reactive oxygen species (ROS). Electrons (e^-) that leak from the ETC can react with oxygen to form superoxide (O_2^-), which is normally converted to hydrogen peroxide (H_2O_2) by manganese superoxide dismutase (MnSOD). In the presence of free metal ions, H_2O_2 can be converted to the highly reactive hydroxyl radical (OH^-). Collectively, superoxide, H_2O_2, and OH^- are ROS and can cause oxidative damage to cellular structures (e.g., proteins, lipids, DNA). ROS can react with NO to produce reactive nitrogen species (RNS), that also can damage these structures. Glutathione (GSH) is an important endogenous antioxidant that is imported from the cytosol into the mitochondria. The active thiol in GSH is used to reduce lipid peroxides or H_2O_2 to water or lipid alcohols with the concomitant formation of oxidized glutathione (GSSG); it can be recycled to GSH by glutathione reductase (GR), which utilizes reducing equivalents from NADH. Unlike cells, mitochondria cannot export GSSG, and elevations in GSSG in mitochondria that lead to protein disulfides (protein-SSG) formation. This can be particularly detrimental to ETC activity due to the presence of reactive thiol groups in these proteins. The ETC is comprised of nuclear and mitochondrially encoded (mtDNA) proteins. The nuclear-encoded proteins must be transported into the mitochondria, which is facilitated by both outer membrane translocase (TOM) and inner membrane translocase (TIM) proteins. *This figure was adapted from Wallace (1999).*

are all under nuclear regulation. Consequently, mitochondrial function depends upon the tightly coordinated interaction between nDNA and mtDNA-encoded proteins, protein assembly factors, and chaperone proteins involved in protein folding, protein scaffolding, and structural support (Nijtmans et al., 2002; Rabilloud et al., 2002; Ryan and Hoogenraad, 2007).

Nuclear-encoded proteins destined for the mitochondria must be unfolded prior to transport through the outer and inner membrane translocase protein channels (Ryan and Hoogenraad, 2007). After transit through these channels, the proteins are refolded within the mitochondria by chaperone proteins, such as heat shock protein (Hsp) 70, Hsp 60/10 (also called chaperonin 60/10), Hsp 78, and a number of proteases. Chaperone protein expression increases during stress (e.g., heat, oxidative, toxin-mediated), when they are particularly important in repairing damaged proteins.

The D loop of mtDNA contains regulators of mitochondrial transcription and replication. Differences in D-loop

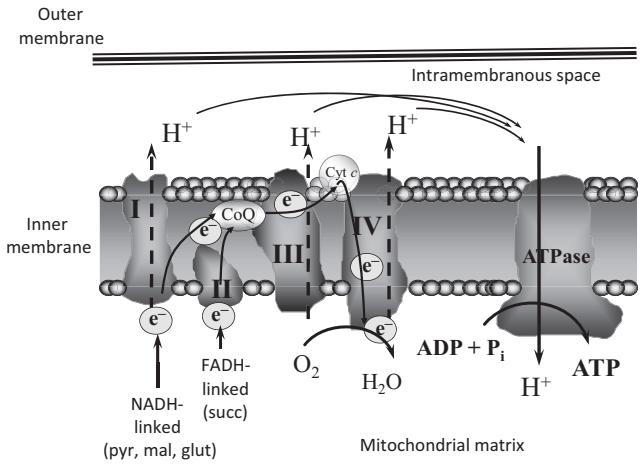

FIGURE 4.2 Diagrammatic representation of the mitochondrial electron transport chain (ETC) (based on Lehninger et al., 1993). The respiratory chain consists of five multiprotein complexes (complex I, II, III, IV, and V). Electrons (e^-) enter the ETC either through complex I from NADH-linked energy substrates (e.g., pyruvate, malate, glutamate), or at complex II from FADH-linked substrates (e.g., succinate). The electrons are passed down the ETC (solid arrows) to the terminal electron acceptor, oxygen that is reduced to water. Coenzyme Q (CoQ, ubiquinone) is responsible for the transfer of electrons from complex I and II to complex III. Associated with the movement of electrons along the ETC is the movement of protons (H^+, dashed arrows) from the mitochondrial matrix into the intramembranous space, setting up a proton motive force. The movement of protons through the adenosine triphosphate (ATP) synthase (complex V) provides the energy to support ATP synthesis.

mtDNA have been used to identify animals with different mitochondrial types. Some proteins are part of the mitochondrial import machinery, whereas others are needed for expression of the mitochondrial genome and metabolism. Other proteins are required for mitochondrial roles in apoptosis (Liu and Kitsis, 1996), redox cell signaling, and homeostasis (Bogoyevitch et al., 2000; Levonen et al., 2001; Droge, 2002). Rabilloud et al. (2002) indicated that "mitochondrial function in general, and mitochondrial protein synthesis in particular, depend on the conjugated and coordinated expression of both mitochondrial and nuclear genomes." A complex communication network between mitochondria and the nucleus also exists to coordinate mitochondrial biogenesis and function (Poyton and McEwen, 1996).

4.1.4 Mitochondrial Fusion and Fission

Mitochondria are not discrete or static structures. Rather, they are part of a network that constantly undergoes complex fission and fusion processes, thus enabling mitochondria to communicate and "form into local and widespread mitochondrial syncytia within cells" (Hoppins et al., 2007). Mitochondrial fission and fusion processes are controlled by highly conserved dynamin-related proteins—large GTPase proteins that regulate many membrane-associated activities (Praefcke and McMahon, 2004). Mitochondrial fusion ensures the distribution of mtDNA to maintain functionally competent mitochondria throughout a cell. In contrast, mitochondrial fission ensures that competent mitochondria are distributed equally during cell division and mitochondrial biogenesis. Mitochondrial fission and fusion processes may also play roles in promoting or delaying apoptosis, respectively (Hoppins et al., 2007).

4.1.5 The Respiratory Chain and ATP Synthesis

The ETC, first described by Kennedy and Lehninger (1949), consists of five multiprotein enzyme complexes: complex I (nicotinamide adenine dinucleotide (NADH): ubiquinone oxido-reductase), complex II (succinate: ubiquinone reductase), complex III (ubiquinol: cytochrome *c* oxidoreductase), complex IV (cytochrome *c* oxidase), and the F_1F_0 ATP synthase or ATPase (complex V), and two mobile electron carriers, ubiquinone (Q) and cytochrome *c* (cyt *c*) (Figures 4.1 and 4.2). Electrons enter the respiratory chain at complex I for NADH-linked substrates (e.g., malate and pyruvate) or at complex II for succinate, an $FADH_2$-linked substrate (Figure 4.2). Ubiquinone carries electrons from complex I and II to complex III, whereas cyt *c* shuttles electrons from complex III to complex IV. Electron transfer to O_2 (the terminal acceptor) results in full reduction of O_2 to water.

Electron movement coincides with proton pumping to establish a proton motive force consisting of a membrane potential ($\Delta\psi_m$) and pH (proton) gradient, that provide energy for ATP synthesis as protons flow back into the matrix through ATP synthase (complex V). Protons can also cross at sites other than the ATP synthase due to anion carrier proteins (e.g., adenine nucleotide transporter, glutamate transporter), uncoupling proteins (UCPs), and intrinsic

membrane characteristics (Brown and Brand, 1991; Brand et al., 1994, 2005; Rolfe and Brand, 1997; Brookes et al., 1997). Proton leak therefore consumes O_2 and dissipates the membrane potential without ATP synthesis. Uncoupling represents an inefficiency of mitochondrial function, but it minimizes ROS production (see below). Although mitochondrial uncoupling is important in heat generation in brown adipose fat tissue in mammals, brown adipose tissue has not been reported in any avian species; it appears to have been lost early in evolution of the avian lineage from a common ancestor of birds and mammals (Mezentseva et al., 2008).

4.1.5.1 Ubiquinone (Coenzyme Q)

Electron transfer from complex I to complex III and from complex II to complex III is carried out by ubiquinone (coenzyme Q; e.g., CoQ_9 and CoQ_{10}). Auto-oxidation of CoQ is a major source of mitochondrial ROS production (Chance et al., 1979; Turrens et al., 1985; Turrens and Boveris, 1980). Animals with relatively more CoQ_{10} had lower mitochondrial ROS production than those with higher CoQ_9 levels (Lass and Sohal, 1999), and CoQ content is highly correlated with complex I and II activities (Ernster and Forsmark-Andree, 1993; Forsmark-Andree et al., 1997).

4.1.5.2 Cardiolipin

Cardiolipin (tetra-acyl-diphophatidyl-glycerol) is a unique phosphoglyceride with four long-chain fatty acids (compared to two side chains in typical phospholipids), and is essential for membranes involved in coupled (oxidative) phosphorylation (Hoch, 1992). Full activity requires the interaction of each complex (I–V) with cardiolipin. Yeast lacking cardiolipin exhibited impaired mitochondrial function (Koshkin and Greenberg, 2000). Exogenously added cardiolipin depressed respiratory chain coupling but increased ATP synthase activity in isolated liver mitochondria (Bobyleva et al., 1997).

4.1.6 Assessing Mitochondrial Function

4.1.6.1 Polarographic Method

A standard method of assessing mitochondrial function uses an O_2 electrode in a Warburg apparatus to measure O_2 consumption with different respiratory states in freshly isolated mitochondria (Estabrook, 1967). In the presence of NADH- and FADH-linked energy substrates, mitochondria exhibit an initial slow rate of O_2 consumption (state 2 respiration). The addition of ADP stimulates ETC activity and initiates rapid O_2 consumption, that is followed by a slower rate of O_2 consumption (state 4 respiration) when ADP levels decline (i.e., ADP is limiting) due to oxidative phosphorylation and synthesis of ATP (from ADP and inorganic phosphorus). Functional indices calculated from these data include the respiratory control ratio (RCR) and ADP:O ratio (Estabrook, 1967). The RCR represents the degree of coupling or efficiency of respiratory chain activity and is calculated as state 3 (active respiration) divided by state 4 (resting) respiration rate. The ADP:O ratio is the amount of ADP phosphorylated per nanoatom of monomeric oxygen consumed during state 3 respiration and is an index of oxidative phosphorylation. Electron movement down the transport chain is coupled to proton pumping, setting the proton motive force that synthesizes ATP as protons flow through the F_1F_0 ATPase. The ADP:O ratio, an index of oxidative phosphorylation, is determined as ADP added per nmol monomeric oxygen consumed in state 3 respiration. Theoretical ADP:O ratios are 2 (for succinate) and 3 (for malate), which enter at complex I and II, respectively.

ATP synthesis is not 100% efficient, due in part to electron and proton leak. Decreases in the ADP:O ratio (increased O_2 use that is uncoupled from ATP synthesis) occur by proton leakage across the inner mitochondrial membrane at sites other than the F_1F_0 ATPase (Brand et al., 1994) or by electron leakage from the respiratory chain that reacts with O_2 to form ROS, such as superoxide and H_2O_2 (Chance et al., 1979; Boveris and Chance, 1973).

4.1.6.2 Measurement of Oxygen Flux (Flux Analysis) in Intact Cells

A relatively new approach to assess mitochondrial function in intact cells using flux analysis of the oxygen consumption rate (OCR) was reported by Wu et al. (2007). The advantage of this method is that mitochondrial function can be assessed within intact cells, which eliminates any artifacts (e.g., shear stress) that might be introduced from the stirring that is required in the polarographic method (Estabrook, 1967). Assessment of glycolytic activity can also be determined simultaneously by assessment of extracellular acidification rate.

4.1.7 Mitochondrial Role in Apoptosis

Mitochondria are critical in initiating programmed cell death or apoptosis (Wallace, 1999). Sandwiched between the inner and outer mitochondrial membranes are cytochrome *c*, apoptosis-inducing factor, and caspases (proteases) that contribute to apoptosis. Apoptosis is initiated by formation of the mitochondrial permeability transition pore (mtPTP) on the inner membrane. The mtPTP forms by the coalescing of the voltage-dependent anion channel (VDAC), adenine nucleotide translocator (ANT), BCL-2-associated X protein, and cyclophilin D. When the mtPTP is formed, the mitochondrial membrane potential is dissipated, followed shortly thereafter by mitochondrial swelling and release of caspases and apoptosis-initiating factor. The proteolytic caspases released into the cytoplasm degrade

the cytoskeletal architecture. Events that trigger the opening of the mtPTP include a decrease in energetic capacity of the mitochondria, excessive influx of ionic calcium, and increased ROS generation.

4.2 MITOCHONDRIAL INEFFICIENCIES

4.2.1 Electron Transport Defects and Oxidative Stress

4.2.1.1 Reactive Oxygen Species

Mitochondria are a major source of endogenous oxidative stress. Approximately 2–4% of O_2 used by mitochondria may be converted to ROS by univalent reduction of O_2 to form superoxide ($O_2^{\bullet-}$) following electron (e^-) leak from the respiratory chain (Chance et al., 1979; Turrens and Boveris, 1980; Boveris and Chance, 1973). Superoxide dismutase (SOD) converts $O_2^{\bullet-}$ to H_2O_2 that is reduced to H_2O by glutathione peroxidase (GPx). The relatively nonreactive H_2O_2 is converted to the highly reactive hydroxyl radical ($^{\bullet}OH$) in the presence of Fe^{2+} and Cu^{2+}; due to its lipid solubility, it is able to cross membranes and oxidize proteins, DNA, lipids, and carbohydrates throughout the cell (Yu, 1994) (Figures 4.1 and 4.3).

4.2.1.2 Identification of Site-Specific Defects in Electron Transport

Figure 4.3 shows sites of e-leak that are accentuated by treatment with various chemical inhibitors. The use of these chemicals for identifying e^- transport defects were pioneered by Boveris and co-workers (Chance et al., 1979; Turrens and Boveris, 1980; Boveris and Chance, 1973). Numerous reports followed that confirmed complex I and III as predominant sites of mitochondrial e^- leak, which is associated with numerous metabolic conditions in humans, including Alzheimer disease, cancer, diabetes, and aging (Yu, 1994).

4.2.1.3 Mitochondrial ROS Generation in Avian Species

Chemical inhibitors (Figure 4.3) have been used to assess mitochondrial ROS production in birds. In broilers, site-specific defects in e^- leak at complex I and III were identified in liver, lung, skeletal, and cardiac mitochondria obtained from birds exhibiting fulminant pulmonary hypertension syndrome (Cawthon et al., 2001; Iqbal et al., 2001; Tang et al., 2002). Greater ROS production due to site-specific defects in e^- transport was also identified in complex I and III skeletal muscle, liver, and duodenal mitochondria associated with low feed efficiency in broilers (Bottje et al., 2002; Iqbal et al., 2004;

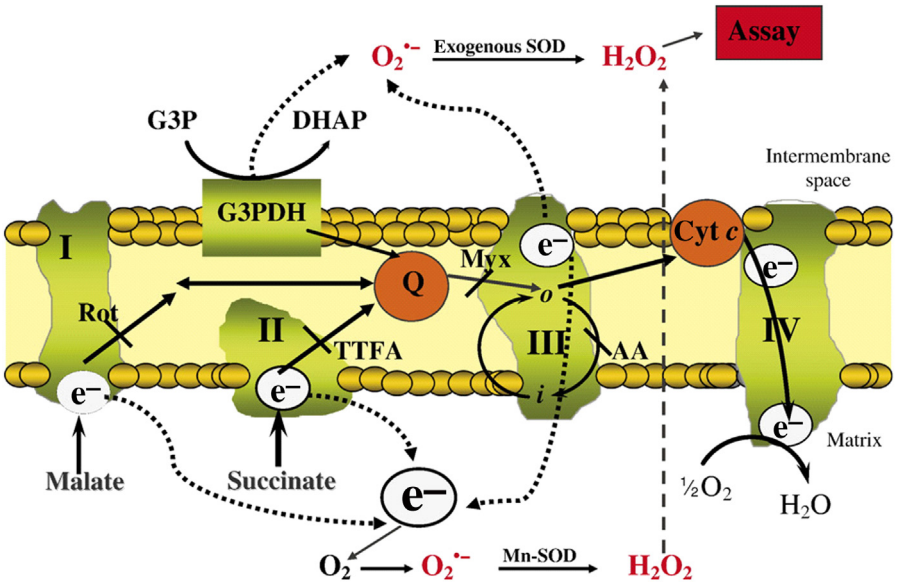

FIGURE 4.3 Diagrammatic representation of identification of site-specific defects in the electron transport chain using chemical inhibitors. The movement of electrons (e^-) along the respiratory chain are shown by solid arrows from complex I or complex II to complex III by the e^- carrier, coenzyme Q (Q) and to complex IV by cytochrome *c* (cyt *c*). The terminal step of electron transport is the full reduction of oxygen (O_2) to water by cytochrome *c* oxidase. Chemical inhibitors of to block e^- transport and identify site-specific defects are rotenone (Rot) at complex I, thenotrifluoroacetone (TTFA) at complex II, and myxothiazol (Myx) (at the outer membrane (*o*)) and antimycin A(AA) (at the inner membrane (*i*)) within complex III. If a site-specific defect exists at any of these sites following chemical inhibition, e^- leak (dotted arrows) results in the univalent reduction of O_2 to superoxide ($O^{\bullet-}$), which is reduced to hydrogen peroxide (H_2O_2) by superoxide dismutase (SOD). Topology of H_2O_2 formation (as in index of reactive oxygen species, ROS) can be determined by adding exogenous SOD to the media in isolated mitochondrial preparations that distinguishes it from endogenous ROS, which is by the mitochondrial located MnSOD (see Miwa et al., 2003). Extramitochondrial e^- leak can also occur when glyceraldehyde 3-phosphate (GSP) is converted by G3P dehydrogenase (G3PDH) to dihyroxacetone phosphate (DHAP). *Reprinted with permission from Ojano-Dirain et al. (2007a).*

Ojano-Dirain et al., 2004, 2007a) as well as complex II in duodenal tissue (Ojano-Dirain et al., 2004). Greater ROS production was likely responsible for higher oxidative stress and lower respiratory chain complex activities consistently observed in animals exhibiting a low feed efficiency phenotype (Ojano-Dirain et al., 2007b; Bottje and Carstens, 2009) and may have been involved in differential gene expression in feed efficiency in broilers (Bottje and Kong, 2013). Mitochondrial ROS production has also been shown to play a role in heat stress (Abe et al., 2006; Mujahid et al., 2006, 2007a,b).

4.2.1.4 Mitochondrial ROS in Normal Cell Function

Although high levels of mitochondrial ROS are detrimental, low levels of mitochondrial ROS are recognized as being vital for normal cell function, acting as second messengers in signal transduction processes (Giulivi and Oursler, 2003; Crawford et al., 1997; Carper et al., 1999; Greiber et al., 2002; Li et al., 2002; Kemp et al., 2003). Baughman and Mootha (2006) hypothesized that there is "a homeostatic role for ROS in maintaining stable respiratory phenotypes across genetic variants of the mitochondrial genome."

4.2.1.5 Mitochondrial ROS and Longevity

Mitochondrial ROS production is generally lower in avian species compared to comparable-sized mammalian species, with an inverse relationship between longevity and mitochondrial ROS production (Herrero and Barja, 1997, 1998). Figure 4.4 presents data of heart mitochondrial ROS production in comparable sized mammals and birds (Herrero and Barja, 1997, 1998) in the presence or absence of ETC inhibitors (Figure 4.3). This species difference is even more remarkable because birds have a number of characteristics that should favor heightened mitochondrial radical production, such as higher body temperatures, metabolic rates, and blood glucose concentrations (Holmes and Austad, 1995; Holmes et al., 2001). The fact that birds have much lower mitochondrial ROS production has been hypothesized to explain lower mitochondrial DNA diversity in avian species compared to mammalian species (Hickey, 2008).

4.2.1.6 Nitric Oxide and Reactive Nitrogen Species

Nitric oxide (NO) produced by mitochondrial nitric oxide synthase (NOS) near the site of the ETC (Giulivi et al., 1998; Giulivi and Oursler, 2003) competitively inhibits cytochrome oxidase, thus regulating mitochondrial O_2 consumption. The release of NO in the presence of ROS can produce a large number of reactive nitrogen species (e.g., peroxynitrite) that damage proteins by nitrosylation. Peroxynitrite was reported to be responsible for decreased activities of complex I and II in mitochondria (Riobo et al., 2001).

4.2.1.7 Mitochondrial ROS: DNA Damage and Respiratory Chain Complex Activities

A balance of mtDNA- and nDNA-encoded proteins is needed for the functional integrity of mitochondria (Nijtmans et al., 2002). Due to its proximity to the respiratory chain and a lack of protective histones, mtDNA is more susceptible to mitochondrial ROS-mediated oxidation than nDNA, and mtDNA oxidation can lead to mitochondrial dysfunction (Kristal et al., 1994; Wei, 1998). Oxidant-medicated repression of

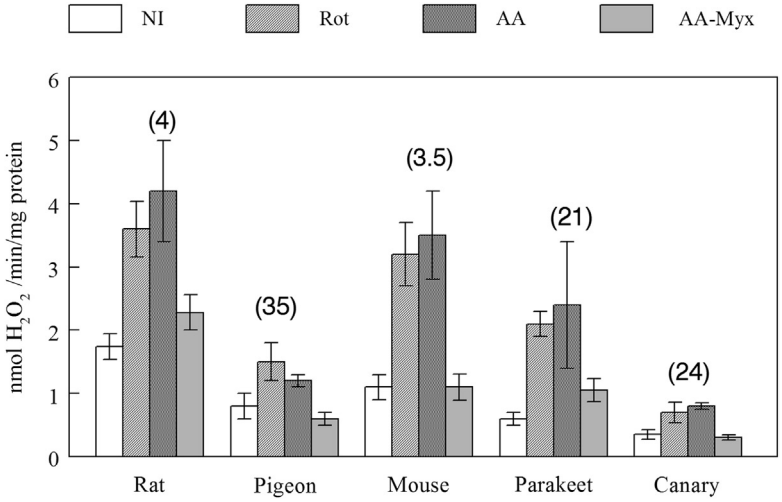

FIGURE 4.4 Hydrogen peroxide (H_2O_2) production rates (expressed as nmol/min/mg protein) in heart mitochondria isolated from mammals and birds of comparable body weights (rat versus pigeon; mouse versus parakeet and canary). Rates of H_2O_2 production are shown for mitochondria treated with no-inhibitor (NI, basal rate), and for mitochondria treated with inhibitors of complex I (rotenone, Rot), and two inhibitors of complex III (antimycin A, AA and myxothiazol, Myx, alone and in combination). The maximum life span for each animal species is shown in parentheses. *Data was obtained from Herrero and Barja (1997, 1998).*

mitochondrial transcription exacerbates dysfunction by inhibiting respiratory protein synthesis (Kristal et al., 1997). Restricted availability of mt-encoded subunits or damaged proteins can lead to diminished complex activities and cell respiration (Wallace, 1999). There are also specific thiols in proteins of complexes I, II, and IV that are particularly susceptible to oxidation and their oxidation leads to decreased complex activity upon exposure to oxidants (Lin et al., 2002b). Inverse relationships between oxidative stress and complex activity were noted in animals with low feed efficiency (Ojano-Dirain et al., 2005; Bottje and Carstens, 2009).

4.2.2 Antioxidants

It is difficult to discuss oxidation without including antioxidant protection. Oxidative stress is unavoidable in eukaryotic organisms and occurs during normal metabolism, primarily within mitochondria. Oxidative stress develops when the generation of ROS overwhelms antioxidant protection (Yu, 1994). Repair of damaged structures (e.g., lipids, proteins) is energetically expensive, requiring considerable input of ATP to either repair or recycle materials within the cell. Mitochondrial ROS are normally metabolized by the enzymatic antioxidants SOD and glutathione peroxidase, as well as by nonenzymatic antioxidants GSH and α-tocopherol (Yu, 1994).

Glutathione is the major endogenous antioxidant system both in the cytosol and within mitochondria (Meister, 1984; Griffith and Meister, 1985; Martensson et al., 1993). Glutathione exists in either a reduced (GSH) or oxidized (GSSG; glutathione disulfide) form; the GSSG:GSH ratio is used as an indicator of oxidative stress. The glutathione reduction-oxidation (redox) system consists of GSH and the GSH recycling enzymes, GSH peroxidase (GPx), and GSH reductase (GR) (Meister, 1984). The enzyme GPx metabolizes peroxides (e.g., H_2O_2), using reducing equivalents from GSH, and catalyzes the reaction shown in Eqn (4.1) (see Figure 4.1 also):

$$2GSH + H_2O_2 \rightarrow GSSG + 2H_2O \qquad (4.1)$$

Low levels of GSSG are maintained by GR, which uses nicotinamide adenine dinucleotide phosphate ($NADPH_2$) to reduce GSSG to GSH, as shown in Eqn (4.2):

$$GSSG + NADPH_2 \rightarrow 2GSH + NADP^+ \qquad (4.2)$$

The glutathione redox system is a vital defense mechanism of mitochondria against free radical damage because mitochondria lack catalase (Martensson et al., 1990), γ-glutamyl synthetase (the rate-limiting enzyme in GSH synthesis) (Meister, 1984), and the ability to export GSSG (Olafsdottir and Reed, 1988). Martensson et al. (1990) noted that the mitochondrial GSH transport system might be designed to efficiently conserve mitochondrial GSH at the expense of cytosolic GSH.

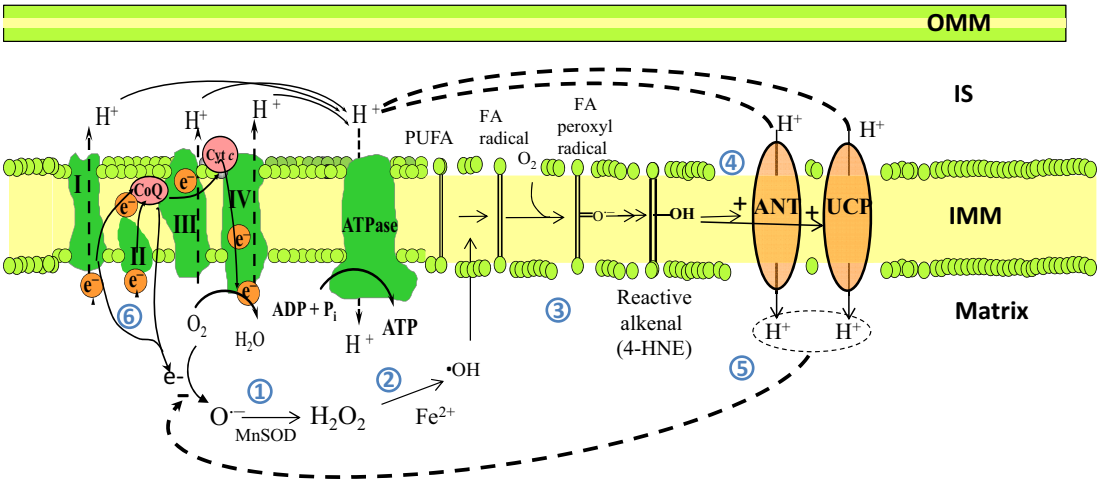
During oxidative stress, toxic levels of GSSG can accumulate within mitochondria (Olafsdottir and Reed, 1988; Cawthon et al., 1999). Unlike cells, mitochondria are unable to export GSSG from the mitochondria, leading to thiolation of critical proteins in the ETC and diminished activities for the respiratory chain complexes. Augustin et al. (1997) reported that mitochondria are not damaged by ROS as long as the mitochondria are in an energized state in which ROS production is minimized. Other research indicates that GSH levels are critical in maintaining or protecting respiratory chain complex activity from oxidation, and positive correlations between GSH and respiratory chain activity have been reported (Bolanos et al., 1996; Cardoso et al., 1999; Ojano-Dirain et al., 2005).

4.2.3 Mitochondrial Uncoupling and Attenuation of Oxidative Stress

Proton motive force provides the power that drives ATP synthesis when protons flow back into the matrix through ATP synthase (complex V). However, protons that flow into the mitochondrial matrix at sites other than the ATP synthase (proton leak) dissipate proton motive force, diminish mitochondrial membrane potential, and short-circuit ATP synthesis (Brand et al., 1994). Oxygen consumption from proton leak can represent 25% of total basal metabolic rate in animals (Rolfe and Brand, 1997). Basal proton leak is facilitated by the intrinsic characteristics of membranes and the presence of intramembranous proteins (e.g., UCPs, ANT) (Dilger et al., 1979; Brown and Brand, 1991; Rolfe and Brand, 1997; Brookes et al., 1997, 1998; Brand et al., 2005). Free fatty acids enhance proton-translocating activities of ANT, UCPs, and phosphate and glutamate carrier proteins (Andreyev et al., 1988, 1989; Echtay et al., 2001; Samartsev et al., 1997; Jaburek et al., 1999). Proton leak is also stimulated or diminished by hyperthyroidism and hypothyroidism, respectively (Hafner et al., 1990).

Proton leak represents an energetic inefficiency, but it plays an important role in attenuating mitochondrial ROS production and endogenous oxidative stress. A self-limiting feedback of superoxide on mitochondrial ROS production (Skulachev, 1996, 1997) is due to increased expression and activity of UCPs and ANT (Echtay et al., 2002; Murphy et al., 2003; Brand et al., 2004). This mechanism is depicted in Figure 4.5, which is a composite of Figures 1 and 2 from Brand et al. (2004).

Uncoupling to reduce mitochondrial ROS generation has been clearly demonstrated in several avian species. In birds, the initial sequencing of the avian uncoupling protein (avUCP) was reported by Raimbault et al. (2001) and Toyomizu et al. (2002). Uncoupling of mitochondria represents an important physiological response to attenuate oxidative stress during both cold and heat stress



ROS-mediated uncoupling
① e⁻ leak increases superoxide ($O^{\cdot-}$) that is reduced to H_2O_2 MnSOD
② In the presence of Fe^{2+}, H_2O_2 is converted to hydroxyl radical ($^{\cdot}OH$)
③ OH initiates lipid peroxidation leading to formation of a stable reactive alkenal (4-HNE)
④ 4-HNE stimulates ANT and UCP activity and expression which
⑤ Increases proton leak that dissipates proton motive force that
⑥ Reduces e⁻ leak and ROS formation.

FIGURE 4.5 Attenuation of mitochondrial reactive oxygen species formation by increased uncoupling activity of adenine nucleotide translocator (ANT) and uncoupling protein (UCP). Shown in the figure are the outer and inner mitochondrial membranes (OMM and IMM) and intramembranous space (IS), within which proton motive force is generated by pumping of protons from the matrix into the IS. Proton leak occurs when protons move across the IMM at sites other than the adenosine triphosphate synthase. Electron leak from flavin and iron-sulfur centers in proteins of complex I and from coenzyme Q into the mitochondrial matrix cause univalent reduction of oxygen to superoxide ($O^{\cdot-}$). The presence of free iron (Fe^{2+}) that can be released from oxidative damage of matrix proteins (e.g., aconitase) results in the formation of a hydroxyl radical ($^{\cdot}OH$), which abstracts an electron from polyunsaturated fatty acid to form a carbon-centered fatty acid radical (FA radical) and an FA peroxyl radical in the presence of oxygen. This leads to the formation of a stable reactive alkenal, 4-hydroxy 2-nonenal (4-HNE), which stimulates uncoupling activity (proton leak) by ANT and UCP. Increased proton leak in turn dissipates proton motive force and mitochondrial membrane potential, which reduces electron leak and mitochondrial ROS formation. *Based on Echtay et al. (2002), Murphy et al. (2003), and Brand et al. (2004).*

conditions. Toyomizu et al. (2002) reported upregulation of both ANT and UCP mRNA in cold-stressed chicken skeletal muscle. Increased UCP and ANT expression has been observed in skeletal muscle of chickens (Toyomizu et al., 2002), king penguins (Talbot et al., 2003, 2004), and cold-acclimated ducks (Rey et al., 2010) that attenuates cold-induced increases in mitochondrial ROS production. Increased mitochondrial ROS and oxidative stress has also been observed in heat-stressed chicken skeletal muscle (Mujahid et al., 2007a,b). It was determined that olive oil attenuated mitochondrial ROS production during heat stress (Mujahid et al., 2009). The increased ROS production during heat stress was due to a combination of down-regulation of avUCP expression and an increase in inner mitochondrial membrane potential (Mujahid et al., 2006; Kikusato and Toyomizu, 2013).

Differences in proton leak and mitochondrial membrane potential have also been linked to the phenotypic expression of feed efficiency in broilers (Ojano-Dirain et al., 2007a; Bottje et al., 2009). Enhanced ROS production was observed in muscle, liver, and duodenal mitochondria in broilers with low feed efficiency compared with broilers with high feed efficiency due to site-specific defects in electron transport (Ojano-Dirain et al., 2004; Bottje et al., 2004; Iqbal et al., 2005). Using a number of different chemical treatments, broilers with a high feed efficiency phenotype exhibited proton leak that was either lower or equal to, but never higher than, proton leak in broilers exhibiting a high feed efficiency phenotype (Bottje et al., 2009). Observations of increased (<0.06) expression of avUCP and lower membrane potential in low feed efficiency mitochondria (Ojano-Dirain et al., 2004, 2007c) are consistent with the model presented in Figure 4.5 to minimize or attenuate mitochondrial ROS formation.

4.3 MATCHING ENERGY PRODUCTION TO ENERGY NEED

4.3.1 Mitochondrial Biogenesis

Although mitochondria divide during mitosis to ensure daughter cells are provided a full complement of functional mitochondria, mitochondrial biogenesis is stimulated in response to increased energy demand. An early

demonstration of mitochondrial biogenesis was provided by Paul and Sperling (1952), who observed that there were more mitochondria in breast muscle in pigeons that are more active than the relatively sedentary commercial chicken. One of the first factors identified to increase mitochondrial biogenesis was PGC-1α (Puigserver et al., 1998; Wu et al., 1999). Cold exposure increased the mRNA expression of PGC-1α, which in turn increased the expression of several mitochondrial proteins, including ATP synthase and cytochrome *c*-oxidases II and IV. PGC-1α and PGC-1β stimulate nuclear respiratory factors (NRF-1 and NRF-2) and mitochondrial transcription factor A (Nisoli et al., 2003, 2004) that upregulate mitochondrial transcription factor A (mtTFA) by independent mechanisms (Meirhaeghe et al., 2003; Lin et al., 2002a). NRF-1 and NRF-2 stimulate mitochondrial protein synthesis, such as ETC proteins, whereas mtTFA stimulates mitochondrial DNA transcription, that is instrumental in synthesis of mitochondrial proteins during mitochondrial biogenesis. Because of its role in mitochondrial biogenesis, PGC-1α has been termed the master regulator of mitochondrial protein synthesis (Nisoli et al., 2003, 2004).

4.3.2 AMP-Activated Protein Kinase

AMP-activated protein kinase (AMPK) is critical for sensing cellular energy (AMP/ATP) status and stimulating mitochondrial biogenesis (Zhou et al., 2001; Hardie et al., 2003; Hardie, 2007; Carling, 2005), as well as regulating animal food intake and overall energy balance (Minokoshi et al., 2004). Once AMPK is phosphorylated by serine–threonine kinase 11 (LKB1) (Hardie, 2005), the activated AMPK phosphorylates several proteins involved in carbohydrate, lipid, and protein metabolism (Kemp et al., 2003; Hardie, 2004, 2007). In general, AMPK reduces ATP-utilizing (anabolic) pathways (e.g., fatty acid synthesis) and increases ATP-generating (catabolic) pathways (e.g., fatty acid oxidation, glycolysis). AMPK is required for stimulating glucose uptake and glycolysis in skeletal muscle cells and astrocytes (Zhou et al., 2001; Almeida et al., 2004). AMPK also upregulates PGC-1α expression (Ojuka, 2004) and therefore presumably plays a role in mitochondrial biogenesis. In conjunction with thyroid hormone receptor activation, PGC-1α upregulates ANT and UCP3 expression, that uncouple mitochondrial oxidative phosphorylation (Masatoshi et al., 2005). Choi et al. (2001) presented evidence that AMPK and the AMPK cascade mechanisms are sensitive to ROS, particularly H_2O_2. Colombo and Moncada (2009) provided evidence that mitochondrial ROS-mediated upregulation of AMPK was associated with an increase of several cellular antioxidants. Thus, AMPK is very important in sensing energy status in cells and could be a pivotal component in growth and development; also, it is responsive to mitochondrial-generated ROS production. The expression of AMPK was higher in species exhibiting a high feed efficiency phenotype (Bottje and Kong, 2013).

4.3.3 Sirtuins

The sirtuins are a family of conserved NAD-dependent deacetylases that regulate many cellular activities including stress response and energy metabolism (Haigis and Sinclair, 2010). SIRT4 is located mainly in mitochondria (Haigis et al., 2006), where it inactivates glutamate dehydrogenase by ADP-ribosylation. The inactivation of glutamate dehydrogenase that converts glutamate to α-ketoglutarate indicates that SIRT4 regulates entry of energy substrates into the Krebs cycle. Knockdown of SIRT4 increased gene expression of mitochondrial and fatty acid metabolism enzymes in hepatocytes and myocytes, and changes in gene expression were associated with SIRT1-dependent fatty acid oxidation (Nasrin et al., 2010). Chau et al. (2010) reported that fibroblast growth factor 21 (FGF21) regulates energy homeostasis in adipocytes through phosphorylation and activation of AMPK by increasing cellular NAD^+ levels as well by deacetylation and activation of PGC-1α and histone 3. Activation of AMPK maintains energy balance by enhancing mitochondrial biogenesis and oxidative metabolism (Hardie, 2007). AMPK increased SIRT1 (NAD^+-dependent type III deacetylase sirtuin 1) by increasing NAD^+ levels that modulate several downstream SIRT1 targets (Canto et al., 2009). AMPK and SIRT1 act in concert with PGC-1α to regulate energy homeostasis in response to differences in nutritional and environmental factors (Reznick and Shulman, 2006; Hardie, 2007).

Ov Nucleus ovoidalis
PE Nucleus pontis externus
PrV Nucleus sensorius principalis nervi trigemini
RPcvm Ventromedial part of the parvocellular reticular formation
Rt Nucleus rotundus
sP Nucleus subprincipalis
SCi Intermediate part of the core nucleus of the pre-isthmic region (Puelles et al. (1994)
SI Primary somatosensory cortex
SII Secondary somatosensory cortex
SS Synsacral segment
SSp Nucleus supraspinalis
St Striatum
Uva Nucleus unaeformis
VB Ventrobasal complex

5.1 INTRODUCTION

Despite the lengthy interim between this and the previous volume, there has been only a limited amount of new information gathered on the avian somatosensory system. This is largely due to the fact that two protagonists in this area of research, Reinhold Necker and Jaap Dubbeldam, have long since retired. The reader will hopefully understand, therefore, the reasons for the relatively few recent publications in this area and the admittedly biased nature of this author's presentation. New recruits to the study of avian somatosensation are clearly needed!

Necker's (2000a) chapter on the avian somatosensory system was a concise overview of its basic organization, from the types, distribution, and physiology of mechanoreceptors and other sensory receptors found in avian skin, to the synaptic and functional connectivity of the somatosensory pathways ascending throughout the neuraxis (Figure 5.1). He divided the avian somatosensory system into two parts, spinal and trigeminal, noting that the former innervates the body surface and extremities and the latter mainly the beak. However, with regard to ascending systems, the word "spinal" usually implies an origin in the spinal cord itself, rather than in the periphery,

Sturkie's Avian Physiology.

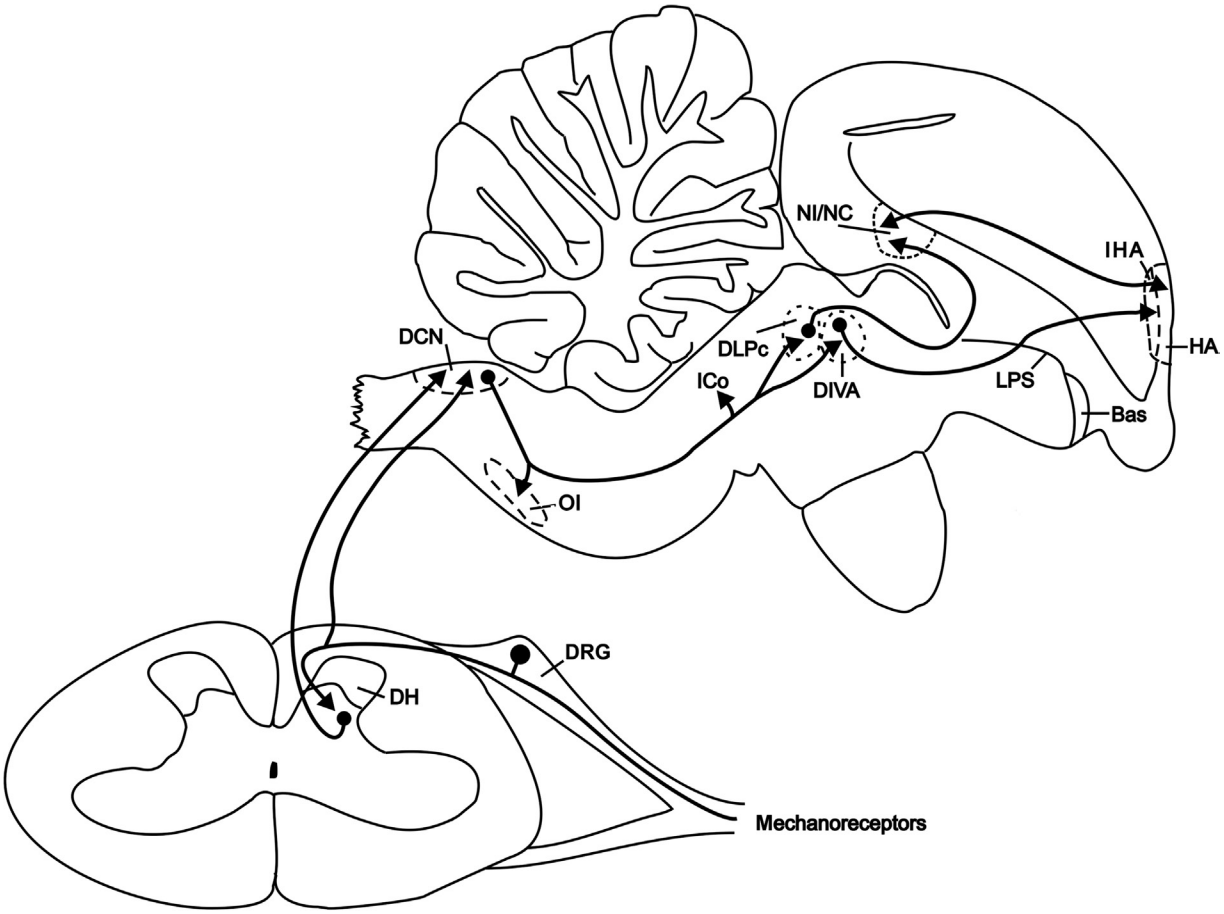

FIGURE 5.1 Schematic drawing of the brain of a pigeon showing the main somatosensory pathways. Filled circles denote cell bodies, arrow heads denote terminations. Note that there are substantial deviations from this plan in other species (see text and Figure 5.2). *Adapted from Necker (2000a).*

and "trigeminal" seems to exclude other primary afferent projections from the head, such as the tongue, which is not innervated by the trigeminal nerve in birds. In this chapter, therefore, a division of somatosensory origins into the body (including wings, legs, and claws) and beak and tongue is preferred. Nevertheless, to better appreciate the following material, the reader should first consult Necker's chapters on the somatosensory system (Necker, 2000a) and the spinal cord (Necker, 2000b)—both in the fifth edition of this book.

5.2 BODY SOMATOSENSORY PRIMARY AFFERENT PROJECTIONS IN DIFFERENT SPECIES

5.2.1 Spinal Cord

Our knowledge of primary afferent projections to the bird's spinal cord is based on a variety of techniques, such as tracing degenerating fibers following dorsal rhizotomy (van den Akker, 1970; Leonard and Cohen, 1975a), injections of tracer into dorsal root ganglia or application of tracer to the cut ends of dorsal roots (Necker, 2001), injections of tracer into feather follicles (Wild, 1985), injections or applications of tracer to whole wing and leg nerves (Wild, 1985; Necker and Schermuly, 1985; Schulte and Necker, 1994), cutaneous nerves and skin (Woodbury and Scott, 1991), the vibration sensitive interosseus nerve (Ohmori and Necker, 1995), ankle joint receptors (Gentle et al., 1995), and muscles (Wild, 1985) in pigeons and chickens. Physiological analyses of pigeon dorsal horn responses have been provided by Necker (1985a,b, 1990) for pigeons and by Woodbury (1992) for chickens.

Although the different techniques provide different patterns of projections to the cord and brainstem, it is clear that primary afferent fibers enter and terminate in the cord differently depending on their diameter, as in mammals. Necker (2001) found that at the entry level of C5, for instance, large-diameter fibers entered the dorsal horn from its medial aspect, between laminae IV and V. These fibers continued into the ventral horn, where they terminated densely, and some continued laterally to terminate in the marginal nuclei. Fine-diameter fibers entered the dorsal horn laterally and terminated in various parts of the horn at

the level of entry, whereas other fine fibers extended as far as C1 rostrally and at least as far as C8 caudally. Intermediate diameter fibers entered the dorsal horn from dorsal and medial positions to terminate from C1 to C8 in lamina IV and medial lamina V. Some fibers crossed in the dorsal commissure to terminate in similar areas on the contralateral side.

That the primary afferent projections are somatotopically organized is indicated by the fact that the follicles of primary flight feathers and their coverts of the wing are represented in lamina I and medial lamina II, whereas the follicles of secondary flight feathers and their coverts are represented at the lateral edge of the dorsal horn (Wild, 1985; Necker, 1990). Terminal fields of chicken ankle afferents are found in laminae I–III and VI, with a few terminals in deeper laminae (Gentle et al., 1995), which is similar to the projections from the cutaneous nerves of the leg in chicks (Woodbury and Scott, 1991). It should be remembered, however, that in birds as well as in mammals, different types of tracer tend to produce labeling in different laminae, with wheat germ agglutinin tending to produce labeling in laminae I and II, and cholera toxin B-chain producing labeling predominantly in lamina III and IV (Robertson and Grant, 1985).

Primary afferent terminations in the dorsal horn can extend over several segments and are not necessarily heaviest at the level of entry of the dorsal root fibers. Gentle et al. (1995), for instance, found that although ankle joint afferents entered the cord predominantly over synsacral level SS5–7, terminations were split such that there was a small field in SS7 and 8 and a larger field in SS3 and 4. Split terminal fields were also found for whole nerve inputs by Woodbury and Scott (1991). Terminations of wing nerve fibers extend well beyond the rostrocaudal extent of incoming rootlets, although the density of terminations declines with increasing distance from the entry zone (Leonard and Cohen, 1975a; Wild, 1985). These terminations are likely collaterals of fibers ascending or descending to more distant levels. In the case of wing nerve afferents, at least, fibers ascending in the dorsal column to the medulla provide collaterals to the dorsal horn of most, if not all, of the dozen or so cervical segments (Wild, unpublished observations in pigeons). In the greenfinch wing, nerve afferent terminations in the cervical cord are concentrated in medial lamina V (Wild, 1997), as are primary afferent fibers in budgerigars (Wild et al., 1997). Neurons at similar locations and in the nucleus of Bischoff in the upper cervical spinal cord of pigeons can be retrogradely labeled from injections of tracer into either a dorsal thalamic somatosensory nucleus (DIVA; see below) or a multimodal thalamic nucleus (DLP; see below) (Wild, 1989), which could suggest the presence of a spinothalamic projection from medial lamina V of upper cervical spinal cord segments. These findings should be contrasted with those of Schneider and Necker (1989), who found that DIVA injections retrogradely labeled very few cells in the brachial spinal cord intermediate region, but many cells at lumbar levels, suggesting a spinothalamic projection mediating lower limb somatosensory input, but the virtual absence of one from the wing.

5.2.2 Brainstem

Primary afferent projections from the body to the brainstem were first visualized in pigeons by van den Akker (1970) using degeneration techniques following dorsal rhizotomies, and later using the transganglionic horseradish peroxidase (HRP) technique by Wild (1985). Neck primary afferents were also visualized in pigeons by Necker (2001) and limb primary afferents have been visualized in pigeons, chickens, greenfinches, and barn owls (Schulte and Necker, 1994; Necker and Shermuly, 1985; Gentle et al., 1995; Wild, 1997; Wild et al., 2001).

At caudal levels of the dorsal column nuclei (DCN; i.e., gracile, cuneate, and external cuneate nuclei[1]) in pigeons, leg afferent terminations in the gracile nucleus lie medial to those of the wing in the cuneate nucleus, but more rostrally there is substantial overlap of leg and wing inputs throughout the DCN, although wing inputs extend further laterally around the periphery of the medulla than leg inputs. A picture of the representation of the wings can be gained by imagining them spread out over the dorsal and dorsolateral periphery of the medulla. Only in the barn owl have terminations from the wing and leg been seen to be confined to clearly separate gracile and cuneate nuclei (Wild et al., 2001). In pigeons, neck primary afferents were found by Necker (2001) to project rostrally and ventrolaterally in the DCN complex, where they terminated in the external cuneate nucleus (CuE), in a nucleus that he compared with the intermediate nucleus of Cajal, as well as in another nucleus he thought comparable to nucleus *x* located lateral to the nucleus of the descending trigeminal tract (nTTD) and ventral to the descending vestibular nucleus, well rostral to the obex.

As in mammals, primary afferent projections to the DCN are supplemented by a dorsal column postsynaptic system (Figure 5.1), which in pigeons takes its origin from lamina IV of the brachial spinal cord, where mechanosensitive neurons have been located (Necker, 1985a,b, 1991).

In pigeons, finches and barn owls primary afferent projections extend ipsilaterally throughout the medulla and into the pons, where they terminate sparsely in proximity to PrV (Wild, 1985, 1997). In the Australian budgerigar

[1] The avian external cuneate nucleus is not the equivalent of the same named nucleus in mammals, because its inputs are not confined to upper limb proprioceptors and, at least in pigeons, it does not project to the cerebellum (Wild, 1985; Reinke and Necker, 1996).

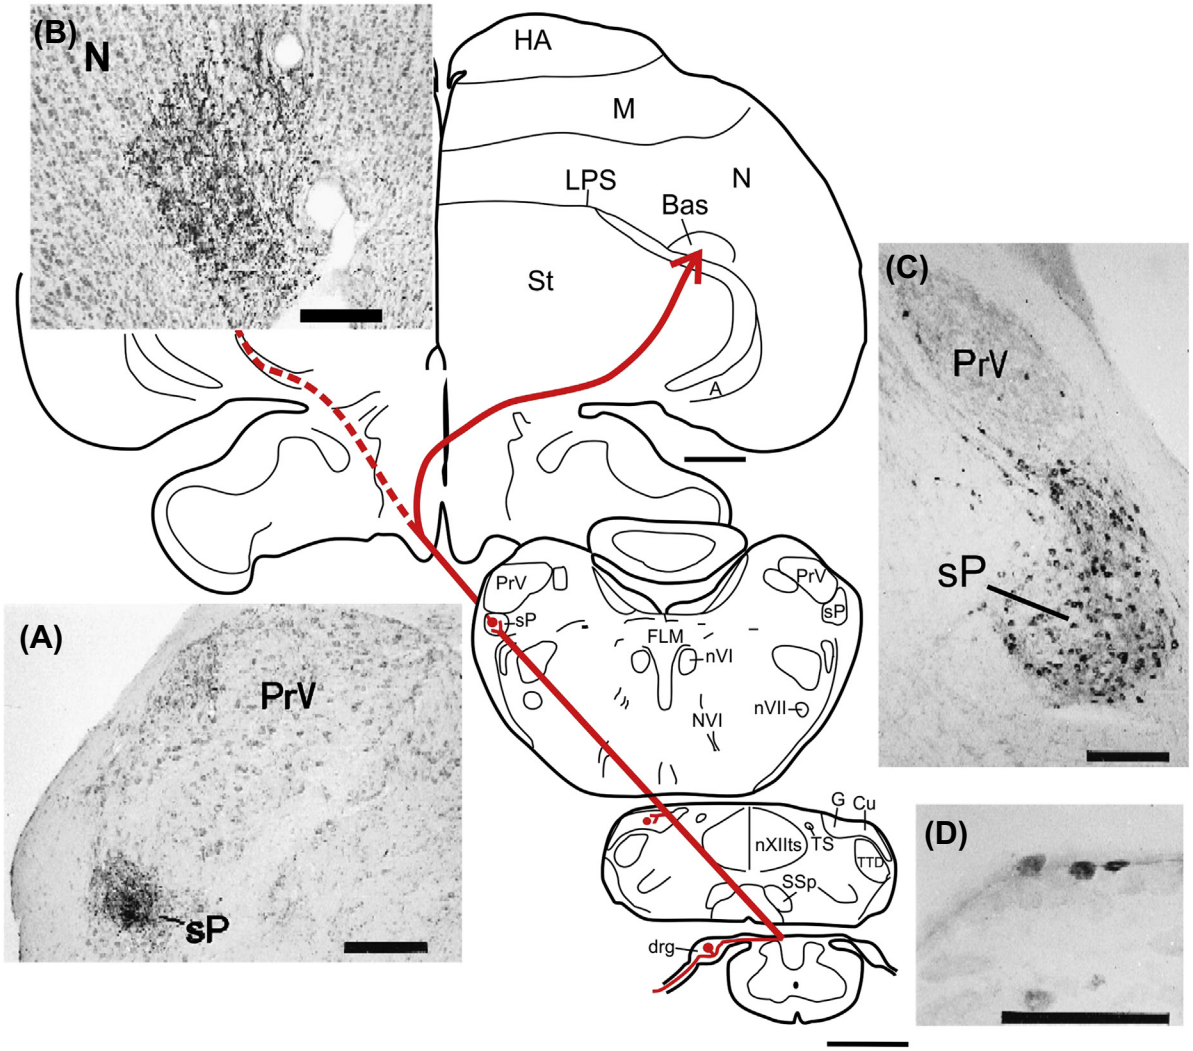

FIGURE 5.2 Depiction of the somatosensory pathway in the budgerigar. Primary afferent fibers project to and terminate in the ipsilateral nucleus subprincipalis (sP), cell bodies of which project their axons to the body regions of Bas, predominantly contralaterally (solid lines). Scale bars for schematics: 1 mm. (A) Terminal field in sP following an injection of horseradish peroxidase-conjugated cholera toxin B-chain (CTB) in the ipsilateral radial nerve. The terminal field of sciatic fibers (not shown) is located ventrolateral to the wing terminal field. (B) Terminal field (note its precise borders) in the body part of Bas following an injection of biotinylated dextran amine (BDA) in the contralateral sP. (C) Retrogradely labeled cells in sP following an injection of CTB in the contralateral body part of Bas. (D) Retrogradely labeled cells in a dorsal root ganglion of a spinal segment from the brachial enlargement, following an injection of BDA in the ipsilateral sP. Scale bars for photomicrographs: 200 mm *Adapted from Wild et al. (1997).*

(*Melopsittacus undulatus*) (Wild et al., 1997) and possibly other psittaciforms (Wild, 1981), primary afferents from both wing and leg also reach pontine levels, where they terminate densely and topographically in a previously undescribed nucleus immediately subjacent to PrV, hence called subprincipalis (sP). One implication of these findings in the budgerigar is that here at pontine levels there is a striking instance of a complete, somatotopic representation of the whole body, with the beak and tongue and possibly some other parts of the head being represented massively in PrV (see below) and, ventral to PrV, a smaller representation of the rest of the body in sP (Figure 5.2).

5.3 ASCENDING PROJECTIONS OF THE DORSAL COLUMN NUCLEI

As in mammals (Berkley et al., 1986), the DCN in birds project predominantly contralaterally to several more rostral nuclei via a medial lemniscus, en route to their final targets in the thalamus (Wild, 1989, 1997). The inferior olive (OI) is the first of these, which then projects to the cerebellum via the inferior cerebellar peduncle. Because in pigeons, at least, the DCN do not project directly to the cerebellum, the route to the cerebellum via the OI may be one way that somatosensory inputs serve sensorimotor control.

Another significant target of the DCN is the midbrain, where there are terminations not only in intercollicular regions surrounding the auditory nucleus mesencephalicus lateralis, pars dorsalis (MLd), but also within it (Karten, 1967; Leibler, 1975; Wild, 1989, 1995, 1997). Units recorded electrophysiologically in the region between the dorsal border of MLd and the tectal ventricle respond to both somatosensory and visual stimuli (Ballam, 1982). The region ventral to more caudomedial regions of MLd forms a distinct nucleus called the intermediate part of the core nucleus of the pre-isthmic region (SCi; Puelles et al., 1994). Its neurons are exquisitely sensitive to tactile stimuli applied to feathers and body surface and respond with large-amplitude action potentials (Wild, 1995). Its ascending projections require further definition, but the location of terminations around the ventral periphery of the thalamic auditory nucleus ovoidalis (Ov), which is the main target of MLd projections (Karten, 1967), closely mirrors the location of SCi with respect to MLd (Wild and Williams, 2000). In pigeons and finches, it appears that the DCN also project directly to MLd, where diffuse terminations overlap the much denser terminations of brainstem auditory nuclei (Wild, 1989, 1995, 1997). Speculations concerning the functions of the somatosensory projection to MLd can be found in Wild (1995). In the barn owl, there is a similar but more restricted DCN projection to rostrodorsal parts of MLd (known in barn owls as the central nucleus of the inferior colliculus; Wild et al., 2008). These findings represent but one of several instances in the avian brain of somatosensory and auditory proximity or overlap.

At caudal thalamic levels, the DCN target the medial spiriform nucleus (SpM), which then projects to the cerebellum (Wild, 1992), and a nucleus called dorsolateral posterior thalami (DLP) in pigeons or unaeformis (Uva) in finches (Wild, 1987, 1994; Funke, 1989a). DLP and Uva tend to be multimodal (Korzeniewski, 1987; Korzeniewski and Güntürkün, 1990; Wild, 1994) and in this respect are perhaps similar to the posterior group of thalamic nuclei of mammals (Gamlin and Cohen, 1986). According to Korzeniewski (1987), the whole body, including the beak and head, is represented in DLP in pigeons. However, the origin of the somatosensory inputs that might account for the beak responses requires further specification, despite the fact that Korzeniewski and Güntürkün (1990) found retrogradely labeled cells in nTTD (to which beak afferents project) following tracer injections in DLP (see also Wild, 1989). In the mallard, projections to the diencephalon from nTTD were not observed (Arends, 1981; Arends and Dubbeldam, 1984).

Rostral to DLP, the DCN target the nucleus DIVA, which lies immediately dorsal and lateral to the auditory nucleus Ov and the visual nucleus rotundus (Wild, 1989, 1997). Unlike DLP, DIVA is specifically somatosensory; although it contains a representation of most body parts (including toes, but not the beak), it is weakly somatotopically organized (Schneider and Necker, 1996). DIVA is probably homologous to part of the ventrobasal complex (VB) of mammals.

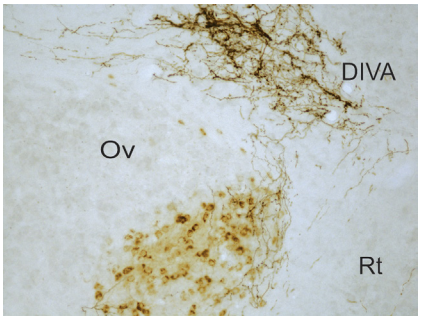

FIGURE 5.3 Labeled fibers and terminations (black) in the lateral part of ovoidalis (Ov) and the overlying dorsal thalamic somatosensory nucleus following an iontophoretic injection of BDA in the dorsal column nucleus (section midline is to the left). Neurons in the lateral part of Ov (brown) were retrogradely labeled by an injection of cholera toxin B-chain in the lateral part of Field L, the primary thalamorecipient auditory field in the telencephalon.

In zebra finches, there is a small but distinct projection from the DCN to the ventrolateral part of Ov, as fibers pass to the overlying DIVA (Figure 5.3). This is yet another instance in the avian brain of somatosensory and auditory proximity or overlap.

Unlike the case for mammals (Berkley et al., 1986), there is some evidence in finches, at least, that single DCN neurons project to more than one more rostral nucleus (e.g., intercollicular nucleus and DIVA) via branched axons (Wild, 1997).

To complete this section, I again note the curious case of the budgerigar, in which the DCN project ipsilaterally to sP in the pons (Wild et al., 1997), as do primary afferents from the wings and legs. Whether the DCN also project to the thalamus in this species is not known. Another variation on the DCN projections occurs in the barn owl, in which there is a projection from both gracile and cuneate nuclei to a large nucleus at the lateral edge of the pons called pontis externus (PE) (Wild et al., 2001). Such a nucleus, which in the barn owl does not receive primary afferent projections directly from the body surface, has thus far not been described for any other species. PE may, however, be the functional equivalent of sP in budgerigar because, like sP, it provides a major body somatosensory and topographically organized input to nucleus basorostralis pallii (Bas) (see below).

The various ascending somatosensory pathways are depicted for four species in Figure 5.4.

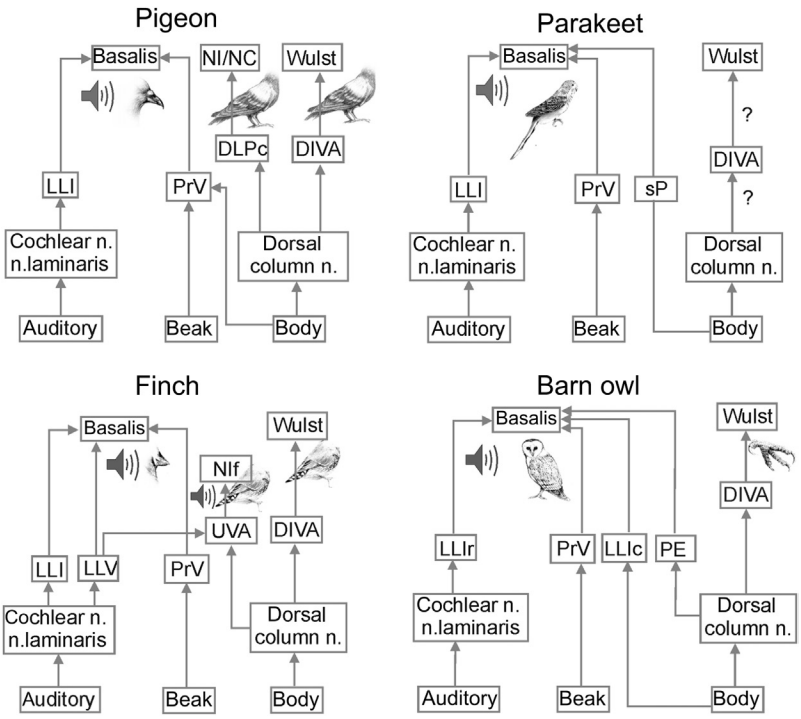

FIGURE 5.4 Comparative schematic of ascending somatosensory and auditory projections to the telencephalon via thalamic and nonthalamic pathways in different avian groups. Note the "beakless" representation of the body in the rostral Wulst of pigeons and finches and the complete body + beak + auditory representation in Bas of parakeets (budgerigars) and barn owls (auditory representations are symbolized by speakers). Note also the auditory projection to Nlf of finches, which is relayed via projections of the ventral nucleus of the lateral lemniscus to nucleus unaeformis (Coleman et al., 2007), and perhaps by projections of ovoidalis to the nucleus interface (not shown; Wild, unpublished observations). *From Wild et al. (2008).*

5.4 TELENCEPHALIC PROJECTIONS OF THALAMIC NUCLEI RECEIVING SOMATOSENSORY INPUT

The ascending projections of DLP/Uva and DIVA are quite separate. In pigeons, DLP projects to the intermediate and caudal parts of the nidopallium (NI/NC: Gamlin and Cohen, 1986; Funke, 1989a; Wild, 1987). The terminal field of more rostral parts of DLP (DLPr) lies medially adjacent to the visual entopallium, whereas the terminal field of more caudal parts of DLP (DLPc) is more caudal, closer to the thalamorecipient auditory field L, and is predominantly somatosensory (Wild, 1987; Funke, 1989b). In finches, which are songbirds, the equivalent region of the nidopallium to which Uva projects is called nucleus interface (NIf), which is usually regarded as belonging to the song system (Nottebohm et al., 1982). It is possible, however, that following a sufficiently fine-grained electophysiological and anatomical analysis, this region of the nidopallium may be subdivided into visual, somatosensory, and auditory components (Wild, unpublished observations); perhaps only the latter provide an important input to HVC of the song control system in songbirds (Nottebohm et al., 1982; Wild, 1994; Vates, 1996).

In both pigeons and finches, the ascending projections of DIVA are specifically to the interstitial hyperstristum accessorium (IHA) of the rostral, somatosensory Wulst (Wild, 1987, 1997; Funke, 1989a). In finches, the input to IHA is distinctly and regularly patchy, but a somatotopic organization has not been examined. In pigeons, there is a very weak somatotopic organization of this region (Funke, 1989b).

It has been suggested that the somatosensory area in the rostral Wulst of birds may be equivalent to SI in mammals, whereas the more caudal somatosensory area in NI/NC is equivalent to SII (Wild, 1987). The two regions are reciprocally connected (Wild and Williams, 1999). Unlike the somatosensory inputs to SI in mammals, however, the avian classical three-neuron sequence of somatosensory projections from the body surface to the telencephalon—via primary afferent projections to the DCN, contralateral DCN projections to the dorsal thalamus, and DIVA projections to the rostral Wulst—mediates a decreasingly specific somatotopic organization as it ascends. In the spinal dorsal horn, the somatotopy is both anatomically and electrophysiologically clear cut (see above; Necker, 1990; Woodbury, 1992); in the caudal parts of the DCN, it is reasonably clear, but much less clear in more rostral parts of the DCN (Wild, 1985). In DIVA, the somatotopy is unimpressive (Schneider and Necker, 1996), as it is in the rostral Wulst (Funke, 1989b). Furthermore, the beak appears not to be represented in DIVA, but the toes and foot joints are (Schneider and Necker, 1996).

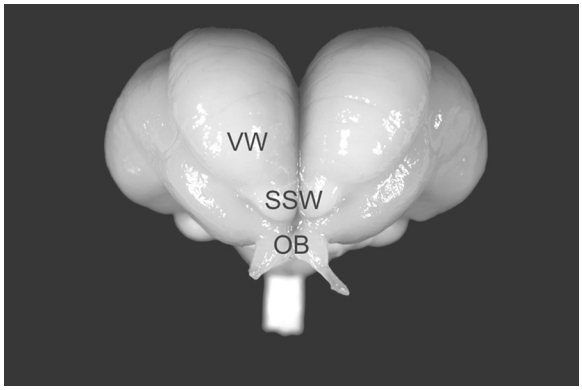

FIGURE 5.5 Photograph of the brain of a barn owl viewed from in front. VW, visual Wulst; SSW, somatosensory Wulst (claw area); OB, olfactory bulb. *From Wild et al. (2008).*

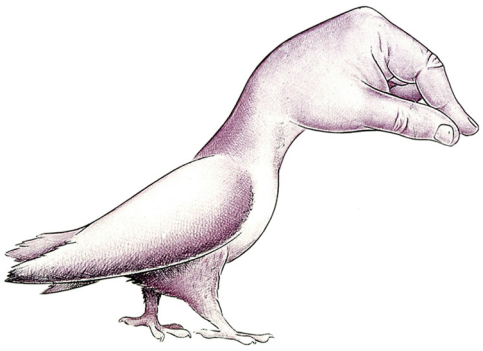

FIGURE 5.6 Illustration of the pigeon body and human hand to illustrate the functional nature of the bird's beak as a combined thumb-and-forefinger grasper and mouth.

In the barn owl, rostral to the rostral Wulst, there is an apparently unique bulge at the frontal pole of the brain that contains a detailed somatotopic representation of the contralateral claw (Manger et al., 2002; Wild et al., 2008) (Figure 5.5). Curiously, a representation of more proximal parts of the lower limb, or of any other body part, was not found in or near this bulge, but the foot and other parts of the body are also represented in what is now called Bas (Reiner et al., 1996, and see below). Apparently, sensory input from the claw is all important for the predatory barn owl. It would be most interesting to determine the representation of the claw in other predatory avian species that strike and capture their prey in a similar way to barn owls, such as eagles.

5.5 SOMATOSENSORY PRIMARY AFFERENT PROJECTIONS FROM THE BEAK AND TONGUE TO THE TRIGEMINAL COLUMN

5.5.1 Principal Sensory Trigeminal Nucleus

The bird's beak or bill varies hugely in shape and size between different species (e.g., compare the beaks of pelican, spoonbill, tucan, kiwi, flamingo, duck, cockatoo, wren)—a variation that is generally correlated with the different feeding habits and preferred foods, on the one hand, and with the size and morphological complexity of the principal sensory trigeminal nucleus (PrV; to which trigeminal beak afferents project)—on the other (Stingelin, 1961). As an instance of microevolutionary processes at work, the size and shape of the beaks of Galapagos finches may even vary according to the annual availability of preferred types of food (Weiner, 1995).

In many species, there are specializations of the beak for various feeding strategies or for probing the substrate. For instance, ducks have an elaborate bill tip organ packed with mechanorecptors (Berkhoudt, 1980), which enable the discrimination of food items through dabbling and sifting. Many shorebirds, such as sandpipers (Scolopacidae), possess Herbst corpuscles densely packed into honeycomb-like cavities in the bill, which enable the detection of food items even remote from the bill (Gerritsen and Meiboom, 1986). This is similar in kiwi, for probing the substrate during their nightime foraging (Cunningham et al., 2007; Martin et al., 2007). In many other species, such as parrots and finches, however, the mechanoreceptors are not in the bone but lie more superficially, nearer the bill surface for the detection, manipulation, and guidance of food items within the mouth (Demery et al., 2011; Krulis, 1978). During feeding, these processes are aided by tongue movements, but differently in different species. Again in parrots and finches, the tongue is loaded with mechanoreceptors (Herbst and Grandry corpuscles) that enhance the efficiency of the cracking and husking of seeds in conjunction with the beak (Krulis, 1978; Wild, 1990; Demery et al., 2011). In contrast, in pigeons the beak functions as a simple grasper, like the forefinger and thumb of humans (Figure 5.6). Once the food object is grasped, the tongue aids the transport of food objects, such as peas or grain, from the beak tip to the back of the mouth, and these items are then swallowed whole (Zweers, 1982).

PrV receives topographic projections from the beak by way of ophthalmic (upper beak), maxillary (palate, lower eyelid), and mandibular (lower beak) branches (Dubbeldam, 1980; Dubbeldam and Karten, 1978; Wild and Zeigler, 1996). Depending on the species, it may also receive projections from the tongue, but not by way of the trigeminal nerve in birds. In pigeons, there does not appear to be a representation of the tongue in PrV (Wild, unpublished observations), whereas in finches, parrots and ducks, there is a substantial lingual representation in PrV.

In ducks, lingual afferents are carried by the glossopharyngeal nerve and terminate in a dorsomedial portion of PrV (Dubbeldam et al., 1979; Dubbeldam, 1980). In finches and parrots, they are carried by the hypoglossal

nerve and terminate in a dorsolateral portion of PrV (Wild, 1981, 1990) (Figure 5.7). These afferents are unlikely to be trigeminal afferents that hitchhike via glossopharyngeal nerves (CNs) IX or XII, because their cell bodies are not located in the trigeminal ganglion, but in a combined "jugular" ganglion (Dubbeldam et al., 1979; Wild, 1981). The innervation of the orderly arrays of sensory receptors (Herbst and Grandry corpuscles: Berkhoudt, 1980; Gottschaldt, 1985) in the tongue can be visualized by injecting the hypoglossal nerve with cholera toxin B-chain (CTB), or staining tongue sections with a trichrome stain (Figure 5.7). These receptors have also been visualized with electron microscopy (Toyoshima and Shimamura, 1991), although the source of their innervation was apparently not known to these authors.

5.5.2 Nucleus of the Descending Trigeminal Tract (nTTD)

Because PrV is the principal origin of projections to the telencephalon, it has overshadowed interest in the descending component of the trigeminal column. In fact, there is still only one systematic anatomical analysis of the combined afferent and efferent projections of the spinal trigeminal nucleus in birds, namely that in the mallard duck (Arends and Dubbeldam, 1984; Arends et al., 1984), and few electrophysiological analyses (Silver and Witkovsky, 1973). With Karten, Dubbeldam went on to study the descending trigeminal projections in the pigeon (Dubbeldam and Karten, 1978), using lesions of the trigeminal ganglion to induce axonal degeneration in the tract and nuclei, as had been done previously in ducks. A more recent study of these projections in pigeons was carried out using injections of HRP-conjugated CTB into the three nerve branches or their innervated territories (Wild and Zeigler, 1996), and also CTB in chickens (Wild and Krützfeldt, 2012). The various studies show a fairly consistent pattern of descending projections throughout the three subdivisions of the spinal nucleus, there being a roughly inverted representation of mandibular, maxillary, and ophthalmic afferents throughout pars interpolaris and parts of caudalis, but a clear-cut mediolateral representation at upper cervical spinal levels. Corneal afferents terminate specifically in a ventral portion of the ophthalmic representation in pars caudalis and in the laterally adjacent external cuneate nucleus (Wild, 1999). Dubbeldam and Karten (1978) also described a lateral descending tract in the pigeon, which is also present in certain snakes possessing infra-red detection and hence in birds might carry thermosensitive afferents (see Wild and Zeigler, 1996).

As in mammals, mechanosensitive afferents that terminate in nTTD in birds arrive over other nerves in addition to the trigeminal. In the mallard tongue, afferents traveling in the glossopharyngeal nerve terminate dorsomedially in nTTD (Dubbeldam et al., 1979). In finch tongue, afferents that travel in the lingual branch of the hypoglossal nerve terminate dorsolaterally in pars interpolaris and pars caudalis of nTTD, but most medially at upper cervical spinal

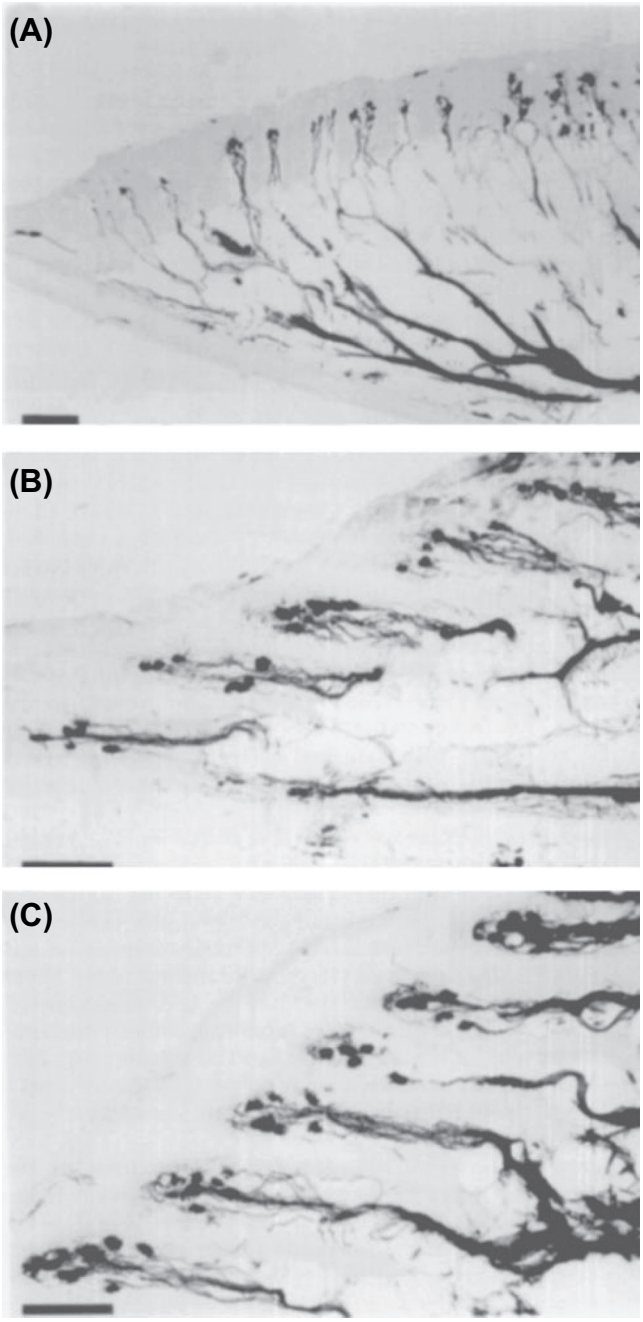

FIGURE 5.7 Photomicrographs of horseradish peroxidase-conjugated cholera toxin B-chain labeled hypoglossal nerve branches innervating the papillae of the tongues of a zebra finch (A), a greenfinch (B), and a gold finch (C), anterior to the left. The terminal "blobs" visible at this magnification (bars = 200 μm) are terminal cell receptors at the sides and apices of the bowls of flask-shaped papillae. Note how the papillae of the zebra finch tongue are perpendicular to the surface, whereas those of the other two species lie in the horizontal plane and are hence at approximately 45° to the surface. *From Wild (1990).*

cord levels. Interestingly, this suggests that although the tongue makes contact with both upper and lower beaks during feeding, in the brainstem lingual afferents are aligned with mandibular afferents (which innervate the lower beak) rather than with ophthalmic ones (which innervate the upper beak).

5.6 NUCLEUS BASOROSTRALIS

Anatomical knowledge of trigeminal components of the avian somatosensory system has existed for much longer than knowledge of its spinal components, Wallenberg (1903) described a direct projection from PrV to a nucleus in the rostrobasal part of the avian forebrain via the quintofrontal tract in 1903. Although considerable anatomical and physiological attention has been directed to Bas in several species in the last 40 years, the nucleus remains enigmatic from both an anatomical and to some extent from a functional point of view. The absence of a thalamic relay in the PrV projection remains puzzling, at least in comparison to the organization of the somatosensory system in mammals (Cohen and Karten, 1974). Although Bas has been known for decades to play a major function in the sensory control of feeding in pigeons and ducks, it is now known to be more than a forebrain nucleus dedicated solely to the somatosensory representation of the beak (Witkovsky et al., 1973).

Dubbeldam and colleagues in the 1980s used the mallard to investigate the functional morphology of Bas in relation to the duck's feeding apparatus and its various mechanoreceptors involved in the different sensory phases of feeding (Berkhoudt, 1980). The projections of PrV subnuclei were traced to Bas (Dubbeldam et al., 1981) and the nucleus was mapped electrophysiologically to reveal a distinct functional topography based on the representations of the glossopharyngeal and trigeminal nerve branches innervating the tongue and beak, respectively (Berkhoudt et al., 1981). Projections of PrV to Bas were also traced in pigeons (Wild et al., 1985) and in zebra finches (Wild and Farabaugh, 1996), but Bas is much smaller in these species than in ducks and does not lend itself so readily to detailed electrophysiological mapping. In budgerigars, as in ducks, however, Bas lies atop the pallial–subpallial border rather that lateral to it, so a complete mapping of the representations of beak and tongue has been performed (Wild et al., 1997) (Figure 5.8). As in ducks, a large lingual representation is present rostrally in Bas, but this is hypoglossal territory rather than glossopharyngeal. Behind is an even larger representation of the beak, followed by a smaller one of the head. On the lateral aspect of the head, representation is an indentation that includes a representation of the cochlea and possibly of the semicircular canals; these representations seemingly mirror the position on the lateral aspect of the skull of the cochlear and vestibular apparatus at the medial end of an external auditory meatus. Progressively more

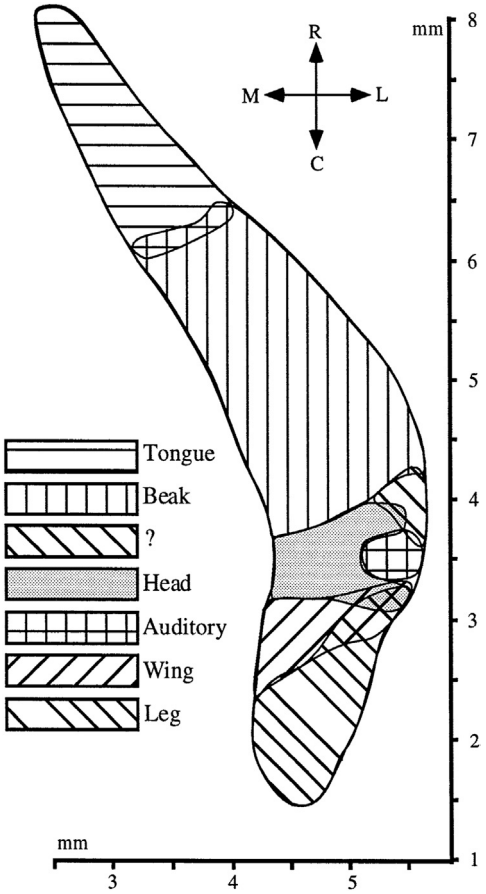

FIGURE 5.8 A two-dimensional map of Bas on the right side of the budgerigar brain. The map is based primarily on systematic recordings of evoked multiple-unit activity in Bas. The area rostral to the auditory area possibly receives inputs from a vestibular nucleus. *From Wild et al. (1997).*

caudal to the representation of the head are representations of the wings, body, and legs and feet. These body inputs are relayed predominantly by the contralateral nucleus sP, lying ventral to PrV, which supplies the beak and tongue inputs. Thus, in the budgerigar, there is a complete representation of the body in Bas, much as there is at pontine levels (see above).

The auditory representation in Bas of all species thus far examined reflects its input from the intermediate nucleus of the lateral lemniscus (LLI, which lies close to PrV), a projection first defined in pigeons (Arends and Zeigler, 1986) and later in zebra finches (Wild and Farabaugh, 1996). In these last two species, however, complete body representations have not been found in Bas, although in finches, as in parrots, there is a large lingual (hypoglossal) representation rostrally in the nucleus.

The largest Bas thus far encountered is that of the barn owl, in which there also appears to be a complete body representation, including a tonotopically organized auditory component (Wild et al., 2001). Injections of tracers in Bas retrogradely label neurons in the massive PE nucleus that

forms a bulge on the lateral aspect of the pons and lies ventrolateral to the equally large anterior and posterior divisions of the dorsal nucleus of the lateral lemniscus (LLda and LLDp). In turn, injections in PE retrogradely label neurons in the DCN, thereby completing a three-neuron sequence of somatosensory projections from the body periphery, but one that is quite different from the classic sequence projecting via the thalamus. Medially adjacent to PE is a smaller LLI that presumably provides most of the auditory input to Bas, although Bas seems also to receive a small auditory projection from LLDa.

5.7 THE MEETING OF THE SPINAL AND TRIGEMINAL SYSTEMS

In his chapter on the spinal cord, Necker (2000b) briefly mentioned a difference between pigeons and chickens in the laminar organization of the dorsal horn—a difference that warranted further examination (Wild et al., 2010). In pigeons, the dorsal horn laminae are arranged in mammalian fashion, with lamina II lying dorsal to lamina III; however, in chickens the latter lies medial, not ventral, to the former (cf. Brinkman and Martin, 1974; Leonard and Cohen, 1975b). In fact, as Woodbury (1998) showed, the majority of bird species resemble chickens, rather than pigeons, in the bifid, side by side arrangement of laminae II and III. Nevertheless, the functional organization of these laminae in chickens and their kin is not dissimilar to that in pigeons and their kin, in that smaller diameter and unmyelinated primary afferents terminate in lamina I and II, whereas larger diameter, myelinated primary afferents terminate in lamina III (Woodbury and Scott, 1991; Wild, 1985).

Many years ago, Woodbury asked a related, interesting question about the organization of the trigeminal dorsal horn: Since this was generally considered to be a direct continuation of the spinal dorsal horn, and to have a similar organization, did this organization reflect the organization present at spinal levels in species in which II and III were side by side rather than arranged in mammalian-type laminar fashion? In other words, was the trigeminal dorsal horn also split in chickens, etc., with a side by side arrangement of superficial and deeper laminae? This question has been recently answered, and the findings compared with those in pigeons (Wild and Zeigler, 1996; Wild et al., 2010). It was found that the trigeminal dorsal horn in chickens was organized in a laminar fashion, as it is in pigeons, and remained laminar down to about the level of C3. Thereafter, however, lamina III gradually, over a couple of segments, shifted medially, until from C5 caudally laminae II and III came to lie side by side. It was also shown that, although the three branches of the trigeminal nerve in the chicken terminated throughout the dorsal horn in a similar fashion to that in pigeons—with ophthalmic afferents laterally, mandibular afferents medially and maxillary afferents in between—they did not extend further caudally than about C3, in contrast to C6 or C7 in pigeons. Thus, it appears that trigeminal primary afferents in the chicken do not terminate at cervical spinal levels, having a side by side arrangement of dorsal horn laminae. These findings suggest a discontinuity of spinal and trigeminal dorsal horn organization, the reason for which remains obscure. What is clear, however, is that Woodbury's (1998) hypothesis of a side by side arrangement of laminae II and II defining a novel clade of birds is not supported, for when an appropriate phylogenetic analysis is performed, a reversion to the mammalian type of arrangement of dorsal horn lamina is seen to have occurred several times in avian evolution (Wild et al., 2010).

5.8 THE SOMATOSENSORIMOTOR SYSTEM IN BIRDS

In mammals, somatosensory inputs to the cortex initiate somatomotor responses that reach brainstem and spinal targets via corticobulbar and corticospinal components of the pyramidal tract. Such a tract in birds originating in the rostral part of the Wulst was proposed by Zecha (1962) and shown with contemporary tracing techniques in pigeons and zebra finches by Wild and Williams (2000). The pyramidal tract equivalent originates in the hyperpallium apicale (HA) of the rostral Wulst, implying rather direct connections between somatosensory inputs to IHA and somatomotor outputs from HA. The tract and its terminations are far from meager. As in mammals, the red nucleus is a prime target, which then projects to all levels of the spinal cord (Wild et al., 1979). Further caudally, the tract terminates profusely throughout wide regions of the brainstem reticular formation and secondary sensory nuclei, such as the external cuneate nucleus, but does not proceed further caudally than the upper cervical levels.

An interesting but little-known somatosensorimotor link in the brainstem reflects control of the lower eyelid, which relaxes during sleep to cover the eye, in contrast to the descent of the upper lid in mammals. During waking hours, the lower eyelid appears to be under tonic control to keep the eye open, until a corneal stimulus initiates a defensive reaction. These actions are mediated via corneal afferent input to the ophthalmic part of nTTD and projections of nTTD to the dorsal motor nucleus of the trigeminal motor complex that innervates the two muscles of the lower eyelid (Wild, 1999).

In contrast to motor output from rostral HA via the pyramidal tract, outputs of Bas exit the telencephalon from the arcopallium at the caudal pole of the brain. They reach the arcopallium indirectly via an overlying part of the frontal nidopallium and the caudolateral part of the nidopallium (NCL) (Wild et al., 1985; Dubbeldam and Visser, 1987). In finches, beak and auditory components of Bas were shown to follow this route independently (Wild and Farabaugh,

1996). The descending projections of different major parts of the arcopallium were originally described by Zeier and Karten (1971) in pigeons and shown to include secondary sensory nuclei in the brainstem. This was specifically confirmed using contemporary tracing techniques in zebra finches, in which Bas-recipient components of the lateral arcopallium were shown to target the spinal trigeminal nucleus (Wild and Farabaugh, 1996) and the ventromedial part of the parvocellular reticular formation (RPcvm), which is a major nexus of premotor projections to the jaw and other upper vocal tract motor nuclei (Wild and Krützfeldt, 2012).

5.9 SOMATOSENSORY PROJECTIONS TO THE CEREBELLUM

In the pigeon cerebellum, there are two somatosensory areas—one rostrally (lobules I–VI) and another caudally (lobule IX) (Necker, 2000a; see also Whitlock, 1952). Somatosensory projections to these regions are relayed from the spinal cord (Necker, 1992, 2000a; Okada et al., 1987). Spinal inputs to the anterior cerebellum arise predominantly from neurons in Clarke's column and hence are proprioceptive. Spinal inputs to the posterior cerebellum arise primarily from cervical lamina IV neurons, which are mechanosensitive (Necker, 1992). Another source of putative mechanosensitive spinocerebellar fibers is the paragriseal cells, which in the lumbosacral spinal cord are contacted by the axons of neurons in the contralateral accessory lobes of Lachi (marginal nuclei) (Necker, 1997). These lobes comprise a sensory component of a lumbosacral specialization involved in a sense of equilibrium (Necker, 1999; Necker et al., 2000; Rosenberg and Necker, 2000).

5.10 MAGNETORECEPTION AND THE TRIGEMINAL SYSTEM

The link between magnetoreception and the trigeminal system is highly controversial, which is fully discussed by Mouritsen in the present volume (Chapter 8). My own involvement in this area of research has been fascinating but has also produced some apparently inconsistent results. Initially, I was able to contribute to a careful laboratory conditioning study of magnetic intensity discrimination in homing pigeons by sectioning either the ophthalmic branch of the trigeminal nerve (which innervates the upper beak where the magnetoreceptor was suspected to lie) or the olfactory nerve (as a control)—first in different birds and then in the same birds (Mora et al., 2004). The results showed that a learned discrimination between the presence versus the absence of a magnetic anomaly was reduced to chance by sectioning the ophthalmic nerve but not by sectioning the olfactory nerve. At about the same time, our group showed what appeared to be approximations between cholera toxin B chain-labeled ophthalmic afferents and iron-containing structures in the base of the upper beak—structures that we thought might be some sort of mechanoreceptor that could perhaps signal a magnetic stimulus (Williams and Wild, 2001). Together, these studies seemed to support the work of Beason and Semm (1987) and Semm and Beason (1990), who reported electrophysiological responses of trigeminal nerve cells to magnetic stimulation in the transequatorial migratory bobolink.

Then, together with Anna Gagliardo and colleagues in Pisa, Italy, we performed the same surgery (ophthalmic or olfactory nerve sections) in two groups of homing pigeons prior to releasing them from unfamiliar territory approximately ~50 km from their home loft. The results were exactly the opposite of those gathered in the laboratory (Gagliardo et al., 2006). That is, trigeminal deafferentation had no effect whatsoever on measures of either orientation or homing performance, whereas olfactory nerve deafferentation produced severe effects in both, with the majority of birds never to be seen again. Variations on this theme were performed in subsequent experiments, all with the same effect (Gagliardo et al., 2008, 2009). The role of olfaction in pigeon homing, although fascinating (Gagliardo, 2013), is not relevant here. What is relevant is that, despite the results of these behavioral, real-life homing experiments, other anatomists have produced evidence either in favor of beak (trigeminal) mediated magnetoreception (Fleissner et al., 2003) or completely against it (Treiber et al., 2012).

Then, working with Mouritsen, we showed that the trigeminal ophthalmic nerve was not involved in the detection of magnetic compass information in a European migrant, the European robin (Zapka et al., 2009), but it did appear to be involved in mediating the detection of magnetic field changes, as indicated by stimulus-dependent zenk protein activation in PrV and in parts of the spinal trigeminal nucleus (Heyers et al., 2010).

What the outcome of these results will be is not clear, especially in the absence of unequivocal evidence of a magnetoreceptor in the beak of either pigeons (Treiber et al., 2012) or in any species thought to use the Earth's magnetic field to guide migration. Furthermore, electrophysiological recordings of responses to magnetic stimuli in the trigeminal brainstem complex have not thus far been replicated, although recordings in other brainstem regions have. Technical difficulties in ruling out artifactual responses to electrical and metal components of the recording apparatus should also be appreciated in studies of magnetoreception. Perhaps there are magnetoreceptors in other peripheral locations, such as the lagenar or vestibular apparatus (Wu and Dickman, 2012), but it should be noted that removal of the lagenar was shown to have no effect on homing in pigeons (Walraff, 1972). These and other issues, and the

evidence in favor of light-dependent magnetoreception, are discussed by Mouritsen (2013).

5.11 SUMMARY AND CONCLUSIONS

It is hoped that this chapter will lead to the realization and appreciation of considerable diversity in the organization of the somatosensory system in birds. Even within the few species so far examined, there seem to be major deviations from the commonly accepted mammalian-type sequence of somatosensory projections throughout the brain. Of course, within mammals also, there are huge differences in the species-specific representation of the integument and of parts of the head—representations that, as in birds, reflect the functional importance of the body part in the everyday behavior of the animal. However, these distorted representations in mammals are the end stations of a common three-neuron sequence of somatosensory projections from the periphery to the cortex, via the DCN and the thalamus. In contrast, in some species of birds, even the DCN are not an obligatory relay in the sequence of ascending projections from the periphery. Furthermore, in parrots, at least, there appears to be a complete representation of the body and head at pontine levels—a phenomenon not encountered in mammals, or probably in many other species of birds.

Another striking and equally puzzling feature of the somatosensory projections in birds is the complete or partial separation of the representations of the beak and body in Bas or the rostral Wulst, respectively. The great majority of beak inputs are relayed via PrV to Bas. In barn owls and budgerigars, the representation of the beak in Bas is but one part, albeit a major part, of a complete representation of the whole body. In ducks, pigeons, and finches, a representation of the rest of the body is apparently absent in Bas (or has not yet been found), except for that of the cochlea.

In pigeons, the somatosensory, rostral part of the Wulst comprises a weakly somatotopic representation of the body minus the beak, with a second nonsomatotopic body representation further caudally in the nidopallium (Wild, 1987; Funke, 1989a). Whether there is a somatosensory representation of the body in the rostral Wulst of ducks and parrots remains to be determined. In barn owls, the claw—and only the claw—is represented in what may be a specialization of the rostral Wulst. In the dunlin (Pettigrew and Frost, 1985), the finding of a tactile fovea in the rostral part of the telencephalon, representing the specialized probing beak tips, is intriguing, but whether the recording electrodes were in Bas or a body representation in another part of the telencephalon is not clear.

In the final analysis, we should remind ourselves—obvious though it may be—that one of the main functions of the body somatosensory system, at least for most birds, is to enable flight. Once thought to be a meager system (Ariëns Kappers et al., 1936), the complexity of its organization can now be appreciated with the help of the tools of modern neuroanatomy and electrophysiology. With the help of cameras fixed to flying birds (jdp.co.uk/programmes/earthflight), we can marvel at the feedback from feather follicles this system must provide to guide the birds through their aerial worlds (Bilo and Bilo, 1983; Necker, 1985c).

ABBREVIATIONS

Aivm Ventromedial portion of the intermediate archopallium
CM Caudal nidopallium
ICc Central nucleus of the inferior colliculus
ICx External nucleus of the inferior colliculus
ILD Interaural level difference
ITD Interaural time difference
LLDp Posterior part of the ventral nucleus of the lateral lemniscus
MLd Nucleus mesencephalicus lateralis pars dorsalis
NA Nucleus angularis
NCM Caudal medial nidopallium
Nd Dorsal nidopallium
NL Nucleus laminaris
NM Nucleus magnocellularis

6.1 INTRODUCTION: WHAT DO BIRDS HEAR?

Birds are very vocal. They communicate by a multitude of vocalizations, ranging from simple calls and cries to extremely varied songs, which are often also beautiful to our ears. Unlike simple calls and like human speech, birdsong must be learned and can serve to recognize other birds individually. Even beyond communication, the sense of hearing has special meaning to many birds. Owls that hunt hidden prey or at night rely on their keen sense of hearing. Some birds use echolocation to find their way in dark caves. However, some myths about the hearing of birds also abound. Perhaps the most notorious is the assertion that they can hear ultrasound—that is, frequencies too high for humans to hear. Bird scare devices based on broadcasting ultrasound might scare a lot of mammals, but they are inaudible to birds. Although some birds' songs may contain ultrasonic components (Pytte et al., 2004), they do not hear those themselves. Avian hearing typically remains restricted to below 10 kHz (Figure 6.1), somewhat lower than human hearing. As a rule of thumb, small birds hear better at high frequencies than larger birds and vice versa (Dooling et al., 2000; Gleich and Langemann, 2011). Some birds, most notably owls, are exquisitely sensitive and able to hear fainter sounds than we can (Figure 6.1).

In many standard behavioral auditory tests, such as frequency or intensity discrimination, birds do just as well as a typical mammal, including humans (Dooling et al., 2000). On some measures of temporal resolution, especially tasks that require the perception of fast-fluctuating fine structures, birds often outperform mammals (Dooling et al., 2000). Localizing sounds is more of a problem for birds because of their generally small head size which, in combination with their restricted upper hearing range, offers only small interaural cues (Klump, 2000; Köppl, 2009). As a rule, birds can localize sounds in azimuth as well as any mammal of comparable size. However, they cannot localize in elevation. The only exceptions to this are several owl species, which show extraordinary localization performance and prominent specializations associated with that (Klump, 2000). In more naturalistic auditory tasks, birds have been shown to group complex sounds into perceptual categories and patterns, much like humans do with speech syllables, for example (Dooling et al., 2000). Birds also form "auditory objects"—that is, they group concurrent sounds in a complex scene into perceptual objects, such as different individual birds singing or tonal patterns forming galloping rhythms (Dooling et al., 2000).

Obviously, the auditory world of birds is rich, and hearing plays an important part in their lives. This chapter summarizes the sensory aspects of hearing in birds. How do birds' ears work and how is sound processed in the brain? It should be pointed out that, although not the focus of this chapter, much of what is discussed below also applies to crocodilians, which, together with birds (and a lot of extinct forms), are classified as archosaurs (Carroll, 1988). Like birds, crocodilians are quite vocal and their auditory system is very similar (Vergne et al., 2009; Young et al., 2014).

6.2 OUTER AND MIDDLE EAR

6.2.1 No Specialized Outer Ear Structures, Except in Owls

Birds, like all nonmammals, do not have external ears or pinnae. This is easily explained by their generally small body (and consequently head) size in combination with a range of hearing limited to frequencies below about 10 kHz. The mammalian pinna is a sound reflection and filtering device that provides cues about the direction of a sound source relative to the head (Pickles, 2008). For this to be effective, sound wavelength, as a rule of thumb, must be smaller than head diameter—a condition that is generally not met in birds within their limits of hearing. Some very specialized owls, however, exploit similar principles by bearing asymmetrical outer ears consisting of a facial ruff, skin flaps, and/or even asymmetrical bony ear canals (Norberg, 2002). Effectively, one of the outer ears is pointing slightly upwards and the other downwards, which differentially reflects frequencies above 4 kHz or so (Keller et al., 1998). If the inputs from both ears are compared, this conveys a sensitivity for sound source elevation (see Section 6.4.2). Remarkably, such asymmetrical outer ears arose several times independently, in different owl genera, as an adaptation to hunting by auditory cues (Norberg, 2002).

6.2.2 The Single-Ossicle Middle Ear

Middle ears arose independently in a number of land vertebrate lineages during the Triassic period (Clack and Allin, 2004). In all nonmammalian lineages, the middle ear consists of a simple, piston-like device. It is for the most part homologous with the mammalian stapes (Manley and Sienknecht, 2013). The middle ear of birds consists of an elongated, mostly bony columella that bears a footplate on its medial end that abuts the bony inner-ear capsule. At its peripheral end, the columella grades into the mainly cartilaginous extracolumella that, with one of its several projections, makes close contact to the eardrum (Figure 6.2). The most important part of the extracolumella is the inferior process, which connects the edge of the eardrum to somewhere close to its center. About halfway along its length, the extracolumella is connected almost at a right angle to the columella; the flexible cartilage connection permits the columella to move in a piston-like fashion. Eardrum motion causes the inferior process to tilt on its fulcrum (at the edge of the eardrum), which exerts a force on the columella (Figure 6.3). The force at the columellar footplate greatly exceeds that of the sound arriving at the eardrum because (1) the columella inserts at (roughly) half the length of the extracolumella and (2) the surface area of the eardrum is much larger than that of the footplate (Saunders et al., 2000). By these means, the middle ear acts as an impedance-matching device allowing sound from the low-impedance medium air to very effectively change the pressure in the high-impedance fluids of the inner ear (Figure 6.3). Without it, the inner ear would be about 40 dB less sensitive (Gummer et al., 1989).

An enigma remains the paratympanic organ, which is a receptor patch almost exclusively found in birds and crocodiles, situated on the wall of the tympanic cavity

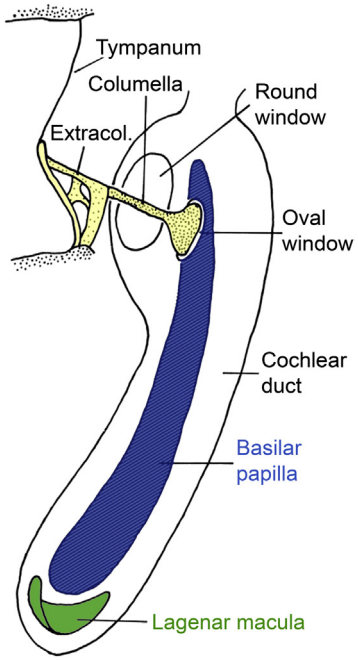

FIGURE 6.2 Schematic drawing of the cochlear duct of a typical bird, and its connection to the eardrum (tympanum) via the columella and extracolumella (yellow) of the middle ear. The dorsal, vestibular part of the inner ear is not shown. Two sensory hair-cell organs are located in the cochlear duct: the auditory basilar papilla (blue) and the vestibular lagenar macula (green).

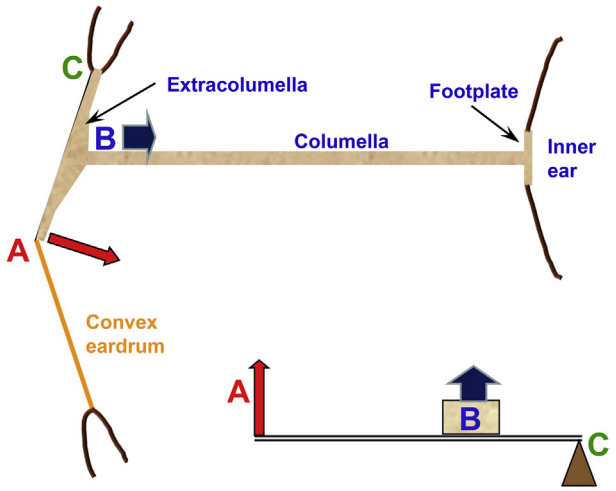

FIGURE 6.3 A schematic diagram of the middle ear of birds and its function. The extracolumella is attached flexibly to the columella, such that movement of the eardrum inwards results in a piston-like movement of the columellar footplate. The illustration at the lower right shows that these structures together build a lever of second order. The arrow length is proportional to the displacement amplitude, whereas the arrow width is proportional to the force behind the movement. Thus, at point B, the displacement is smaller than at A, but the force proportionately larger. C is the fulcrum, the axis of rotation of the lever.

(von Bartheld and Gianessi, 2011). It is made up of hair cells that are innervated by the facial nerve. However, its function is unknown. It has been speculated to act as a barometric device.

6.2.3 Coupled Middle Ears?

The middle ears of birds are not enclosed in bullae as they are in mammals, but are acoustically connected through skull spaces collectively termed the interaural canal. Part of the interaural canal is formed by wide Eustachian tubes that open into the buccal cavity (Christensen-Dalsgaard, 2011). However, there are very likely multiple routes through the highly trabeculated avian skull that have been difficult to visualize. The functional implication of interaural connections is that the ears function as pressure difference receivers, with sound reaching each eardrum from both sides. Depending on the physical dimensions of the head, the wavelength, and the attenuation across the interaural canal, significant interactions between the sounds reaching the eardrum from both sides may result in increased directional cues. Although agreed in principle, the precise extent of those effects in different species of birds is still controversial and measurements by different laboratories vary (reviews in Christensen-Dalsgaard, 2011; Klump, 2000). Small birds probably experience more of such acoustic crosstalk, whereas larger birds experience less and are limited to lower frequencies. Indeed, in the barn owl, interaural canal transmission appears to play no role in the high-frequency range that the owl uses for prey localization (Calford and Piddington, 1988; Moiseff and Konishi, 1981b).

6.3 BASILAR PAPILLA (COCHLEA)

6.3.1 General Morphology and Physiology

The inner ear or labyrinth houses both the vestibular organs and the auditory organ, the basilar papilla. The hearing part is commonly referred to as cochlea or cochlear duct, which is correct in the sense that it is homologous to the mammalian cochlea (Manley and Clack, 2004). However, the avian version is not coiled and the term cochlea ("snail") is thus not entirely appropriate. The cochlear duct houses the auditory basilar papilla and the vestibular lagenar macula, which forms the apical tip of the labyrinth (Figure 6.2). This is another salient difference to mammals, which have lost the lagenar macula. In spite of earlier evidence to the contrary, the avian lagenar macula does not respond to sound (Manley et al., 1991) and does not send afferent fibers to the cochlear nuclei (Kaiser and Manley, 1996).

The avian basilar papilla is typically only slightly curved and a few millimeters long; it tapers from being wide near the apical end to narrow at the basal end (Figures 6.2 and 6.4(A)) (Gleich and Manley, 2000). It is composed of several thousand sensory hair cells, plus supporting cells surrounding each hair cell in a roughly hexagonal pattern (Figure 6.4(C) and (D)). The epithelium sits on a basilar membrane that is largely suspended over the fluid of scala tympani. At both edges, the structure is anchored to the cartilaginous limbus and at the inner (or neural) edge; a varying proportion of hair cells actually sits atop this solid tissue, not on the basilar membrane (Figure 6.5). There are two types of hair cells, tall and short (see Section 6.3.2). All hair cells are covered by the tectorial membrane, an acellular, proteinaceous structure (Goodyear and Richardson, 2002). Sound sets the basilar papilla in motion, which ultimately deflects the mechanosensitive bundles of its hair cells through a shear motion between them and the tectorial membrane. However, the precise modes of mechanical excitation in the avian papilla are still unclear. The basilar papilla is tonotopically organized, such that hair cells at apical locations are maximally sensitive to low frequencies, typically down to about 100 Hz, and those at basal locations are maximally sensitive to high frequencies, typically 5–8 kHz (Gleich et al., 2004). A traveling wave has been observed at the level of the basilar membrane (Gummer et al., 1987). However, unlike in the mammalian cochlea, its frequency resolution does not approximate the known selectivity at the neural level. Furthermore, the hair cells conveying the most sensitive responses appear to sit on or at the edge of the solid limbus (Gleich, 1989; Smolders et al., 1995), suggesting that basilar-membrane motion would not be their direct input. Hair cells in the avian basilar papilla show a very unique and complex pattern of bundle orientation (Gleich and Manley, 2000) (Figure 6.4(B)), which has prompted speculation about excitation waves moving obliquely across the tectorial membrane (Tilney et al., 1987); however, this remains experimentally untested.

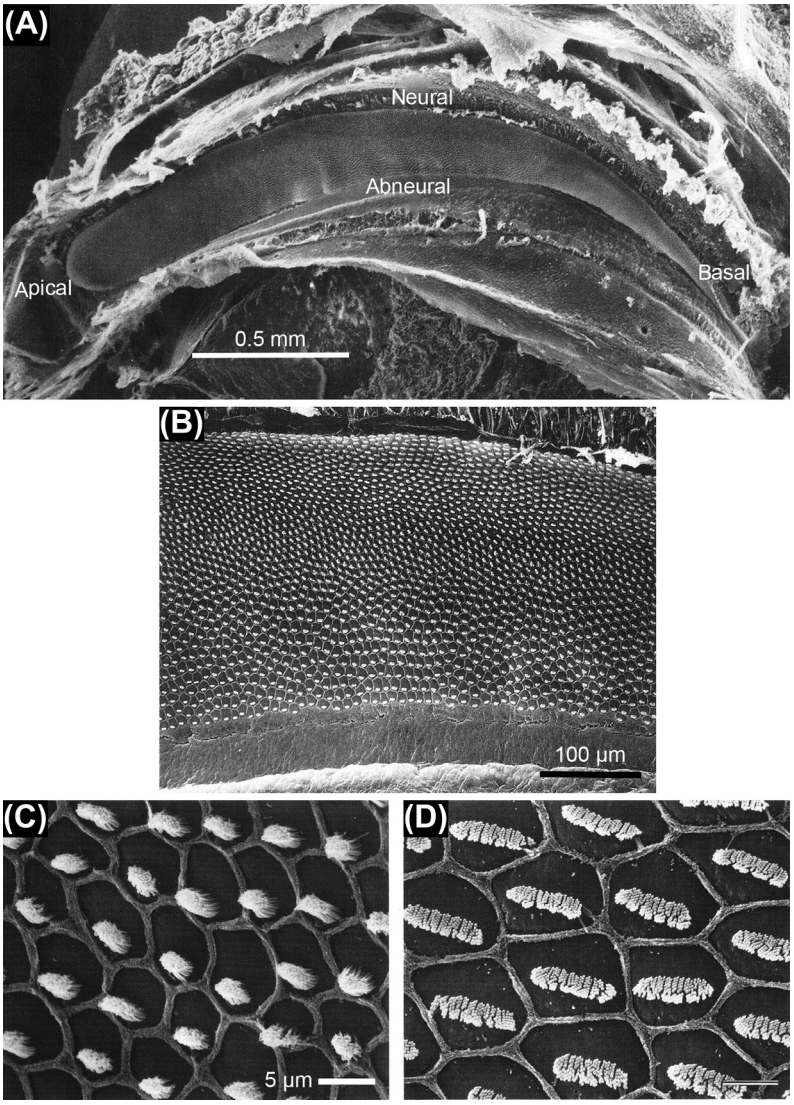

FIGURE 6.4 Surface morphology of the basilar papilla. (A) Low-magnification scanning electron micrograph of the exposed papilla of a chicken, after removal of the overlying tegmentum vasculosum and tectorial membrane. (B) View onto a segment of basilar papilla. Individual hair bundles are identifiable as white structures whose orientation changes across the epithelium. (C) and (D) High-magnification view onto a small group of hair cells. Note the hexagonal fringe of supporting cells surrounding each hair cell and the mechanosensitive hair bundles composed of tightly packed stereovilli. Note also that hair cells from apical regions (C) have smaller but taller bundles than those from basal regions (D). *Reproduced from Cotanche et al. (1994), with permission from Springer Science + Business Media.*

Transduction by the hair cells can be assumed to work according to the "gating-spring" principle established in other hair-cell systems (Fettiplace and Ricci, 2006). Deflection of the mechanosensitive hair bundle directly modulates the open probability of transduction channels associated with the tip links in the bundle. Opening of the transduction channels leads to the depolarizing influx of cations, chiefly K^+ and Ca^{2+}. The movement of K^+ into the cell is due to the unusual ionic composition and electrical potential in the endolymphatic environment facing the apical surfaces of the hair cells. As is typical for the inner ear of all vertebrates, a high K^+concentration and low Na^+ concentration, close to intracellular conditions, are maintained in endolymph, together with a slight to moderate positive potential, the endocochlear potential (Runhaar et al., 1991; Schmidt, 1963; Wangemann, 2002). In the cochlear duct of birds, this metabolically demanding task is carried out by the tegmentum vasculosum, the tissue separating scala vestibuli and scala media and thus directly overhanging the basilar papilla (Figure 6.5). An endocochlear potential of about +15 mV is maintained in avian endolymph (Necker, 1970), much lower than in the mammalian cochlea but higher than in the vestibular parts of the inner ear (Wangemann, 1995).

Hair-bundle morphology varies characteristically along the basilar papilla and thus along the tonotopic gradient.

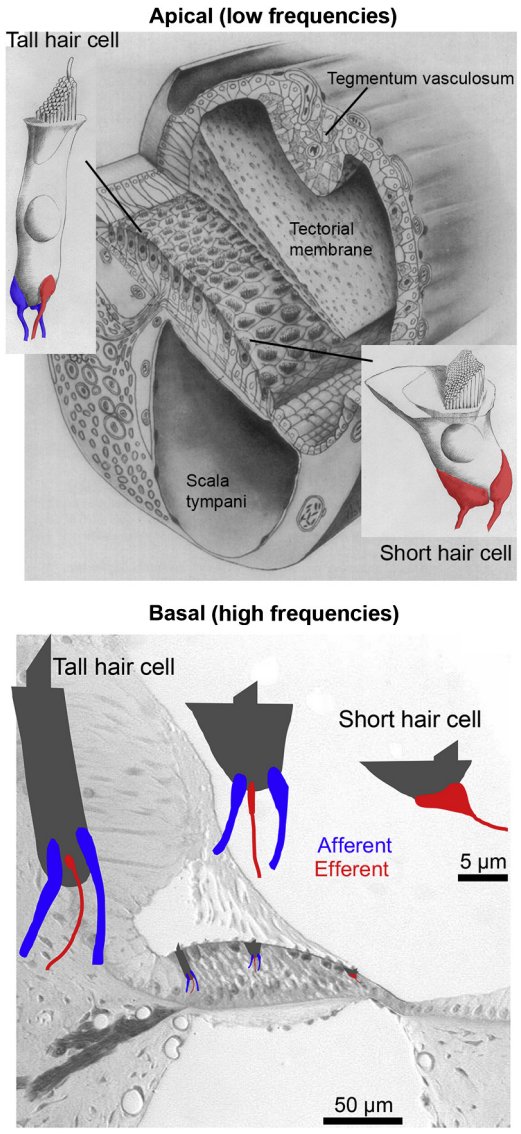

FIGURE 6.5 Overview of basilar-papilla morphology and innervation. The top panel shows a three-dimensional (3D) rendering of a typical cross-section through the apical, low-frequency part. The papilla is wide, with many hair cells across, most of which are tall hair cells. Insets are 3D drawings of two representative hair cells, with afferent (blue) and efferent (red) nerve terminals attached The lower panel shows a light-microscopical cross-section through the basal, high-frequency part, with some hair cells schematically highlighted and also shown enlarged. The lower scale bar applies to the histological image, the upper one to the drawings. The schematic drawings also show the typical innervation pattern, with afferent terminals drawn in blue and efferent terminals in red. *Top panel reproduced from Takasaka and Smith (1971), with permission from Academic Press. Insets reproduced from Manley and Ladher (2008), with permission from the artist, Johanna Kraus. Bottom panel reproduced from Köppl (2011a), with permission of Elsevier BV.*

Hair cells at apical locations have relatively tall bundles composed of relatively few stereovilli, whereas hair cells at basal locations have shorter bundles with many stereovilli (Gleich and Manley, 2000) (Figure 6.4(C) and (D)). This morphology is a major determinant of bundle stiffness and, as in all vertebrates, it is believed that this contributes to tune a hair cell's mechanical frequency response. In addition, avian hair cells are electrically tuned to respond preferentially to different frequencies. This is achieved by varying the number and/or kinetics of two principal ion channels in the cell membrane: voltage-gated Ca^{2+}-channels and Ca^{2+}-activated K^{+}-channels (Art and Fettiplace, 2006; Tan et al., 2013). However, electrical tuning is likely to be less effective or even absent at the highest frequencies (Wu et al., 1995).

One of the most fascinating aspects of hair-cell function is the ability for reverse transduction—that is, the ability to generate mechanical forces and thus to actively amplify low-level stimuli. Active movements of hair bundles have indeed been observed in isolated hair cells in vitro. It is currently believed that this ability is inherent to the hair cells' transduction mechanism, although the molecular components remain unidentified (see review in Martin, 2008). In mammalian cochlear outer hair cells, an additional mechanism evolved, conveying somatic motility through the voltage-sensitive protein prestin in the cell membrane (see review in Russell, 2014). This appears to dominate amplification in the high-frequency range of several kilohertz and above in mammals. Hair cells of the avian basilar papilla have been suggested to represent an intermediate case in which reverse transduction and somatic motility may literally join forces (Beurg et al., 2013). However, this is still controversial and much remains to be learned about the precise mechanisms of active amplification in the bird inner ear. Nevertheless, the presence of amplification is undisputed. One of its indirect manifestations is the occurrence of otoacoustic emissions, which are faint sounds emitted by the inner ear that are believed to be an epiphenomenon of the active processes. Otoacoustic emissions are only measurable under shielded, very quiet laboratory conditions. They may be present spontaneously or can be evoked by a range of stimulation protocols, and they have been observed in a wide range of vertebrates, including birds (Manley and van Dijk, 2008; Taschenberger and Manley, 1997).

Hair cells are secondary sensory cells; they thus do not form an axon. They are contacted by two basic types of neurons, afferent and efferent to the central nervous system (Figure 6.5). Afferent neurons have their cell bodies located in a compact ganglion close to the basilar papilla. Their peripheral fibers enter the basilar papilla at its inner or neural edge and contact typically only one hair cell each. The afferent synapses are of the specialized ribbon synapse type, which occurs only in vertebrate hair cells and photoreceptors and in retinal bipolar cells. They are believed to enable high, sustained rates of transmitter release (see review in Matthews and Fuchs, 2010). The central axons of the afferents collectively form the auditory nerve and terminate on the brainstem neurons comprising the cochlear nucleus. A truly unique feature of the avian auditory papilla

is that typically 20–25% of the hair cells receive no afferent contacts (see also Section 6.3.2). In contrast, all hair cells receive efferent input from neurons located in the ventral brainstem (see review in Köppl, 2011b). The predominant effect of evoked efferent activity on the hair cells is inhibitory. However, very little is known about the behavioral contexts in which efferents are active and, consequently, about their broader role in hearing.

6.3.2 Hair-Cell Types: A Remarkable Example of Evolutionary Convergence in Birds and Mammals

When the ancestors of birds and mammals separated, their common heritage included a dedicated auditory hair-cell field, the basilar papilla. This ancestral basilar papilla is likely to have been small, with a uniform hair-cell type, and sensitive to low frequencies only (Manley and Köppl, 1998). Thus, although the basilar papilla itself is homologous between the groups, its specializations are not. The auditory hair-cell types in particular represent remarkable convergent evolutionary developments.

Cross-sections of avian basilar papillae, at first glance, do not show any of the prominent and uniquely mammalian features, such as the tunnel of Corti or the strict arrangement of one row of inner and three rows of outer hair cells. However, looking more closely at the fine structure of the hair cells and especially their innervation, a very salient analogy emerges. Like mammals, birds have two types of hair cells, here called tall and short hair cells. Unlike in mammals, those types are not sharply separated. The extremes are clearly different and well defined, but the two types grade into each other (Gleich and Manley, 2000). Tall hair cells are found on the inner (neural) side of the epithelium and gradually transition into short hair cells towards the outer (abneural) edge (Figure 6.5). Furthermore, the relative numbers of tall and short hair cells are not fixed in the manner of inner and outer hair cells in mammals, but change along the tonotopic gradient. Basal, high-frequency regions show a predominance of short hair cells and vice versa. Most strikingly, short hair cells receive large efferent terminals but are devoid of afferent innervation (Fischer, 1994a) (Figure 6.5). This may be the only example of a sensory cell entirely losing its primary function. It is even more extreme than the innervation of mammalian outer hair cells, which also receive large efferent terminals but retain a sparse afferent innervation (Raphael and Altschuler, 2003). Clearly, avian short hair cells are not the principal sensory cells for hearing. The analogy to the mammalian cochlea, in which inner hair cells take most of the classical sensory role and outer hair cells are specialized for mechanical amplification (Dallos, 1996), is palpable. However, much remains to be learned about the assumed amplificatory role of short hair cells, as there is currently little direct evidence for it. Although short hair cells do exhibit bundle motility in vitro, tall hair cells do as well (Beurg et al., 2013), so it remains unclear what the specific role(s) of short hair cells may be.

6.3.3 Hair-Cell Regeneration: Birds Never Lose Their Hearing

Because human hearing loss often involves damage to and ultimately death of hair cells through noise or ototoxic medication, similar treatments were used on birds in order to find a good preparation to study the underlying phenomena. This led to the remarkable discovery that adult birds are able to regenerate functional hair cells (see review in Rubel et al., 2013). It very quickly became apparent that, in contrast to humans, birds did not necessarily suffer permanent hearing loss. Instead, and unexpectedly, hearing thresholds returned to normal or near-normal within a matter of weeks following damage. This discovery initiated an excited search for the underlying cellular and genetic processes. It is now known that after insult and hair-cell death, new hair cells are regenerated from the surviving supporting cells, either by rekindled cell division or by direct transdifferentiation into hair cells (see review in Stone and Cotanche, 2007). The regeneration process is extensive and detailed. Specific, local hair-cell characteristics, such as hair-cell shape, bundle shape, and orientation, are so well matched to the surviving adjacent areas that it can be difficult to distinguish an undamaged cochlea from a recovered one. In addition, nerve fibers reconnect with the new hair cells and the overlying tectorial membrane is at least partly replaced (Cotanche, 1999), in total leading to an impressive functional recovery (Ryals et al., 2013; Smolders, 1999). Regeneration reaches its limits, however, if the damage extends over very large areas of the basilar papilla and includes supporting cells (Cotanche, 1999; Smolders, 1999).

Even without severely damaging experience, the avian basilar papilla appears to continuously regenerate hair cells at a low level (Ryals and Westbrook, 1990). Thus, there is probably no such thing as age-related hearing loss in birds. Indeed, starlings in aviaries often reach ages of more than 10 years (five times their expected ages in the wild) and they can still have close-to-normal hearing thresholds at that age (Langemann et al., 1999). It is not without irony that human breeding of certain races of songbirds for their loud songs unknowingly involved these mechanisms. Belgian Waterslager canaries have an inherited high-frequency hearing loss and sing a louder and lower-pitched song than normal canaries (Okanoya and Dooling, 1985). In the basilar papilla of those birds, hair cells continuously die at abnormal rates—a process that is incompletely offset by ongoing regeneration of new hair cells (Gleich et al., 1997; Wilkins et al., 2001). Unfortunately, the hope of initiating the same kind of regeneration of hair cells in mammalian cochleae has so far not been fulfilled (Brigande and Heller, 2009).

6.3.4 Cochlear Specializations: Auditory Foveae, Infrasound Hearing

As mentioned above, the basilar papilla is tonotopically organized. Apical regions respond most sensitively to low frequencies, and the characteristic frequency gradually increases towards the basal end. In a typical avian basilar papilla, this tonotopic map is well described by a near-logarithmic function—that is, each doubling of frequency (equivalent to one octave) corresponds to an approximately equal length of papilla (Figure 6.6) (Gleich et al., 2004). However, there are interesting exceptions to this rule. In analogy to visual foveae, regions of enhanced frequency representation, where some frequencies occupy disproportionally more space along the basilar papilla, have been termed *auditory foveae*. In birds, the best known example of such an auditory fovea is the barn owl, and a similar case has been suggested for the kiwi. In the barn owl, the frequencies of the highest octave perceived (5–10 kHz) fully occupy the basal half of the basilar papilla (Köppl et al., 1993), as much space as the lower five or six octaves together (Figure 6.6, red curve). These are the frequencies shown behaviorally to be the most useful for prey localization (Payne, 1971). The anatomical gradients of the owl cochlea, which at least partially determine the frequency response of the hair cells, hardly change along the basal half of the cochlea, concordant with a large expansion of the area processing higher frequencies (Fischer et al., 1988). Because a visual fovea is associated with improved acuity, a larger cochlear representation is often assumed to correlate with enhanced frequency resolution. Interestingly, this is not the case in the barn owl (Köppl et al., 1998), suggesting that the role of the fovea instead may be to lay the foundation for massive parallel processing by increasing the numbers of afferent fibers from this behaviorally important frequency region (Fischer, 1994b; Köppl, 1997b). Although there are no physiological data from the ear of the kiwi, studies of hair-cell morphology also suggested a foveal expansion of frequency representation in the upper range of kiwi hearing, estimated at 4–6 kHz (Corfield et al., 2011).

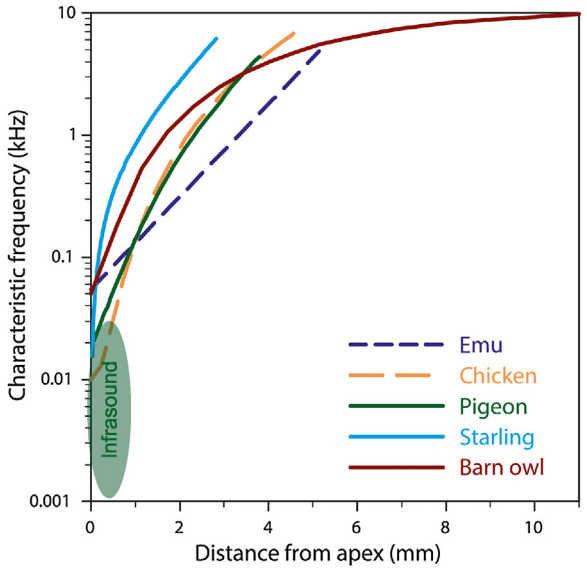

FIGURE 6.6 Tonotopic frequency representation along the avian basilar papilla. The differently colored curves show the mapping functions for several species of birds, as determined from labeling physiologically characterized auditory-nerve fibers to reveal their innervation sites in the papilla. Note the exceptional length of the barn owl basilar papilla and the shallow slope of its frequency map over most of its extent, indicating an auditory fovea (i.e., expanded spatial representation of a narrow, high-frequency band). Infrasound sensitivity in the pigeon was found over the most apical millimeter but it may not be strictly tonotopic and is therefore represented by the green area. *Data from Chen et al. (1994), Gleich et al. (2004), Köppl et al. (1993), Köppl and Manley (1997), and Smolders et al. (1995).*

An equally amazing specialization for extremely low-frequency hearing has been found in pigeons. For some time, it had been known from behavioral experiments that pigeons are sensitive to infrasound, defined as frequencies below those audible to humans (i.e., <15 Hz; Kreithen and Quine, 1979). Schermuly and Klinke (1990b) traced the origin of this sensitivity to hair cells located in the extreme apical-abneural regions of the pigeon basilar papilla. The afferent fibers connecting to these hair cells did not respond to normal acoustic frequencies, but showed responses to infrasound at levels comparable to the behavioral thresholds shown previously (Schermuly and Klinke, 1990a). Quite in contrast to the high-frequency foveae discussed above, the infrasound receptive region appears to co-exist over the most apical 1 mm of the basilar papilla, alongside a conventional logarithmic frequency representation (Figure 6.6, green) (Smolders et al., 1995). The behavioral significance of infrasound hearing remains unknown. Although it has been suggested that pigeons use it as a navigational cue (Hagstrum, 2000; Kreithen and Quine, 1979), conclusive evidence is lacking. Infrasound sensitivity may also not be unique to pigeons. Morphological evidence for an unusual hair-cell area at the apex of the chicken cochlea has also been described (Lavigne-Rebillard et al., 1985) and some neurons in the cochlear nucleus of the chicken have best response frequencies at least as low as 10 Hz (Warchol and Dallos, 1989).

6.3.5 Auditory Nerve: What the Ear Conveys to the Brain

All information that the brain receives about the outside acoustic world is encoded in the activity of the auditory-nerve fibers. Beginning with Sachs et al. (1974), who recorded single-unit activity in the pigeon auditory nerve, there have been numerous studies on the responses of afferent fibers in various bird species to simple, well-controlled stimuli. Here, I briefly summarize the encoding of frequency, sound level, and temporal fine structure.

All avian auditory nerve fibers are spontaneously active. Mean spontaneous rates vary between 45 and 90 spikes/s, depending on species, in adult birds (Köppl, 1997a). Unlike in mammals, there is no consistent, strong correlation in birds between spontaneous rate and sensitivity to tonal stimulation and there is no population of fibers with very low spontaneous activity (<1 spike). Spontaneous activity is irregular and the interspike interval distribution is typically Poisson-like, modified by the refractory period (Gleich and Manley, 2000; Neubauer et al., 2009). Interestingly, a significant number of fibers show preferred intervals, with periods at or close to their characteristic frequency for tonal stimulation. Although some of this activity for very sensitive fibers may be attributable to inadequate sound shielding during experiments, the bulk of evidence points to this being a genuine phenomenon that reflects spontaneous oscillations of the hair-cell membrane potential due to electrical tuning and/or active mechanical amplification processes in the avian cochlea (Gleich and Manley, 2000; Taschenberger and Manley, 1997).

Sound frequency is, of course, collectively coded according to the place principle, where the tonotopic gradient along the basilar papilla is preserved in the projections to the brain. Upon tonal stimulation, each auditory-nerve fiber responds most sensitively to one particular frequency, its characteristic frequency. At increasingly lower and higher frequencies, the fiber's sensitivity decreases rapidly, so that its response area forms a narrow, V-shaped frequency tuning curve (Figure 6.7(A)). In birds, these curves are very sharply tuned, with higher mean quality factors than mammalian responses at the same frequencies, and typically almost symmetrical (Gleich and Manley, 2000). However, the best thresholds of fibers within any narrow range of characteristic frequencies in an individual ear vary in birds more widely than in mammals, by as much as 50 dB (Figure 6.7(B)).

Sound level is encoded in the discharge rates of auditory-nerve fibers. The dynamic ranges over which individual fibers are able to encode have been studied in depth in response to short tonal stimuli of 50–100 ms and vary characteristically. There are (1) saturating fibers, whose discharge rate rises rapidly above threshold, then also levels off abruptly at a break point; (2) sloping-saturating fibers, whose rate does not show an abrupt saturation but continues to rise more slowly above the break point (Figure 6.7(C)); and (3) straight fibers, whose discharge rate slowly rises with a nearly uniform, shallow slope over a broad range of sound levels (Gleich and Manley, 2000; Köppl, 2011a). This shows remarkable parallels to mammals, where the same three types were originally described. However, in contrast to mammals, there are no correlations with other fiber properties in birds. It is believed that in both cases, the discharge behavior of auditory-nerve fibers with sound level is shaped by the underlying processes of active amplification, effecting a compressive nonlinearity. However, in birds, the nonlinearity is suggested to develop and vary locally, perhaps at the level of individual hair cells, while in mammals stronger coupling leads to a shared nonlinear response of larger groups of hair cells (Köppl, 2011a). The wide range of thresholds and the different dynamic ranges together ensure that the avian auditory nerve is able to encode a very wide range of sound levels indeed.

Finally, temporal information is encoded by phase locking of auditory-nerve fibers; that is, spikes are discharged preferentially at a specific phase of a sinusoidal or near-sinusoidal stimulus. It is important to point out that a spike need not occur in every cycle of the stimulus (Figure 6.7(D), inset). Indeed, at frequencies above 300–400 Hz, which is the upper range of sustained discharge rates, many cycles may be skipped, but phase locking still persists into the kilohertz range. Phase locking critically depends on the ability to control spike timing within the temporal window of one stimulus cycle. Thus, the requirement for temporal precision rises with increasing frequency (and shorter cycles) and phase locking invariably fails above a species-specific frequency limit. Avian auditory-nerve fibers typically phase lock up to 3–4 kHz (Figure 6.7(D)), which compares favorably to other vertebrates, including mammals. A famous exception is the barn owl, for whom phase locking persists to frequencies near 10 kHz, corresponding to a precision of spiking, or temporal jitter, of only 20–30 μs (Figure 6.7(D), red curve) (Köppl, 1997c). Although it remains unknown what cellular mechanisms enable this extraordinary precision, it is clearly an adaptation and prerequisite for the superb sound localization abilities of the barn owl (see Section 6.4.2).

6.4 THE AUDITORY BRAIN

6.4.1 Basic Organization of Auditory Pathways

The principal pathways of the avian auditory brain follow a general layout shared by all land vertebrates (Figure 6.8) (Carr and Code, 2000; Grothe et al., 2004). The major afferent pathways flow from the cochlear nucleus, either directly or indirectly, through the brainstem areas of the superior olive and lateral lemniscus, to the midbrain inferior colliculus (also termed torus semicircularis, or nucleus mesencephalicus lateralis pars dorsalis). From there, projections go to multimodal layers of the optic tectum (or superior colliculus) and to the auditory thalamus and from the latter on to the auditory forebrain. Beyond this very general pattern, however, the specific nuclei or subdivisions of nuclei can differ substantially between the major vertebrate groups, and the evolutionary origin and homology of many auditory areas beyond the broad categories outlined above is quite controversial. In general, differences in the central auditory pathways mirror the major types of basilar-papilla specializations and thus are now believed to also be the result of

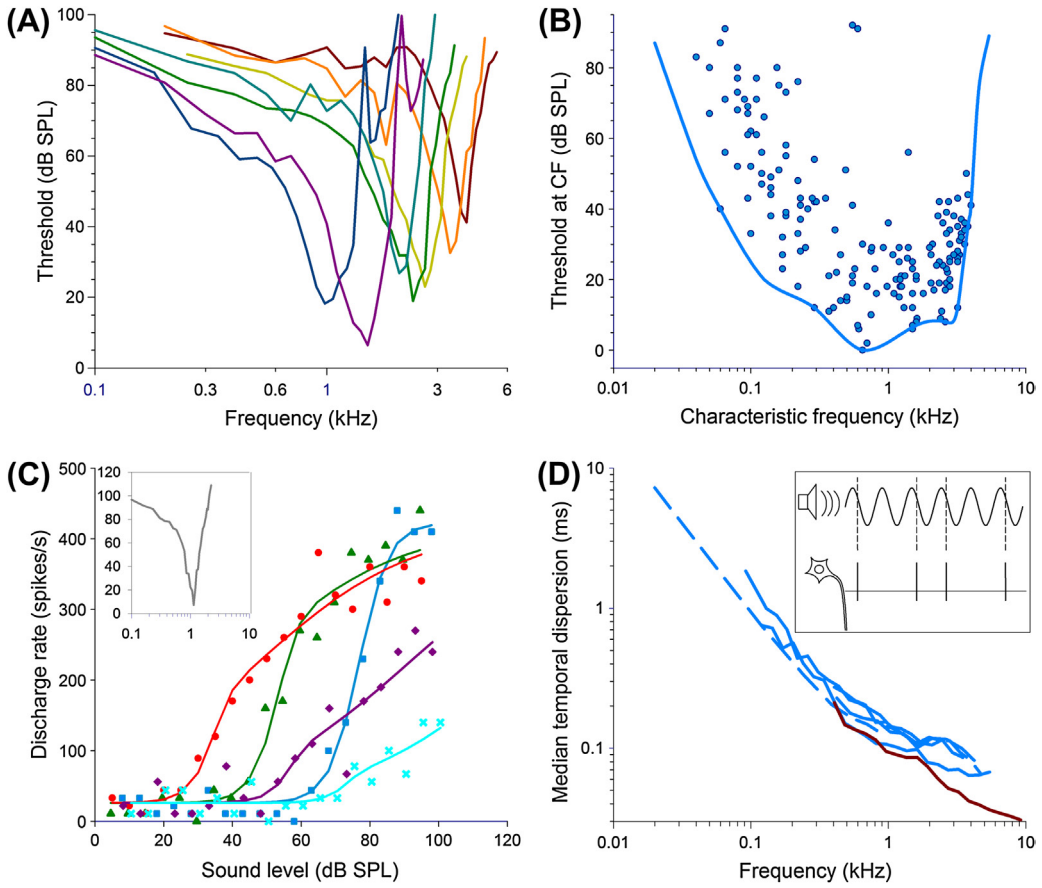

FIGURE 6.7 Salient characteristics of single auditory-nerve fiber activity. (A) Examples of frequency tuning curves from the emu (Manley et al., 1997). (B) Distribution of the most sensitive thresholds of a population of fibers from the emu (Manley et al., 1997), as a function of characteristic frequency. Note the large range of thresholds at any one frequency, which is typical and not due to damage. The solid line joins data from the most sensitive fibers, which gives an approximation of the emu's audiogram. (C) Rate-level functions for one particular auditory-nerve fiber in the emu, in response to several different frequencies within the fiber's response area shown in the inset. Note the pronounced sloping-saturating behavior at the most sensitive, characteristic frequency (shown in red). *(Data from Yates et al. (2000).)* (D) The inset illustrates schematically the temporal relationship between a sinusoidal stimulus and phase-locked action potentials. In real auditory-nerve fibers, individual spikes vary in their timing around a mean preferred phase. Median values for this temporal jitter or dispersion are shown in the main graph, as a function of frequency, for several bird species: barn owl (red; Köppl, 1997c), emu (dashed blue; Manley et al., 1997) and, all in blue, chicken (Salvi et al., 1992), pigeon (Hill et al., 1989), starling (Gleich and Narins, 1988), and redwing blackbird (Sachs et al., 1980).

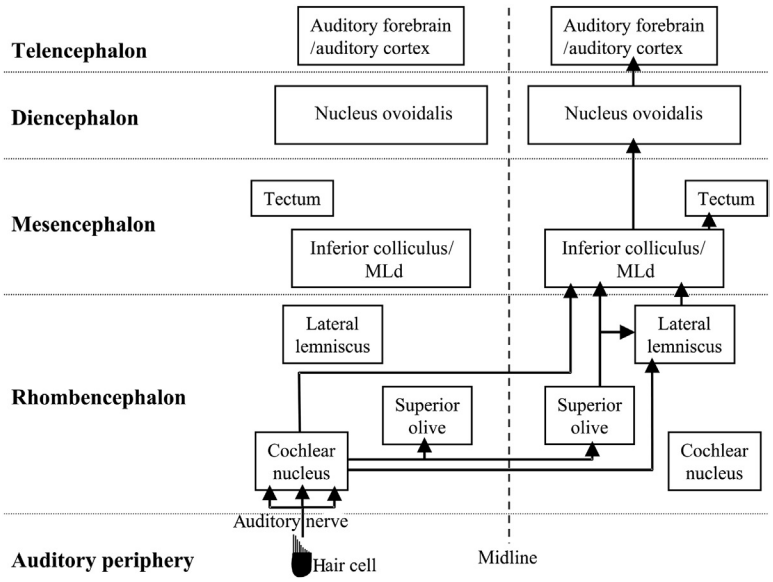

FIGURE 6.8 Principal wiring diagram of the central ascending auditory pathway of birds. Each box represents a major center that may contain multiple subareas. *Modified from Grothe et al. (2004), with permission from Springer Science + Business Media B.V.*

independent evolution (Grothe et al., 2004). Birds follow an archosaurian pattern that they share with crocodilians; it is also most similar to that of other, more distantly related, "reptiles".

The cochlear nucleus of birds has two major subdivisions, nucleus magnocellularis (NM) and nucleus angularis (NA), both of which receive a shared input by collaterals of each auditory-nerve fiber. NM and NA probably form the starting points of several auditory processing streams that specialize in different aspects. NM is the relatively more simple of the two, containing one predominant neuron type that is clearly specialized for preserving or even enhancing the temporal information conveyed through phase-locking from the auditory nerve (Carr and Boudreau, 1993; Sullivan and Konishi, 1984). NM is thus the starting point of a "time pathway". The best-known function of this time pathway is the extraction of interaural time differences used in sound localization (see Section 6.4.2). NA then appears to be the origin for everything else, although it is commonly referred to simply as the "intensity pathway" (which does not do justice to the complexity already seen at this level). NA contains a range of cell types having distinct anatomical and physiological properties (see reviews in Grothe et al., 2004; MacLeod and Carr, 2007). Although cell-specific connection patterns have not yet been investigated, NA neurons collectively have several projection targets in the superior olive and lemniscal nuclei, as well as direct projections to the inferior colliculus. Thus, the potential for different functional processing streams is present. In the barn owl, a specific involvement in deriving interaural level differences for sound localization has been demonstrated (see Section 6.4.2).

Although the cochlear nuclei are still strictly monaural, all higher levels show more or less pronounced binaural interaction. A tonotopic organization is, however, retained in the brainstem nuclei. All afferent auditory information then converges again in the midbrain nucleus mesencephalicus lateralis pars dorsalis (MLd), which is considered homologous to the mammalian inferior colliculus (Carr and Code, 2000). The definition of MLd subdivisions differs between authors but, in general, a "core and belt"-type organization is recognized; the common terms used for those are central nucleus (ICc) and external nucleus (ICx). Brainstem projections terminate in the ICc regions which, in turn, project to ICx. The physiology of the avian auditory midbrain has mostly been studied in the context of sound localization (see Section 6.4.2). In the barn owl, successive processing steps culminate in the formation of a neural map of auditory space in the ICx (see review in Konishi, 2003). It is currently unclear to what extent this generalizes to other birds. In a songbird, the zebra finch, responses of MLd neurons cluster into functional groups that were suggested to represent cues for fundamental acoustic percepts, such as pitch, timbre, and rhythm (Woolley et al., 2009).

As a general principle in vertebrates, although a tonotopic representation is maintained in parts of the auditory midbrain, pure tones are often not the most effective stimuli. Instead, selectivity for other derived sound features, such as location or temporal modulation, begins to predominate.

In parallel to the connections from the ICc to the ICx (and on to the superior colliculus), the ICc also initiates the forebrain ascending auditory pathway by projecting to the thalamic nucleus ovoidalis (Figure 6.8) (Carr and Code, 2000). The morphology and connections of nucleus ovoidalis are quite well characterized, but its functional role remains unclear and few studies have probed it physiologically (Carr and Code, 2000; Ondracek and Hahnloser, 2014; Proctor and Konishi, 1997). Nucleus ovoidalis projects on to the primary auditory forebrain area in birds. It is important to point out that the nomenclature used in the avian forebrain has seen major revision in recent years, driven by growing evidence that early interpretations of avian forebrain organization had been erroneous and that the classic nomenclature derived from it was seriously misleading (Jarvis et al., 2005). According to the revised nomenclature, the avian auditory forebrain consists of Field L in the caudal nidopallium, the caudal mesopallium (CM), the dorsal nidopallium (Nd), and the ventromedial portion of the intermediate arcopallium (Aivm) (Wang et al., 2010). Field L is further divided into subregions, with only L2 being the primary thalamorecipient layer. It has been argued that all four avian auditory forebrain areas together form a circuit highly similar in both its columnar and laminar organization to the mammalian auditory cortex (Figure 6.9) (Wang et al., 2010). The physiology of the avian auditory forebrain has been studied most extensively in songbirds (see also Section 6.4.4). Here, a hierarchy of responses is apparent, with a clear tonotopic organization and spectrally defined responses in thalamorecipient neurons, and striking specificities to

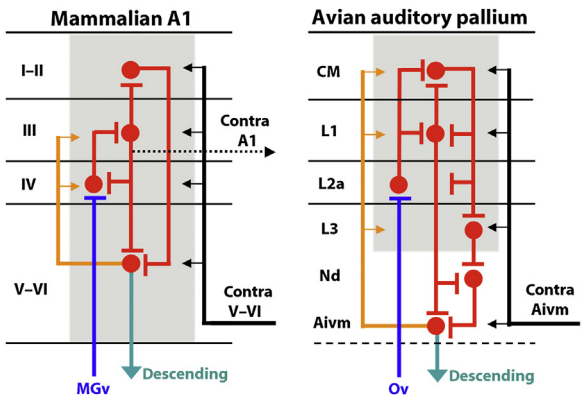

FIGURE 6.9 Suggested analogy in the circuitry between the different layers of mammalian auditory cortex and the principal nuclei of the avian auditory pallium. Thalamic inputs, intrinsic connections, and descending projections are shown in blue, red, and turquoise, respectively. Orange lines and arrows indicate recurrent projections from the deep layers to the more superficial layers. Reentrant projections from the other side of the brain are drawn in black. *Reproduced from Wang et al. (2010).*

species-specific vocalizations emerging in higher-order neurons. Also, correlates of perceptual categories of auditory streaming, such as galloping rhythms, have been found in the responses of Field L neurons (Bee and Klump, 2005; Itatani and Klump, 2011). In the barn owl, the forebrain ascending auditory pathway appears to independently generate a second representation of auditory space that resides in the arcopallium. However, the forebrain representation is different in several salient aspects and probably serves different functions to the midbrain topographical map of space (Cohen and Knudsen, 1999; Vonderschen and Wagner, 2009).

6.4.2 The Generation of an Auditory Space Map in the Barn Owl

Beginning with the classic studies of Roger Payne (1971), who first demonstrated that barn owls use acoustic cues to precisely locate and strike their prey in the dark, many general principles about how the location of sounds in the environment is reconstructed by the brain have been learned from this bird. Unlike vision, the sense of hearing cannot rely on a spatial image of the external world being projected onto the primary receptor surface and relayed to the brain. Sound localization requires central auditory computation, using indirect cues. For birds, these cues are largely binaural in nature—that is, the inputs from both ears are compared for the minute differences in timing and level that arise from different path lengths of the sound to both ears and from sound shadowing effects of the head and body (Klump, 2000). For most birds, both interaural time differences (ITDs) and interaural level differences (ILD) are cues for sound source azimuth; however, the asymmetrical facial ruff of the barn owl (see Section 6.2.1) generates ILDs as a function of sound source elevation. This changes the meaning of ILDs but not necessarily the neural processing steps to derive them. Much of what has been learned from the barn owl is believed to reflect general principles of the neural computation of sound location in birds, if not vertebrates (Grothe et al., 2010; Konishi, 2003; Takahashi, 2010). In the barn owl, the binaural comparisons of time and level are carried out in parallel processing streams in brainstem nuclei that are specialized for each task. At the midbrain level, this information is then combined and used to create a "space map"—that is, a two-dimensional representation of auditory space in azimuth and elevation.

Contrary to intuition, the computation of ITD is not based on a comparison of sound onset at the two ears, but largely relies on ongoing temporal information from neural phase locking in the auditory nerve (see Section 6.3.5). This was shown by clever behavioral experiments with owls wearing headphones that allow for the presentation of stimuli that artificially dissociate onset and ongoing ITDs (Moiseff and Konishi, 1981a). The phase locking of auditory-nerve fibers is preserved by the monaural cochlear NM, which then projects to the binaural nucleus laminaris (NL). NL neurons perform arguably one of the most challenging and extreme tasks in the nervous system: they receive the phase-locked inputs from each side and fire selectively if their inputs coincide within a very narrow, submillisecond time window (Funabiki et al., 2011; Kuba, 2007). Of course, such coincidence naturally occurs only when sounds originate directly in front (or back) of the animal. To encode more lateral sound locations, the incoming NM axons contact several NL neurons serially, thus forming functional delay lines that match and compensate for the range of natural acoustic interaural delays (Figure 6.10). This principle of an array of coincidence detectors, receiving temporal information by delay lines from both sides to create a topographical map of auditory azimuth, was originally formulated by Jeffress (1948). It appears beautifully implemented in the NM–NL circuit of birds in general (Burger and Rubel, 2008; Kubke and Carr, 2006), with the owl displaying a hypertrophied form and achieving the highest temporal resolution (Carr and Boudreau, 1993; Funabiki et al., 2011). The initial topographic map of auditory azimuth is created many times over in NL, separately in each frequency band of the tonotopically organised nucleus. An important task of subsequent processing steps within the ICc of the midbrain is to converge this information across frequencies and thus remove inherent ambiguities due to the cyclic nature of the phase code underlying it (Konishi, 2003).

The first binaural comparison of sound level occurs in the posterior part of the ventral nucleus of the lateral lemniscus (LLDp, formerly also called VLVp). Here, excitatory inputs from the contralateral ear (coming in via the cochlear NA) compete with inhibitory inputs from the ipsilateral ear (coming in via NA and the contralateral LLDp). Depending on the relative strengths of excitation and inhibition, the responses of individual LLDp neurons decrease at different relative levels of ipsi- and contralateral sound,

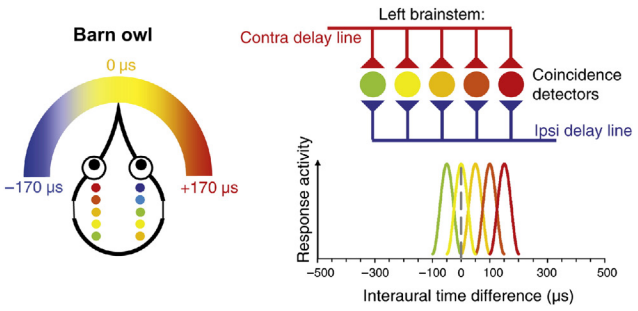

FIGURE 6.10 Schematic illustration of the coding of interaural time differences according to the Jeffress (1948) model and as seen in the barn owl. Each half of the brainstem contains a representation of interaural time differences, corresponding to sound sources mostly in the contralateral acoustic hemifield. This map is created by the basic circuit of delay lines and coincidence detectors illustrated for the left side of the brainstem. Typical responses of barn owl coincidence detector neurons in nucleus laminaris are shown below the circuit diagram, as a function of interaural time difference. Together they cover the interaural time difference range experienced by the owl and form a topographic representation of the auditory azimuth. *Reproduced from Köppl (2009), with permission from Cell Press.*

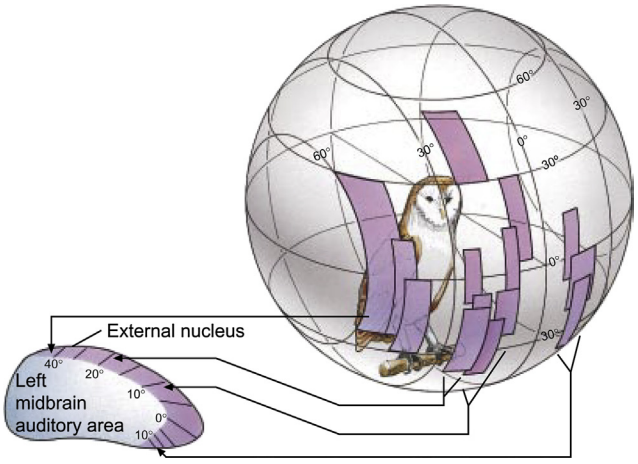

FIGURE 6.11 Auditory space map in the midbrain of barn owls. In the external nucleus of the inferior colliculus (purple), the auditory spatial receptive fields of neurons change systematically with position along the nucleus. Some examples of receptive fields are illustrated as purple rectangles on a sphere surrounding the owl. This spatial map is synthesized from auditory responses selective for specific interaural time and level differences. *Reproduced from Konishi (1993), with permission from Jana Brennings.*

or ILD. Inhibitory strength systematically decreases along the dorsoventral axis of the nucleus and thus establishes a first topographic representation of ILD (see review in Konishi, 2003). At the level of the ICc, the sigmoidal response functions of inputs from LLDp neurons sharpen into bell-like curves, only showing responses to a restricted range of ILDs. However, it remains unknown exactly how this is achieved (see review in Konishi, 2003).

Finally, in the ICx, a two-dimensional map of space-specific neurons with receptive fields bounded both in azimuth and elevation is synthesized (Figure 6.11) (Knudsen and Konishi, 1978), where the azimuthal axis is based on the selectivity for ITD and the elevational axis on the selectivity for ILD (Konishi, 2003; Takahashi et al., 2003). At the level of the individual space-specific neurons, both inputs are combined by a multiplicative process that further sharpens their resulting receptive field (Peña and Konishi, 2001). This auditory space map is relayed from ICx to bimodal neurons of the optic tectum (or superior colliculus), forming a combined auditory-visual spatial representation that contributes to stereotypical orienting behaviors (Knudsen, 2002).

6.4.3 Developmental Plasticity: Auditory Space is Calibrated by Vision

As just outlined, the auditory space representation in the barn owl's midbrain is a computational map generated from indirect cues (ITD and ILD) to sound location. These cues vary with details of head size and shape and are thus to some extent individual (Keller et al., 1998). How does the bird know which ITD and ILD values to associate with precise locations in space? Experiments manipulating the auditory cues of young owls by plugging one ear showed that owls learned, over some weeks, to again precisely localize sounds under these conditions. If instead their visual world was shifted by fitting prism spectacles, it was still the sound localization behavior that slowly adapted to match the changed visual environment (Knudsen, 2002). Thus, owls use vision to learn to associate certain ITDs and ILDs with the correct locations in space. The visual system, with its direct projection map of the retinal image, provides the objective spatial representation of the outside world against which the computational map of the auditory system is calibrated. The site of this plasticity has been identified as the ICx, the site where the auditory space map is first synthesized (Figure 6.12). Additional anatomical connections from the ICc can be induced here, whose ITD selectivity matches the corresponding visual receptive field in the optic tectum; those new connections come to dominate the response of ICx neurons over previously formed, now mismatched, inputs (Knudsen, 2002). The required error signal appears to be provided by reciprocal projections from the optic tectum to the ICx, an area traditionally thought to be exclusively auditory. Like many forms of experience-dependent plasticity, this learning of the meaning of auditory cues is limited to young owls and gradually diminishes in early adult life (Knudsen, 2002). Many of the principles shown for the learning of auditory localization in the owl also apply to the mammalian auditory system (King et al., 2000).

6.4.4 The Special Processing of Birdsong

Much of the research on higher-order auditory processing in birds has concentrated on songbirds for two reasons. First, the behaviorally most relevant acoustic signals are clearly defined and can guide the design of stimuli to test. Second, birdsong is a learned vocalization—a rare trait shared only with human speech and few other avian and mammalian vocalizations (Bolhuis et al., 2010; Jarvis, 2004). Together, this makes the songbird auditory system a rich source for unraveling how vocalizations are processed and learned. Not surprisingly, songbirds have very well-developed auditory forebrain areas (Figure 6.13(A)). However, in addition to that, a whole set of sensorimotor "song nuclei" is present, which are involved in vocal learning and plasticity and which have no clear equivalent in vocal nonlearning birds (Figure 6.13(B)) (see review in Farries, 2004). Of central importance is the nucleus HVC, which appears to be the pivotal interface between the auditory input and the motor output for singing. It is also the nucleus where neurogenesis in adult animals was first shown to produce functional neurons, in this case seasonally (Nottebohm, 2004). In HVC, extremely selective

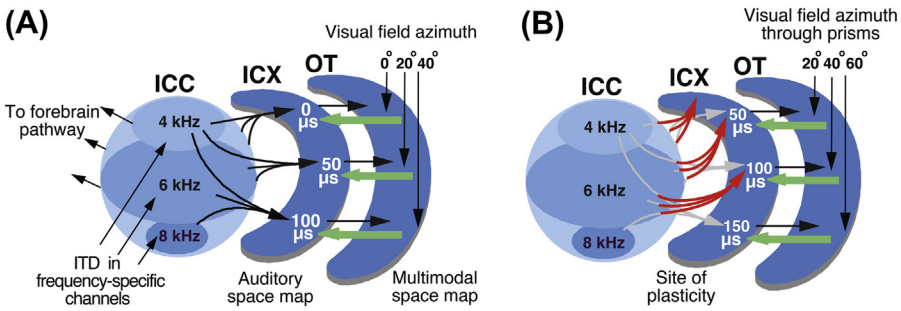

FIGURE 6.12 Schematic summary of adaptive plasticity in the auditory space map of the barn owl, after modified visual experience in early life. (A) Normally, different tonotopic regions from the central nucleus (ICc) that share selectivity for a common interaural time difference converge in the external nucleus (ICx). Together, many such convergent projections contribute the azimuthal axis of the space map that is relayed and combined with matching visual receptive fields in the optic tectum (OT). (B) When visual receptive fields are artificially shifted by fitting prims goggles to the owl, the auditory space map shifts accordingly, by forming new and matching connections between ICc and ICx (red arrows). Green arrows represent an instructive feedback projection from the OT to ICx. *Reprinted from Knudsen (2002), with permission from Macmillan Publishers Ltd.*

auditory responses, not just for species-specific vocalizations but for the individual bird's own song, appear for the first time (Konishi, 2004). HVC is then the starting point of two major motor pathways (Figure 6.13(B)): (1) a fairly direct, posterior pathway projects to the robust nucleus of the arcopallium (RA) and from there to various brainstem motor nuclei controlling the syrinx and respiration (Farries, 2004); and (2) the so-called anterior forebrain pathway, which eventually also leads to RA but via a whole set of intermediate nuclei that are believed to be homologous to the mammalian basal ganglia (Perkel, 2004). The anterior forebrain pathway has been shown to be critical for song learning in young birds (Brainard, 2004). In addition, there is evidence for an involvement in the plastic control of song, even in species that do not normally learn new songs as adults (Konishi, 2004). Therefore, it is believed that the anterior forebrain pathway, although not strictly necessary to produce song in an adult, continuously monitors what the bird actually sings and initiates corrections when necessary.

The purely auditory ascending forebrain pathway (Figure 6.13(A)), which eventually feeds into the specialized sensorimotor song nuclei system, comprises the primary field L and the secondary CM, both shared with other birds, and the secondary caudal medial nidopallium (NCM), an area unique to songbirds. Responses in these auditory areas never show the particular selectivity for the individual bird's own song (Theunissen et al., 2004). However, selectivity for conspecific song arises. As a rule, neurons in the primary auditory area field L are poorly driven by simple tones or noise but respond selectively to spectrotemporal features that characterize conspecific song and other natural sounds (Theunissen and Shaevitz, 2006). Many individual neurons appear to specialize in either spectral or temporal modulation selectivity and cluster accordingly in specific subregions (Nagel et al., 2011). The secondary auditory forebrain areas NCM and CM may add selectivity for familiar songs versus novel songs and have thus been implicated in auditory memory formation (Ondracek and Hahnloser, 2013; Theunissen and Shaevitz, 2006).

6.4.5 Echolocating Birds

Among the fascinating curiosities of the bird world are some species that use echolocation. These are the neotropical oilbird, *Steatornis caripensis*, and the paleotropical swiftlets of the genera *Aerodramus* and *Collocalia*. Both groups have independently evolved echolocation as a means of navigating in the dark caves where they roost and nest (see review in Brinkløv et al., 2013). This lifestyle has many superficial similarities with bats. However, the birds' echolocation calls are not ultrasonic but fall well within the typical avian hearing range. Due to this lower frequency range of the calls, avian echolocation cannot approach the spatial resolution of bat ultrasonic navigation, but few rigorous tests have been conducted (Griffin and Thompson, 1982; Konishi and Knudsen, 1979). Furthermore, the birds were reported to use echolocation only under conditions where they were unable to navigate by vision (Griffin, 1953; Novick, 1959), although anecdotal observations of foraging birds suggest this may be worth re-examining (Brinkløv et al., 2013).

Both the oilbird and the cave swiftlets use brief clicks that are produced by the syrinx (Suthers and Hector, 1982, 1985) and typically emitted in pairs or short trains (Konishi and Knudsen, 1979; Thomassen and Povel, 2006). The dominant frequencies in the clicks are in the range of several kilohertz and appear to match the birds' sensitive hearing range. However, due to their remote geographical distributions, very few species and individuals have been tested. From the studies available, it appears that the hearing capabilities of echolocating birds are unremarkable (Coles et al., 1987; Konishi and Knudsen, 1979). Anatomical data on the relative size of the auditory midbrain suggest a slight enlargement, which may indicate moderate specializations for echolocation processing (Cobb, 1968; Iwaniuk et al., 2006).

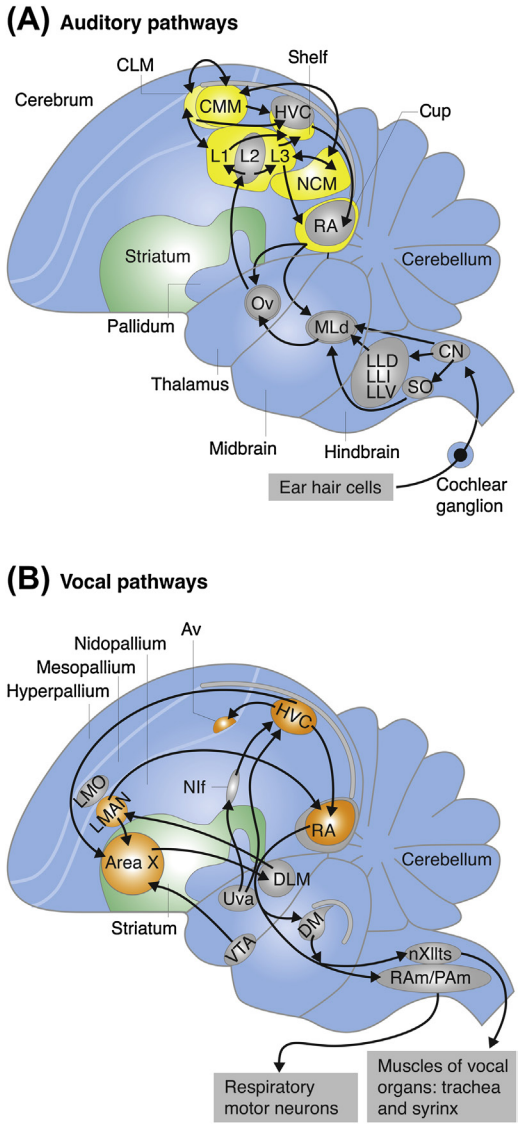

FIGURE 6.13 Schematic diagram of a composite view of parasagittal sections of a songbird brain, giving approximate positions of nuclei and brain regions. (A) Auditory ascending pathways, with brain regions that show increased neuronal activation when the bird hears song highlighted in yellow. (B) Vocal motor pathways. Depicted are connections between the nuclei, of both the direct posterior pathway and the anterior forebrain pathway. Both pathways together form the so-called song system. The orange nuclei in the song system show substantially enhanced neuronal activation when the bird itself is singing. 6.5 SUMMARY

The sense of hearing has special meaning to many birds, be it for communication, hunting, or orienting in the dark. Avian hearing typically remains restricted to below 10 kHz, somewhat lower than human hearing and much lower than in a typical mammal. However, within that range, avian hearing is just as sensitive and discriminative. Important insights into auditory physiology have come from studies on birds, such as the mechanisms of regeneration of sensory hair cells after damage, the neural computations underlying sound localization, or the neural processing and learning of vocalizations. Some fascinating auditory specializations in birds are infrasound hearing in pigeons, asymmetric ears in owls, and echolocation in oilbirds and swiftlets.

7.1 CHEMICAL SENSES

The chemical senses generally fall into three categories: chemesthesis (irritation and pain), olfaction (smell), and gustation (taste). Traditionally, the emphasis in describing responsiveness to chemical stimuli has been placed on taste and smell. The reality is more complex. For example, the sensory afferents for chemesthetic perception are in close proximity with olfactory receptors in the nasal cavity and with gustatory receptors in the oral cavity. Because external chemical stimuli can be processed by multiple sensory systems, there has been a great deal of confusion in the literature on the importance of individual sensory modalities. Generally, the principal mediating sensory modality may be related to stimulus type, concentration, and presentation. However, when perception of external chemical stimuli occurs via the integrated perception across modalities, the combined perceptual quality is commonly referred to as flavor.

7.2 CHEMESTHESIS

Chemesthesis is the perception of chemically induced pain. The first neural mediator of noxious stimuli is the nociceptor (Woolf and Ma, 2007). These primary sensory neurons are the interface between the internal and external environments. Nociceptors have cell bodies located in the dorsal root ganglion, a peripheral axon that innervates tissues, and a central axon that enters the spinal cord to transfer information to the central nervous system. Nociceptors have three functions: (1) detection of potentially damaging external noxious stimuli, which is useful in warning an animal to the risk of injury; (2) detection of endogenous inflammatory stimuli, which is useful in initiating and promoting behaviors conducive to healing and repair; and (3) detection of neural damage and ectopic firing. This latter function is a pathological condition of chronic pain. Nociceptors have high thresholds for exogenous stimuli, presumably because it would be maladaptive to defensively respond to every external assault. Nociceptors have low thresholds for endogenous stimuli. This is an adaptive response to promote healing once damage has occurred (Patapoutian et al., 2009).

A major component of the chemesthetic system is the trigeminal nerve (TN). The TN is the principal somatic sensory nerve of the head, and its primary function is the coding of mechanical and thermal stimuli. However, the TN also contains chemoreceptive fibers that mediate the detection of chemical irritants (Silver and Maruniak, 1981). The somatosensory system is the primary somatic sensory system of the rest of the body. Like the TN, the somatosensory system primarily codes for mechanical and thermal stimuli, but it does have sensory afferents that are chemosensory (Gentle, 2011; Necker, 2000; Wild, 1985).

7.2.1 Trigeminal and Somatosensory Nerves

The morphological organization of the peripheral TN in birds is not very different from that found in mammals (Dubbeldam and Karten, 1978; Dubbeldam and Veenman, 1978; Gottschaldt, 1985). The TN is the fifth cranial nerve in birds, arising from the rostrolateral medulla near the caudal surface of the optic lobe (Getty, 1975; Schrader, 1970).

The TN travels along the trochlear nerve (IV), entering a fossa in the floor of the cranial cavity where the trigeminal ganglion (TG) is found. The TG is subdivided into a smaller medial ophthalmic region and a larger lateral maxillomandibular region, from which the nerve splits into three branches. In the chicken (*Gallus gallus domesticus*) the ophthalmic branch innervates the frontal region, the eyeball, upper eyelid, conjunctiva, glands in the orbit, the rostrodorsal part of the nasal cavity, and the tip of the upper jaw. The ophthalmic branch as a communicating ramus with the trochlear nerve serves for motor control of the eye region. This aspect can provide for reflexive response to irritating stimuli to the ocular region. The larger medial ramus accompanies the olfactory nerve into the nasal fossa via the medial orbitonasal foramen. The maxillary branch provides sensory input from the integument of the crown, temporal region, rostral part of the external ear, upper and lower eyelids, the region between the nostrils and eye, conjunctival mucosa, the mucosal part of the palate, and the floor of the medial wall of the nasal cavity. The mandibular branch provides sensory input from the skin and rhamphotheca of the lower jaw, intermandibular skin, wattles, oral mucosa of rostral floor of the mouth, and the palate near the angle of the mouth (Getty, 1975; Schrader, 1970).

7.2.2 Performance Characteristics of Nociceptors

Pain and irritation perception begin with activation of primary sensory nociceptors. In birds, chemosensitive fibers in the TN and somatosensory nerves are similar to mammalian afferents. Most are unmyelinated C-type polymodal nociceptors with conduction velocities of 0.3–1 m/s. However, some myelinated A-delta high-threshold mechanoreceptors with conduction velocities of 5–40 m/s also respond to chemical stimuli. The discharge patterns and conduction velocities for the chicken, mallard (*Anas platyrhyncos*), and pigeon (*Columba livia*) are similar to those observed in mammals (Gentle, 1989; Necker, 1974).

Although birds have slightly different neural architecture relative to mammals, the underlying functions of neural connections have been evolutionarily preserved (Butler and Cotterill, 2006; Dugas-Ford et al., 2012; Güntürkün, 2012). This also applies to the underlying physiological and biochemical processes of chemically induced pain. Generally, birds have the same classes of neuropeptides as mammals, but their structures are not totally homologous. Avian endogenous pain-promoting substances such as substance P, 5-HT, histamine, bradykinin, and acetylcholine evoke inflammation and pain-related behaviors in chickens, pigeons, rats, dogs, and guinea pigs (Szolcsanyi et al., 1986; Gentle and Hill, 1987; Gentle and Hunter, 1993; Koda et al., 1996; Hu et al., 2002; Ohta et al., 2006). Prostaglandins that modulate the pain response in mammals also serve this function in birds, and their effects can be abolished by prostaglandin biosynthase inhibitors such as aspirin-like analgesics (Clark, 1995).

Despite these physiologically mediated similarities, there are profound differences in how birds and mammals respond to exogenous chemical stimuli. In mammals, chemicals such as capsaicin are potent trigeminal irritants. These irritants deplete substance P from afferent terminals and the dorsal root ganglion, producing an initial sensitization followed by desensitization to further chemical stimulation (Szolcsanyi, 1982). In contrast, birds are insensitive to capsaicin (Mason and Maruniak, 1983; Szolcsanyi et al., 1986). Peripheral presentation of capsaicin to pigeons and chickens does not cause release of substance P in avian sensory afferents (Pierau et al., 1986; Szolcsanyi et al., 1986; Sann et al., 1987). These taxon-specific responses to exogenous chemical stimuli underscore taxonomic differences in both endogenous neuropeptides and receptors, whose significance has been implicated in the evolutionary ecology of the taxa (Mason et al., 1991; Clark, 1998; Tewksbury and Nabhan, 2001).

7.2.3 Receptor Mechanisms

Nonselective transient receptor potential (TRP) cation channels are involved in sensory neuron activation events, neurotransmitter release, release of inflammatory mediators, and other aspects of pain transduction (Cortright et al., 2007; Figure 7.1). Most of what is known about TRP channels is derived from work done on mammals (Holzer, 2011). However, increasingly more comparative evolutionary similarities and differences are being characterized for other taxa (Saito and Shingai, 2006; Saito et al., 2011). TRPV1 (initially called VR1) was first cloned in mammals and found to respond to the exogenous vanilloid, capsaicin (Caterina et al., 1997), as well as endogenous agonists, anandamide, and 12-HPETE, which are structurally similar to capsaicin (Zygmunt et al., 1999; Hwang et al., 2000). TRPV1 is also activated by heat (>43 °C) and acid (pH ≤ 6). The sensation that TRPV1 activation evokes in humans via these polymodal nociceptors is one of tingling and burning, like the sensation produced by capsaicin found in chili peppers. Like its mammalian counterpart, the TRP receptor in birds (cTRPV1, chick dorsal root ganglion) responds to high temperatures (≥45 °C) and extracellular acid solution (pH ≤ 4). However, cTRPV1 is different, showing a 68% identity and 79% similarity to rat TRPV1. These differences in receptor composition manifest as a poor response to capsaicin (Jordt and Julius, 2002) and explain the behavioral differences in capsaicin sensitivity between birds and mammals; mammals are behaviorally sensitive to capsaicin and birds are not (Mason et al., 1991; Norman et al., 1992).

Currently, 28 TRP channels, grouped into six functional subfamilies, have been characterized. The subfamilies are

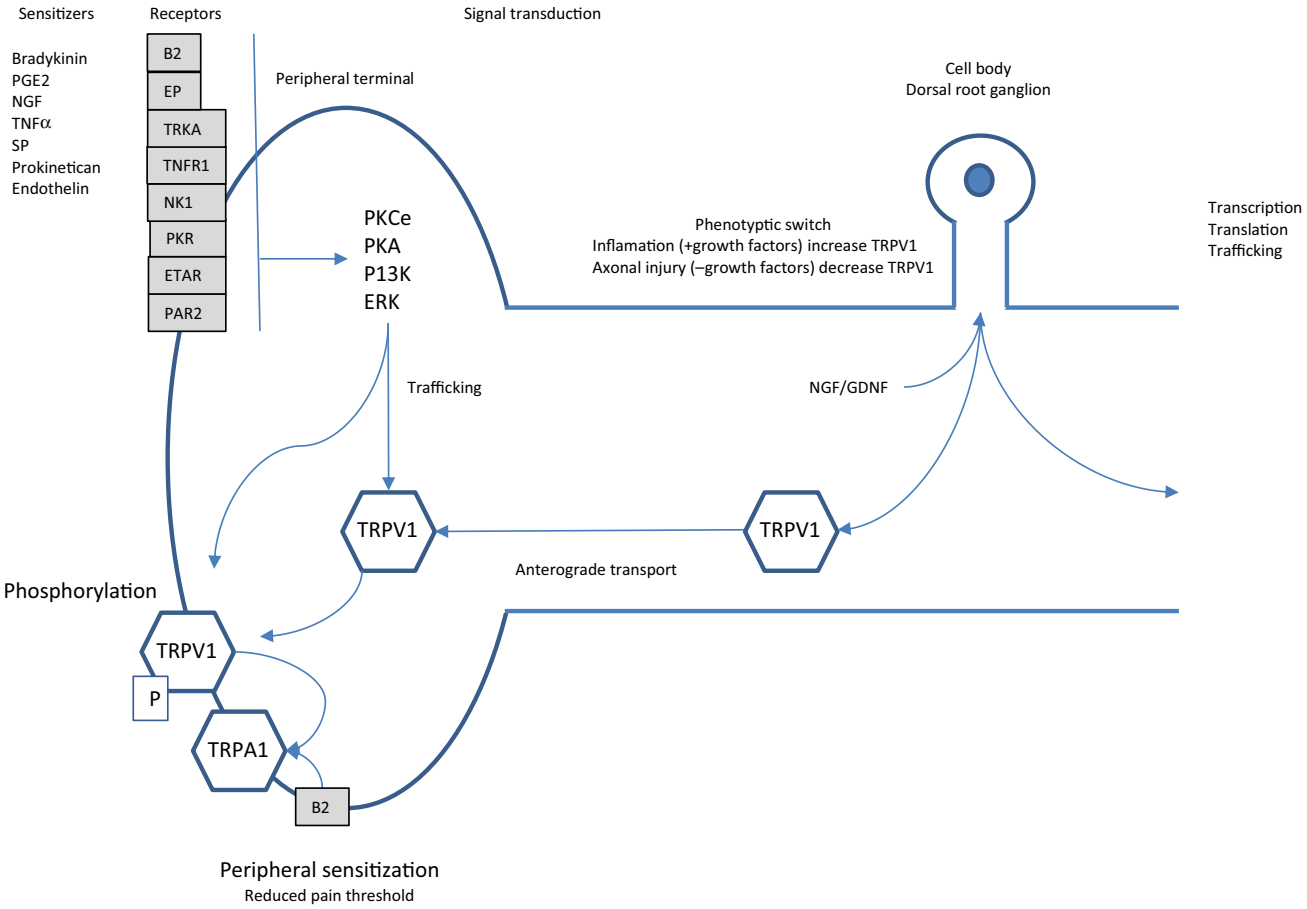

FIGURE 7.1 Changes in transient receptor potential (TRP) channels produced by inflammation. Endogenous sensitizers act on receptors expressed by nociceptors to activate intracellular signal transduction pathways. Pathways phosphorylate TRP channels, altering trafficking to the membrane, thresholds, and kinetics. Growth factors, such as nerve growth factor (NGF), are retrogradely transported to the cell body of the nociceptors. Through intracellular signaling pathways, expression of TRP channels is increased and they are transported to the peripheral terminal. Changes in transcription and translation of TRP channels and other proteins can switch the chemical phenotype of the neurons from their state in naive conditions to an altered state during inflammation. B2, bradykinin receptor; ERK, extracellular signal-regulated kinase; ETAR, endothelin receptor type A; GDNF, glial-cell-derived neurotrophic factor; NK1, neurokinin receptor 1; PAR2, protease-activated receptor 2; PGE2, prostaglandin E2; PI3K, phosphoinositide 3-kinase; PK, protein kinase; PKR, prokineticin receptor; TNFα, tumor necrosis factor α; TNFR1, TNF receptor 1; TRKA, tyrosine kinase receptor A. *Adapted from Patapoutian et al. (2009).*

responsive to exogenous compounds that code for qualitative perceptual similarities (e.g., the "hotness" of capsaicin, the "burn" of cinnamon oil, the "coolness" of menthol, the irritation of mustard oil; Holzer, 2011). Although the specific homologies for other TRP channels in birds are generally not known, based on behavioral responsiveness to a variety of mammalian irritants, it is anticipated that TRP channel receptor molecules in birds would be structurally similar and/or have similar expression in nociceptors to that found in mammals for cinnamon oil, allicin (garlic/onion), and menthol and divergent for mustard oil and anthranilate (grape) compounds (Clark, 1998; Stucky et al., 2009).

Digital fluorescence imaging of intracellular calcium $[Ca^{2+}]_I$ in vitro preparations of chicken and rat trigeminal dorsal root ganglia show that there are separate and overlapping populations of neurons that are sensitive to the well-described avian irritant, methyl anthranilate, and capsaicin (Kirifides et al., 2004). In the chicken, 48% of neurons responded to methyl anthranilate, whereas only 16% responded to capsaicin. Moreover, there was a greater change in $[Ca^{2+}]_I$ to equimolar concentrations of methyl anthranilate (78%) relative to capsaicin (43%). Increases in $[Ca^{2+}]_I$ were dependent upon extracellular calcium for both methyl anthranilate and capsaicin. However, responses to methyl anthranilate, but not capsaicin, were dependent on extracellular sodium. This suggests different transduction mechanisms for the two compounds. Together, these observations provide further rationale for the observed behavioral differences in birds to these two compounds. Starlings (*Sturnus vulgaris*) demonstrate congenital avoidance to methyl anthranilate but not capsaicin, although they could be trained to avoid capsaicin in conditioned

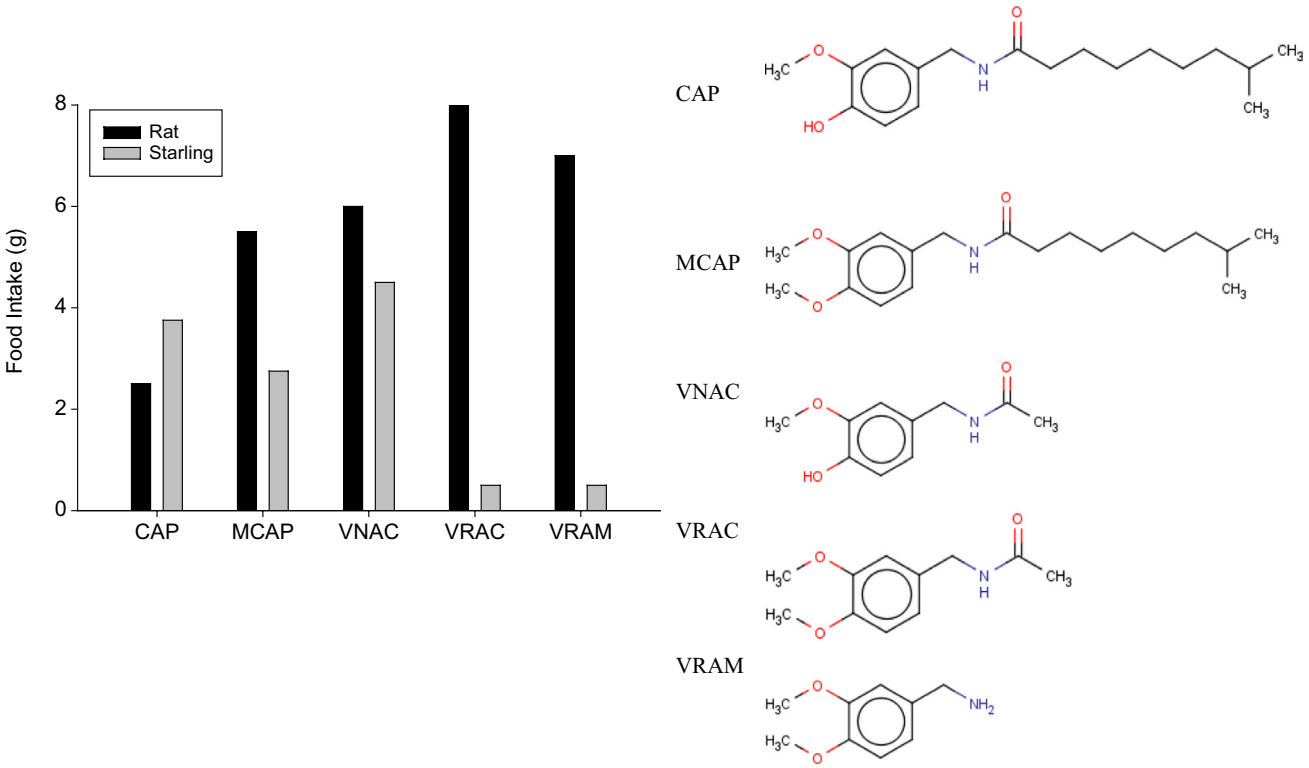

FIGURE 7.2 Consumption of food treated with capsaicin (CAP), methyl capsaicin (MCAP), vanillyl acetamide (VNAC), veratryl acetamide (VRAC), and veratryl amine (VRAM) in rats and starlings. Note the general inverse relationship of consumption as structure changes, suggesting functional receptor differences in the two taxa. Bird repellents are more basic and rigid (planar) than mammal aversive compounds. Concentration applied: 1000 ppm. Consumption of 4 g of untreated food is control baseline intake for both species. *Data adapted from Mason et al. (1991).*

avoidance paradigms, and that avoidance was contingent upon an intact ophthalmic branch of the TN (Mason and Clark, 1995). These observations also suggest that while birds can perceive capsaicin, although somewhat poorly, it is not coded as pain, highlighting the importance of central processing in the perceptual interpretation of peripheral signals.

7.2.4 Chemical Structure–Activity Relationships to Irritants

Despite the apparent insensitivity of birds to capsaicin, they can respond to other vanilloid compounds (Figure 7.2). Aromatic compounds that are considered aversive by birds are qualitatively characterized as having an aromatic heterocyclic core, high degree of basicity, high degree of lipophilicity, and a high degree of electronegativity (Figure 7.3). The core aromatic heterocycle of a repellent compound is enhanced by substitutions that affect electron donation: amino > methoxy > methyl > hydroxyl groups. Resonance of lone pairs of electrons enhances repellency as a function of substituent position: ortho > para > meta. Acidic substituents in the electron withdrawing group detract from aversive qualities of the compound. Steric effects and extreme delocalization of lone pairs of electrons, as might occur in meta isomers and aromatic structures with multiple substituted electron donating groups, tend to interfere with repellency (Mason et al., 1989; Clark, 1991a; Clark and Shah, 1991, 1994; Clark et al., 1991; Shah et al., 1991).

Quantitative structure–activity relationships of aromatic compounds and repellency are consistent with earlier qualitative studies. The aversive properties of 14 derivatives of cinnamic acid compounds are characterized by heat of formation (DH(f)), polarizability (XY and YY), and superdelocalizability (Sr). All of these descriptors are electronic (Watkins et al., 1999). These findings generally align with a reanalysis of the quantitative structure–activity relationships of the 117 compounds described above (Clark, 1997). Canonical analysis of the relationship of physicochemical, topological, and electrostatic descriptors and the response shape of the four-parameter fluid intake curve showed that 94% of variance in the response profile could be accounted for by five parameters: polarizability, ES2, ANC, KAPPA2, and CHI2. Polarizability is the relative susceptibility of the electron cloud of a molecule to be distorted by presence of an external electric field. Owing to distortion, an induced electric dipole moment appears. Temporary dipoles induce dipoles in other molecules, resulting in van der

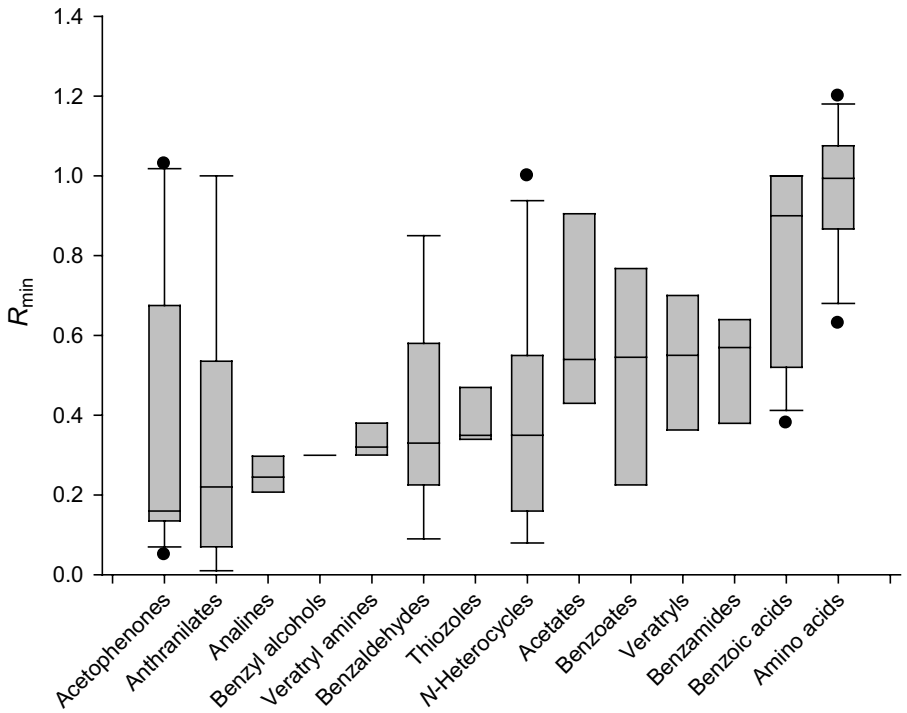

FIGURE 7.3 The relative reduction of fluid intake for solutions as a function of chemical class, which assumes a benzene parent structure with the nomenclatural taxonomy defined by the principal electron withdrawing group. Fluid intake is the asymptotic minimum intake in one-bottle 6-h drinking trials (R_{min}). Strongly aversive solutions (where R_{min} is not statistically distinguishable from zero) have $R_{min} \leq 0.2$. Moderately aversive solutions have $0.2 < R_{min} \leq 0.4$, weakly aversive solutions have $0.4\ R_{min} \leq 0.6$, and solutions with $R_{min} > 0.6$ are not aversive at all (not statistically different from water controls). Median R_{min} (solid bars), R_{min} 25–75th percentile (shaded box), R_{min} 5–95th percentile (capped line), and the range of R_{min} (open symbols). *Adapted from Clark (1997).*

Waals intermolecular forces by orienting the temporary and induced dipoles with each other. ES2 is an electrotopological descriptor that describes electronic interactions between molecules. ANC is a partial negative electronic charge descriptor of electrostatic potential that influences molecular interactions. CHI2 and KAPP2 are valence connectivity and shape descriptors that may describe the rigidity of the molecule and accessibility of the molecule to receptor systems. The importance of electronic features of molecules is consistent with studies of TRPA1 channel modulation and activation of cysteine-reactive chemicals. TRP channel activation was found to be more dependent on chemical reactivity relative to molecular shape (Hinman et al., 2006; Macpherson et al., 2007). However, the importance of gaining access to proximity of the TRP channels owing to influences of molecular flexibility and shape still remains to be more fully explored.

7.2.5 Responses to Respiratory Stimuli

Changes in carbon dioxide concentration in the nasopharynx region can cause species-specific changes in reflexive breathing in birds (Hiestand and Randall, 1941). However, concentrations of carbon dioxide that are sufficiently high to be irritating to mammals have no effect on blood pressure, heart rate, tidal volume, breathing frequency, upper airway resistance, or lower airway resistance in geese (*Anser anser*) and chickens. Geese and chickens respond differently than mammals to exposure to sulfur dioxide, but in a similar manner when exposed to ammonia and phenyl diguanide (Callanan et al., 1974; McKeegan et al., 2005).

7.2.6 Nasal and Respiratory Irritation and Interaction of Olfaction and Chemesthesis

The TN is important in the perception of odors (Tucker, 1971; Silver and Maruniak, 1981; Keverne et al., 1986). Electrophysiological evidence shows that the TN responds to odors, although it is generally less sensitive than the olfactory nerve (Tucker, 1963). Behavioral assays yield similar results. Pigeons trained to respond to odors fail to respond after olfactory nerve transections. However, odor responding can be reinstated if the odor concentration is increased (Michelsen, 1959; Henton, 1969; Henton et al., 1966). Odor sensitivity of pigeons decreased by 2–4 log units (vapor saturation) after olfactory nerve transaction (Walker et al., 1979).

Although olfaction can modulate responding to chemical irritants, it is relatively unimportant (Clark, 1995). In European starlings, avoidance of anthranilate compounds

was partially a consequence of olfactory cues. When the olfactory nerves were transected, avoidance was only mildly diminished. When the ophthalmic branches of the TN were transected, the starlings became insensitive to the aversive properties of the anthranilates (Mason et al., 1989).

7.2.7 Behavioral Responses to Irritants

Many aromatic molecules are aversive to birds (Kare, 1961; Mason et al., 1989; Crocker and Perry, 1990; Clark and Shah, 1991, 1993; Crocker et al., 1993). Several lines of evidence suggest that a variety of compounds have intrinsic properties that cause them to be aversive on a purely sensory basis. First, the aversive quality is unlearned; that is, avoidance occurs upon initial contact (Clark and Shah, 1991). Second, there is no evidence that consumption is altered by gastrointestinal feedback; intake of fluid treated with those sensory stimuli is constant over time (Clark and Mason, 1993). Third, unlike mammals, birds seem unable to associate the aversive quality of the stimulus with other chemosensory cues, suggesting that conditioned flavor avoidance learning does not occur (Clark, 1996; Clark and Avery, 2013). Fourth, birds do not habituate to the stimulus; avoidance persists in the absence of reinforcement (Clark and Shah, 1994).

7.2.8 Applications

Current interest in chemesthetic function and properties in birds is largely focused in four areas: (1) the evolutionary phylogenetic relationships of receptor mediated perception of noxious stimuli and its consequence to the foraging ecology of birds (Clark, 1998; Tewksbury and Nabhan, 2001); (2) the applicability of using aversive compounds in modulating feeding behavior of birds to develop repellents for prevention of crop damage or otherwise mitigating against damage caused by birds (Mason and Clark, 1997; Clark and Avery, 2013); (3) efforts to gain a better understanding of pathologic pain caused by "debeaking" and promotion of animal welfare in domestic chicken production through better management methods or development of appropriate analgesics (Kuenzel, 2007; Gentle, 2011); and (4) discovery of better analgesics for management of pain in veterinary clinical settings.

7.3 OLFACTION

7.3.1 Morphology of Olfactory System

Air entering a bird's nasal cavity passes through a series of mucous-covered, invaginated chambers called nasal conchae. Nasal conchae influence air flow dynamics and direct odors to the caudal-most chamber, which contains the chemically sensitive olfactory epithelium (reviewed in Roper, 1999; see also: Bang, 1960, 1961, 1963, 1964, 1965, 1966; Bang and Cobb, 1968). The surface of the olfactory epithelium is composed of receptor cells, which detect odorous compounds and occur at the ends of olfactory nerve dendrites. Each receptor cell is surrounded by a cluster of supporting cells and ends in a knob bristling with 6–15 cilia that extend into the lumen. The length of cilia varies by species. Black vultures, for example, have cilia of 40–50 μm, whereas domestic fowl have cilia of 7–10 μm (Shibuya and Tucker, 1967). To gain access to the cilia of receptor cells, odor molecules must diffuse through a mucous membrane. Cilia themselves provide no transport function. Rather, secretions covering cilia provide rapid flow for odor molecules. Olfactory gland secretions must be removed and replaced to maintain diffusion and avoid receptor habituation to odorant molecules. Traction of nearby respiratory cilia facilitates removal of secretions.

The extent of scrolling of caudal conchae correlates with the surface area of olfactory epithelium and the relative size of the olfactory bulb, which is the region of the brain that processes odor input (Bang and Cobb, 1968; Bang, 1971; Bang and Wenzel, 1985; reviewed in Roper, 1999; Hagelin, 2007a). Avian orders with relatively larger olfactory bulbs have lower detection thresholds, indicating they are more sensitive to certain odorous compounds than those with relatively small olfactory bulbs (Clark et al., 1993; Table 7.1, Figure 7.4). Elaborated olfactory systems typically belong to species with demonstrated reliance on odor cues in the field (Stager, 1964; Hutchison and Wenzel, 1980; Hagelin, 2004) and, in some species, correlate positively with the number of olfactory receptor genes (Steiger et al., 2008). Fossil evidence also indicates olfactory bulb size was relatively large early in bird evolution, revealing a previously unrecognized emphasis on smell (Zelenitsky et al., 2011).

Although a larger olfactory bulb size or greater scrolling of receptor epithelium likely indicates greater functional capacity (e.g., more cells and neural circuits; Meisami, 1991), it is important not to dismiss avian species with relatively "unelaborate" olfactory systems (Hagelin, 2007b). Both field and laboratory tests indicate that several taxa with relatively small olfactory bulbs can discriminate between and/or adaptively employ certain odors, such as those related to breeding and nesting (e.g., crested auklets (*Aethia cristatella*) Hagelin et al., 2003; European starlings Clark and Mason, 1985; Gwinner and Berger, 2008; Corsican Blue Tit (*Parus caeruleus ogliastrae*) Petit et al., 2002).

7.3.2 Innervation of Olfactory Receptors

Olfactory receptor cells from each nasal cavity transmit information via the olfactory nerve to the olfactory bulb, located in the anterior region of each brain hemisphere. Each olfactory bulb is composed of concentric cell layers.

TABLE 7.1 Summary of Mean Ratios of Ipsilateral Olfactory Bulb Diameter to Cerebral Hemisphere Diameter and Their Standard Errors (SE) for Several Orders of Birds

Order	*N*	Ratio	SE	Order	*N*	Ratio	SE

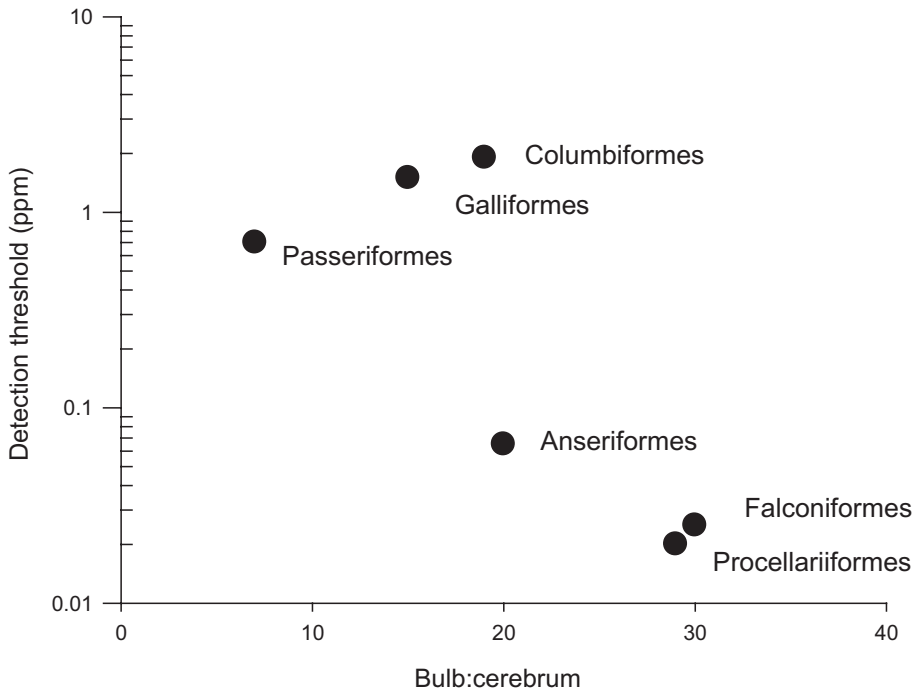

FIGURE 7.4 Relationship between olfactory detection threshold and relative size of the olfactory bulb for different orders of birds. *Adapted from Clark and Shah (1993).*

Incoming olfactory nerve fibers constitute the outer layer. Branching nerve terminals penetrate into the adjacent, glomerular layer, where they connect with dendrites of mitral and tufted cells in spherical arborizations called glomeruli. The perikarya of these cells are in the deeper mitral cell layer, where their axons leave to project to many areas of the forebrain.

Like other vertebrates, the olfactory bulbs of birds are bilaterally symmetrical; each is associated with its own (ipsilateral) brain hemisphere. The layering of different cell types within avian olfactory bulbs is qualitatively similar to reptiles, in that well-defined cell layers (like those of mammals) are lacking (Allison, 1953; Andres, 1970). However, there are many interneuron connections in the cell layers

between the mitral and glomerular regions. There are no direct connections between the two (contralateral) olfactory bulbs (Rieke and Wenzel, 1978).

Although birds clearly have olfactory bulbs, they appear to lack an accessory olfactory system (Rieke and Wenzel, 1974, 1978). Both olfactory and accessory olfactory structures commonly occur in other vertebrates. The accessory olfactory system is frequently linked to conspecific scent stimuli that modulate social behavior (e.g., reproduction, aggression). However, there is good evidence for mammals that both the main olfactory and accessory olfactory systems can detect and process overlapping sets of odor stimuli (Keller et al., 2009). Accessory olfactory structures include the vomeronasal organ and accessory olfactory bulb. It is possible that accessory olfactory bulbs in birds occur during early embryonic development only, but are lost later on (Matthes, 1934). This idea, however, has received little scientific attention.

7.3.3 Olfactory Neuronal Response

Electrophysiological responses to odor stimuli are taken as definitive evidence of olfactory capacity. These can be recorded from a single "unit" (neuron) or multiunit nerve fibers. Recordings of black vultures indicate that the electro-olfactogram appears primarily during inspiration, which coincides with peak spike activity (Shibuya and Tucker, 1967). Electrophysiological recordings of mammals, amphibians, reptiles, and birds all show similar responses, irrespective of the size of a species' olfactory apparatus (Tucker, 1965; Shibuya and Tonosaki, 1972).

Single-unit responses from within the olfactory bulb of domestic chickens show widely variable rates of spontaneous firing (mean 4.9 spikes/s, range 0.1–32.4 spikes/s) prior to odor exposure (McKeegan, 2002). Odor stimulation modifies spontaneous firing via excitation or inhibition. Avian firing rates appear to fall in between rates reported for mammals and reptiles (McKeegan, 2002, 2009). Single units of chickens responded to two or more odors and revealed surprising sensitivity to biologically relevant scents associated with captivity (e.g., hydrogen sulfide). Responses to extremely low (<0.5 ppm) stepwise changes in concentration to hydrogen sulfide revealed a level of fine-tuning not previously reported for other vertebrates (McKeegan et al., 2002). Continuous presentation of a stimulus can result in physiological adaptation of both single-unit (McKeegan and Lippens, 2003) and nerve-unit recordings, like mammals. Recovery can be achieved within a few minutes of rest.

Olfactory nerve fibers are unmyelinated, which produces slow conduction velocities of about 1.5 mJ/s (Macadar et al., 1980). Interestingly, transected olfactory nerves (which experimentally inhibit olfaction) can repair and recover full physiological capacity within 30 days (Tucker et al., 1974). Although healed nerves are scarred and smaller, recordings and autonomic reflexes to odorants did not differ between controls and nerves that had been cut at least 6 months earlier (Tucker, 1971; Tucker et al., 1974).

Another means of quantifying olfactory neural responses involves calcium imaging (Restrepo et al., 1995). This method uses fluorescence to quantify changes in the flux of calcium ions associated with neural activation (i.e., signal transduction) of a single olfactory receptor neuron (ORN). Jung et al. (2005) tested responses of acutely dissociated ORNs from olfactory epithelium of embryonic domestic chicks. Avian ORNs were placed in Ringer's solution containing liquid solutions of odorants. The fluorescence patterns, which correspond to increases or decreases in Ca^{2+} concentration, were remarkably similar to those of other vertebrates (mammals and fish) that had been tested with the same set of odorants (Jung et al., 2005).

7.3.4 Laboratory Detection Thresholds, Discrimination, and Seasonal Change

Physiological responses (e.g., change in respiration or heart rate) to novel odor stimuli have been observed (Wenzel and Sieck, 1972). Habituation to the stimulus under this paradigm, however, is problematic. Operant and classical conditioning paradigms that use positive or negative reinforcement (Michelsen, 1959; Henton et al., 1966; Henton, 1969) are usually poor at determining olfactory thresholds or discrimination (Calvin et al., 1957). However, two process learning paradigms, such as cardiac conditioning, have proven to be a successful technique for detection, discrimination, and threshold testing (Rescorla and Solomon, 1967; Walker et al., 1986; Clark and Mason, 1989; Clark and Smeraski, 1990; Clark, 1991a; Clark et al., 1993). During cardiac conditioning, an odor (the conditional stimulus) is paired with an aversive experience, such as a shock (the unconditional stimulus). Heart rate is compared before and after stimulus presentation during training until a level of cardiac acceleration is reliably achieved, indicating a bird has learned to associate the odor in anticipation of a shock. Thereafter, tests of detection or odor discrimination can proceed. Most birds tested with this paradigm have shown olfactory capabilities comparable to mammals (Davis, 1973). Even passerines, with the least developed olfactory system, demonstrate behavioral responsiveness to odors (Clark and Mason, 1987; Clark and Smeraski, 1990; Clark, 1991a; Clark et al., 1993) (Table 7.2).

European starlings offer an interesting case study of olfactory structure, function, and seasonality. Male starlings incorporate green plants that are rich in aromatic volatiles into nests, some of which act as a fumigant against parasites and pathogens (Clark and Mason, 1985, 1987, 1988; Clark, 1991b; Gwinner, 1997; Gwinner et al., 2000; Gwinner and Berger, 2005). Starlings are most sensitive to, and can discriminate between, plant odors during spring only, rather than

in summer and fall. Spring is coincident with nest building and suggests a hormonal influence (Clark and Smeraski, 1990).

Birds treated with testosterone (T), a hormone that enlarges song-learning nuclei of the brain and alters behavior, exhibited enlarged olfactory bulbs year-round, indicating a proximate effect on bulb structure. However, perception of plant odor in T-implanted males was greatest during spring only, indicating that perception was independent of T-treatment and olfactory bulb volume. One hypothesized but untested mechanism is that an increase in receptor cell density in starling olfactory epithelium occurs in spring (DeGroof et al., 2010).

7.3.5 Development

Volatile compounds diffuse through avian eggshell (Rahn et al., 1979), providing an opportunity for odor exposure within the egg (Tolhurst and Vince, 1976; Sneddon et al., 1998). Many vertebrates, including birds, detect and learn chemical information as embryos (e.g., humans: Schaal et al., 2000; Mennella et al., 2001; other mammals: Hepper, 1988; Bilko et al., 1994; amphibians: Mathis et al., 2008; birds: Porter and Picard, 1998; Bertin et al., 2012). Early exposure can cause changes in neuroanatomy, which alters chemosensory perception in a way that can adaptively shape responses later in life (e.g., to food, mates, etc.) (Todrank et al., 2011).

Studies of domestic chickens, the avian model for development, indicate that odor detection can occur before or after young pierce the egg's air sac and begin breathing air (Tolhurst and Vince, 1976; Bertin et al., 2012; Hagelin et al., 2013). ORNs are functional 6 days prior to air-breathing (on embryonic developmental day 13; Lalloué et al., 2003), when nasal passages are full of amniotic fluid. Embryos at this stage swallow frequently, facilitating fluid movement, similar to mammals in utero (Sneddon et al., 1998). Airbreathing begins approximately 2 days prior to hatching, on embryonic developmental day 19 (Tolhurst and Vince, 1976).

The magnitude of embryonic response varies relative to stimulus concentration and timing of exposure (Bertin et al., 2010). Later developmental stages show relatively greater responses to odors (Gomez and Celli, 2008; Bertin et al., 2012). Detectable stimuli include artificial odors (Sneddon et al., 1998), as well as naturally occurring scents, such as nest materials (Gwinner and Berger, 2008), food-related odors (Burne and Rogers, 1999; Cunningham and Nevitt, 2011), and compounds found in plumage scent of at least one alcid species (Hagelin et al., 2013).

7.3.6 Field Studies and Behavioral Ecology

Like other vertebrates, birds detect and respond adaptively to odors (reviewed in Roper, 1999; Hagelin, 2007a; Balthazart and Taziaux, 2009; Caro and Balthazart, 2010). Hagelin (2007a) made a distinction between environmentally derived odors (e.g., food, predators) and those produced by birds themselves (e.g., body odors, fecal odor, preen gland secretions). The latter can have social and reproductive implications. This section considers examples of adaptive olfactory responses to environmental odors as well as bird-derived scents.

The use of olfactory cues for locating food has been documented for numerous species, such as procellariids, vultures, corvids, hummingbirds, honeyguides, parrots, and kiwis (Roper, 1999). Turkey vultures (*Cathartes aura*), for example, are attracted to ethyl-mercaptan, a volatile associated with decomposed carcasses (Stager, 1964, 1967), and locate food without visual cues (Houston, 1986). Procellariiforms also forage over considerable distances. Black-footed albatrosses (*Diomedea nigripes*) respond to bacon grease over 31 km away (20 miles; Miller, 1942), whereas Leach's storm petrel (*Oceanodroma leucorhoa*) home to scent targets at a distance of 1–12 km (Clark and Shah, 1992). Some procellariiformes also respond to a compound that is correlated with prey called dimethyl-sulfide (DMS) (Nevitt et al., 1995). DMS smells like rotten seaweed and results from the breakdown of metabolic products of marine algae (phytoplankton). Petrels, however, do not feed on phytoplankton. Rather, DMS concentrates in locations where a bird's prey (zooplankton, such as krill) is actively grazing on phytoplankton. Grazing by zooplankton lyses phytoplankton cells and thereby creates a DMS odor plume, which some birds follow to locate food (Nevitt, 2011).

With regard to predators, the scent of urine and/or feces has an aversive effect on some avian species (blue tits (*Cyanistes caeruleus*), Amo et al., 2008; house finches (*Carpodacus mexicanus*), Roth et al., 2008; red junglefowl (*Gallus gallus*), Zidar and Løvlie, 2012), but not all (eastern blue birds (*Sialia sialis*), Godard et al., 2007; house wren (*Troglodytes aedon*), Johnson et al., 2011). Application of predator odor can also deter breeding ducks and songbirds (Eicholz et al., 2012; Forsman et al., 2013). Responses appear to be innate rather than learned (Amo et al., 2011b), although sleeping birds are unreactive (Amo et al., 2011a).

Odors are also germane to avian orientation and navigation (reviewed in Wallraff, 2005; Gagliardo, 2013). Homing pigeons, for example, exhibit larger olfactory bulbs than nonhoming breeds (Rehkämper et al., 1988, 2008). Investigators have also altered pigeon homing behavior via experimental disruption of the olfactory system. Manipulations include olfactory nerve transection (Papi et al., 1971; Gagliardo et al., 2006, 2009), anesthesia of olfactory mucosa (Wallraff, 1988), ablating the central piriform cortex of the brain (Papi and Casini, 1990), and nostril plugging. The last of these manipulations indicates that pigeons rely more on their right nostril for olfactory information (Gagliardo et al., 2007, 2011). *ZENK*, an

immediate early gene expressed in olfactory neurons, also implicates the use of olfaction during the process of homing (Patzke et al., 2010).

Emerging evidence for passerine species further supports olfaction during migration. For example, adult gray catbirds (*Dumetella carolinensis*) rendered temporarily anosmic (by washing the olfactory tissues with zinc sulfate) oriented differently from adult controls but similarly to juvenile birds, which were migrating for the first time and therefore unable to navigate (Holland et al., 2009). With regard to cellular mechanisms, black-headed buntings (*Emberiza melanocephala*) increase activation of olfactory tissues (as measured by c-fos immunoreactivity) during migration. These birds exhibit a seasonally enhanced emphasis on olfaction while migrating, compared to visual systems (Rastogi et al., 2011).

Many birds produce a variety of odorous compounds (Table 7.3; reviewed in Campagna et al., 2011). For example, a seabird colony, with its dense numbers of birds, burrows, and feces, makes for a potent chemosensory experience. Pioneering work by Grubb (1974) on Leach's storm petrel showed differential return rates to nest sites after surgical manipulation, indicative of olfactory-based homing: 91% for controls, 74% for sham surgery, and 0% for olfactory nerve section. Several petrel species have since been shown to discriminate between the odor of their own nest and conspecific burrows (Mínguez, 1997; De León et al., 2003; Bonadonna et al., 2003a,b). Attraction to home nest odor is also reported for passerines (Caspers and Krause, 2010; Krause and Caspers, 2012).

TABLE 7.3 Some Avian Orders Considered To Be Very Odorous by Ornithologists

Order	Common Name	Number of Species[1]
Procellariiformes	Petrels, shearwaters, diving petrels	16
Ciconiiformes	Herons, storks, new world vultures	12
Anseriformes	Ducks, geese, swans, screamers	49
Charadriiformes	Sandpipers, gulls, auks	23
Psittaciformes	Parrots	14
Cuculiformes	Cuckoos	16
Coraciiformes	Kingfishers, rollers, hoopoes, woodhoopoes	14
Piciformes	Woodpeckers, barbets, tucans	33
Passeriformes	Grackles, starlings, ravens, finches, honeycreepers	46

[1]*Data compiled from Weldon and Rappole, 1997.*

Avian chemical substances are linked with a variety of social contexts (reviewed in Hagelin, 2007a; Hagelin and Jones, 2007; Balthazart and Taziaux, 2009; Caro and Balthazart, 2010). Uropygial gland secretions, for example, show some level of hormonal control and exhibit individual, sex, and age-specific patterns (e.g., Procellariiformes: Mardon et al., 2010, 2011; Anseriformes: Kolattukudy et al., 1987; Galliformes: Karlsson et al., 2010; passerines: Whittaker et al., 2010; Whelan et al., 2010; Shaw et al., 2011; Amo et al., 2012a). Pioneering work by Balthazart and Schoffeniels (1979) indicated male mallards decreased social displays and sexual behavior toward females when their olfactory nerves were sectioned, suggesting that intact olfactory system is critical to courtship and mating. Crested auklets produce a seasonally elevated scent associated with a stereotyped behavior that focuses on the scented region of the body (the nape). Auklets are attracted to natural feather odor, a chemical cocktail of odor compounds, and scented decoys, which suggests odor has a social function (Hagelin et al., 2003; Jones et al., 2004; Hagelin, 2007a). Odorous compounds of crested auklets can also negatively impact ectoparasites in experimental tests (Douglas, 2008, 2013).

Procellariiform seabirds show a surprising level of body odor discrimination, in that they are attracted to mate odors and avoid self-odor (Antarctic petrel (*Pachyptila desolata*) Bonadonna and Nevitt, 2004; blue petrels (*Halobaena caerulea*), Mardon and Bonadonna, 2009). Furthermore, preference for the odor of unrelated individuals over those of kin was recently discovered (European storm petrel (*Hydrobates pelagicus*), Bonadonna and Sanz-Aguilar, 2012). Such results suggest that body odors could provide a mechanism for inbreeding avoidance, known as self-referent phenotype matching (Mateo and Johnston, 2000). This may be particularly important in petrels which are a long-lived philopatric species that mates for life. Petrels are also likely to encounter kin on their natal breeding grounds that they have never met before (Bonadonna and Nevitt, 2004; Bonadonna and Sanz-Aguilar, 2012). Recent evidence for passerines suggests that conspecific odor may provide relevant social information. Bird responses to scent correlated with social rank (house finch, Amo et al., 2012b), sex (European starling, Amo et al., 2012a), and body size (dark-eyed junco (*Junco hyemalis*), Whittaker et al., 2011).

7.3.7 Summary

Every bird tested has exhibited a functional sense of smell (Bang and Wenzel, 1985). The extent of olfactory development also is on par with that found in mammals. However, ornithologists have largely overlooked the role of olfaction in avian biology. Many birds adaptively employ

environmental odors; they also produce and respond to conspecific scents. Although passerines have a relatively poorly developed olfactory anatomy, they nonetheless show some degree of olfactory acuity. Other species, such as procellariiformes, have olfactory systems that are acutely sensitive to odor cues and capable of a surprisingly detailed level of conspecific odor discrimination. Given the broad range of contexts that implicate avian olfaction, future interdisciplinary research that compares olfactory mechanisms in birds to better-known vertebrate systems, such as mammals and fish, holds exciting promise.

7.4 GUSTATION

7.4.1 Taste Receptors

Relative to other vertebrates, birds have fewer taste receptors and taste receptor genes (Berkhoudt, 1985; Shi and Zhang, 2005) (Table 7.4). Notwithstanding these observations, birds have a well-developed system for gustation with functional significance for their behavior, ecology, and evolution. Taste receptors are located in taste buds throughout the oral cavity. The greatest concentration of avian taste receptors is found around salivary glands in the soft epithelium of the palate, the posterior tongue, and the oropharynx (Bath, 1906; Lindenmaier and Kare, 1959; Saito, 1966; Ganchrow and Ganchrow, 1985). Afferent taste signals in birds are carried in the glossopharyngeal nerve (cranial nerve IX; Duncan, 1960). The glossopharyngeal nerve innervates the posterior buccal and pharyngeal areas (Kare and Mason, 1986). Unlike mammals, the facial nerve (VII) does not innervate the avian tongue (Wenzel, 1973). Rather, glossopharyngeal afferents in birds enter the medulla and join fibers from the facial (including chorda tympani) and vagus nerves (X) to form a well-developed *fasciculus solitarius* (Lindenmaier and Kare, 1959). The chorda tympani innervates taste buds adjacent to the anterior mandibular salivary glands, situated in the buccal epithelium of the lower jaw (Kare and Mason, 1986).

TABLE 7.4 Abundance of Taste Buds among Vertebrate Species[1]

Species	Taste Buds	Source
Domestic chick (day-old)	5–12	Lindenmaier and Kare (1959)
Domestic chicken (3 months)	24	Lindenmaier and Kare (1959)
Blue tit	24	Gentle (1975)
Bullfinch	41–42	Duncan (1960)
Pigeon	59	Moore and Elliot (1946)
Japanese quail	62	Warner et al. (1967)
European starling	200	Bath (1906)
Parrot	300–400	Bath (1906)
Domestic cat (juvenile)	473	Elliot (1937)
Lizard	550	Schwenk (1985)
Bat	800	Moncrieff (1946)
Domestic cat (adult)	2755	Robinson and Winkles (1990)
Human	6974	Miller and Reedy (1990)
Rabbit	17,000	Moncrieff (1946)
Pig	19,904	Chamorro et al. (1993)
Ox	35,000	Moncrieff (1946)
Catfish	100,000	Hyman (1942)

[1]*Modified from Kare and Mason (1986) and Mason and Clark (2000).*

7.4.2 Response to Sweet

Birds have a well-developed sense of taste that generally corresponds to their feeding habits. Frugivorous and omnivorous birds tend to perceive and prefer sweet more so than species in other foraging guilds. For example, European starlings prefer 0.5–5% D-fructose solutions (w/v) to distilled water (Espaillat and Mason, 1990). Sugar detection thresholds of cockatiels (*Nymphicus hollandicus*) is 0.36 M sucrose, 0.40 M fructose and 0.16 M glucose (Matson et al., 2000, 2001). The sugar detection thresholds of broad-billed hummingbirds (*Cynanthus latirostris*) is between 1.31 and 1.54 mM sucrose, 0.87–1.31 mM fructose, 1.54–1.75 mM glucose and 1.75–3.5 mM of a 1:1 mixture of fructose and glucose (Medina-Tapia et al., 2012). Interestingly, the sweet taste receptor gene Tas1r2 is absent in all bird genomes sequenced thus far, irrespective of their diet (Zhao and Zhang, 2012), suggesting that additional avian receptors may exist for sweet.

The order of preference among nectivorous passerines is sucrose = glucose + fructose = fructose > glucose > xylose (Lotz and Nicolson, 1996). Lesser double-collared sunbirds (*Nectarinia chalybea*) and Cape sugarbirds (*Promerops cafer*) absorb sucrose, glucose, and fructose from ingested food at nearly 100% efficiency, but xylose was excreted (Lotz and Nicolson, 1996; Jackson et al., 1998a,b). Although nectar composition and concentration are often considered independently, these characteristics may have a synergistic effect on the sugar preferences of nectar-feeding birds (Schondube and Martinez del Rio, 2003).

Sugar preferences among nectarivorous and frugivorous birds are concentration-dependent. Although nectarivorous birds in Africa prefer sucrose when offered a choice of 0.25 M solutions of glucose, fructose, and sucrose, no preference among these sugars was observed when their concentration was increased to 0.73 M; the dietary choices in these species indicate the birds had either reached a limit where they had sufficient energy intake or they were affected by

postingestion constraints (Downs and Perrin, 1996; Downs, 1997). House finches demonstrated no preference for equicaloric, 2% solutions of hexoses (1:1 mixture of fructose and glucose) and sucrose, and strong preference manifest for hexoses but not sucrose at 4, 6, and 10% concentrations; energetics, rather than sucrase deficiency, may determine finches' sugar preferences (Avery et al., 1999).

Studies of unrelated, nectarivorous birds (including a generalist, nonpasserine nectarivore) have demonstrated a distinct switch from hexose preference at low concentrations to sucrose preference at higher concentrations (Lotz and Schondube, 2006; Fleming et al., 2008; Brown et al., 2010a,c). Sucrose preference at higher concentrations may possibly be explained by taste perception due to differences in solution osmolality or a degree of imprinting due to experience with natural nectar compositions. Village weavers (i.e., generalist passerine nectarivores; *Ploceus cucullatus*) preferred hexose solutions at 5% and 10% sucrose equivalents (SE), yet no sugar preference was observed at 15, 20, and 25% SE (Odendaal et al., 2010). In contrast, dark-capped bulbuls (*Pycnonotus tricolor*), an opportunistic nectarivore, significantly preferred hexose solutions, irrespective of concentration (5–25%), when given a choice between equicaloric hexose and sucrose solutions (Brown et al., 2010b). Interestingly, malachite sunbirds (*Nectarinia famosa*) demonstrated either sucrose preference, no preference, or hexose preference when offered equimolar, equiweight, or equicaloric paired solutions of sucrose and hexose, respectively (Brown et al., 2008).

The bananaquit (*Coereba flaveola*) strongly prefers the most concentrated sucrose solution when the lowest concentration ranged from 276 to 522 mM. From 522 to 1120 mM sucrose concentrations, bananaquits adjust their volumetric food intake to maintain constant energy intake. At a sucrose concentration of 276 mM, however, bananaquits did not maintain their rate of energy intake by increasing food consumption (Mata and Bosque, 2004). Although nectarivorous birds generally prefer concentrated over dilute sugar solutions, the concentration difference that they can discriminate is smaller at low concentrations relative to high concentrations; this pattern may be a consequence of the functional form of intake responses that often results in decelerating sugar intakes with increasing sugar concentration (Martinez del Rio et al. 2001; Leseigneur and Nicolson, 2009). With regard to gender-specific food intake among nectarivorous birds, males take longer to digest than females when fed on sucrose-rich nectars as opposed to hexose-rich nectars; therefore, they can allow themselves a relatively lower digestive capacity (Markman et al., 2006). The digestive transit rates of Cape white-eyes (*Zosterops virens*) fed artificial fruit were faster for glucose- than sucrose-based diets, irrespective of concentration; increased food intake with decreasing glucose concentration and no significant differences in food intake with differing sucrose concentrations were observed (Wellmann and Downs, 2009). Indeed, nectar ingestion rate is determined by viscosity, and total food intake is primarily modulated by sugar concentration (Köhler et al., 2010).

Sugar preference and selection among nectarivorous and frugivorous birds are likely to have coevolutionary effects on flowering and fruit-bearing plants. Among 58 wild fruits studied in Hong Kong, all fruit species contained glucose, all but one contained fructose, and only 11 species contained sucrose; birds are known to eat 29 of these species without detectable sucrose and four with sucrose (Ko, 1996). From a comparative analysis of glucose, fructose, and sucrose in the nectar and fruit juice of 525 tropical and subtropical plant species, passerine nectars and fruits had low sucrose and high hexose content, respectively; the nectar of hummingbird flowers had very high sucrose content; microchiroptera nectars showed hexose richness and microchiropteran fruits had a sucrose content similar to passerine fruits; and megachiroptera nectars and fruits were sucrose-rich (Baker et al., 1998). The dichotomy between sucrose-rich nectars in hummingbird-pollinated plants and predominantly hexose-rich nectars in sunbird-pollinated plants appears to have little to do with bird physiology and may rather reflect patterns of nectar secretion or plant physiology and opportunist nectar feeders (Nicolson and Fleming, 2003; Fleming et al., 2004).

The hummingbird-passerine dichotomy was strongly emphasized until the discovery of South African plants with sucrose-dominant nectars, which are pollinated by passerines that demonstrate sucrose digestion and preference (Lotz and Schondube, 2006). Flowers adapted for specialized passerine nectarivores have nectar similar to that of hummingbird flowers in terms of volume (approx. 10–30 mL), concentration (15–25% w/w) and sucrose content (40–60% of total sugar). In contrast, flowers adapted to generalized bird pollinators are characterized by large volumes (approximately 40–100 mL) of extremely dilute (8–12%) nectar with minimal sucrose (0–5%; Johnson and Nicolson, 2008).

Rufous hummingbirds (*Selasphorus rufus*) preferred 50% sucrose to higher and lower concentrations, and they could distinguish solutions differing by only 1% sucrose (Blem et al., 2000). Sucrase activity is 10 times higher in hummingbirds than in passerines (Schondube and Martinez del Rio, 2004). Neither sex nor temperature affected sugar preferences among green-backed firecrown hummingbirds (*Sephanoides sephaniodes*; Chalcoff et al., 2008). Patterns of hummingbird sugar preference can be affected by different mechanisms, both pre- and postingestive. At low concentrations, gustatory thresholds may play an important role in sugar selection. At intermediate and high concentrations, however, sugar selection can be explained by sugar assimilation rates and velocity of food processing generated by osmotic constraints (Medina-Tapia et al., 2012).

Species belonging to the Sturnidae–Muscicapidae lineage do not express intestinal sucrase, despite having generalist diets comprising fruits with sugars of diverse kinds (Gatica et al., 2006). Members of the Sturnidae-Muscicapidae lineage are intolerant of solutions or fruit above 11–15% sucrose (Brown et al., 2012). Considering the phylogenetic constraint hypothesis for sucrose digestion in the Muscicapoidea superfamily, the lack of sucrase activity is a shared, derived character only for the Cinclidae–Sturnidae–Turdinae lineage (Gatica et al., 2006).

Within an experimental meal with varying sucrose concentration, captive whitebellied sunbirds (*Cinnyris talatala*) demonstrated a measurable increase in feeding frequency and food intake within 10 min after a decrease in sucrose concentration (Köhler et al., 2008). Similarly, Knysna turacos (*Tauraco corythaix*) preferred an artificial sucrose diet to an equicaloric glucose diet at low concentrations, whereas purple-crested turacos (*Gallirex porphyreolophus*) showed no preference for either diet. Both turacos species preferred a sucrose diet to an equimolar glucose diet at low concentrations. At high concentrations, neither species showed a preference for either equicaloric or equimolar diets; thus, energy requirements influence food preferences more than sugar type and birds will select fruit that is higher in energy irrespective of sugar type (Wilson and Downs, 2011).

7.4.3 Response to Salt

A comparison of the sodium chloride rejection thresholds among 58 bird species illustrated rejection thresholds ranging from 0.35% NaCl in a parrot to 37.5% NaCl in the pine siskin (*Carduelis pinus*; Rensch and Neunzig, 1925). Red-winged blackbirds (*Agelaius phoeniceus*) and European starlings preferred 0.1–1% NaCl solutions (w/v) to distilled water (Espaillat and Mason, 1990). The salt detection threshold of cockatiels is 0.16 M NaCl (Matson et al., 2000) and 0.16 M potassium chloride (Matson et al., 2001). With regard to the mechanism of salt perception, sodium in the oral cavity can cross the taste sensory cell membrane through the epithelial Na^+ channel (ENaC), thus triggering an action potential (Roura et al., 2012). Pigeons (*C. livia domestica*) learned to discriminate a safe 0.06 M NaCl solution and a toxic equimolar LiCl solution. Because the pigeons avoided the LiCl solution within a short presentation period of 5 minutes, it is unlikely that the birds were using an interoceptive stimulus of faint, postingestive malaise as a conditioned cue; thus, the pigeons' discrimination performance between the two chloride solutions was attributed to gustation (Nakajima and Onimaru, 2006).

7.4.4 Response to Sour

Sourness is related to the acidity of food, which is often caused by bacterial fermentation and typically evokes a rejection response. With regard to the mechanism of sour perception, the receptors for sour taste are thought to be transmembrane channels that are selective for hydrogen ions (Roura et al., 2012). Red-winged blackbirds and female starlings preferred distilled water to 0.01–0.1 M citric acid solutions (Espaillat and Mason, 1990). For the purpose of investigating sour detection thresholds, Matson et al. (2000) defined sourness as a pH, and they achieved sourness by varying the pH of a 0.05 M citrate buffer system. The sour detection threshold of cockatiels is pH 5.5 citric acid.

7.4.5 Response to Bitter

Bitter taste perception likely evolved as a protective mechanism against the ingestion of harmful compounds in food (Davis et al., 2010). Red-winged blackbirds and European starlings preferred distilled water to 0.5–5% tannic acid solutions (w/v; Espaillat and Mason, 1990). The bitter detection thresholds of cockatiels is 100 μM quinine, 1000 μM gramine, 500 μM hydrolysable tannin and 10,000 μM condensed tannin (Matson et al., 2004). Compared with pigs, chickens showed a lower sensitivity to glucosinolates (i.e., bitter plant metabolites); compared to ruminants, however, chickens showed a higher aversion to glucosinolates (Roura et al., 2012).

Bitter detection thresholds indicate that a birds' rejection of quinine occurs at lower concentrations than phytophagic mammals (Matson et al., 2004). White Leghorn and Rhode Island Red chickens were able to detect 2.0 mM quinine hydrochloride; broiler chickens detected 0.5 mM quinine hydrochloride (Kudo et al., 2010). Domestic chicks (14 days old) can discriminate between an untreated diet and a diet treated with 0.2% quinine hydrochloride (Ueda and Kainou, 2005).

Johnson et al. (2006) explored the functional significance of the phenolic compounds that impart a dark brown color to the nectar of the South African succulent shrub, *Aloe vryheidensis*. Dark-capped bulbuls were more likely to probe model flowers containing dark nectar than those containing clear nectar, suggesting a potential signaling function of dark nectar. The main effect of the phenolics, however, appears to be repellency of ''unwanted'' nectarivores that find their bitter taste unpalatable. Nectar-feeding honey bees and sunbirds are morphologically mismatched for pollinating *A. vryheidensis* flowers and strongly reject its nectar. Thus, the dark phenolic component of the nectar appears to function as a floral filter by attracting some animals visually and deterring others by its taste (Johnson et al., 2006).

The taste receptor type 2 (Tas2r) gene family encodes the chemoreceptors that are directly responsible for the detection of bitter compounds. The Tas2r cluster encodes up to 18 functional bitter taste receptors in the white-throated sparrow (*Zonotrichia albicollis*; Davis et al., 2010). Although

the tens to hundreds of taste buds observed among birds pales in comparison to the hundreds to thousands of taste buds found in other vertebrates (Table 7.4), this relative deficit does not preclude birds from detecting bitter compounds as effectively as those species with more taste buds. Future biochemical and genetic studies will be needed to identify the natural ligands for avian Tas2r gene clusters, and the intra- and inter-specific differences in these genes with variation in bitter taste perception (Davis et al., 2010).

7.4.6 Response to Umami

Male starlings preferred 0.7–1% L-alanine solutions to distilled water (Espaillat and Mason, 1990). The T1R1 umami receptor gene and the T1R3 sweet/umami receptor gene have been identified in chickens (Shi and Zhang, 2005). Moreover, the expression of T1R1 has been reported in hypothalamus, liver, and abdominal fat (Byerly et al., 2010). Thus, avian taste receptors and umami receptor genes may be involved in the orchestration of postingestive and metabolic events (Roura et al., 2012). Further research is needed to comparatively investigate avian feeding responses to umami tastants.

7.4.7 Response to Calcium

Calcium-deprived chickens preferred calcium-rich diets when offered a choice (Wood-Gush and Kare, 1966; Hughes and Wood-Gush, 1971). Similarly, consumption of supplementary calcium was inversely related to chicken's dietary calcium content (Taher et al., 1984). Further research is needed to distinguish the behavioral responses of birds to calcium as a tastant (i.e., sensory cue) versus the pre- and postingestive attributes of calcium-rich supplements. Although it is clear that animals can detect calcium in micromolar or low millimolar concentrations, it is less clear what they detect or how they detect it (Tordoff, 2001). The notion that calcium is a distinct taste quality is an anathema to many psychophysicists, who argue that there are very few basic taste qualities (sweet, sour, salty, bitter, and umami). To them, calcium taste is a complex of basic tastes, such as bitterness, sourness, and saltiness (Tordoff, 2001).

Calcium taste varies with both the form and the concentration of salt tested, but it nearly always includes sour and bitter components (Tordoff, 2001). The extracellular calcium-sensing receptor (CaR) is a multimodal sensor for several key nutrients, notably Ca^{2+} and L-amino acids, and is expressed abundantly throughout the gastrointestinal tract in humans (Conigrave and Brown, 2006). Although the T1r3 receptor gene in mice (Tordoff et al., 2008) and the CaR have been identified as calcium sensors, it is yet uncertain if they mediate calcium appetite or taste (Roura et al., 2012) in birds.

7.4.8 Taste Behavior and Applications

Deterrents based merely on offensive flavors are not likely to be effective in the absence of aversive postingestive effects (Provenza, 1995). In this context, flavor is the perceptual integration of chemesthetic, olfactory, and gustatory stimuli. Red-winged blackbirds conditioned with sodium chloride paired with an intraperitoneal injection of a gastrointestinal toxin (lithium chloride) or a free choice of a postingestive, cathartic purgative (anthraquinone) or a postingestive, cholinesterase inhibitor (methiocarb) subsequently avoided the flavor (NaCl; Figure 7.5) and color of food experienced during conditioning. In contrast, blackbirds conditioned with sodium chloride paired with an intraperitoneal injection of an opioid antagonist (i.e., chemesthetic; naloxone hydrochloride) or a free choice of a preingestive, trigeminal irritant (methyl anthranilate) subsequently avoided only the color (not flavor; Figure 7.5) of food experienced during conditioning. Thus, red-winged blackbirds reliably integrate gustatory (and visual) experience with postingestive consequences to procure nutrients and avoid toxins (Werner and Provenza, 2011).

Avian taste behavior has been investigated in context of agricultural production, chemical defenses of insects and plants, coevolution in predator-prey and pollination systems, chemical ecology, conservation biology, and comparative physiology and taxonomy. For example, although avian feeding responses to secondary metabolites are species-specific (Saxton et al., 2011; Rios et al., 2012), increased sugar concentrations (not decreasing acid concentrations) are a functional cue for the onset of bird damage to ripening grapes (Saxton et al., 2009). Although increased sucrose content may deter sucrase-deficient birds from damaging commercial fruit (Brugger and Nelms, 1991), increased sucrose may also lead to increased crop damage by other species obligated to consume more of the less-digestible fruit to meet their energy requirements (Lane, 1997). This compensatory feeding hypothesis notwithstanding, McWhorter and Martinez del Rio (2000) observed a physiological constraint on sugar consumption among nectarivorous hummingbirds; the rate of intestinal sucrose hydrolysis can limit sugar assimilation and reduce sucrose preference. Indeed, the intake responses of nectar-feeding birds manifest from the integration of a behavioral response with the physiological processes that shape it (Martinez del Rio et al., 2001).

Several tastants have been used to condition aversions among birds associated with agricultural production. The risk of accidental poisoning of birds may be reduced by adding an aversive tastant (e.g., D-pulegone, quinine hydrochloride) to granular pesticides (Mastrota and Mench, 1995; Clapperton et al., 2012). Garlic oil was identified as an effective chemical repellent for European starlings (Hile et al., 2004) and quinine sulfate (bitterant) was used to

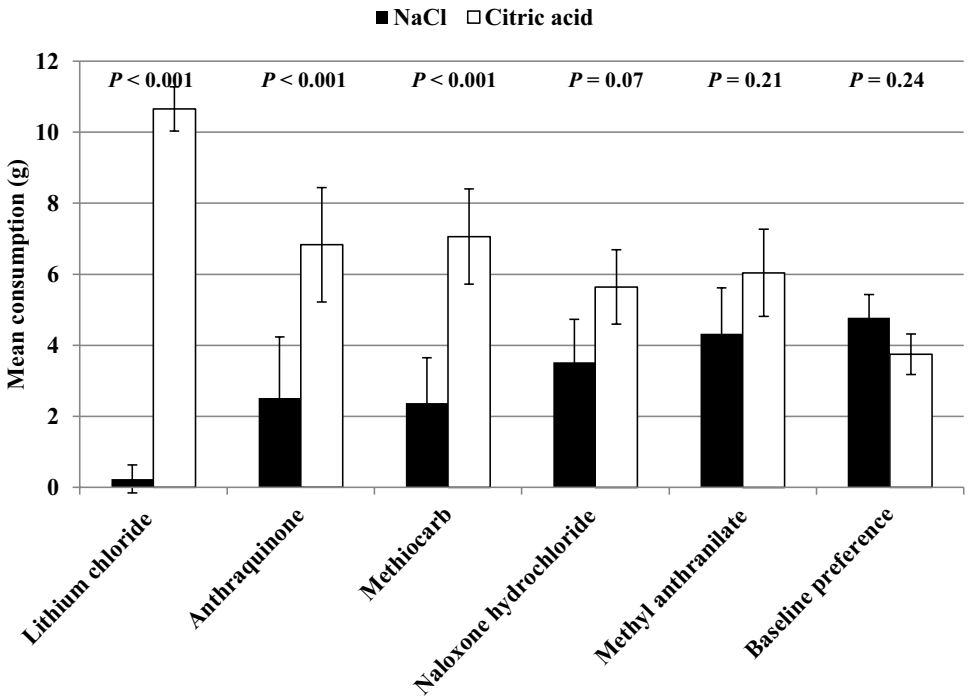

FIGURE 7.5 Mean consumption (±2 SEM) of sodium chloride and citric acid subsequent to NaCl conditioning with: an intraperitoneal injection of a gastrointestinal toxin (lithium chloride), or a free-choice of a postingestive, cathartic purgative (anthraquinone) or a postingestive, cholinesterase inhibitor (methiocarb); or an intraperitoneal injection of an opioid antagonist (naloxone hydrochloride) or a free-choice of a pre-ingestive, trigeminal irritant (methyl anthranilate) in red-winged blackbirds (*Agelaius phoeniceus*). *From Werner and Provenza (2011), baseline preference data from Werner et al. (2008); with permission.*

condition taste aversions and thus reduce destructive feather pecking among laying hens (Harlander-Matauschek et al., 2009, 2010).

Relative preference for specific tastants has been used to enhance feeding for poultry production. The preference of chickens for oily diets (i.e., long-chain versus medium-chain triacylglycerol) is mediated by gustation (Furuse et al., 1996; Mabayo et al., 1996), not satiety (Vermaut et al., 1997). In contrast, the avoidance of a saponin-rich diet is not mediated by taste in domestic chicks (Ueda and Shigemizu, 2001); rather, crop distension causes decreased feed intake associated with tea saponin (Ueda et al., 2002).

Domestic chicks can use unpalatable taste (e.g., quinine) to adapt their visual foraging decisions (Rowe and Skelhorn, 2005; Skelhorn et al., 2008). Moreover, European starlings and domestic chicks can learn to use bitter taste cues to regulate consumption of toxic prey (Skelhorn and Rowe, 2010; Barnett et al., 2011). Similarly, red-winged blackbirds use affective processes (flavor-feedback relationships) to shift preference for both novel and familiar flavors (Werner et al., 2008).

7.4.9 Summary

The conventional notion regarding the "limited ability of birds to taste" (Kassarov, 2001) was shaped by a historic paradigm of taste research (i.e., elementary structure and function). Avian taste perception is currently investigated in context of ontogenetic and phylogenetic relationships within ever-changing environments. Birds use taste cues to select nutrients and avoid toxins; thereby, they affect the distribution, diversity, and coevolution of their prey. Thus, taste cues and postingestive consequences have behavioral, ecological, and evolutionary implications for domestic and wild birds. Future avian gustation research will develop our understanding of comparative biochemistry, molecular biology, and ethology—from an emphasis on anatomical structure to the physiological bases of behavior and performance.

Chapter 8

Magnetoreception in Birds and Its Use for Long-Distance Migration*

Henrik Mouritsen

Institut für Biologie und Umweltwissenschaften, Universität Oldenburg, Oldenburg, Germany; Research Centre for Neurosensory Sciences, University of Oldenburg, Oldenburg, Germany

8.1 INTRODUCTION

The Earth's magnetic field provides potentially useful information, which birds could use for directional and/or positional information. It has been clearly demonstrated that birds are able to sense the compass direction of the Earth's magnetic field and that they can use this information as part of a compass sense. Magnetic information could also be useful as part of a map sense, and there is a growing body of evidence that birds are able to determine their approximate position on the Earth on the basis of geomagnetic cues. In addition to direct uses for orientation and navigation, magnetic information also seems to be able to influence other physiological processes, such as fattening and migratory motivation, as a trigger for changes in behavior. Although the behavioral responses to geomagnetic cues are relatively well understood, the physiological mechanisms enabling birds to sense the Earth's magnetic field are only starting to be understood, and understanding the magnetic sense(s) of animals, including birds, remains one of the most significant unsolved problems in biology. It is very challenging to sense magnetic fields as weak as that of the Earth using only biologically available materials. Only two basic mechanisms are considered theoretically viable in terrestrial animals: iron-mineral-based magnetoreception and radical-pair based magnetoreception. On the basis of current scientific evidence, iron-mineral-based magnetoreception and radical-pair-based magnetoreception mechanisms seem to exist in birds, but they seem to be used for different purposes. Plausible primary sensory molecules and a few brain areas involved in processing magnetic information have been identified in birds for each of these two types of magnetic senses. Nevertheless, we are still far away from understanding the detailed function of any of the at least two different magnetic senses existing in some if not all bird species, and, at present, no primary sensory structure has been identified beyond reasonable doubt to be the source of avian magnetoreception. This is an exciting but challenging field in which several major discoveries are likely to be made in the next 1–2 decades.

8.2 MAGNETIC FIELDS

Moving electric charges such as electrons produce magnetic fields. On the microscopic scale, electron (and nuclear) spins can generate magnetic fields. On the macroscopic scale, a magnetic field, **B**, is, for instance, generated around a wire when current runs through it. The magnetic field at a given location can be described as a three-dimensional (3D) vector for which the strength, **B**, is measured as magnetic flux density using the unit "Tesla" (T), $1\,T = 1\,(V*s)/m^2 = 1\,(N*s)/(C*m) = 10{,}000$ Gauss (V = Volt, s = second, m = meter, N = Newton, C = Coulomb). Some materials, which are called "ferromagnetic," can be permanently magnetized by a magnetic field, and this magnetization remains after the magnetizing field has been removed. Magnetite (Fe_3O_4), an iron oxide, is a well-known example of a ferromagnetic mineral (Mouritsen, 2013).

* Because our knowledge of magnetoreception did not change dramatically over the last few months, there is significant text and content overlap between the present chapter and a chapter focusing on magnetoreception in all kinds of organisms and titled "The Magnetic Senses," which I recently wrote for the textbook *Neurosciences*: Mouritsen, H., 2013. The magnetic senses. In: Galizia, C.G., Lledo, P.M. (Eds), *Neurosciences—From Molecule to Behavior: A University Textbook*. © Springer-Verlag Berlin Heidelberg, pp. 427–443, doi: 10.1007/978-3-642-10,769-6_20. Springer Verlag has permitted the reuse of significant parts of the *Neurosciences* textbook chapter text and figures in the present chapter. Specific references to this text are not given at every location where text is reused because such references would compromise readability and could be misunderstood to be referring to primary research findings.

8.3 THE EARTH'S MAGNETIC FIELD

The Earth generates its own magnetic field (the geomagnetic field), which is mostly caused by electric currents in the liquid outer core of the Earth (the "dynamo effect"). The magnetic field measured at the Earth's surface is similar to the magnetic field one would expect to see if a large dipole magnet was placed in the center of the Earth (see Figure 8.1). The Earth's magnetic field currently has a magnetic field South Pole near the Earth's geographic North Pole (referred to as "Magnetic North" or "Magnetic North Pole" in biology). Throughout this chapter, I will follow the convention used in the bird orientation research literature and use the term "Magnetic North" or "Magnetic North Pole" to refer, not to the physical magnetic North Pole, but to the magnetic pole located closest to the geographic North Pole. Likewise, the magnetic field North Pole near the Earth's geographic South Pole will be referred to as "Magnetic South" or "Magnetic South Pole" (Mouritsen, 2013).

The magnetic field lines leave the Magnetic South Pole and re-enter the Magnetic North Pole. The polarity of the magnetic field lines always points toward Magnetic North; therefore, they can provide a highly reliable directional reference that can be used as the basis for a magnetic compass anywhere on planet Earth except at the magnetic poles. At the magnetic poles, the field lines point directly into the sky (at the Magnetic South Pole) or directly into the Earth (at the Magnetic North Pole). At the magnetic equator, the magnetic field lines are parallel to the Earth's surface. The angle between the magnetic field lines and the Earth's surface is called "magnetic inclination." Thus, magnetic inclination changes gradually from −90° at the Magnetic South Pole to 0° at the magnetic equator to +90° at the Magnetic North Pole (see Figure 8.1). The Earth's magnetic field intensity ranges from c. 30,000 nT (nano-Tesla = 10^{-9} T; 1 T = 1 Vs m^{-2}; 1 nT = 10^{-5} Gauss) near the magnetic equator to c. 60,000 nT at the magnetic poles. Earth-strength magnetic fields are usually measured with a calibrated three-axial flux-gate magnetometer. In theory, magnetic inclination and magnetic intensity can be useful for determining one's position, but, on most parts of the Earth, magnetic inclination and intensity changes predominantly from North to South but not much from East to

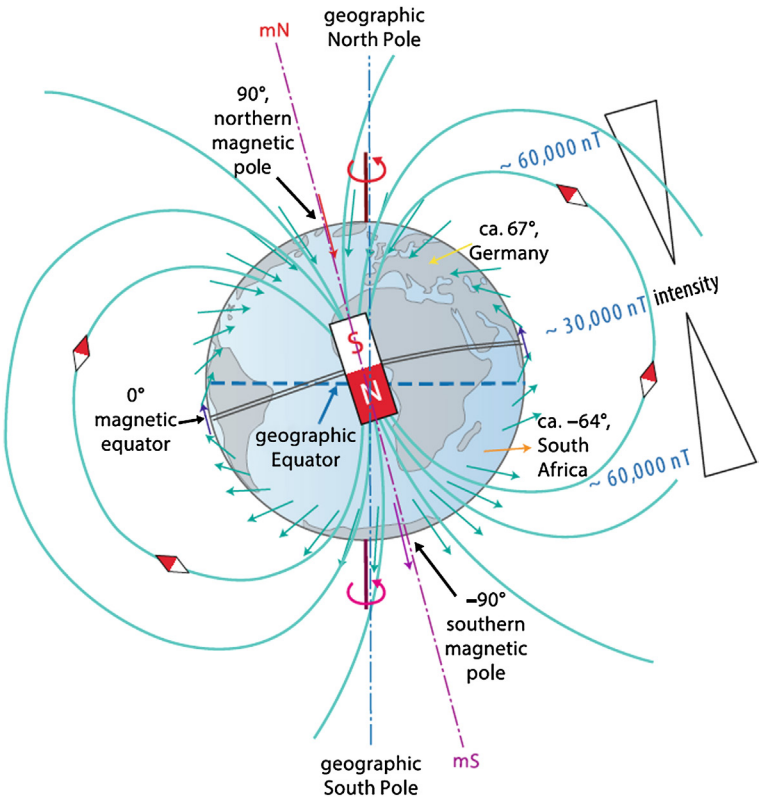

FIGURE 8.1 The Earth's magnetic field (the geomagnetic field). Notice that the southern and northern magnetic poles and the magnetic equator do not coincide with the geographical poles and the geographic equator. Also notice that the magnetic field lines intersect the Earth's surface at different angles depending on the magnetic latitude (blue-green lines and vectors). The intersection angle is called the magnetic inclination. Magnetic inclination is +90° at the Magnetic North Pole (red vector), c. +67° at the latitude of Germany (yellow vector), 0° at the magnetic equator (dark blue vectors), c. −64° at the latitude of South Africa (orange vector), and −90° at the Magnetic South Pole (magenta vector) *(Adapted with permission after Wiltschko and Wiltschko (1996) and Mouritsen (2013).)* The magnetic intensity varies from c. 60,000 nT near the magnetic poles to c. 30,000 nT along the magnetic equator.

West; therefore, it seems easier to determine latitude than longitude from geomagnetic field information (Mouritsen, 2013).

The Magnetic North Pole is currently located in northern Canada, and the Magnetic South Pole is currently located south of Australia. Consequently, the geographic and magnetic poles do not coincide (see Figure 8.1). The deviation between geographic and Magnetic North is called the "magnetic declination." Magnetic declination is the angle between Magnetic North (i.e., the direction in which the north end of a compass needle points in) and Geographic North. The declination is positive when Magnetic North is east of Geographic North and negative when Magnetic North is west of Geographic North. Declination is mostly small, but near the magnetic poles declination can pose a serious problem for navigating birds using a magnetic compass unless they find a way to compensate for it. On the other hand, magnetic declination could, in theory, be a useful parameter to determine, for example, East-West position if it would be combined with other map cues (Mouritsen, 2013).

8.4 CHANGING MAGNETIC FIELDS FOR EXPERIMENTAL PURPOSES

The direction of the magnetic field around a wire can be determined by the "right hand rule": If you grasp around the wire with your right hand so that your thumb is pointing in the direction of the current, then the magnetic field around the wire runs in the direction in which your fingers are pointing. The magnetic field decreases with distance as you move away from the wire. If you create a coil of wire, then the magnetic field created is much stronger inside of the coil than on the outside of the coil because many parallel magnetic field lines created by different parts of the wire coincide and thus add up in the center of the coil. This is the reason why coil constructions are typically used to produce and alter magnetic fields (Mouritsen, 2013).

The typical coil constructions, which are used to produce Earth-strength magnetic fields for scientific experiments, are so-called "Helmholtz coils"—a pair of parallel coils placed one radius apart from each other (Kirschvink, 1991). In a pair of Helmholtz coils, the magnetic field is very homogeneous within a central space of c. 60% of the radius of the coils (Kirschvink, 1991). The magnetic field generated in the center of a pair of Helmholtz coils is $\mathbf{B} = (0.9*10^{-6}\,\mathrm{T\,m/A}*n*I)/R$, where T is the unit Tesla, n is the number of turns in each coil, I is the current flowing through the coils measured in ampere (A), and R is the radius of the coils measured in meters (m) (Kirschvink, 1991). One pair of Helmholtz coils can only alter the magnetic field along one axis. To make any desired 3D magnetic field, three pairs of Helmholtz coils oriented perpendicular to each other are ideally needed. If one adds an artificially created field to an existing field (such as that of the Earth), then the resultant field is calculated by simple vector addition of the two fields (see Figure 8.2; Kirschvink, 1991). Therefore, it is also possible to use a single pair of Helmholtz coils to make any 3D magnetic field, but in that case, this single pair of coils must be oriented very precisely in 3D space (see Figure 8.2; Mouritsen, 2013).

Although the Helmholtz arrangement is easy to calculate and construct, the central homogeneous space can be increased to c. 110% of the radius of the coils by using more elaborate coil designs such as the Merritt-4-coil system (Kirschvink, 1991; Zapka et al., 2009, Figure 20.2 in Mouritsen, 2013). To control for artefacts, one would—independent of the coil design chosen—expect the coils to be "double wrapped" (Kirschvink, 1991; Kirschvink et al., 2010). This means that during construction of the coils, each coil contains two separate but identically wrapped wires, each with separate connectors, so that one can either run current through both halves of the windings in the same direction (then the magnetic field in the center of the coil will change), or one can run the current through one half of the coils in one direction but in the opposite direction through the second half of the windings. In that case, the current running through one half of the windings will create a magnetic field, which exactly cancels the magnetic field produced by the other half of the windings, and the background field is not changed. By using double-wrapped coils, exactly the same amount of current is sent through the coils whether the magnetic field is being changed or not. Double-wrapped coils also allow for truly double-blinded experiments (Kirschvink, 1991; Zapka et al., 2009; Harris et al., 2009; Hein et al., 2010, 2011; Engels et al., 2012). An excellent presentation of the theoretical background and practical instructions on how to construct various coil designs for changing Earth-strength magnetic fields can be found in Kirschvink (1991).

8.5 BIRDS USE INFORMATION FROM THE EARTH'S MAGNETIC FIELD FOR ORIENTATION AND NAVIGATION

Orientation and navigation skills are essential for the survival of all migratory birds. All first-time migrants are faced with the challenge of finding an unfamiliar wintering area, often thousands of kilometers away (Berthold, 1991; Mouritsen and Mouritsen, 2000; Mouritsen, 2003). Many bigger birds are day migratory and travel in groups, which means that young birds of these species might simply follow experienced birds that know the way. However, most small songbirds are night-migratory and travel alone without contact with their parents. Consequently, all of their navigational skills must be based on inherited sensory capabilities and strategies (Mouritsen, 2003). No cues requiring previous

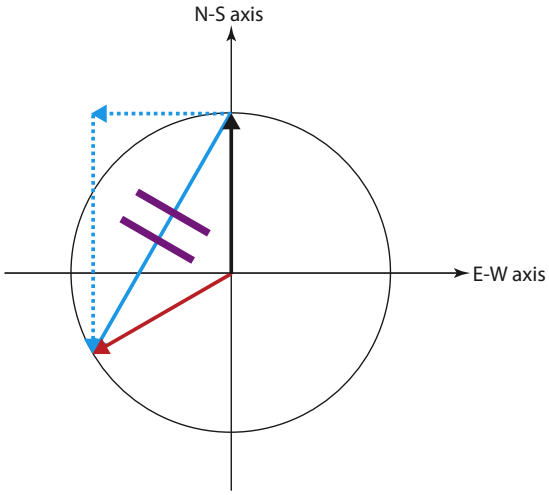

FIGURE 8.2 Magnetic fields are vector fields and can easily be turned with pairs of coils. If we consider the geomagnetic field, it will point toward North (0°) and have a vertical and a horizontal component. Let's say that we want to create a magnetic field with the same strength and inclination as the geomagnetic field but that is turned horizontally 120° counterclockwise. In that case, the vertical component of the field should remain unchanged, and we only have to consider the two dimensions in the horizontal plane. Let's say that the Earth's magnetic field at the relevant location has a horizontal field component of 18,000 nT pointing toward Magnetic North (black vector). If we want to turn the field to point toward 240° (a 120° counterclockwise turn, red vector), then we need to produce a magnetic field vector (the blue vector) that connects the tip of the black vector to the tip of the red vector. The needed field can be produced by a single pair of Helmholtz coils (symbolized by the violet lines) if the coil frames are oriented on the axis defined by half of the wanted angular turn (in this case 120°/–60°) given that the final wanted intensity should remain unchanged. Simple trigonometry can be used to calculate the needed field strength, B_{blue}, of the blue vector. In this case, $B_{blue} = (((\cos(\alpha_{black})*B_{black}) - (\cos(\alpha_{red})*B_{red}))^2 + ((\sin(\alpha_{black})*B_{black}) - (\sin(\alpha_{red})*B_{red}))^2)^{1/2}$, where $\alpha_{black} = 360°$, $\alpha_{red} = 240°$, and $B_{black} = B_{red} = 18{,}000\,nT \Rightarrow B_{blue} = ((\cos(360°)*18{,}000\,nT - \cos(240°)*18{,}000\,nT)^2 + (\sin(360°)*18{,}000\,nT - \sin(240°)*18{,}000\,nT)^2)^{1/2} = (((27{,}000\,nT)^2 + (-15{,}588\,nT)^2)^{1/2}) = 31{,}177\,nT$. If the strength of the final vector should have a different intensity than the original vector, or if the vertical component also needs to be changed, then again a single pair of coils can, in principle, do the job (the needed calculations are 3D), but accurately orienting this pair of coils is very difficult in real life. Therefore, if excellent control of static magnetic fields is required, usually 3D systems of perpendicularly oriented coils are used. Because magnetic fields are vector fields, which all need to be added up to get the total resultant field, instead of producing the direct vector (the blue vector) that connects the tip of the black vector to the tip of the red vector, we can produce two vectors (the dashed blue vectors) along the two coil axes, which in total connect the tip of the black vector to the tip of the red vector. With such systems, each of the needed vectors is much easier to calculate. The needed N–S component is $\cos(\alpha_{black})*B_{black} - \cos(\alpha_{red})*B_{red}$, and the needed E–W component is $\sin(\alpha_{black})*B_{black} - \sin(\alpha)*B_{red}$. If one uses a 3D magnetometer oriented with the x-axis toward North and the y-axis toward East, and one just wants to calculate the values that should be on the display when the wanted field is present, *X* should read $\cos(\alpha_{red})*B_{red}$ and *Y* should read $\sin(\alpha)*B_{red}$. Thus, in the case of a 120° counterclockwise turn of the above-mentioned field, *X* should read $\cos(240°)*18{,}000\,nT = -9000\,nT$ and *Y* should read $\sin(240°)*18{,}000\,nT = -15{,}588\,nT$. All formulas presented here are valid for geographical angles (North = 0° = 360°, East = 90°, South = 180°, and West = 270°) but have to be modified if mathematical angles are used (East = 0°, North = 90°, West = 180°, and South = 270°). What should the same magnetometer read on *X* and *Y* if the same geomagnetic field is turned horizontally to 165°?[#]

[#] $X = -17{,}387\,nT$; $Y = +4659\,nT$.

experience with the goal can be involved in the orientation strategies of solitary, first-year migrants. These considerations strongly limit the number of possible orientation cues to a few classes of globally or at least regionally consistent cues (Mouritsen, 2003):

1. Celestial cues, including the Sun, the stars, and maybe the polarized light pattern of the sky
2. Geomagnetic cues

In addition to these cues, some authors have suggested that chemical cues, including odors, (Wallraff and Andreae, 2000; Wallraff, 2005; Gagliardo et al., 2006, 2008, 2009) infrasound (sound with frequency below c. 20 Hz; Hagstrum, 2013 but see Wallraff, 1972; Holland, in press), and/or Coriolis forces (the phenomenon that moving liquids and moving air are deflected slightly to the right on the Northern Hemisphere and slightly to the left on the Southern Hemisphere because of the Earth's rotation; Coriolis, 1835) might also be used for orientation and navigation.

However, there seems to be no physiological structure inside of birds that would enable them to detect the Coriolis effect with a reasonable signal-to-noise ratio (Rosenblum et al., 1985; Adair, 1991; Kirschvink et al., 2010). Likewise, it is difficult to imagine how an inexperienced migrant could know, in advance, what the infrasound or odor "landscapes" along its migratory path looks like, and it is difficult to imagine that the infrasound and/or odor landscapes would be simple and consistent enough to be used by inexperienced birds as a primary map cue over thousands of kilometers (but see Wallraff and Andreae, 2000). Furthermore, because the width of the bird's head is much smaller than the wavelength of infrasound, it would be challenging for a

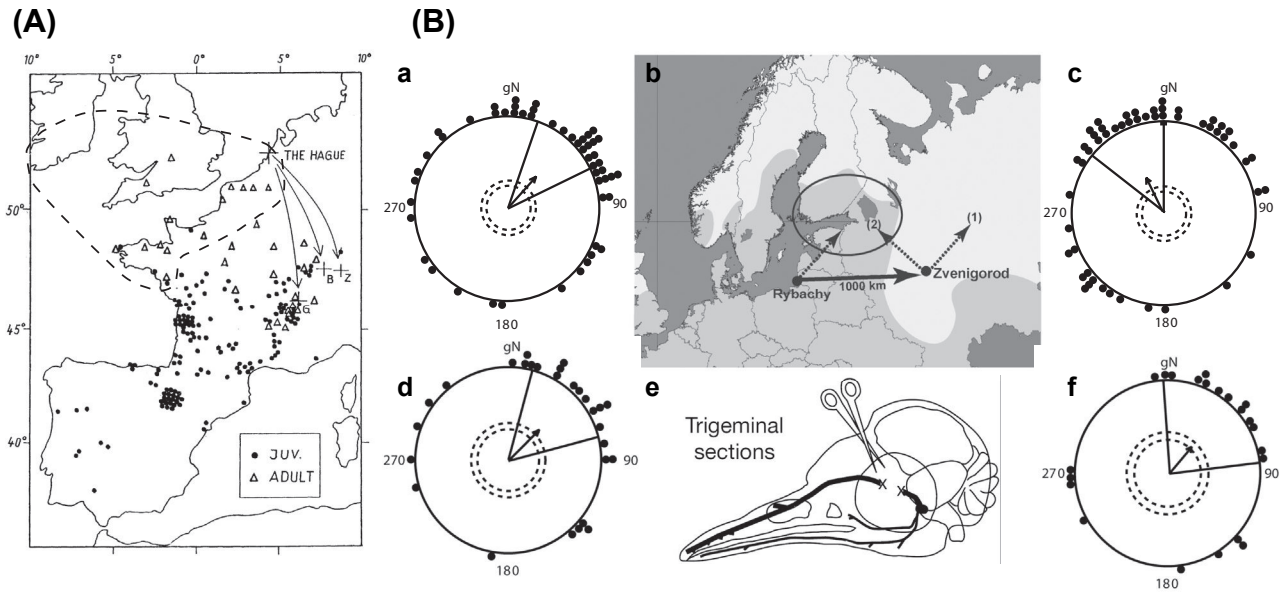

FIGURE 8.3 Displacement experiments provide key evidence for understanding the spatiotemporal orientation strategies of migratory birds. (A) Perdeck's classical experiments in which he displaced >10,000 starlings from Holland S/SSE (→) to Switzerland during autumn migration showed that young starlings (•) on their first autumn migration were unable to correct for the displacement. The young birds show a parallel displaced migration pattern relative to the wintering area of nondisplaced controls (dashed area) whereas adult starlings (Δ) orient directly back to the normal population-specific wintering area of nondisplaced controls *(From Mouritsen (2003) after Schmidt-Koenig (1965); Perdeck (1958))*. (B) Displacement experiments, in which Eurasian Reed Warblers (*Acrocephalus scirpaceus*) were tested in Emlen funnels (Emlen and Emlen, 1966; Mouritsen et al., 2009) before and after displacement, showed that young birds on their first spring migration are already able to correct for 1000-km eastward displacements to a location where they have certainly never been before (b). (a) Orientation of birds at the capture site (Rybachy). (c) Orientation of the same birds after the 1000 km eastward translocation to Zvenigorod. Each dot at the circular diagram periphery indicates the mean orientation of one individual bird. The arrows show group mean directions and vector lengths. The dashed circles indicate the length of the group mean vector needed for significance according to the Rayleigh test (5% and 1% level for inner and outer dashed circles, respectively). The lines flanking group mean vectors indicate the 95% confidence intervals for the mean direction. gN = geographic North. On (b), a map of the displacement region is shown. The shaded light-gray zone represents the breeding range of Eurasian Reed Warblers and the dashed arrows show the expected results in case of (1) no compensation for the displacement or (2) compensation toward the eastern part of the breeding range. Notice that intact birds compensate for the displacement whereas birds that had the ophthalmic branch of the trigeminal nerve cut (d–f) could no longer compensate for the displacement. *Re-assembled after Chernetsov et al. (2008); Kishkinev et al. (2013).*

small bird with a 2 cm wide head to determine from which direction infrasound originates (Mouritsen, 2013).

Thus, the primary orientation system of young inexperienced migrants on their first autumn migration is likely to be based primarily on celestial and magnetic cues, and it is known that when first-time autumn migrants are displaced away from their migration route, they are unable to correct for displacements (Drost, 1938; Perdeck, 1958; Mouritsen and Larsen, 1998; Mouritsen, 2003; Thorup et al., 2007; Holland, in press). Instead, they choose a migration route parallel to their normal route; thus, they do not seem to possess a map sense (see Figure 8.3). The migratory program of first-season solitary migrants can be described as a "clock-and-compass," "calendar-and-compass," or "vector navigation" strategy (Mayr, 1952; Perdeck, 1958; Schmidt-Koenig, 1965; Rabøl, 1978; Berthold, 1991; Mouritsen, 1998b; Mouritsen and Mouritsen, 2000; Mouritsen, 2003) in which the birds fly in a specific direction for a given amount of time independent of their present location. Because the system includes little (see below under magnetic signposts) or no location-related feedback, the orientation strategy of first-time solitary migrants can be mathematically described as a directed random walk: The birds choose their flight direction randomly from a normal-like distribution pointing in their mean migratory direction each evening independent of previous events (Mouritsen, 1998b; Mouritsen and Mouritsen, 2000; Mouritsen et al., 2013). This strategy predicts that the statistical distribution of first-time migrants should be parabolic, and it has been shown that this prediction fits very well with the actual distribution of ringing recoveries of free-flying, first-time migrants in Western Europe (Mouritsen, 1998b; Mouritsen and Mouritsen, 2000).

The orientation task facing adult migrants and young migrants on their first spring migration is fundamentally different from the task faced during their first autumn migration (Kramer, 1957; Rabøl, 1978; Berthold, 1991; Mouritsen, 2003; Holland, in press). Adult migrants and young migrants on their first spring migration are migrating back toward a region with which they have had previous experience; therefore, their orientation system is likely to include local (map) information gained through previous migration experience. Birds that would use sensory information from all useful senses, which would improve their

ability to find their way (e.g., magnetic sense, olfaction, vision, and hearing), should have an evolutionary advantage over birds that would only use a single cue or sense. Thus, it is likely that the orientation strategies of experienced migrants are multisensory and involve learned maps (Mouritsen, 2003, 2013; Holland, in press). Indeed, in contrast to first-time migrants, experienced migrants are able to correct for displacements (Perdeck, 1958; Mewaldt, 1964; Thorup et al., 2007; Chernetsov et al., 2008; Kishkinev et al., 2010, 2013) and thus have added a learned map to their orientation program (see Figure 8.3). Interestingly, this map is also functional at locations that have not been visited previously: Birds can appropriately correct their orientation when they are experimentally displaced to faraway locations where they have certainly never been before (Perdeck, 1958; Mewaldt, 1964; Thorup et al., 2007; Chernetsov et al., 2008; Kishkinev et al., 2010, 2013). If their learned map would have been based exclusively on previously experienced local landmarks, then it should not have worked at unfamiliar locations. Although the functional basis of this map sense is not yet understood (Holland, in press), it is almost certainly based on multiple cues and it must involve the detection of larger scale gradients, which can be extrapolated and thus enable birds to return from unfamiliar locations.

8.6 THE MAGNETIC COMPASS OF BIRDS

Friedrich W. Merkel and Wolfgang Wiltschko discovered that birds have a magnetic compass sense in the mid-1960s (Merkel and Wiltschko, 1965; Wiltschko, 1968). When birds are placed in a round cage at night, they show migratory restlessness (or *Zugunruhe* in German, Kramer, 1949): The birds primarily jump/flutter in their migratory direction, and when the magnetic field is turned horizontally in the absence of celestial cues, the birds turn their orientation with the magnetic field (see Figure 8.4). This is the behavioral evidence required to show that a migratory bird species possesses and is able to use a magnetic compass (Wiltschko and Wiltschko, 1995). A magnetic compass has been found in more or less every migratory bird species properly tested for it (Wiltschko and Wiltschko, 1995); therefore, it is quite safe to presume that all migratory birds and potentially birds in general possess a magnetic compass.

It is important to note that there are at least two different magnetic field properties that could potentially

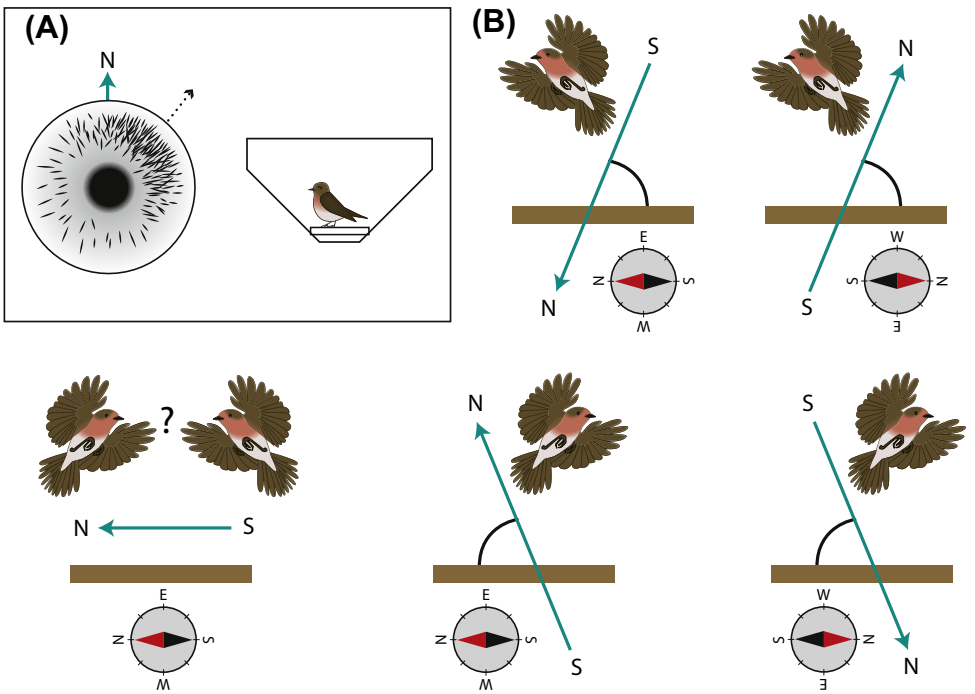

FIGURE 8.4 The Emlen funnel and the inclination compass. (A) The so-called Emlen funnel is the most commonly used orientation cage (Emlen and Emlen, 1966). The mean jumping direction of the birds are recorded on scratch-sensitive paper lining the inclined wall of the funnel (Mouritsen et al., 2009). (B) Early experiments by Wiltschko and Wiltschko (1972) have shown that birds have an inclination compass, which means that the birds measure the angle between the magnetic field lines and the Earth's surface or gravity; thereby, the birds separate between poleward and equatorward, not between North and South like a polarity compass would do (if birds use a polarity compass, then they should have oriented in the direction indicated by the red end of the inserted technical compass). Birds are disoriented in a horizontal magnetic field like the one occurring at the magnetic equator. The flight direction of the inserted bird indicates the springtime mean direction chosen by all bird species tested so far in the given magnetic field (Wiltschko and Wiltschko, 1995). The red arrows indicate the direction if the magnetic field lines. Brown bar = the Earth's surface, N = geographic North, S = geographic South. *Figure and legend is reused from Mouritsen (2013).*

be used as input for a magnetic compass sense. A magnetic polarity compass (e.g., the human ship compass) uses only the horizontal component of the field lines, which points toward Magnetic North anywhere on Earth except at the magnetic poles. On the other hand, a magnetic inclination compass detects only the angle between the geomagnetic field lines and the Earth's surface or gravity—not the polarity of the field lines. The smallest angle between the Earth's surface and the geomagnetic field lines indicates the direction "toward the magnetic equator" whereas the greatest angle indicates "toward the magnetic pole." Because the inclination is opposite on the Northern and Southern Hemisphere, respectively, this holds on both hemispheres. All bird species properly tested so far have a magnetic inclination compass (Wiltschko and Wiltschko, 1972, 1995; see Figure 8.4). Thus, the magnetic compass of night-migratory birds does not separate between North and South like our ship compass, but it distinguishes between "toward the magnetic equator" and "toward the magnetic pole" (the Magnetic North Pole in the Northern Hemisphere and the Magnetic South Pole in the Southern Hemisphere). Furthermore, the birds' magnetic compass sense seems to have a rather narrow functional intensity window, but this window seems to be extendable to new intensities after a few hours of adaptation to a changed magnetic field intensity (Wiltschko, 1978).

8.7 DO BIRDS POSSESS A MAGNETIC MAP?

Many studies have reported that magnetic cues play an important role in birds' sense of position (i.e., that birds have a "magnetic map"). However, the existence of a magnetic map is heavily debated, and the views among researchers range from a magnetic map with a precision of a few kilometers being an established fact (Walcott, 1991; Wiltschko and Wiltschko, 1995; Wiltschko et al., 2010a) to a magnetic map sense being an evergreen phantom (Wallraff, 2001; Gagliardo et al., 2009). One thing is for sure; the natural map sense of birds is multifactorial. It relies on input from olfaction (Papi, 1991; Wallraff, 2001, 2005; Gagliardo et al., 2006, 2008, 2009) and vision (Guilford et al., 2004) and possibly also from magnetic sensing (Dennis et al., 2007; Holland, 2010; Kishkinev et al., 2013) and maybe even from hearing (Hagstrum, 2013 but see Wallraff, 1972; Holland, in press).

Pigeons with opaque lenses that prevented them from detecting any local visual landmarks can return to within c. 5 km of their loft (Schmidt-Koenig and Walcott, 1978). Thus, the precision of nonlandmark-based navigation seems to be a few kilometers, but which cue(s) enable pigeons to home to within c. 5 km of their loft without being able to use visual landmarks? At present, informed neutral observers of the olfaction contra magnetic map controversy agree (Able, 1996; Mouritsen, 2013; both are orientation researchers who have never performed a pigeon release; thus, they have no vested interest in any of the camps) that the evidence suggesting that chemical cues (odors) play an important role in the nonlandmark-based part of pigeons' map sense (Papi, 1991; Wallraff and Andreae, 2000; Wallraff, 2001, 2005; Gagliardo et al., 2006, 2008, 2009) is much more convincing than the evidence supporting an important role of magnetic cues in the pigeons' map (e.g., Walcott, 1991; Wiltschko and Wiltschko, 1995; Dennis et al., 2007; Wiltschko et al., 2010a; Holland, 2010). However, remember that in the end, both camps may be right. The map will be multifactorial because a bird using all available input from all of its senses will have an evolutionary advantage over a bird using only a single cue for a task so essential for the survival of a bird. In any case, it remains very difficult to understand how a magnetic-field-based map sense should be able to function on a scale less than 10 km. Why is that?

The problem for a bird wanting to use a magnetic map is that the average change in magnetic field intensity is only c. 3 nT/km on the North-South axis: The geomagnetic field changes c. 30,000 nT from one of the magnetic poles to the magnetic equator, which are c. 10,000 km apart. Likewise, magnetic inclination changes only c. 0.009°/km along the North-South axis (a 90° change over 10,000 km). On the East-West axis, there is generally very little change in magnetic field intensity and magnetic inclination. Thus, any magnetic-field-based input to a reasonably precise map would require a very accurate magnetic sensory system and a very accurate sense of gravity. However, even if birds have such a system, daily, partly stochastic, natural variations in the geomagnetic field on the order of 30–100 nT in more or less random directions mean that it is very difficult to imagine how a magnetic-field-based map sense could have a precision less than 10–30 km (during magnetic storms generated primarily by the Sun, the geomagnetic field variability can reach 1000 nT; Courtillot and Le Mouël, 1988). Therefore, it is possible that magnetic parameters may only help determine position where the expected differences in the magnetic field parameters are consistently larger than the daily magnetic variations (Mouritsen, 2013).

Other cues such as odors and familiar landmarks may be more significant map parameters at shorter distances. It is much easier to imagine that a magnetic map could be relevant on a much larger spatial scale, and intriguing data exist that suggest that some songbirds can use magnetic cues as an approximate geographic "signpost", which, for example, tells the birds when to increase their fat reserves before crossing the Sahara Desert (Fransson et al., 2001) or when to change their migratory heading (Henshaw et al., 2010). This case, in which specific magnetic parameters trigger a change in behavior, is referred to as a magnetic signpost (Mouritsen, 2013).

8.8 INTERACTIONS WITH OTHER CUES

In most orientation-related contexts, magnetic cues interact with several other sources of similar and/or conflicting information. For instance, night-migratory songbirds not only have a magnetic compass, they also have a Sun compass and a star compass (Emlen, 1975; Schmidt-König et al., 1991; Mouritsen and Larsen, 2001; Cochran et al., 2004; Zapka et al., 2009). They only need information from any one of these compasses to orient in the appropriate direction (Mouritsen, 1998a; Muheim et al., 2006b; Chernetsov et al., 2011; Liu and Chernetsov, 2012). If the three compasses provide conflicting information, then it is not consistent which compass the birds prefer. The preference is probably dependent on the ecological context, the details of the experimental setup, and the conditions under which the birds were housed and tested, and it is likely that various calibrations are taking place in nature (see Figure 8.5,

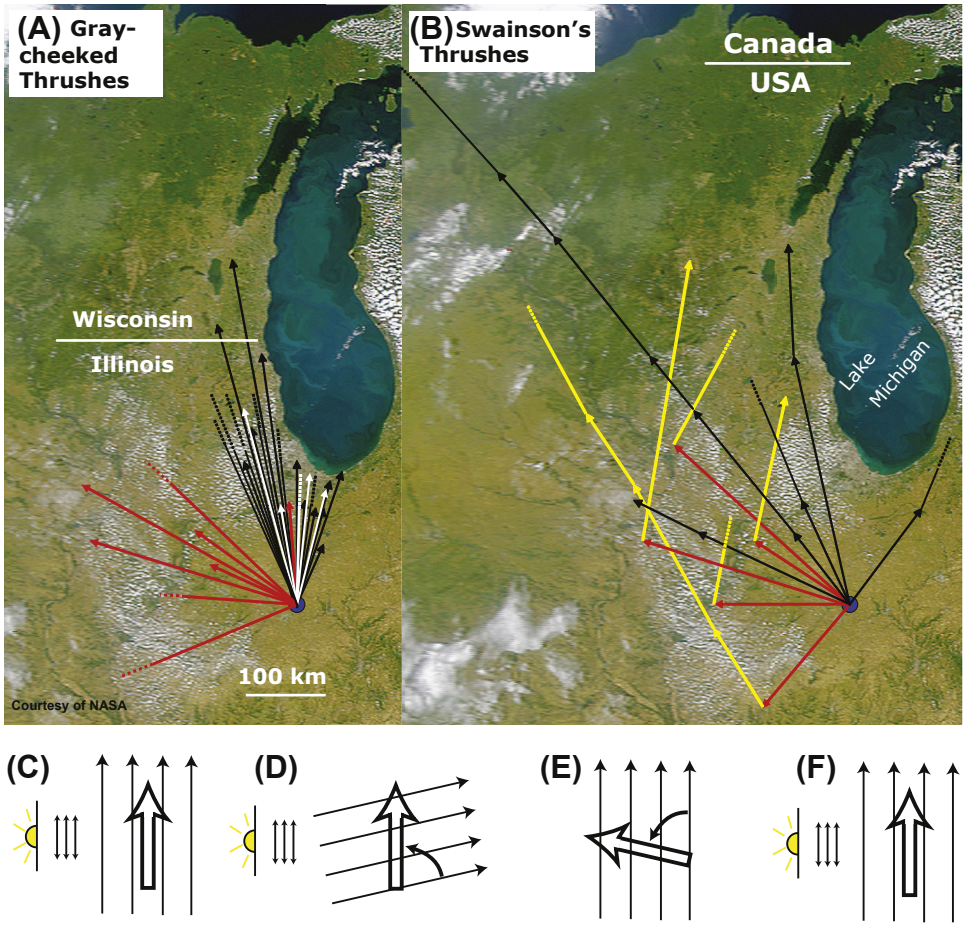

FIGURE 8.5 Some birds calibrate their magnetic compass from celestial cues around sunset. Tracks of free-flying Gray-Cheeked Thrushes (A) and Swainson's Thrushes (B) released from Champaign, Illinois, are shown. The arrows indicate the direction and ground tracks of migratory flights when wind effects were discarded. Black arrows indicate migratory flights of nonmanipulated individuals. Red arrows indicate migratory flights of experimental birds that had experienced a magnetic field turned to 80° East before takeoff, and yellow arrows indicate the migratory flights of the experimental birds during subsequent nights. White arrows indicate the migratory flight paths of experimental birds that did not migrate on the night of magnetic treatment, but they did so 1–6 days later. Connected arrows show flights of the same individual during successive nights. Data are depicted differently in (A) and (B) because for Grey-Cheeked Thrushes, experimental and control birds are different individuals whereas in Swainson's Thrushes, the same experimental individuals were followed for at least two successive nocturnal migrations (because of the large spread in natural headings). Broken lines indicate that birds were lost during tracking at the site where the broken lines start. Notice that the birds that experienced a magnetic field turned 80° to the East during sunset and that were released after all light from the Sun had disappeared migrated toward the West when they embarked on migration on the same night. On later nights, they migrated in the appropriate northerly spring migratory direction. These results mean that the birds had calibrated their magnetic compass from their Sun compass before takeoff and that this calibration happens daily. The reasons are illustrated in (C–F): (C) For control birds all cues gives the same information. (D) If experimental birds calibrate their magnetic compass from sunset-related cues, they will calibrate their magnetic compass so that 80° counter-clockwise to the magnetic field lines will be their "North" for the coming night. (E) After release, the experimental birds experience the natural field lines. Because all light from the Sun has disappeared, no new calibration is possible at time of release and their wrongly sunset-calibrated magnetic compass makes them fly 80° counter-clockwise relative to the natural field lines, which is towards the west for the rest of the first night. (F) On then second night after release, Sun and magnetic cues are in agreement and the birds will reorient into their intended migratory direction. The four thin parallel arrows (C–F) indicate the horizontal direction of the magnetic field lines experienced by the birds. The thick arrow indicates the expected orientation of the birds. The setting Sun and the three lines with double arrowheads indicate whether Sun and polarized light cues were available for calibration. *Figure and parts of the legend from Cochran et al. (2004).*

Cochran et al., 2004; Muheim et al., 2006a; Liu and Chernetsov, 2012). The only experiment with truly free-flying birds performed so far suggested that two species of North-American songbirds used the magnetic compass as their primary compass in midair during spring migration, but that they calibrate this compass on the basis of celestial cues during the sunset period (Cochran et al., 2004); however, this mechanism is not universal (Chernetsov et al., 2011). Other evidence suggests that polarized light cues might be crucial for this calibration (Muheim et al., 2006a); however, so far, it is not understood how a bird's eyes can detect polarized light.

In pigeon homing or any other map-related task, the interactions between different cues seem to be even more complicated. Homing pigeons have been shown to use olfactory cues (Papi, 1991; Wallraff and Andreae, 2000; Wallraff, 2001, 2005; Gagliardo et al., 2006, 2008, 2009), visual landmarks of various kinds (Guilford et al., 2004), outward journey information (reviews in Wiltschko and Wiltschko, 1995; Wallraff, 2005), and maybe magnetic cues (Walcott, 1991; Wiltschko and Wiltschko, 1995; Dennis et al., 2007; Wiltschko et al., 2010a) to estimate their position relative to home when released from a previously unknown location. The relative importance of these map cues is hotly debated, with many apparently contradictory results occurring in the literature. One reason may very well be that in one location, one type of cue may be particularly reliable whereas another cue is more reliable in a different location; therefore, the animals predominantly rely on different cues in different locations. The most convincing experiments performed to date involved cutting of the olfactory nerves or cutting of the ophthalmic branch of the trigeminal nerves in experienced and inexperienced pigeons. The experiments showed that homing pigeons tested around Pisa in Italy need intact olfactory nerves but not intact "magnetic" nerves (see Section 8.9) to home (Gagliardo et al., 2006, 2008, 2009). In procellariiform seabirds such as albatrosses and shearwaters, olfactory cues also seem to be much more important for navigation than magnetic cues (Mouritsen et al., 2003; Nevitt and Bonadonna, 2005; Bonadonna et al., 2005; Gagliardo et al., 2013).

8.9 HOW DO BIRDS SENSE THE EARTH'S MAGNETIC FIELD?

It is challenging to detect the weak geomagnetic field with biological materials. Considering the anatomical constraints and known structures found within small birds, careful models of putative sensory mechanisms often find it hard to explain how a 50,000 nT magnetic field can result in reliable signals in the presence of thermal fluctuations (kT) and other sources of noise. In fact, any biological mechanism that can, in principle, allow detection of 50,000 nT fields is noteworthy (Ritz et al., 2010; Mouritsen, 2013). Only three basic mechanisms are currently considered to be physically viable: (1) induction in highly sensitive electric sensors, (2) iron-mineral-based magnetoreception, and (3) radical-pair based magnetoreception.

8.10 THE INDUCTION HYPOTHESIS

Electromagnetic induction is the production of voltage across an electric conductor situated in a changing magnetic field or a conductor moving through a stationary magnetic field. Thus, in practical terms, if one has an electric wire and one moves this through a magnetic field, then a current will be generated in the wire. If this wire is ring or coil-shaped, directional sensitivity can be achieved. In biological tissues, one would need conductive, liquid-filled, ring-like structures of sufficient size and diameter to generate measurable electrical signals that can be picked up by an electrically sensitive receptor cell. For electromagnetic induction, Lorenzini ampullae are a concrete realization of an electrically sensitive cell operating in saltwater fish (von der Emde, 2013). Their function uses the fact that saltwater is electrically conductive, and aquatic animals could potentially use induction to sense the geomagnetic field (Kalmijn, 1981; Molteno and Kennedy, 2009). However, no strong evidence currently exists that fish actually use their electric sense to deduce information from the geomagnetic field (Kirschvink et al., 2010; Mouritsen, 2013). In land-based animals, it is difficult to imagine how induction could be used to sense the geomagnetic field because air has low conductivity; therefore, the needed structures would have to be realized inside of the animals themselves. In fact, biophysical considerations effectively eliminate induction as a potential source of magnetodetection in terrestrial animals: The required physiological structures filled with conductive liquid would be large and easily detectable, but no such structures have been reported (Kirschvink et al., 2010; Mouritsen, 2013). Thus, for terrestrial animals such as birds, another mechanism must be responsible for magnetoreception.

8.11 THE IRON-MINERAL-BASED HYPOTHESIS

When human beings want to use the direction of the geomagnetic field for orientation, we use a technical compass that is based on a needle made of magnetized iron or a magnetic iron compound that moves in the horizontal plane. Therefore, the first suggestion almost any human thinks of when one asks them how birds may detect the geomagnetic field is "Maybe they have little compass needles in their head." It is not surprising that this suggestion was also the first suggestion scientists came up with. A compass needle-like structure has been realized inside of magnetotactic bacteria (see Figure 8.6(A), Blakemore, 1975; Frankel and Blakemore, 1989). A chain of single-domain magnetite crystals (Blakemore, 1975; Frankel and Blakemore, 1989; Kirschvink et al., 2010) or other very similar iron oxides (Falkenberg

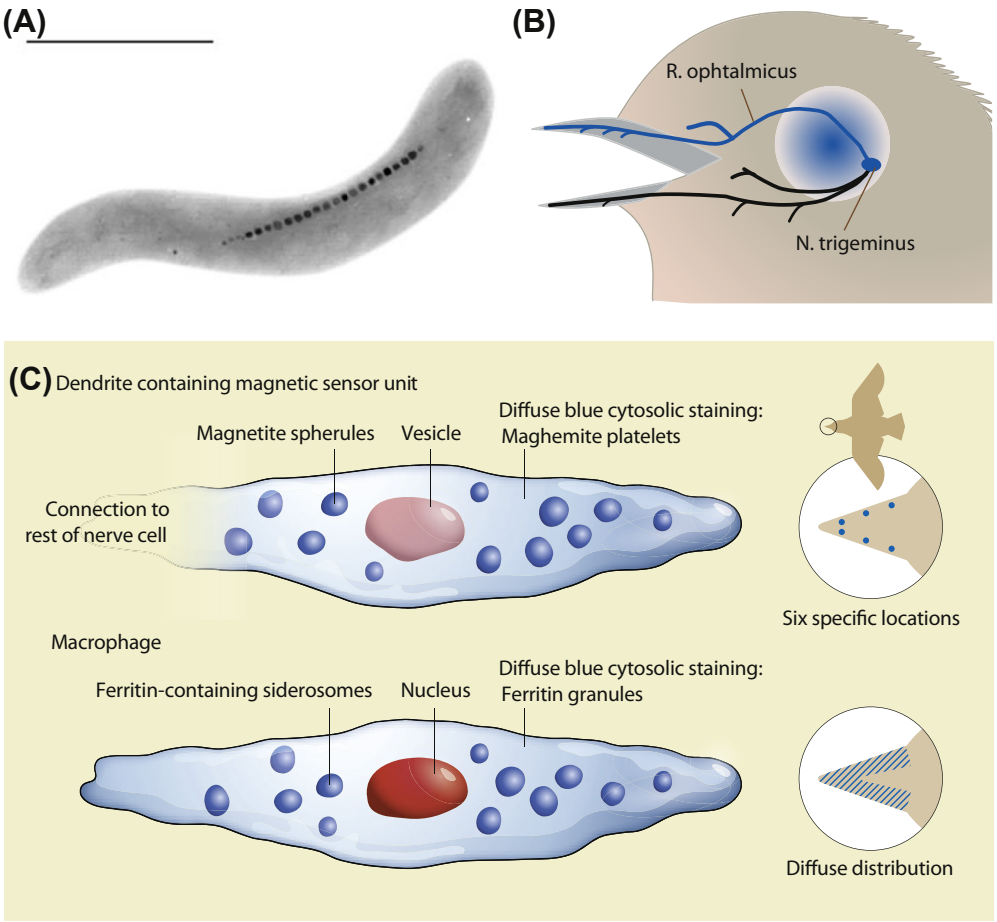

FIGURE 8.6 Iron-mineral structures in birds. (A) Transmission electron micrograph of the magnetotactic bacteria, *Magnetospirillum magnetotacticum*, showing the magnetosome chain inside of the cell. Scale bar: 1 μm *(Photograph © Richard B. Frankel)*. Magnetosomes would be the most straightforward solution for a magnetic field sensor in the nervous system of a bird, but, so far, magnetosomes have not been proven to occur in any bird. (B) Bird head schematically illustrating the anatomical location of the three branches of the trigeminal nerve. (C) Schematic drawing of iron mineral-containing structures in birds' upper beak illustrating the opposing interpretations of Fleissner et al. (2003) and Treiber et al. (2012). *Part (C) reproduced with permission from Mouritsen (2012), (B) and panel composition is reproduced from Mouritsen (2013).*

et al., 2010) would be the easiest realization of a small compass-needle-like structure inside of a bird, but other arrangements of iron-mineral crystals could also work as a magnetic field detector (Solov'yov and Greiner, 2009; Kirschvink et al., 2010). The iron-mineral crystals are expected to transduce the magnetic signal by opening or closing pressure-sensitive ion channels (Johnsen and Lohmann, 2005).

Many studies have documented the presence of magnetite or some other kind of iron mineral crystals in almost any animal, in which researchers have seriously looked for such crystals (e.g., in *Caenorhabditis elegans*, mollusks, insects, crustaceans, and various vertebrates; Mouritsen, 2013). However, the mere existence of iron mineral crystals or even magnetite does not represent significant evidence by itself that such structures have any relevance to magnetoreception (Mouritsen, 2013). Iron is an important element required for proper function of most organisms. Consequently, iron homeostasis is important, and iron mineral deposits may just be a way for an organism to get rid of excess iron. Therefore, only if iron mineral structures are found at consistent, specific locations and are associated with the nervous system do the iron mineral structures qualify as serious magnetosensory candidate structures (Mouritsen, 2013). The existence of magnetite crystal chains, which lead to a magnetically oriented swimming behavior in so-called "magnetotactic bacteria" (Blakemore, 1975; Frankel and Blakemore, 1989; Bazylinski and Frankel, 2004), unequivocally proves that living cells can, in principle, synthesize magnetite that will align with the geomagnetic field. However, the magnetite crystals in these bacteria are not part of an active sensory system; they only lead to passive alignment (Wiltschko and Wiltschko, 1995; Mouritsen, 2013).

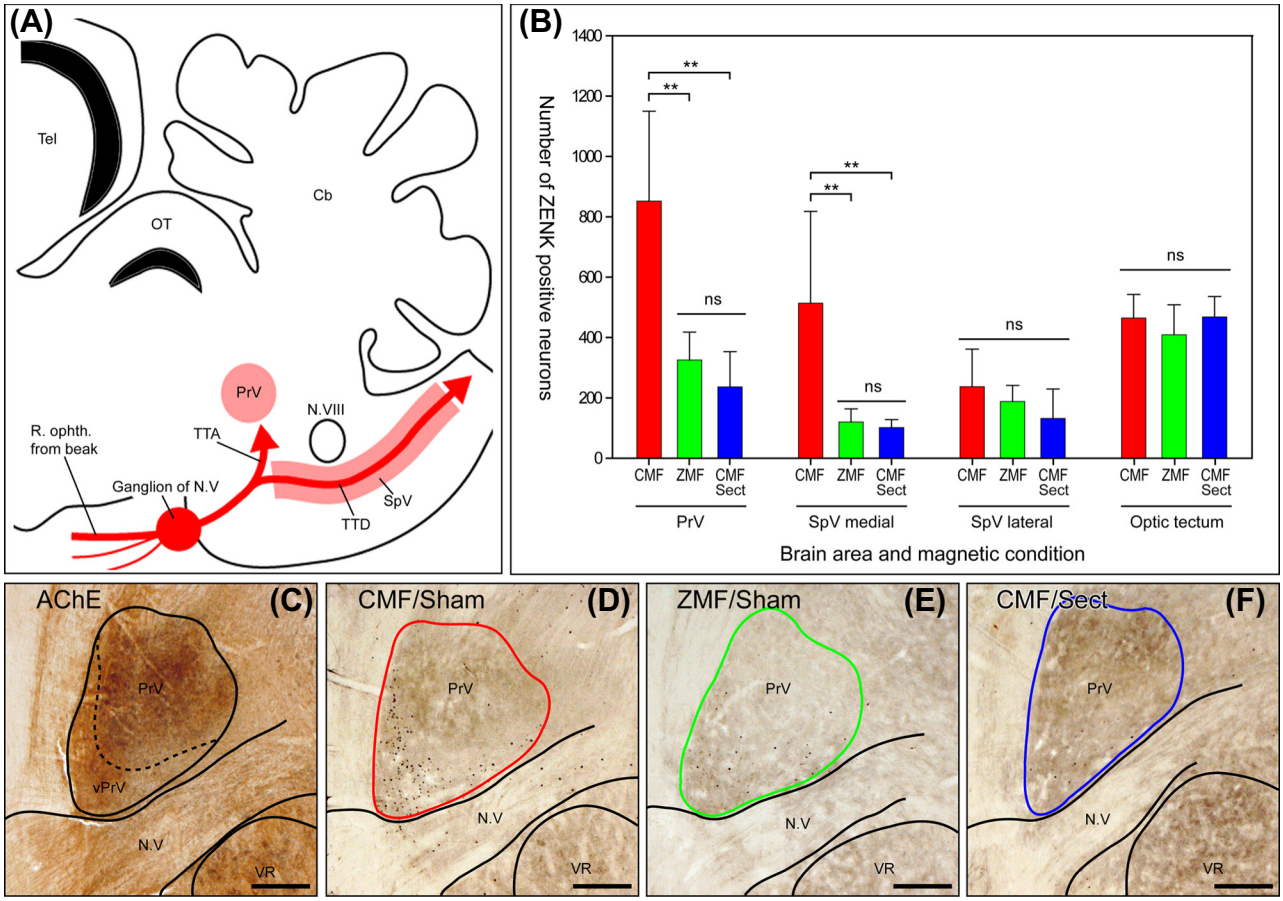

FIGURE 8.7 There are magnetically activated neurons in the two hindbrain regions, PrV and SpV, which receive sensory input from the ophthalmic branch of the trigeminal nerve (V1) in birds. (A) Anatomical overview of the termination of the trigeminal nerve in the avian hindbrain. (B–F) In birds with intact V1 (sham-sectioned nerves; (D)), stimulation with a changing magnetic field (CMF) leads to increased expression of the neuronal activity-dependent gene, *ZENK* (black dots in (D–F) are activated neuronal nuclei), in the hindbrain regions (PrV, shown in (C–F)) and SpV, that receive their primary input from the trigeminal nerve. This activation disappears when the magnetic field stimulus is absent (ZMF = zero magnetic field; (E)). The activation also disappears when the CMF is present but the birds had V1 bilaterally sectioned (CMF Sect; (F)). No magnetic field-dependent activation is seen in control regions such as the optic tectum (B). (C) Acetyl cholinesterase (AChE) is a good anatomical marker for identification of the borders of PrV. *From Heyers et al. (2010).*

The currently most promising, but not proven, active, iron-mineral-based magnetoreceptor candidate structures are those reported from the olfactory epithelium of fish (Walker et al., 1997; Eder et al., 2012). Elaborate iron-mineral-based structures thought to be magnetoreceptors have also been reported in the upper beak of birds (Fleissner et al., 2003; Falkenberg et al., 2010). However, recent findings suggest that these structures are macrophages involved in iron homeostasis (Treiber et al., 2012). Thus, at present, no convincingly documented, iron-mineral-based, magnetoreceptive candidate structures are known from birds (see Figure 8.6(C); Mouritsen, 2012).

Conditioning of birds to magnetic stimuli has also proven to be very difficult, and independent replication is rare. It has been reported that homing pigeons, *Colomba livia*, can be conditioned to respond to strong magnetic fields (Mora et al., 2004; Mora and Bingman, 2013). The conditioned response to a very strong magnetic field (c. 2 times the strength of the geomagnetic field) required intact trigeminal nerves (Mora et al., 2004). Consequently, pigeons seem to, in principle, be able to detect strong magnetic field changes via the ophthalmic branch of the trigeminal nerve. However, to use geomagnetic information for a map, animals must be sensitive to changes in the geomagnetic field, which are 3–5 orders of magnitude smaller than the anomalies used in the successful conditioning experiments. Using a very similar paradigm adapted for European robins and using weaker fields resulted in nicely conditioned responses to auditory stimuli but failed to produce a conditioned response to magnetic field stimuli (Kishkinev et al., 2012).

The ophthalmic branch of the trigeminal nerve (see Figure 8.6(B)) terminates in the principal (PrV) and spinal tract (SpV) nuclei of the trigeminal brainstem complex (Williams and Wild, 2001; Heyers et al., 2010; see Figure 8.7). Recent evidence shows that subpopulations of neurons in PrV and SpV in European robins (*Erithacus rubecula*), a night-migrating songbird, are activated by changing

magnetic field stimuli but not by a zero magnetic field (Heyers et al., 2010). Furthermore, the activation in the changing magnetic field disappears when the ophthalmic branch of the trigeminal nerve is severed (see Figure 8.7(B–F)). These findings suggest that the ophthalmic branches of the trigeminal nerves carry magnetic information in birds (Heyers et al., 2010). However, the sensory origin (most likely iron-mineral-based) and the biological significance of the trigeminally mediated magnetic information are unclear at present (Mouritsen, 2012, see Figure 8.6(C)). Information from the ophthalmic branch of the trigeminal nerve is neither required nor sufficient for magnetic compass orientation in several night-migrating songbird species (Zapka et al., 2009, see Figure 8.8). Homing experiments with pigeons have shown that pigeons tested around Pisa, Italy, need intact olfactory nerves but not intact trigeminal nerves to home (Gagliardo et al., 2006, 2008, 2009).

The most likely function of the trigeminal nerve-related magnetic sense is to detect large-scale changes in magnetic field strength and/or magnetic inclination, which could be used to determine approximate position. A very recent set of experiments has shown that Eurasian Reed Warblers, *Acrocephalus scirpaceus*, are capable of correcting for a 1000 km eastward displacement (Chernetsov et al., 2008), but that this ability disappears when the ophthalmic branch of the trigeminal nerve is cut (Kishkinev et al., 2013, see Figure 8.3). In addition, experiments with night-migratory songbirds exposed to strong magnetic pulses, which are thought to disturb any magnetite-based magnetic sense for days to weeks but should not have any effect after the treatment itself on a light-dependent magnetoreception mechanism, support the idea that the magnetic map or signpost sense is iron mineral-based (Wiltschko et al., 2009; Holland, 2010; Holland and Helm, 2013).

It has also very recently been suggested that the avian lagena (a part of the birds' vestibular system) plays a role in magnetodetection (Wu and Dickman, 2011, 2012). Whether the lagena provides the primary magnetic information or gravity information to the magnetic sense is not yet clear, but if the seemingly very convincing electrophysiological data (Wu and Dickman, 2012) can be independently replicated,

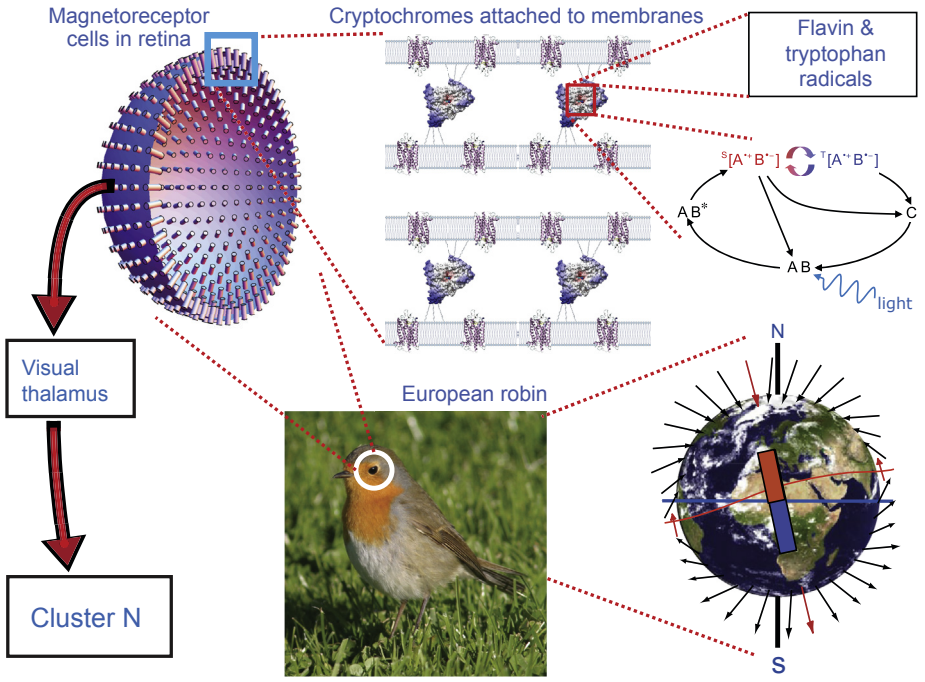

FIGURE 8.8 Summary of the proposed light-dependent magnetic compass sensing hypothesis in birds. Most of the experiments reviewed here were performed on European robins, *Erithacus rubecula (Photo © Henrik Mouritsen)*. The reference direction provided by the Earth's magnetic field is detected in the birds' eyes, where cryptochrome proteins are the most likely light-dependent magnetic sensory molecules. Light absorption is thought to generate long-lived flavin-tryptophan radical pairs within cryptochromes in the retina, the reaction yields of which are determined by the orientation of the molecule with respect to the geomagnetic field vector. If the cryptochromes were associated e.g. with the membrane disks of the outer segments of the photoreceptors, then an ordered structure could result, and different reaction yields in different parts of the retina could be compared to provide a visual impression of the compass bearing (see Figure 8.9). Light-dependent magnetic compass information is transmitted from the retina through the optic nerve to the visual thalamus and from there to Cluster N in the forebrain via the thalamofugal visual pathway (Figure 8.11). If Cluster N is destroyed, European robins can no longer use their magnetic compass (Figure 8.12). The illustration of the cryptochromes bound to photoreceptor membranes is modified from Solov'yov et al. (2010). The reaction scheme is modified from Rodgers and Hore (2009). *Figure and parts of the legend from Mouritsen and Hore (2012).*

then the role of the lagena in magnetoreception is very significant indeed, and the vestibular brainstem nuclei would be a very important processing station for magnetic field information.

8.12 THE LIGHT-DEPENDENT HYPOTHESIS

The magnetic compass behavior of newts (Phillips and Borland, 1992) and birds (Wiltschko et al., 1993; Muheim et al., 2002; Wiltschko et al., 2010b) is dependent on the wavelengths of light being available during behavioral tests. Already in the late 1970s, theoretical considerations led Klaus Schulten to suggest that chemical reactions in photosensitive molecules could form the basis of a magnetic compass sense (Schulten et al., 1978).

The principles of the suggested light-dependent magnetic sensing mechanism are illustrated in Figure 8.8. A light-sensitive molecule (D) absorbs light and uses the light energy to transfer an electron to an acceptor (A); thereby, a radical pair is produced. If this radical pair is long-lived (>1 μs), then it can, depending on the spin of the electrons, exist in one of two states—a singlet state (spins antiparallel) or a triplet state (spins parallel). It is known from chemistry that singlet and triplet states have different chemical properties; thus, they often result in different chemical end products. Earth-strength magnetic fields can theoretically affect this statistical equilibrium and thereby modulate a presently unknown biochemical pathway (Schulten et al., 1978; Ritz et al., 2000, 2010; Rodgers and Hore, 2009; Hore, 2012).

How can we imagine that a bird using a light-induced, radical-pair mechanism would detect the magnetic field? It is possible that a virtual visual image would literally enable birds to "see" the direction of the magnetic field lines (e.g., Ritz et al., 2000, 2010; Solov'yov et al., 2010). If one makes the simple assumption that the sensory molecules are oriented perpendicularly to the eyeball (see Figure 8.9), then the half ball shape of the retina would mean that molecules oriented in all axial directions would occur (Ritz et al., 2000; Mouritsen, 2013). If a bird looks in the direction of the magnetic field lines, then in the line of sight, the retinal molecules would be parallel to the magnetic field and this could lead to a light pixel. At the edge of the eye, the molecules would be perpendicular to the magnetic field, and this could lead to darker pixels. In between, the molecules would be oriented at different angles relative to the magnetic field, and various shades of gray pixels could appear. Altogether, this could lead to a virtual image looking somewhat like the one shown to the right in Figure 8.9 (Ritz et al., 2000; Mouritsen, 2013). This pattern is only for illustrative purposes of the principle. We have much too little information available at present to know what an actual magnetically modulated light pattern seen by a bird would look like (Mouritsen, 2013). The patterns might become easier to see when they move across the retina during so-called head scan behavior (Mouritsen et al., 2004b; Ritz et al., 2010).

If the radical-pair mechanism is responsible for magnetoreception, then it means that it is based on a quantum mechanical effect (Rodgers and Hore, 2009; Ball, 2011; Mouritsen and Hore, 2012; Hore, 2012; Hogben et al., 2012; Solov'yov et al., 2014; Engels et al., 2014). In fact, it might be the only sensory mechanism in biology to be inherently quantum in nature. Critics of the radical-pair mechanism have pointed out that the interaction energy between a geomagnetic field and a radical is typically several orders of magnitude below the background thermal energy, k_BT (Kirschvink et al., 2010). At first glance this might seem like a problem, but because

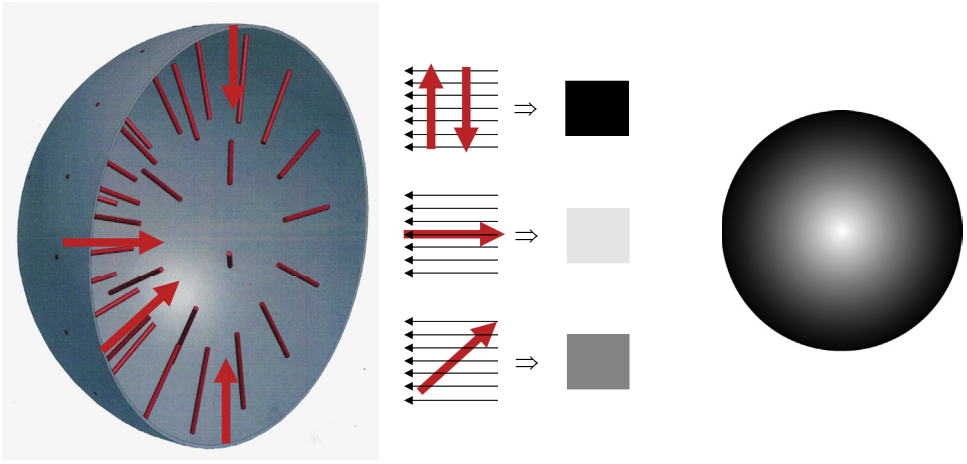

FIGURE 8.9 How the light-dependent, radical pair-based, magnetic sensing mechanism could lead to perception of a visual image. Principal illustration suggesting how birds could, in principle, convert a magnetic stimulus into a putative visual image. Left: 3D illustration of the half-sphere of an eyeball. Red pins simulate cryptochrome orientation all pointing toward the center of the eyeball. If a bird would be looking in the direction of the magnetic field lines, one could imagine that the bird would see a pattern similar to the one illustrated on the right because the light sensitivity of one or more cryptochromes would depend on their orientation relative to the axis of the magnetic field lines. *Redrawn after Mouritsen (2013) inspired by Ritz et al. (2000).*

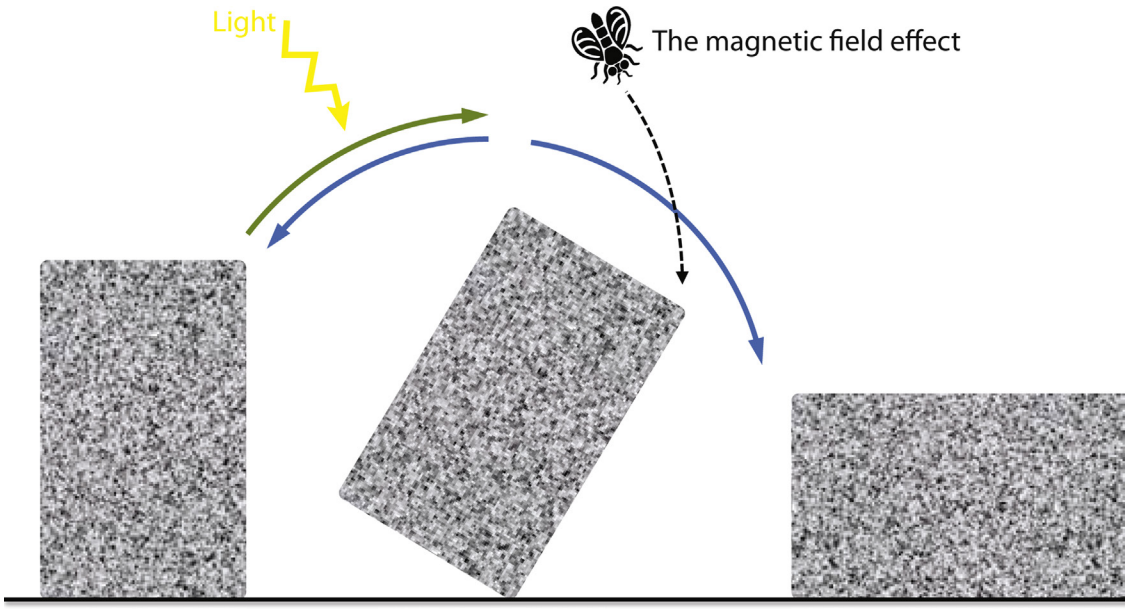

FIGURE 8.10 Granite block analogy of light-dependent magnetoreception. A granite block analogy can help understand how a radical pair-based mechanism can theoretically be used to sense Earth-strength magnetic fields, although the energy exerted by the magnetic field on the radical is much lower than thermal energy, k_BT. Imagine a granite block standing on one of its sides. If a fly lands on the granite block while it is in this position, then there is no way the fly can make the granite block flip over. In fact, quite a lot of energy is needed to move the granite block onto one of its corners, but once it is on one of its corners, a very small amount of energy can influence which way the granite block falls. Now, even a fly landing on the granite block may make it flip over to one or the other side. In the light-dependent, radical pair-based magnetoreception hypothesis, light has much more energy than the magnetic field. It is the absorption of light that brings a photoreceptor molecule (probably a cryptochrome) into an exited state (moves the granite block onto its corner in the analogy), which is then highly sensitive to even very small magnetic field effects (the fly landing onto the granite block in the analogy). *After Hore (2011).*

the spins are not in equilibrium, this is not a fundamental problem. Very weak magnetic interactions can essentially affect radical pair reactions for three reasons (Hore, 2011): (1) radical pair chemistry is controlled by the electron spins in the radicals, (2) the electron spins are not at thermal equilibrium, and (3) the electron spins behave quantum mechanically. Weak magnetic fields affect the coherent behavior of the electron spins in a fundamentally quantum manner in which k_BT plays no role. Instead of comparing interaction energies to k_BT, one must compare the time required for a magnetic interaction to have an effect with the time required for the system to reach thermal equilibrium (Hore, 2011). If the former is shorter than the latter, then the magnetic field can have an effect (Hore, 2011). As an excellent analogy (Hore, 2011), one can imagine a fly and a rectangular granite block. If the granite block is standing on one of its sides (conventional physics, equilibrium), then the fly has no chance to flip the granite block, but if the granite block is balancing on one of its corners (quantum mechanics, nonequilibrium), then, depending on where the fly lands, it might flip the granite block to one or the other side (Figure 8.10).

Which molecule can be responsible for light-dependent magnetoreception? Opsins cannot function as radical-pair-based magnetoreceptors because opsins use the light energy to change a chemical bond, not to transfer an electron. The only currently known photoreceptor molecules found in vertebrates that can use light energy to form long-lived radical pairs are the cryptochromes (Ahmad and Cashmore, 1993; Cashmore et al., 1999; Ritz et al., 2000, 2010; Giovani et al., 2003; Liedvogel et al., 2007a; Biskup et al., 2009; Rodgers and Hore, 2009; Liedvogel and Mouritsen, 2010). Some cryptochromes are known to be involved in circadian clocks (Cashmore et al., 1999; Sancar, 2003). However, in birds, more cryptochromes than the ones thought to be involved in the clock occur; therefore, it is easy to imagine that they can play a role in other biochemical processes (Liedvogel and Mouritsen, 2010). Cryptochromes are related to the DNA repair enzymes called photolyases (Cashmore et al., 1999; Sancar, 2003) and consist of a photolyase homology region and a C-terminal end, which varies greatly between different cryptochromes (Cashmore et al., 1999; Sancar, 2003; Müller and Carell, 2009; Liedvogel and Mouritsen, 2010). The C-terminal is thought to be involved in binding cryptochromes to currently unknown interaction partners (Sancar, 2003; Liedvogel and Mouritsen, 2010; Mouritsen and Hore, 2012). Cryptochromes noncovalently bind the cofactor flavin. The light-induced electron transfer is thought to take place between the flavin and three tryptophane residues within the cryptochrome protein (Gindt et al., 1999; Biskup et al., 2009; Rodgers and Hore, 2009; Solov'yov et al., 2012).

Cryptochromes are predominantly found within photoreceptor cells and ganglion cells in the eyes of birds (Mouritsen et al., 2004a; Möller et al., 2004; Niessner et al., 2011), and cryptochromes are currently the only seriously considered candidate molecules for radical-pair-based magnetoreception in birds (Mouritsen and Ritz, 2005; Rodgers and Hore, 2009; Ritz et al., 2010; Mouritsen and Hore, 2012).

After the suggestion of Klaus Schulten (Schulten et al., 1978), it was shown that the compass orientation behavior of night-migrating songbirds is influenced by the color (i.e., wavelengths) of the light available in the room where the orientation tests are performed (Wiltschko et al., 1993, 2010b). This wavelength dependence is difficult to explain if the eyes and/or pineal organ are not somehow involved in the magnetic compass. In birds, the pineal organ is not needed for magnetic compass orientation (Schneider et al., 1994), but photoreceptor molecules in the pineal organ seem to be essential for magnetic compass orientation in newts (Phillips et al., 2001).

It has been reported that oscillating magnetic fields at specific resonance frequencies in the low-megahertz range disrupt the magnetic compass orientation capabilities of night-migratory songbirds (Ritz et al., 2004, 2009). A recent double-blinded set of experiments has indicated that the disruptive effects of low-megahertz range electromagnetic fields are real, but that they are not limited to specific resonance frequencies (Engels et al., 2014). Furthermore, Engels et al. (2014) could show that anthropogenic electromagnetic noise, omnipresent in most urban environments where birds and humans live, disrupts magnetic compass orientation in migratory European Robins. The intensities of the disruptive fields are ca. 1000 times lower than the current WHO guideline limits for human exposure (Engels et al., 2014). Such effects are still difficult to understand from a theoretical perspective, but they are likely to be diagnostic for the involvement of a fundamentally quantum mechanical mechanism in the birds' magnetic compass sense (Ritz et al., 2009; Mouritsen & Hore, 2012; Engels et al., 2014).

On the molecular level, it has been shown that putatively magnetosensitive cryptochrome molecules exist in the retina of many vertebrates including migratory birds (Mouritsen et al., 2004a; Möller et al., 2004; Liedvogel and Mouritsen, 2010; Niessner et al., 2011). Furthermore, cryptochromes from migratory Garden Warblers (*Sylvia borin*) have been shown to form long-lived radical pairs upon light excitation (Liedvogel et al., 2007a), and effects of Earth-strength magnetic fields on a radical pair reaction in an artificially produced molecule mimicking the reaction principle thought to take place in cryptochromes have supported the theoretical feasibility of the suggested mechanism (Maeda et al., 2008; reviewed in Mouritsen and Hore, 2012).

On the neuroanatomical level, a region named Cluster N (Figure 8.11) is by far the most active forebrain region when night-migrating birds perform magnetic compass orientation, and this activation disappears when the birds' eyes are covered (Mouritsen et al., 2005; Feenders et al., 2008; Zapka et al., 2010). Cluster N consists of parts of the hyperpallium and the dorsal mesopallium (Jarvis et al., 2013) and is the lateral-most part of the visual Wulst in European robins because Cluster N receives its neuronal input from the eyes via the thalamofugal visual pathway (Heyers et al., 2007). The presence and activation of Cluster N at night has been independently replicated in another night-migratory songbird, the Black-Headed Bunting (*Emberiza melanocephala*) (Rastogi et al., 2011). Could Cluster N be a processing center of light-dependent magnetic compass information?

Double-blind experiments with European robins have shown that birds with bilateral Cluster N lesions were unable to orient using their magnetic compass (Zapka et al., 2009, see Figure 8.12). In contrast, sham Cluster N lesions or bilateral sections of the ophthalmic branch of the trigeminal nerves did not influence the robins' ability to use their magnetic compass for orientation (Zapka et al., 2009, see Figure 8.12). Cluster N lesions only affect the magnetic compass because Cluster N lesioned robins orient well using their Sun and star compasses (Zapka et al., 2009, see Figure 8.12). These data (1) show that Cluster N is required for magnetic compass orientation in this species, (2) indicate that Cluster N may be specifically involved in processing magnetic compass information, (3) strongly suggest that a vision-mediated mechanism underlies the magnetic compass in this migratory songbird, (4) indicate that input from the lagena is not sufficient for magnetic compass orientation in robins, and (5) show that the proposed magnetic input to the brain transmitted via the trigeminal nerve is neither necessary nor sufficient for magnetic compass orientation of European robins tested in an orientation cage (Zapka et al., 2009; Mouritsen, 2013). The exact role of Cluster N within the magnetic compass information processing circuit has not been determined, but the existing results raise the distinct possibility that this small part of the visual system enables birds to "see" magnetic compass information (Mouritsen, 2013).

Do these results exclude the possibility that iron-mineral-based and/or trigeminally mediated and/or lagena-mediated magnetoreception exists? Absolutely not! In birds, iron-mineral-based magnetoreception may very well exist, and magnetic field-dependent neuronal activation in trigemino-recipient and lagena-recipient regions has been documented (see previous section). Trigeminally and lagena-mediated magnetoreception just does not seem to be the primary mechanism for the magnetic compass of night-migratory songbirds (Zapka et al., 2009), but it could be a primary source for magnetic positional information (Mora et al., 2004; Kishkinev et al., 2013). In fact, it is likely that light-mediated, radical pair-based magnetoreception and iron-mineral-based magnetoreception

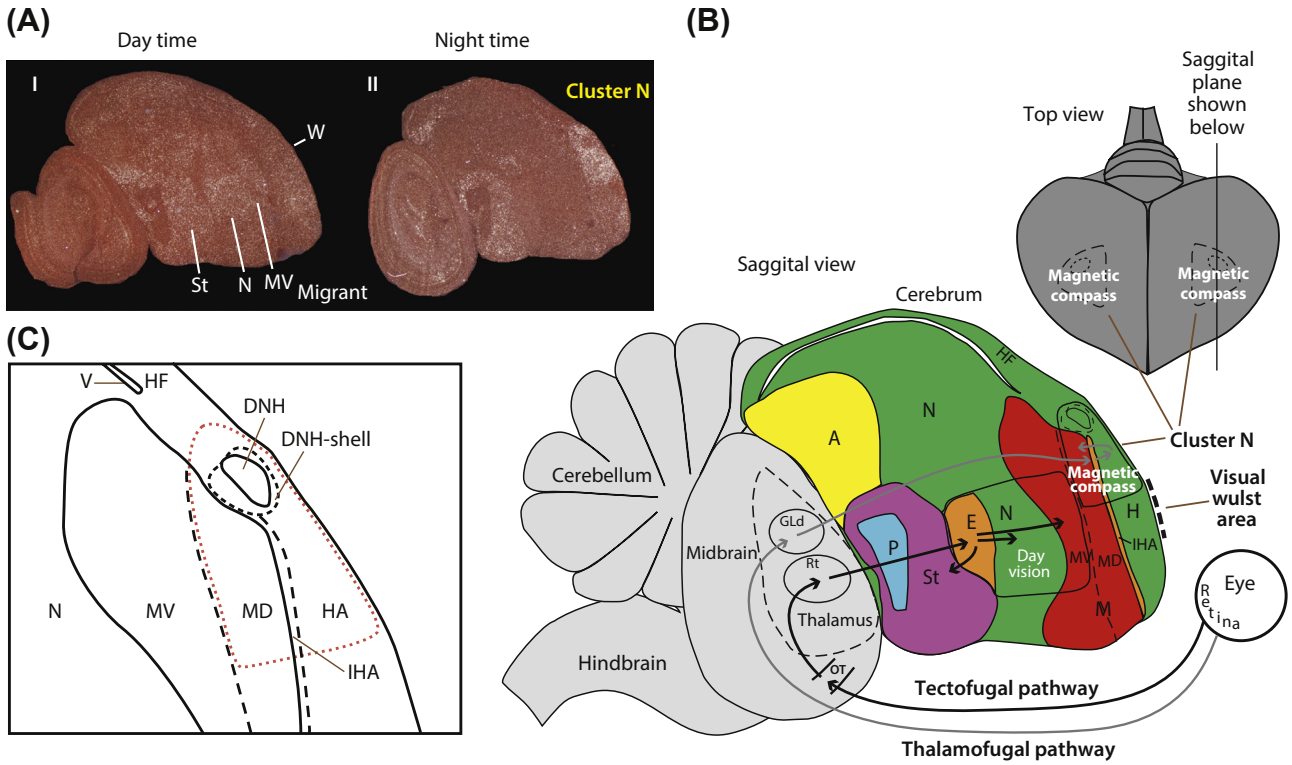

FIGURE 8.11 **Cluster N.** (A) Cluster N is the most active brain area when migratory birds perform magnetic sensing and/or compass orientation at night, and Cluster N is required for magnetic compass orientation (see Figure 8.12). (B) Cluster N is a part of the visual Wulst and receives input from the eyes via the thalamofugal visual pathway (Heyers et al., 2007). Top view of the brain in gray indicates the medial-lateral and the frontal-caudal extent of Cluster N and the DNH and DNH-shell. (C) Cluster N is a functional unit consisting of a part of the hyperpallium, a part of the dorsal mesopallium (Jarvis et al., 2013), and a nucleus embedded within the hyperpallium and named DNH with a shell of cells around the DNH. Anatomy: A = arcopallium, P = pallidum, E = entopallium, St = striatum, N = nidopallium, M = mesopallium, MD = mesopallium dorsale, MV = mesopallium ventrale, H = hyperpallium, v = ventricle, OT = optic tectum, HF = hippocampal formation, IHA = HI = interstitial region of the hyperpallium intercalatum, DNH = dorsal nucleus of the hyperpallium, DNH-shell = shell around the DNH, W = visual Wulst, LGd = Lateral geniculate nucleus, dorsal part, Rt = nucleus rotundus. Scale bar = 0.5 mm. *From Mouritsen (2013) after Mouritsen et al. (2005).*

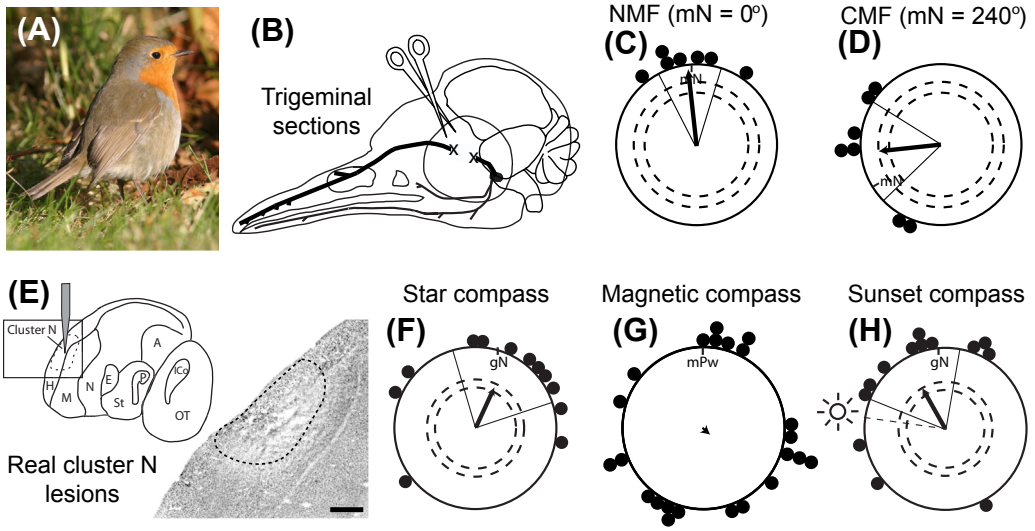

FIGURE 8.12 **The brain region Cluster N is necessary for magnetic compass orientation behavior, but not for star and Sun compass orientation. The trigeminal nerve is neither necessary nor sufficient for magnetic compass orientation in European robins.** (A) The European robin *(Photo © Henrik Mouritsen).* (B–D) Bilateral sectioning of the ophthalmic branch of the trigeminal nerve (B) does not affect the birds' magnetic compass orientation capabilities (C, D; mN = magnetic North). (E–H) Bilateral chemical lesions of Cluster N (E) destroyed the magnetic compass capabilities of the birds (G), whereas star compass orientation in a planetarium (F) and Sun compass orientation outdoors with view of the setting Sun (H) was unaffected by Cluster N lesions. The circular diagrams are explained in the legend of Figure 8.3. (E) A schematic drawing and an example part of a brain section saggitally cut through the center of Cluster N and stained with a neuronal marker. Scale bar = 500 µm. Rostral is left, caudal is right. Note that the tissue where Cluster N should have been in the lesioned bird (E) is destroyed. Anatomy: A = arcopallium, E = entopallium, H = hyperpallium, ICo = intercollicular complex, M = mesopallium, MD = mesopallium dorsale, MV = mesopallium ventrale, N = nidopallium, OT = optic tectum, P = pallidum. *From Mouritsen (2013) after Zapka et al. (2009).*

mechanisms exist side by side in several animal species and that they may provide the animals with different types of magnetic information (Wiltschko and Wiltschko, 2007; Mouritsen and Hore, 2012).

As so often in biology, when there are two hypotheses how something works, it often turns out that both of them are correct to a certain degree. Furthermore, seemingly unnecessary redundancy seems to be a very common occurrence in biology, probably because organisms that can perform a function in several ways will be more robust to changes and thus be favored by evolution (Mouritsen, 2013).

8.13 IRREPRODUCIBLE RESULTS AND THE URGENT NEED FOR INDEPENDENT REPLICATION

Magnetic sense research is strongly influenced by several claims that nobody has ever been able to independently replicate. This is particularly true for electrophysiological evidence (Semm and Demaine, 1986; Beason and Semm, 1987), but there are also many other examples of contradicting or irreproducible results in the literature, including all claims that humans have a magnetic sense (Westby and Partridge, 1986; Baker, 1989) and the claim that the magnetic compass of birds should only be located in their right eye (Wiltschko et al., 2002, 2003; Liedvogel et al., 2007b; Stapput et al., 2010; Hein et al., 2010, 2011; Engels et al., 2012). These problems with reproducibility do not necessarily mean that the original claims were wrong. However, it means that any result in magnetoreception—and in any other field for that matter—should be treated with caution until a given finding has been independently replicated.

This lack of reproducibility in magnetic sense-related research is unfortunately accompanied by an almost complete lack of double-blind procedures. Considering its history and the fact that humans have no intuitive feel for magnetic stimuli (and therefore are less likely to detect even obvious artifacts), double-blind procedures should become the standard, and studies representing the first independent, double-blind replication of key findings in magnetoreception are as important as the original finding (Mouritsen, 2013).

8.14 WHERE DO WE GO FROM HERE?

Although the magnetic senses are still not completely understood, many studies from different fields support the iron-mineral-based and the light-dependent magnetoreception hypotheses. However, fundamental questions remain in all relevant fields.

For example, functional understanding of any particular iron-mineral-based structure proven to be involved in an active sensory system is lacking (Mouritsen, 2012; Mouritsen and Hore, 2012). Likewise, we yet have to understand biophysically how nature designed radical-pair receptors so that they can be sensitive to Earth-strength magnetic fields at physiological temperatures, a feat that has been approximated, but not yet fully accomplished, in man-made radical-pair reactions (Maeda et al., 2008; Rodgers and Hore, 2009). Furthermore, studies at the protein level suggest that bird cryptochromes have properties optimal for magnetic sensing, such as formation of long-lived radical pairs (Liedvogel et al., 2007a). However, we yet have to demonstrate Earth-strength magnetic field effects on bird cryptochromes at the protein level and *in vivo*.

On the neuroanatomical level, we have just begun to explore the brain circuits processing magnetic information, but we are still far from understanding how a bird gets from the detection of magnetic information to a directional choice, which is made based on integration of information from multiple sensory systems. In addition, so far, none of the reported responses of single neurons to magnetic stimuli have been independently replicated. Even at the behavioral level, where most studies about magnetic senses have been published, a clear separation of experimental parameters has proven difficult, and many behaviors appear to be multimodal, or at least modulated by other modalities, such as vision and olfaction (Mouritsen, 2013).

In conclusion, magnetoreception is an important part of life for birds and a wide variety of other animals, and there are still many opportunities to perform new, groundbreaking research on the molecules, cells, and neural processes underlying any kind of magnetoreception.

Chapter 9

The Avian Subpallium and Autonomic Nervous System

Wayne J. Kuenzel
Poultry Science Center, University of Arkansas, Fayetteville, AR, USA

9.1 INTRODUCTION

Since the last edition of *Sturkie's Avian Physiology*, significant progress has been made in avian physiology due to the publication of the chicken genome (Hillier et al., 2004) and genomes of other avian species, including the zebra finch (Warren et al., 2010), turkey (Aslam et al., 2012), Japanese quail (Kawahara-Miki et al., 2013), and scarlet macaw (Seabury et al., 2013). In addition to progress in molecular biology, important events and advances have occurred in avian neurobiology, specifically neuroanatomy. In the late 1990s, Dr Tony Reiner formed a small group of avian neuroanatomists called The Thinktank to address a serious problem with the current nomenclature of the avian brain, particularly the forebrain. The persistent, inappropriate terminology of many structures was based upon an outdated and erroneous assumption of homology to mammalian brain structures. In the fall of 2000, Dr Erich Jarvis initiated a proposal for federal funding to organize an avian brain nomenclature forum, in which avian and comparative neuroanatomists would meet to develop a new terminology for the avian forebrain that was more in line with that developed for the mammalian brain. The result was a 2-year in-depth discussion via email of all specific terms that needed to be changed, based upon an evaluation of the current data. In addition, a voting procedure was developed and agreed upon where each structure would be discussed.

In July 2002, a 3-day meeting supported by the National Institutes of Health and the National Science Foundation was held at Duke University in Durham, North Carolina. Twenty-nine comparative neuroanatomists participated. Individual structures in the forebrain were discussed and new names were adopted. Importantly, the revised nomenclature, for the first time, contained the appropriate terms to eliminate the perception that the avian telencephalon was composed mostly of basal ganglia (as once thought). A number of structures residing in the outer region or cortical areas of the telencephalon now contain the suffix *pallium*. This change immediately showed that an extensive pallium exists in the cortical area of the telencephalon surrounding the basal ganglia of birds. The term *pallium* is used because, in birds and other nonmammalian vertebrates, a laminated structure resembling that of a mammalian neocortex is not evident. Hence, the term *cortex* is inappropriate because, by definition, a cortex comprises six layers of cells. The new terms, their rationale, and images showing the revised terms of all pallial, striatal, and pallidal structures can be found in Reiner et al. (2004) and Jarvis et al. (2005).

Since that nomenclature meeting, new data and advancements have occurred, particularly for another critical neuroanatomical region deep within the forebrain called the *subpallium*. Structural and functional subdivisions of that region were detailed and summarized (Kuenzel et al., 2011). The subpallium comprises the basal ganglia and other anatomical components critical to the survival of a particular species. Specifically, it includes structures that help regulate motor movements and ingestive, reproductive, and defensive behaviors. Indeed, the functions listed are quite similar to the neural functions associated with the autonomic nervous system (ANS). Importantly, some structures residing in the subpallium project directly to central structures that serve as premotor nuclei of the ANS. Therefore, the overall purpose of this review is to provide a summary of the structures and functions of the subpallium and indicate where that basal forebrain region connects with components of the ANS. The last section of the chapter includes specific examples and hypotheses about how the subpallial nervous system, ANS, and neuroendocrine systems are interconnected and integrated to regulate the reproductive system, ingestive/feeding behavior, and selected circannual rhythmic behaviors. By focusing on central neural structures, it is hoped that readers will be directed to brain regions that regulate functions or behaviors of interest and will recognize areas where research is greatly needed due to large gaps in our knowledge.

Sturkie's Avian Physiology.

9.2 COMPONENTS OF THE SUBPALLIUM

The subpallium comprises five major groups: (1) dorsal somatomotor basal ganglia; (2) ventral viscerolimbic basal ganglia; (3) extended amygdala; (4) basal telencephalic cholinergic and noncholinergic corticopetal systems; and (5) septum and septal neuroendocrine systems (Figure 9.1). The five groups occupy the mediobasal region of the telencephalon and are surrounded dorsally and ventrolaterally by the pallium.

Significant advances have been made in understanding the embryonic development of the subpallial region of the chick brain from known proliferative zones based upon gene expression and fate mapping data. Details about the histogenetic zones can be obtained in the following references: Puelles et al. (2000, 2007), Cobos et al. (2001a,b), Marín and Rubenstein (2001), Redies et al. (2001), Flames et al. (2007), Abellán and Medina (2008, 2009), García-López et al. (2008), Abellán et al. (2010), and Kuenzel et al. (2011). Each of the five subpallial groups in posthatching and adult birds is discussed in the following sections.

9.2.1 Dorsal Somatomotor Basal Ganglia

9.2.1.1 Structures

The dorsal somatomotor and ventral viscerolimbic components of the basal ganglia comprise the basal ganglia (BG). Discovery of the abundance of dopamine and acetylcholinesterase in the avian subpallium in the 1960s (Spooner and Winters, 1966; Juorio and Vogt, 1967; Karten, 1969; Nauta and Karten, 1970) began a period that reshaped an understanding of the actual location and extent of the avian BG that occupied only the ventromedial portion of the forebrain (Figure 9.2) and not its extent throughout the entire forebrain as previously thought. A structure that clearly marks the boundary between the BG and pallium is the pallial-subpallial lamina (LPS; Figure 9.2(C)). Importantly, the use of immunohistochemistry and an antibody to tyrosine hydroxylase (an indicator of dopamine) and choline acetyltransferase (synthesizes acetylcholine) clearly showed how similar the avian basal ganglia was to that of mammals regarding its location and relative size compared with the rest of the telencephalon.

Key structures of the dorsal somatomotor basal ganglia include the dorsal and ventral parts of the medial striatum (MSt), lateral striatum (LSt), nucleus intrapeduncularis, and globus pallidus (Figure 9.2). The MSt and LSt are generally considered homologous to the mammalian caudate putamen (Reiner et al., 2004). For details of comparisons among birds, mammals, reptiles, and other vertebrate classes, see Reiner et al. (1998).

9.2.1.2 Functions

Overall, both structurally and functionally there are marked similarities between mammals and birds in the dorsal somatomotor basal ganglia. Specifically, models of the functional organization of the somatic basal ganglia, first developed in mammals, comprised two parallel output circuits that had opposing functions in motor control as well as interactions between them (Albin et al., 1989; DeLong, 1990; Gerfen, 1992). Birds have been shown to have similar direct and indirect pathways (Reiner et al., 1998). A modified representation of the direct and indirect motor pathways involving the avian dorsal somatomotor basal ganglia is shown in Figure 9.3. The direct pathway (Figure 9.3(A)) promotes movement of birds (head, wings, legs). Input into the avian striatum (homologous to mammalian caudate putamen) occurs via the corticostriatal projections (from pallium), shown as glutamatergic excitatory input to the lateral and medial striatum (Veenman and Reiner, 1996; Csillag et al., 1997; Reiner et al., 2001; Ding et al., 2003; Ding and Perkel, 2004; Farries et al., 2005). Modulatory dopaminergic input to the striatum likewise occurs from the substantia nigra, pars compacta (SNc) [A9 catecholaminergic (CA) cell group], ventral tegmental area (VTA; A10 CA group), and retrorubral field (A8 CA group) (Brauth et al., 1978; Kitt and Brauth, 1986b; Bailhache and Balthazart, 1993; Moons et al., 1994; Reiner et al., 1994; Wynne and Güntürkün, 1995) (Figure 9.4). Both the lateral and medial striatum receive excitatory inputs from the pallium. The striatum, in turn, projects inhibitory neurons containing both GABA and substance P (SP) to the medial (interna) region of globus pallidus (Figure 9.3(A)), indicated by GPi, (Anderson and Reiner, 1990, 1991; Reiner, 1986; Reiner and Anderson, 1990; Veenman and Reiner, 1994). The medial area of the globus pallidus projects inhibitory GABAergic neurons to a small thalamic region called the ventrointermediate thalamic area (VIA; Karten and Dubbeldam, 1973; Kitt and Brauth, 1982; Medina et al., 1997). The VIA contains glutamatergic neurons that are excitatory and project to the Wulst in the dorsal region of the pallium, which appears comparable to the mammalian primary somatosensory/somatomotor cortex (Wild, 1987; Korzeniewska and Güntürkün, 1990; Medina and Reiner, 2000).

In addition to the previously described direct pathway facilitating body movement, there is an antagonistic pathway that inhibits bird movements (Figure 9.3(B)). This parallel pathway, distinct from the direct pathway, is called the indirect pathway. It occurs from the striatum, comprises neurons co-localized with GABA and enkephalin (ENK) and functions to inhibit unwanted body movements. Nonetheless it has the same excitatory inputs shown previously for the direct motor pathway (Figure 9.3(B)). Those striatal projection neurons are inhibitory and innervate the lateral (externa) portion of the globus pallidus (GPe, Figure 9.3(B); Brauth, 1984; Reiner et al., 1984a,b; Reiner, 1987; Anderson and Reiner, 1990; Veenman and Reiner, 1994; Veenman et al., 1994). Inhibitory GABAergic neurons project to the avian subthalamic nucleus (STN) which contains excitatory

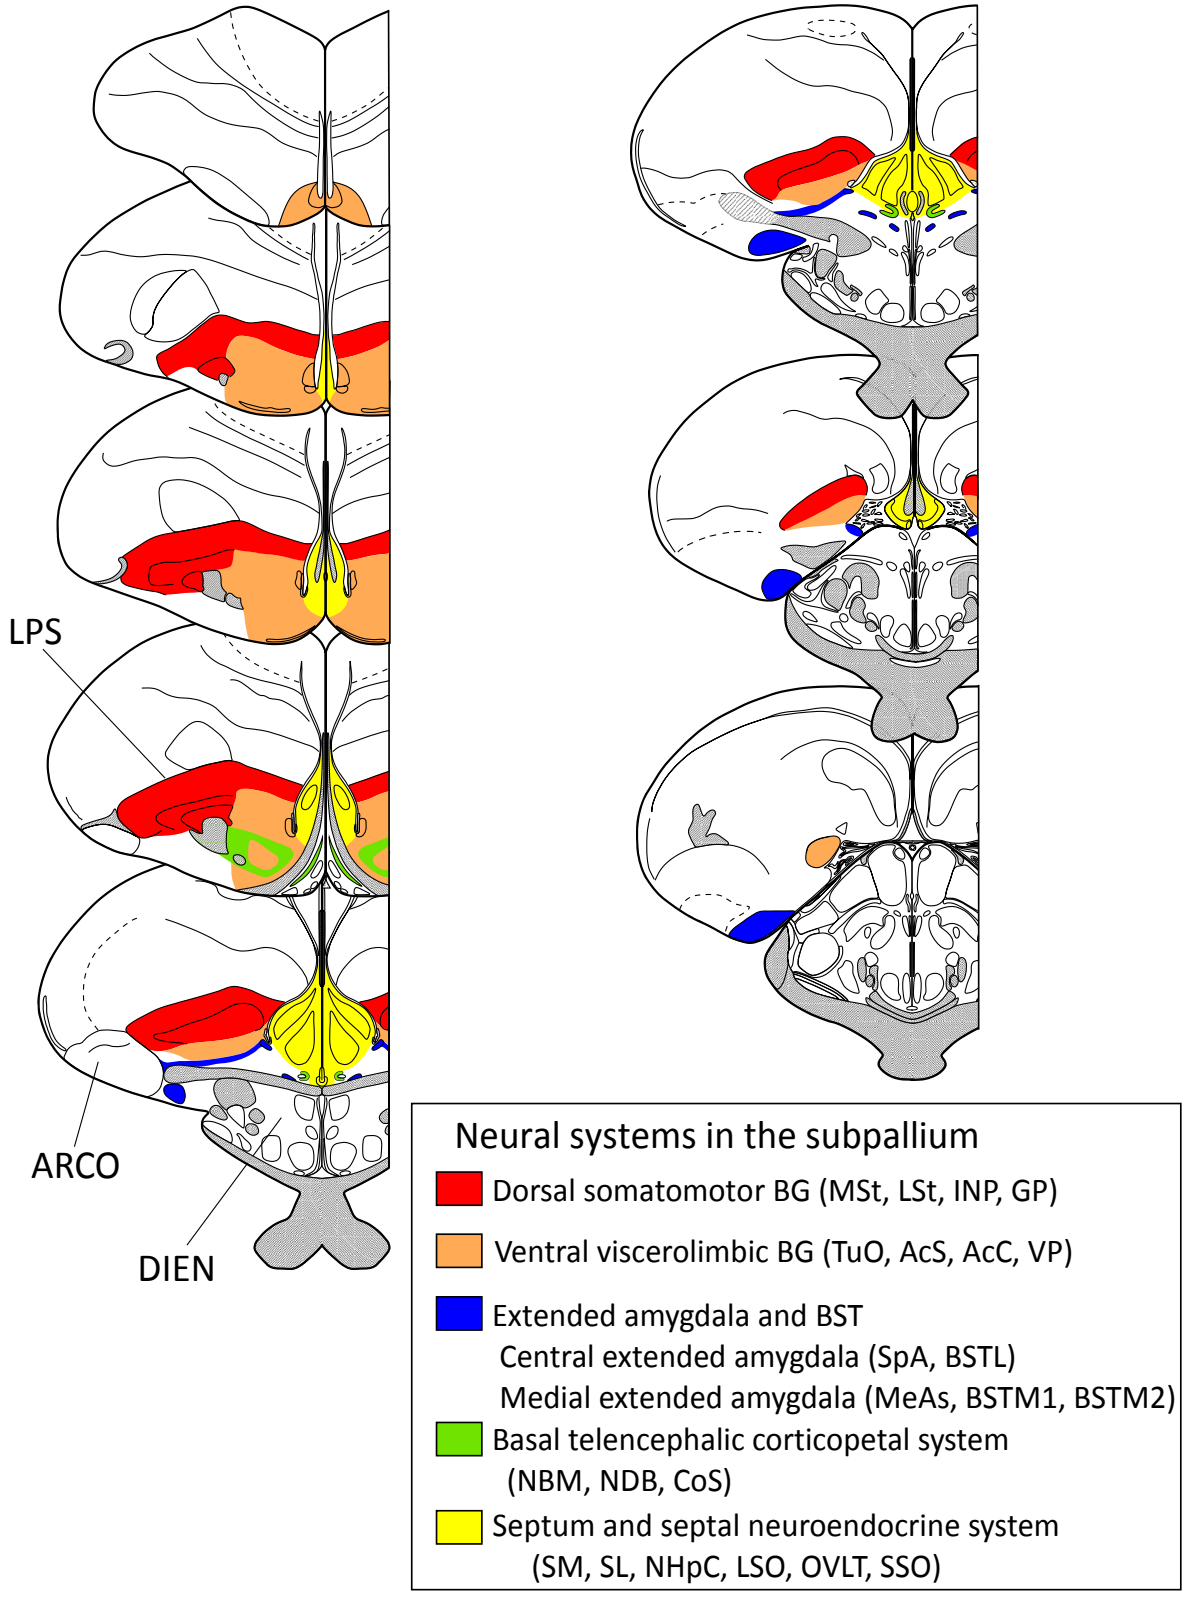

FIGURE 9.1 Five neural systems occupy the avian subpallium: (1) *Dorsal somatomotor basal ganglia* (shown in red) includes the lateral striatum (LSt), medial striatum (MSt), globus pallidus (GP), intrapeduncular nucleus (INP). The LPS marks the dorsal border of the avian subpallium. (2) *Ventral viscerolimbic basal ganglia* (shown in tan) includes the olfactory tubercle (TuO), nucleus accumbens (shell and core, AcS, AcC), ventral pallidum (VP). (3) *Extended amygdala and bed nuclei of the stria terminalis* (shown in blue) include the central extended amygdala and medial extended amygdala. The former is composed of the lateral bed nucleus of the stria terminalis (BSTL) and central extended amygdala (CEA, formerly the dorsal portion of the subpallial amygdala (SpA; see Figure 9.7)); the identification of the central nucleus of the avian amygdala is currently being investigated. The latter comprises the medial bed nucleus of the stria terminalis 1 and 2, (BSTM1, BSTM2), medial extended amygdala (MEA, formerly the ventral portion of the SpA (see Figure 9.7)), and medial amygdala (MeA, formerly the nucleus taeniae amygdala, TnA). (4) *Basal telencephalic corticopetal system* (shown in green) includes the basal magnocellular nucleus (NBM), diagonal band nucleus (NDB) and commissural septal nucleus (CoS). (5) *Septum and septal neuroendocrine system* (shown in yellow) comprise the medial septum (SM), lateral septum (LS), nucleus of the hippocampal commissure (NHpC, formerly known as the bed nucleus of the pallial commissure), and three circumventricular organs: the lateral septal organ (LSO), organum vasculosum of the lamina terminalis (OVLT), and subseptal organ (SSO). Other abbreviations: ARCO = arcopallium, DIEN = diencephalon (hypothalamus, thalamus and epithalamus). *From Kuenzel et al. (2011).*

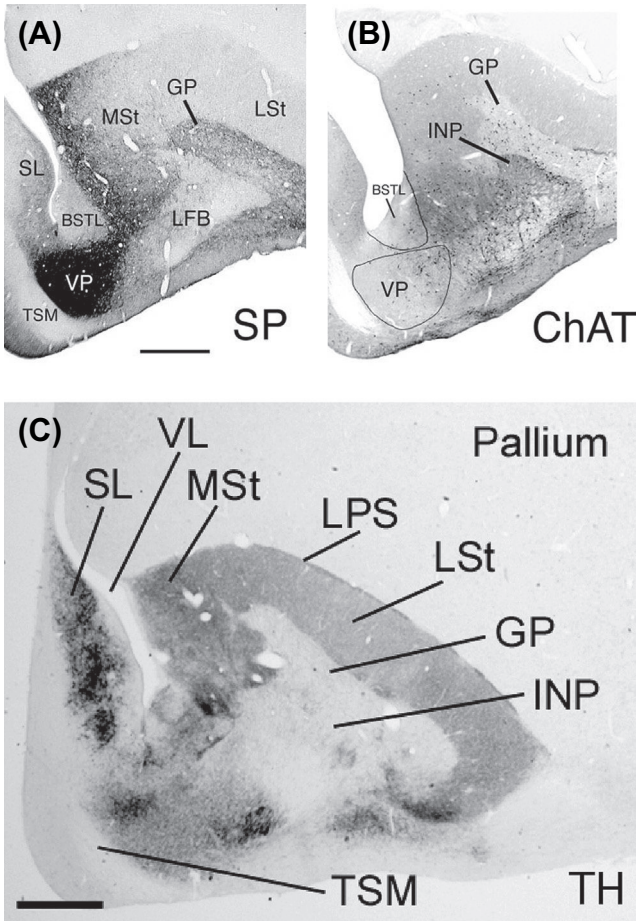

FIGURE 9.2 Components of the dorsal somatomotor basal ganglia. Images of transverse sections of pigeon brain showing immunoreactivity for (A) substance P (SP) and (B) choline acetyltransferase (ChAT). A transverse section of chicken brain shows immunolabeling for (C) tyrosine hydroxylase (TH). The use of TH, an indicator of dopaminergic input, identifies striatal structures of the dorsal somatomotor basal ganglia, particularly the lateral (LSt) and medial striatum (MSt). Note also the increased immunoreactivity of SP fibers in the ventral pallidum (VP), as well as portions of the VP showing increased levels of ChAT neurons and TH fibers. In (B), the field of cholinergic neurons spanning the VP and lateral forebrain bundle (LFB) represents the basal magnocellular cholinergic cell group (NBM). There exists a paucity of ChAT neurons and SP immunoreactivity in the bed neucleus of the stria terminalis (BSTL). Other abbreviations: GP = globus pallidus, INP = intrapeduncular nucleus, LPS = pallial-subpallial lamina, SL = lateral septum, TSM = tractus septo-pallio-mesencephalicus, VL = lateral ventricle. Scale bar = 1 mm. *From Kuenzel et al. (2011).*

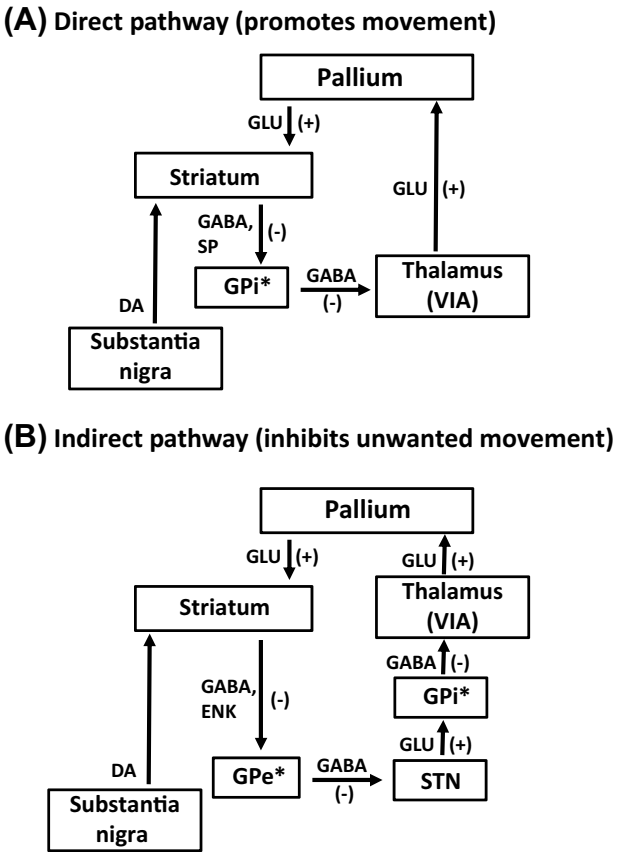

FIGURE 9.3 (A) Schematic diagram showing a direct pathway where excitatory inputs (+) from the pallium and modulatory inputs from the substantia nigra promote skeletal muscle movements in birds. (B) In parallel, an indirect pathway functions to inhibit unwanted movement thereby facilitating the movement initiated by the direct pathway. Abbreviations: DA = dopamine, ENK = enkephalin, GABA = gamma aminobutyric acid, GLU = glutamic acid, GPe* = globus pallidus externa (lateral portion of GP), GPi* = globus pallidus internus (medial portion of GP), STN = subthalamic nucleus, SP = substance P, VIA = ventrointermediate thalamic area.

glutamatergic neurons that in turn project back to the globus pallidus interna (Jiao et al., 2000). The medial globus pallidus comprises predominantly GABAergic inhibitory neurons that project to the VIA. The VIA contains excitatory glutamatergic neurons that project to the pallium (Figure 9.3(B)). In summary, activation of ENK, GABA-containing neurons in the striatum produces an inhibition of neurons in the globus pallidus. The result is a disinhibition of glutatmate containing neurons in the STN. The enhanced excitatory output from the STN causes an increase in GABA release from globus pallidus neurons that project to the thalamic VIA, thereby decreasing glutamate release into specific pallial projection sites. The overall effect of this pathway is to promote suppression of unwanted movements that potentially would conflict with the movements being promoted by the direct pathway (Figure 9.3(A)). Behavioral data supporting the function of the indirect pathway were obtained in rats (Kafetzopoulos and Papadopoulos, 1983; Piallat et al., 1996) and later in pigeons following surgical lesions directed to the STN that produced hyperkinesia and rotation.

Data obtained in lampreys (jawless vertebrates) have shown that this species likewise contains all the major components of the basal ganglia including the striatum, globus pallidus, and STN; thus, it is suggested that this phylogenetic old group of vertebrates had similar, functional direct and indirect pathways forming a core network regulating motor function (Stephenson-Jones et al., 2011). Data

support the general hypothesis that the basal ganglia circuits evolved to support selection of motor actions among vertebrates (Redgrave et al., 1999). Further research has shown the marked conservation of the dual-output pathways throughout vertebrate phylogeny (Stephenson-Jones et al., 2012). Additionally, a neural structure in lampreys found to be homologous to the mammalian pedunculopontine nucleus (PPN), located in the midbrain near the substantia nigra and ventral tegmental area, has been identified (Stephenson-Jones et al., 2012). The PPN is thought to be involved in the initiation and modulation of gait and other stereotyped movements in mammals (Pahapill and Lozano, 2000). In birds, the ventral mesencephalic profundus nucleus identified in avian brain atlases (Karten and Hodos, 1967; Kuenzel and Masson, 1988) was renamed the pedunculopontine tegmental nucleus (PPT or PPN; Reiner et al., 2004) due to the presence of cholinergic neurons and its association with components comprising the basal ganglia. The PPN has been proposed to be an extended part of the basal ganglia among vertebrates due to its connectivity with basal ganglia structures (Mena-Segovia et al., 2004).

9.2.2 Ventral Viscerolimbic Basal Ganglia

9.2.2.1 Structures

The ventral viscerolimbic basal ganglia (VVBG) are organized structurally similar to the dorsal somatomotor basal ganglia (DSBG) in that there is a dorsal striatal and a ventral

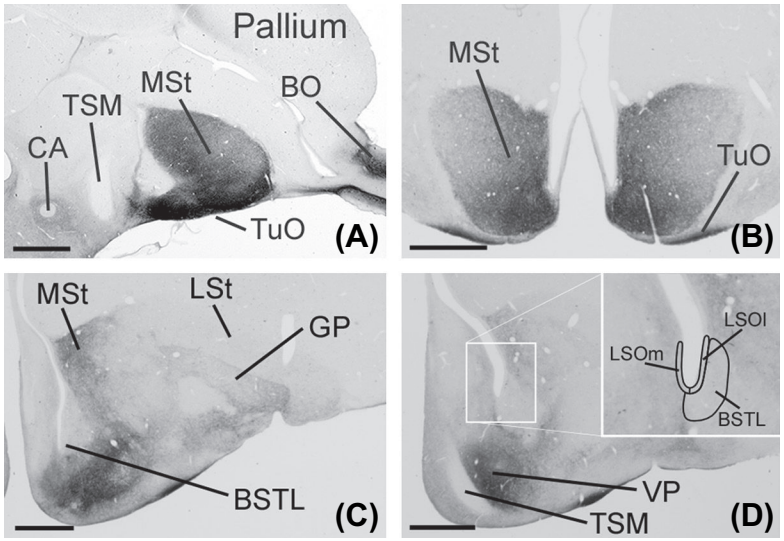

FIGURE 9.5 Sections of chick brain showing components of the viscerolimbic basal ganglia (BG) immunolabeled with an antibody to substance P. (A) Sagittal section near midline showing the ventral portion of medial striatum (MSt) and tuberculum olfactorium (TuO). Note projections from the olfactory bulb (BO) reaching the TuO. (B, C, D) Transverse sections of BG depicting the MSt, TuO and VP. The insert in (D) shows the location of one of the circumventricular organs, the lateral septal organ (LSO), which is associated with the fifth neural system of the subpallium, the septum, and septal neuroendocrine system. Other abbreviations: BSTL = lateral bed nucleus of the stria terminalis, CA = anterior commissure, GP = globus pallidus, TSM = tractus septopallio-mesencephalicus. Scale bars = 1.0 mm. *From Kuenzel et al. (2011).*

pallidal subdivision. The VVBG comprises the ventral portion of the medial striatum, nucleus accumbens (core and shell), olfactory tubercle, and ventral pallidum (Figures 9.5 and 9.6). The striatal subdivision consists of the ventral portion of the medial striatum, nucleus accumbens shell, and core and superficial part of the olfactory tubercle. Striatal components, particularly nucleus accumbens, receive excitatory pallial inputs, most likely glutamatergic (Veenman and Reiner, 1996; Csillag et al., 1997; Reiner et al., 2001; Ding et al., 2003; Ding and Perkel, 2004; Farries et al., 2005). Pallial inputs to the olfactory tubercle come from the olfactory bulb (Figure 9.5), piriform cortex (Bingman et al., 1994), and dorsomedial hippocampus (Atoji and Wild, 2004). Dopaminergic striatal, modulatory input largely originates from the ventral tegmental area A10 cell group (Figure 9.4(B)) and also from the substantia nigra (Figure 9.4(C); Kitt and Brauth, 1986b; Moons et al., 1994; Panzica et al., 1994, 1996). Striatal structures have been shown to have interneurons containing NADPH-diaphorase and nitric oxide synthase (NOS; Vincent et al., 1983; Brüning, 1993; Brüning et al., 1994; Panzica et al., 1994), as well as calcitonin gene-related peptide fibers (Lanuza et al., 2000; Roberts et al., 2002) and thyroid hormone releasing hormone-containing fibers (Jozsa et al., 1988). As stated previously, the striatal subdivision of the ventral viscerolimbic BG, regarding its inputs and outputs, is structurally similar to the DSBG as it receives excitatory glutamatergic input from the pallium and modulatory dopaminergic input largely from the ventral tegmental area (VTA) or A10 cell group and some input from the SNc. Additionally, the medial striatum, nucleus accumbens, and olfactory tubercle of the striatal subdivision, similar to the DSBG, have GABAergic projection neurons co-localized with either substance P or ENK. The viscerolimbic pallidal subdivision includes the ventral pallidum and deep olfactory tubercle (Figure 9.5).

A prominent major structure of the VVBG is the nucleus accumbens. The mammalian nucleus accumbens comprises a central core (AcC) surrounded on its medial, ventral, and lateral sides by a shell (AcS; Herkenham et al., 1984; Záborszky et al., 1985). A third subterritory of the mammalian accumbens has also been identified (Zahm, 2000; Zahm and Brog, 1992; Zahm and Heimer, 1993). Similarly, in avian species, three subterritories of the Ac have been described using antibodies to substance P, neuropeptide Y (NPY), dopamine and cAMP-regulated phosphoprotein (DARPP-32), and calcium-binding proteins (Figure 9.6) (Roberts et al., 2002; Bálint and Csillag, 2007; Abellán and Medina, 2009; Bálint et al., 2011; Husband and Shimizu, 2011). Controversies, however, remain on the boundaries of components of the Ac, the ventral medial striatum, as well as their anatomical organization.

The complex accumbens structure (Figure 9.6), nonetheless, is important to define due to its diverse reciprocal connections with limbic and visceral structures including the hippocampal formation, amygdala, ventral pallidum, lateral hypothalamus, and ventral tegmental area (reviewed in Husband and Shimizu, 2011). It also receives input from central components of the autonomic nervous system, including the lateral hypothalamus (Berk and Hawkin, 1985), lateral bed nucleus of the stria terminalis (Atoji et al., 2006), parabrachial nucleus (Wild et al., 1990), nucleus tractus solitarius (Arends et al., 1988; Bálint and Csillag, 2007), and

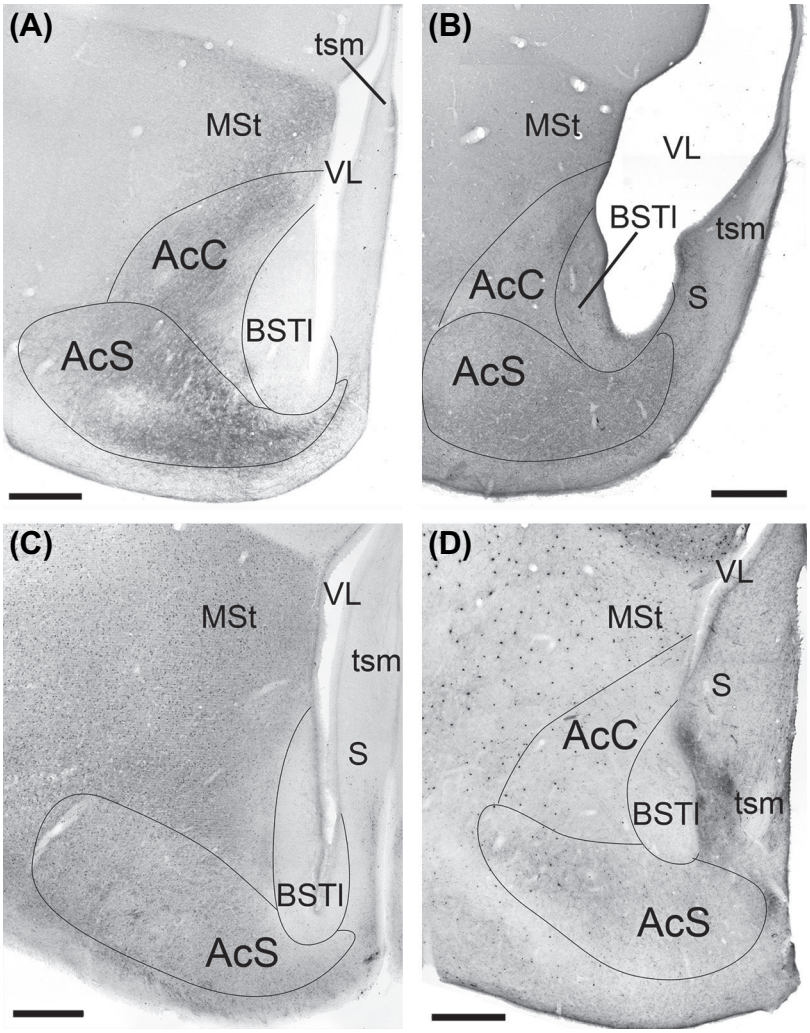

FIGURE 9.6 Transverse sections of chick brain showing the nucleus accumbens (Ac) core (AcC) and shell (AcS) subdivisions immunolabeled with antibodies to the following neuropeptides/proteins. (A) Substance P. (B) Neuropeptide Y (NPY). (C) Dopamine and cAMP-regulated phosphoprotein (DARPP-32). (D) Calbindin. The NPY immunoreactivity is useful for demarcation of the shell. Other abbreviations: BSTl = lateral bed nucleus of the stria terminalis, MSt = medial striatum, S = septum, tsm = tractus septopallio-mesencephalicus, VL = lateral ventricle. Scale bars = 500 µm. *From Kuenzel et al. (2011).*

dorsal motor nucleus of the vagus (Arends et al., 1988). As noted previously, striatal subdivisions have dopaminergic input from the ventral tegmental area and substantia nigra. In addition, the nucleus accumbens receives dense noradrenergic input from the A6 area (locus coeruleus; Figure 9.4(F,G)), particularly in the AcS (Kitt and Brauth, 1986a; von Bartheld and Bothwell, 1992; Bailhache and Balthazart, 1993; Reiner et al., 1994; Moons et al., 1995; Mello et al., 1998). Output of the striatal accumbens nucleus as well as that from some neurons of the striatal olfactory tubercle is to the ventral pallidum (VP). The avian VP in turn projects to several diencephalic sites, including the subthalamic nucleus, paraventricular nucleus, lateral hypothalamic area, thalamic reticular nucleus, dorsomedial thalamus, and habenular nucleus (Kitt and Brauth, 1981; Berk and Hawkin, 1985; Veenman et al., 1995; Medina and Reiner, 1997).

9.2.2.2 Functions

A function most widely associated with the VVBG is reward (reward-seeking effects). A useful definition of reward in animal experiments is a demonstration that an unconditioned stimulus can initiate appetitive behavior and evoke approach behavioral effects (Ikemoto and Panksepp, 1999). It is based largely on the extensive data in mammals showing that rats will self-administer dopamine, amphetamine, or electrical stimulation (each of these is initially an unconditioned stimulus) in the region of the nAc (Broekkamp et al., 1975; Cador et al., 1991). The nAc, especially the shell region, is also responsive to stress (Kalivas and Duffy, 1995; King et al., 1997) and the general accumbens region is associated with passive avoidance learning in chicks (Stewart et al., 1996).

A number of anatomical studies have been conducted in mammals and birds regarding the VVBG such that structural details of each component have been described. Nonetheless, a comprehensive neural circuit model similar to that developed for the dorsal somatomotor BG, describing the function of voluntary muscles via the direct-indirect pathway, has not been forthcoming. Perhaps some of the loop circuits between pallium and basal ganglia type structures, such as the anterior forebrain pathway in song birds (reviewed in Doupe et al., 2005), the proposed direct and indirect pathways involving the vocal learning circuit of song birds (Farries et al., 2005; Gale et al., 2008), or the limbic loop associated with the nAc (Husband and Shimizu, 2011) that have been proposed to date may lead to a promising model for the VVBG, which could be tested for regulating reward-motivated behavior.

9.2.3 Extended Amygdaloid Complex: Central Extended Amygdala and Medial Extended Amygdala

Heimer and coworkers recognized that the mammalian amygdaloid complex comprised two major groups, each of which had neuronal structures that extended from them forming a neuronal corridor. The two corridors were named the extended amygdala, with one originating from the central nucleus of the amygdala, while the second was continuous with the medial amygdaloid nucleus. Both passed through a territory ventral to the globus pallidus (anatomically referred to as sublenticular) and the neuronal corridors ended in different components of the bed nuclei of the stria terminalis (Alheid and Heimer, 1988; Alheid et al., 1995). Each corridor possessed similar neurochemical characteristics of the amygdaloid nucleus from which they were confluent. Functionally, the central and medial amygdaloid nuclei and their respective subnuclei of the complex bed nuclei of the stria terminalis represent the major output nuclei of the amygdala of mammals (Swanson and Petrovich, 1998; Swanson, 2000; Paré et al., 2004).

Developmental, neurohistochemical, hodological, and behavioral data suggest strongly that comparable structures forming a subpallial amygdaloid complex exist in birds (Jurkevich et al., 1997, 1999; Aste et al., 1998; Cheng et al., 1999; Panzica et al., 1999; Absil et al., 2002a,b; Roberts et al., 2002; Reiner et al., 2004; Yamamoto et al., 2005; Abellán and Medina, 2009; Xie et al., 2010, 2011). For clarification of the structures and functions of the subpallial amygdaloid complex, the following sections discuss each of its two basic components, first in mammals and then in birds.

9.2.3.1 Central Extended Amygdala

9.2.3.1.1 Structures

The central nucleus of the amygdala—cells within the corridor of the central extended amygdala and the lateral bed nucleus of the stria terminalis (BSTL)—comprise structures of the central extended amygdaloid complex in mammals. Associated with the central nucleus of the amygdala (CeM) are groups of intercalated cells positioned between the lateral amygdala and the CeM (Paré et al., 2004). The major groups of projection neurons from the central extended amygdaloid complex are GABAergic, similar to the dorsal somatomotor and ventral viscerolimbic basal ganglia discussed previously. A difference is that the GABAergic neurons are typically enriched with one of several neuropeptides, including corticotropin-releasing hormone (CRH), neurotensin (NT), somatostatin (SOM) or ENK (Moga and Gray, 1985; Swanson and Petrovich, 1998; Paré and Smith, 1994; Alheid et al., 1995; Poulin and Timofeeva, 2008; Panguluri et al., 2009). The major descending projections of the central extended amygdaloid complex are to the lateral hypothalamus, central gray, parabrachial nucleus, and nucleus of the solitary tract, all of which are structures in the diencephalon and brainstem that are part of the ANS. Functionally the structures and their connections to the ANS regulate physiological processes and behaviors related to ingestion, and fear/anxiety/stress (Alheid and Heimer, 1988; Alheid et al., 1995; Swanson, 2000; de Olmos et al., 2004).

In birds, a major component of the central extended amygdaloid complex, positioned directly below the globus pallidus, was previously termed the subpallial amygdaloid area (SpA; Reiner et al., 2004). It has been proposed that the SpA and its lateral continuation directly ventral to the lateral striatum (LSt) be renamed the central extended amygdala (CEA, Figure 9.7) (Abellán and Medina, 2009). It was also suggested that part of the caudolateral striatum and lateral continuation of the SpA may be the avian structure homologous to the mammalian central nucleus of the amygdala (Abellán and Medina, 2009). Another avian structure that has been suggested to be homologous to the mammalian central amygdaloid nucleus is the compact division of the posterior pallial amygdaloid nucleus (Atoji and Wild, 2006). A structure termed the striatal capsule (composed of a thin group of subpallial neurons), which is located between the nidopallium and lateral striatum (Puelles et al., 2007), has been proposed to be comparable to the intercalated cell masses of the mammalian amygdala (Abellán and Medina, 2009) that occur juxtapositioned to central amygdaloid nucleus of mammals (Paré et al., 2004). The final structure of the complex is the lateral bed nucleus of the stria terminalis (BSTL; Figure 9.7) and it is regarded as comparable to the mammalian bed nucleus of the stria terminalis due to the presence of CRH (Panzica et al., 1986; Ball et al., 1989; Richard et al., 2004), neurotensinergic (Reiner and Carraway, 1987; Atoji et al., 1996; Reiner et al., 2004) and enkephalinergic (Molnar et al., 1994) neurons. The avian BSTL has been shown to have direct connections to components of the autonomic nervous system including hypothalamic structures, parabrachial nucleus, nucleus of the solitary tract, and dorsal motor nucleus of the vagus (Berk, 1987; Arends et al., 1988; Wild et al., 1990; Atoji et al., 2006; Bálint et al., 2011).

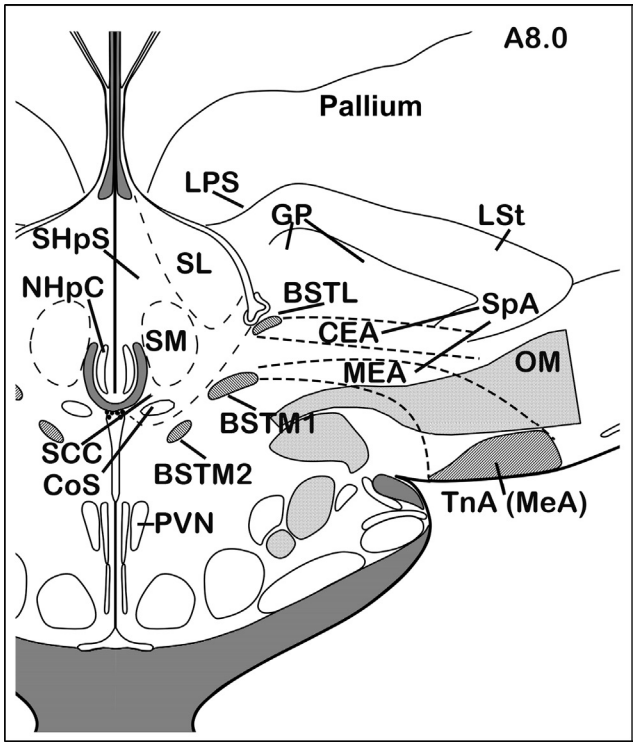

FIGURE 9.7 Components of the subpallial amygdaloid complex and the septum and septal neuroendocrine systems. The central extended amygdaloid complex comprises the lateral bed nucleus of the stria terminalis (BSTL), central extended amygdala (CEA), and central nucleus of the amygdala. Boundaries of the CEA in mature birds and location of the central nucleus of the amygdala require additional studies. The medial extended amygdaloid complex includes the medial bed nucleus of the stria terminalis, which has two subnuclei in chickens (BSTM1 and BSTM2), the medial extended amygdala (MEA) and the medial amygdala (formerly termed the nucleus taeniae amygdala (TnA)). Similar to the CEA, the MEA corridor requires refinement. Formerly, they were termed the subpallial amygdala (SpA). The fifth subpallial system, the septum and septal neuroendocrine system, was shown to consist of four divisions including the lateral septum (SL), medial septum (SM), septohippocampal septum (SHpS), and caudocentral septum (SCC) in birds (Goodson et al., 2004). The four septal divisions extend over a rostral-caudal length of at least 3.0 mm in the 2-week-old chick brain; however, for the purpose of this review, they have been compacted into one plane; therefore, their relative locations within the septum are approximate. Other abbreviations: CoS = commissural septal nucleus, GP = globus pallidus, LPS = pallial-subpallial lamina, LSt = lateral striatum, OM = occipitao-mesencephalic tract, PVN = paraventricular nucleus.

9.2.3.1.2 Functions

In mammals, the central extended amygdaloid complex is thought to be involved in food intake and fear/anxiety/stress behavior due to its connectivity to central components of the autonomic nervous system located in the hypothalamus and caudal brainstem (van der Kooy et al., 1984; Luiten et al., 1987; Paré et al., 2004). In particular, CRH neurons in the bed nucleus of the stria terminalis can affect the regulation of appetite (Heimer and Alheid, 1991; Clark and Kaiyala, 2003; Gallagher et al., 2008; Krogh et al., 2008). The stria terminalis is known to have connections with the lateral hypothalamic area, parabrachial nucleus, nucleus of the solitary tract, and dorsal motor nucleus of the vagus; all of the previously listed structures have connectivity to the ANS. In birds, similar central connections with the ANS have been demonstrated showing that ingestive behavior is regulated by similar neural systems in mammals and birds (reviewed in Kuenzel and Blähser, 1993; Kuenzel, 1994, 2000). The same neuropeptide, CRH, has been shown to be important for the expression of stress and anxiety in mammals (Paré et al., 2004) and CRH administered intracerebroventricularly causes distress vocalizations in chicks (Zhang et al., 2004).

9.2.3.2 *Medial Extended Amygdala*

9.2.3.2.1 Structures

The medial extended amygdaloid complex in mammals comprises the medial amygdala, the neuronal corridor emerging from the medial amygdala, and the medial nuclear complex of the bed nucleus of the stria terminalis. The main input to the medial amygdala originates in the olfactory bulb as well as in the accessory olfactory system and its vomeronasal organ. It is rich in gonadal steroid receptors and projects to various hypothalamic structures involved with reproductive behavior, aggression, and defense (Alheid et al., 1994; Swanson, 2000). Similar to other projection neurons comprising the subpallial structures, the medial extended amygdala has predominantly GABAergic neurons (Alheid et al., 1994, 1995; Swanson, 2000). Glutamatergic neurons have also been identified (Choi et al., 2005).

Avian species have comparable structures. The nucleus taeniae was proposed for some time to be comparable to the mammalian medial amygdala (Cheng et al., 1999) and was officially renamed the nucleus taeniae amygdala (Reiner et al., 2004). Additional data have supported the concept that birds have a medial amygdala and an extended amygdala (Yamamoto et al., 2005). Birds also have the medial bed nucleus of the stria terminalis (BSTM, Figure 9.7) (Jurkevich et al., 1997, 1999; Aste et al., 1998). In addition to arginine vasotocin, neurons of the BSTM of chickens contain galanin (Klein et al., 2006). Embryological studies showed that birds have a subpallial medial amygdala with a corridor of neurons that extends to the BSTM; therefore, it was proposed that birds have a medial extended amygdala (MEA, Figure 9.7) complex (Abellán and Medina, 2009). In addition to GABAergic and glutamatergic neurons, the complex likewise has nitrergic neurons (Panzica et al., 1994; Balthazart et al., 2003) resembling comparable findings of GABAergic and nitrergic neurons in the mammalian medial amygdalar nucleus (Tanaka et al., 1997; Swanson, 2000). In addition to inputs from the olfactory bulbs, the avian subpallial amygdala receives projections from the piriform cortex (Bingman et al., 1994; Veenman et al., 1995). Vasotocin neurons of the BSTM component of the medial extended amygdaloid complex project to the medial

preoptic nucleus (Absil et al., 2002a). The avian medial amygdala is reciprocally connected to the hippocampal formation (Atoji et al., 2002; Atoji and Wild, 2004). Importantly, the medial extended amygdaloid complex contains high concentrations of androgen and estrogen receptors as well as the enzyme aromatase, which converts testosterone to estradiol (Balthazart et al., 1998b; Foidart et al., 1999). The abundance of sex steroid receptors is greater in males in this region (Watson and Adkins-Regan, 1989).

9.2.3.2.2 Functions

As stated previously, in mammals the medial extended amygdaloid complex plays a key role in mating, sexual, defensive, and aggressive behaviors. Olfactory input from the main and accessory olfactory systems are important signals to the complex (Swanson, 2000; Choi et al., 2005). Hodological and behavioral data suggest that the BSTM and medial amygdala play a similar role in birds (Panzica et al., 1998; Thompson et al., 1998; Absil et al., 2002a; Xie et al., 2010, 2011). Due to a lack of a defined accessory olfactory system and small olfactory bulbs in most avian species, it has been thought that pheromones and odors do not serve a critical function in this vertebrate class. Nonetheless, it has been shown that pheromones play a role in avian social and sexual behavior (Balthazart and Schoffeniels, 1979; Caro and Balthazart, 2010) and electrophysiological responses in the avian olfactory bulb to odorants are comparable to those in mammals (McKeegan, 2002). Importantly, structures in the medial extended amygdaloid complex have been shown to be sexually dimorphic in avian species. Specifically, the BSTM has been shown to be larger in males, is steroid-responsive, and plays a role in copulatory behavior in mammals (Del Abril et al., 1987; Guillamón and Segovia, 1997) and birds (Kiss et al., 1987; Voorhuis et al., 1988; Panzica et al., 1998; Viglietti-Panzica et al., 1992; Aste et al., 1998; Jurkevich et al., 1999). A subnucleus of the BSTM in chickens, the BSTM2 (ventromedial BSTM), functions in male appetitive sexual behavior (Xie et al., 2010, 2011).

9.2.4 Basal Telencephalic Cholinergic and Noncholinergic Corticopetal System

9.2.4.1 Structures

The basal corticopetal system, sets of neurons at the base of the forebrain that project to the cortex in mammals or pallium in birds and other vertebrates, is composed mostly of cholinergic neurons that in mammals are found overlapping other neuronal types located in the globus pallidus and ventral pallidum of the basal ganglia, the medial septum-diagonal band nucleus, and the magnocellular preoptic nucleus (Gritti et al., 1993, 2003). In birds, three nuclei have been grouped together that comprise this telencephalic corticopetal system: nucleus basalis magnocellularis (NBM), nucleus of the diagonal band, horizontal limb (NDBh), and commissural septal nucleus (CoS; Figure 9.1). All three avian nuclei have in common the presence of cholinergic neurons (Reiner et al., 2004). In the first nucleus listed, the NBM, the cholinergic neurons are found in and about the ventral globus pallidus, ventral pallidum (VP, Figure 9.2), intrapeduncular nucleus, and in and about the lateral and medial forebrain bundle (Medina and Reiner, 1994; Reiner et al., 2004). Of interest is that the NBM is considered equivalent to the mammalian nucleus basalis of Meynert, which contains cholinergic neurons that project to the neocortex, hippocampus, and amygdala (Záborszky et al., 1999). In birds, the NBM receives input from the ventral visceralimbic basal ganglia, including the nucleus accumbens, as well as the subpallial amygdaloid complex including the arcopallium (Veenman et al., 1995; Medina and Reiner, 1997). The second avian cholinergic nucleus, the NDBh, is similar to cholinergic neurons located in the nucleus of the diagonal band in the mammalian basal forebrain region (Woolf, 1991). The avian NDB projects heavily to the hippocampal and parahippocampal areas (Benowitz and Karten, 1976; Casini et al., 1986; Atoji et al., 2002; Montagnese et al., 2004). The third nucleus, the CoS (Figure 9.7), occurs immediately dorsal to the anterior commissure and just lateral to the midline nucleus, the nucleus of the hippocampal commissure (NHpC, Figure 9.7). The CoS has a major projection to the hippocampus and parahippocampal areas, similar the projections of the NDB (Benowitz and Karten, 1976; Casini et al., 1986; Atoji et al., 2002; Montagnese et al., 2004).

9.2.4.2 Functions

In mammals, the basal forebrain, particularly the nucleus basalis of Meynert, has been implicated in learning and memory. Specifically, corticopetal cholinergic neurons have been shown to play a role in modulating cortical activity and in attentional and arousal processes (Záborszky et al., 1999) that affect learning and memory (Metherate et al., 1988, 1992; Cape and Jones, 2000; Cape et al., 2000). There exists a high correlation between the loss of memory and loss of cholinergic neurons in humans (Auld et al., 2002). Little is known about the role of basal forebrain cholinergic neurons in cognitive processes in birds. Nonetheless, pharmacological blockage of muscarinic cholinergic receptors results in impaired learning and memory in diverse avian species (Patterson et al., 1990; Mineau et al., 1994; Savage et al., 1994; Kohler et al., 1996; Zhao et al., 1997). Additionally, beta-amyloid toxicity, known to damage the basal forebrain cholinergic system in mammals, is known to impair memory in chicks (Gibbs et al., 2010).

9.2.5 Septum and Septal Neuroendocrine Systems

9.2.5.1 Divisions and Structures

The avian septum lies dorsal and anterior to the diencephalon and comprises all neural structures medial to the ventral horns of the lateral ventricle (Figures 9.1 and 9.7). It first appears in rostral coronal sections of forebrain as the ventral horns of the lateral ventricle begin to move apart laterally and the tractus septopallio-mesencephalicus (tsm, Figure 9.6) begins to descend from the hippocampal region into the septum (S, Figure 9.6(B,C,D)). A useful marker of the septal ventral boundary is the anterior commissure, when the mid-septal region appears dorsal to the hypothalamus. Moving caudally, the septum gradually decreases in size. Before the septum disappears, the cortico-habenular and cortico-septal tract that passes through the septum becomes more visible. The septum of mammals has been parcellated into numerous chemoarchitectonic zones that can be grouped into four major divisions (Jakab and Leranth, 1995; Risold and Swanson, 1997a,b). A comparative study was completed using a variety of songbird species and antibodies against 10 neuropeptides and enzymes to develop a nomenclature and framework to establish homologous septal zones among tetrapods (Goodson et al., 2004). Results suggested that the avian septum, similar to that of mammals can be divided into four major divisions: lateral septum (SL), medial septum (SM), septohippocampal septum (SHpS), and caudocentral septum (SCC, Figure 9.7). Coupled with developmental (Puelles et al., 2007; Abellán and Medina, 2009; Abellán et al., 2010) and hodological (Atoji and Wild, 2004; Montagnese et al., 2004, 2008) studies, homologous divisions and structures have been proposed, which will be detailed below.

9.2.5.1.1 Lateral Septum

The developing avian lateral septum (Figure 9.7) comprises three nuclei, the dorsal (SLd) and intermediate (SLi) are striatal derivatives based upon expression of Pax6 and LIM-only gene *Lmo4,* whereas the ventral one (SLv) is a pallidal derivative due to expression of the *Nkx2.1* gene (García-López et al., 2008; Abellán and Medina, 2009; Medina and Abellán, 2009). Hodological studies have shown four major inputs to the lateral septum, including the hippocampal formation, arcopallium/amygdala, diencephalon, and brainstem. Different hippocampal domains project preferentially to different SL regions of birds (Atoji and Wild, 2004; Montagnese et al., 2004, 2008) as well as mammals (Risold and Swanson, 1997b). In addition, in mammals major glutamatergic inputs to the SL have been documented from pyramidal neurons in the hippocampus (Jakab and Leranth, 1995; Risold and Swanson, 1997b). The caudal intermediate arcopallium and nucleus taeniae of the amygdala have been shown to project to the avian SL (Atoji and Wild, 2004; Montagnese et al., 2004, 2008). The mammalian medial amgydala, proposed to be homologous to the avian nucleus taeniae of the amygdala (Thompson et al., 1998; Cheng et al., 1999; Yamamoto et al., 2005), sends projections to the SL (Canteras et al., 1995). Extensive input to the SL originates from the rostral-caudal extent of the ventral diencephalon including the preoptic area (medial preoptic nucleus) (Berk and Butler, 1981; Panzica et al., 1992; Balthazart et al., 1994; Balthazart and Absil, 1997; Atoji and Wild, 2004; Montagnese et al., 2008), hypothalamus (anterior and lateral hypothalamic area), tuberal, and mammillary region (Atoji and Wild, 2004, 2006). Similar projections have been demonstrated in the rat (Canteras et al., 1992, 1994; Risold and Swanson, 1997b). A major output from the mammalian SL descends via the medial forebrain bundle and innervates the medial septal nucleus, nucleus of the diagonal band, lateral hypothalamic area, medial preoptic, anterior hypothalamic, ventral premammillary, and mammillary nuclei (Risold and Swanson, 1997b). The avian SL sends similar projections to the medial preoptic nucleus, anterior and ventromedial hypothalamic nucleus, lateral hypothalamic area, and lateral mammillary nucleus (Atoji and Wild, 2004), thereby showing numerous reciprocal projections between hypothalamic nuclei and SL in birds and mammals. Finally, a fourth extensive set of projections to the mammalian and avian SL originate from the brainstem, specifically from the ventral tegmental area (Kitt and Brauth, 1986b), locus coeruleus (Kitt and Brauth, 1986a), and nucleus raphe/linear caudalis (Cozzi et al., 1991; Atoji and Wild, 2004). Those projections to the SL have been reported to be dopaminergic (Bailhache and Balthazart, 1993; Bottjer, 1993; Moons et al., 1994; Wynne and Güntürkün, 1995), noradrenergic (Bailhache and Balthazart, 1993; Moons et al., 1995; Mello et al., 1998), and serotonergic (Challet et al., 1996), respectively.

Additional chemoarchitectonic studies have shown arginine vasotocin (homologous to mammalian vasopressin) containing dense fiber terminals in the caudal and ventrolateral region of the SL among various vertebrate taxa. Expression of the density of the neuropeptide in vertebrates is testosterone dependent and sexually dimorphic, particularly in mammals (Moore and Lowry, 1998; Goodson and Bass, 2001). The sexual dimorphic expression has been demonstrated in at least three avian species (Voorhuis et al., 1988; Viglietti-Panzica et al., 1992; Jurkevich et al., 1997). The SL is also rich in androgen-concentrating cells (Arnold et al., 1976; Barfield et al., 1978) and in estrogen receptors (Panzica et al., 2001). Other chemoarchitectonic studies have shown that galanin fibers occur in the lateral wall of the septum in Japanese quail (Azumaya and Tsutsui, 1996), collared dove (Dubbeldam et al., 1999), songbirds

(Goodson et al., 2004), chickens (Klein et al., 2006), anuran amphibians (Lazar et al., 1991), and mammals (Melander et al., 1986; Risold and Swanson, 1997a; Chaillou et al., 1999). Of interest is that the distribution of galanin fibers and perikarya, particularly in the lateral septum and medial bed nucleus of the stria terminalis, have been shown to be sexually dimorphic in chickens (Klein et al., 2006), as previously shown for arginine vasotocin. Past studies in mammals have documented galanin and vasopressin co-expression in brain regions known to display sex differences (Miller et al., 1993).

9.2.5.1.2 Medial Septum

The medial septal division in the developing mouse and chicken expresses Tbr1 (Puelles et al., 2000), Lhx6, Lhx7/8, GAD67, and VGLUT2 (Flames et al., 2007; Abellán and Medina, 2009; Abellán et al., 2010) and consists of glutamatergic, GABAergic, cholinergic neurons, and some neurons from pallial septal and pallido-preoptic subdivisions; the latter in the ventral region of the SM expresses some GABAergic neurons (Abellán et al., 2010). Similar to the lateral septum, the medial septum (Figure 9.7) has inputs from the hippocampal complex, the entire rostral-caudal extent of the ventral diencephalon including nuclei from the preoptic, anterior hypothalamus, mammillary and tuberal regions, as well as receives projections from the ventral tegmental area, locus coeruleus, and linear caudalis (Kitt and Brauth, 1986a,b; Atoji and Wild, 2004; Montagnese et al., 2008). Other inputs documented include the nucleus of the diagonal band (Atoji and Wild, 2004; Montagnese et al., 2008), medial division of the bed nucleus of the stria terminalis (Montagnese et al., 2008), and the dorsal lateral nucleus of the anterior medial thalamus (Atoji and Wild, 2004). The SM sends projections to the hippocampal complex (Atoji and Wild, 2004), olfactory tubercle, ventral pallidum, lateral septum, nucleus of the diagonal band, and commissural septal nucleus (Atoji and Wild, 2004; Montagnese et al., 2008). Chemoarchitectonic studies show that most peptidergic and aminergic neurons and fibers show less immunoreactivity compared to the SL. The one exception appears to be the presence of cholinergic neurons, which show their greatest concentration in the medial septum, particularly at caudal levels—not only in a variety of bird species but also the ventromedial septum of most tetrapod groups (Goodson et al., 2004).

9.2.5.1.3 Septohippocampal Septum

A septohippocampal nucleus occurs in mammals (Jakab and Leranth, 1995; Risold and Swanson, 1997a,b) and a third division, the septohippocampal septum (Figure 9.7), has been proposed to exist in birds comprising a small, thin vertical area located above the anterior commissure and extending to the dorsal region of the septum (Goodson et al., 2004). Developmental studies using the pallial marker Emx-1 initially suggested that a discrete, dorsal area of the septohippocampal septum was pallial (Puelles et al., 2007). More recent data using a gene *Lhx5* encoding a transcription factor showed that the entire medial portion of the septohippocampal division from its most dorsal extent ventral to the nucleus of the hippocampal commissure comprises a pallial portion of the septum (Abellán et al., 2010). Chemoarchitectonic data displayed VGLUT2 transporter surrounding the nucleus of the hippocampal commissure, suggesting that the neurons were glutamatergic providing additional support that the septohippocampal septum is a pallial derivative (Abellán et al., 2010). Another source of evidence for its pallial origin comes from the well-known migration of gonadotropin-releasing hormone, type 1 (GnRH-1) neurons from the embryonic olfactory placode into the pallium behind the olfactory bulb and their subsequent migration toward the preoptic, hypothalamic, and septal regions (Figure 9.8(A)). The unusual neuronal migration has been demonstrated in amphibians (Muske and Moore, 1988), mammals (Schwanzel-Fukuda and Pfaff, 1989; Wray et al., 1989), and birds (Murakami et al., 1991; Norgren and Lehman, 1991). Of interest is that for mammalian species, a major portion of the GnRH-1 neurons finally reside in the preoptic area and arcuate nucleus of the hypothalamus (Silverman et al., 1994); in the avian brain such as the chick, 73% of the total GnRH-1 neurons remain in the septum between the medial and lateral septal divisions and surrounding the nucleus of the hippocampal commissure (NHpC, Figure 9.8(B,C); Kuenzel and Golden, 2006). Within the core region of the nucleus of the hippocampal commissure is a dense plexus of corticotropin-releasing hormone fibers (Richard et al., 2004). The avian septohippocampal septum is also characterized by substance P, NPY, and VIP fibers (Goodson et al., 2004). The latter two peptides (NPY and VIP) are associated with reproductive function (refer to Section 9.4.1). Similarly, the septohippocampal n. of rats has been shown to express neuropeptide Y mRNA in cell perikarya and substance P in fibers (Risold and Swanson, 1997a).

9.2.5.1.4 Caudocentral Septum, Cortico-Habenularis, and Cortico-Septal Tract

The fourth major septal area of mammals is the posterior septum, which contains the septofimbrial and triangular nuclei (Jakab and Leranth, 1995; Risold and Swanson, 1997a,b). It has been proposed that birds have a caudocentral septal (Figure 9.7) division that is topographically comparable to the mammalian septofimbrial nucleus and appears to be a caudal expansion of the ventrolateral SL (Goodson et al., 2004). A fiber tract occurs in the caudocentral septum, called the cortico-habenularis and cortico-septal tract. In the rat, a fiber tract that connects the septofibrial nucleus to the hippocampus is the fimbria of hippocampus (Risold and Swanson, 1997b). It has therefore been proposed that the cortico-habenularis and cortico-septal tract be renamed the fimbria

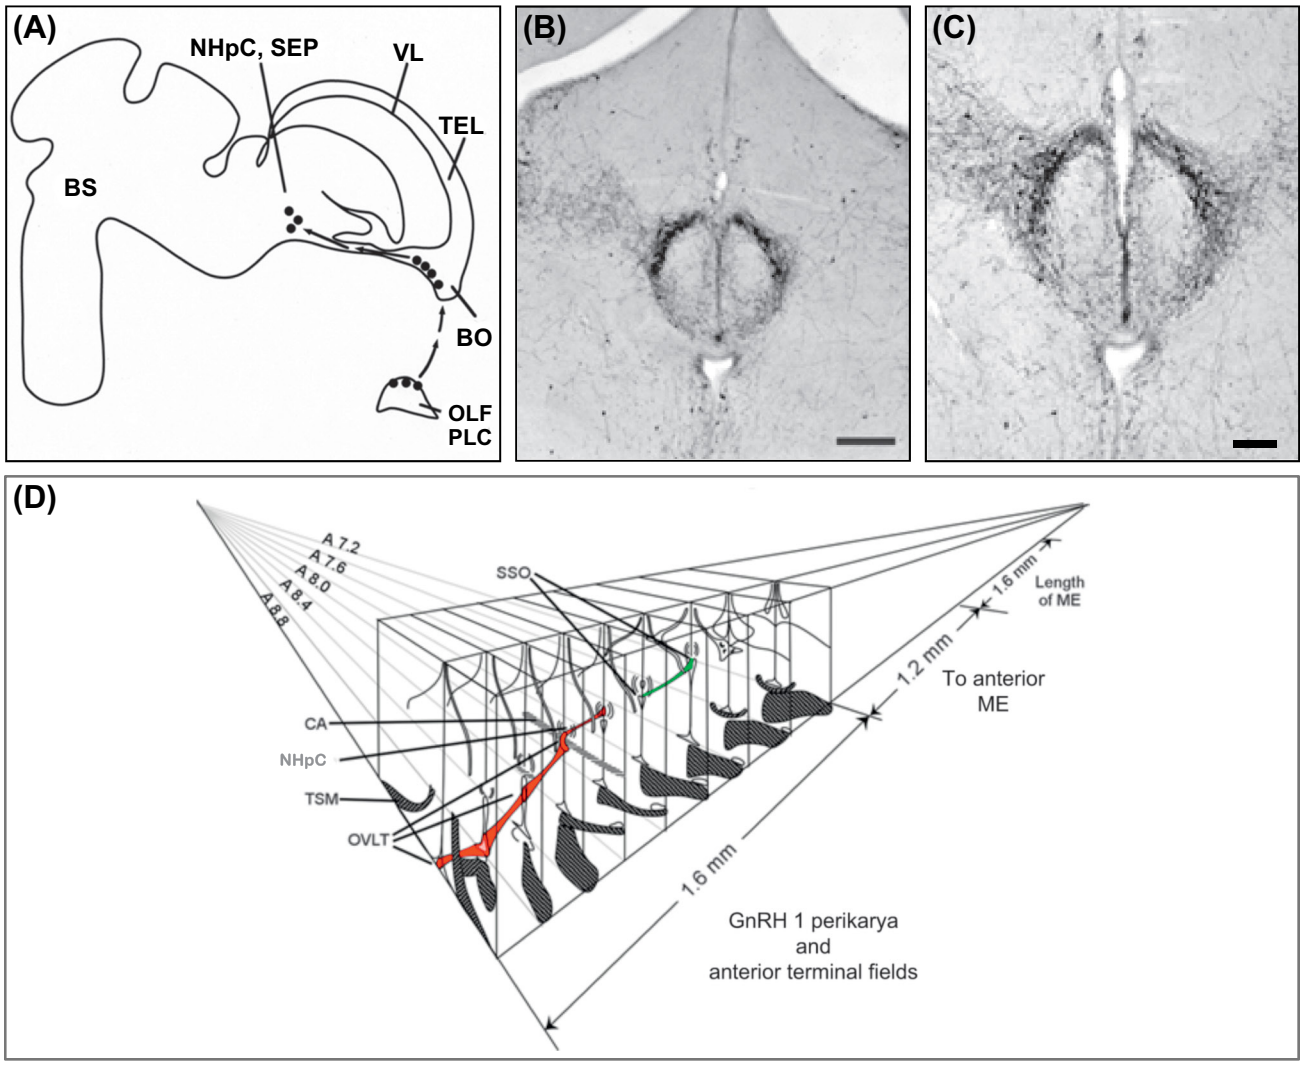

FIGURE 9.8 Origin and distribution of gonadotropin-releasing hormone type one (GnRH-1) neurons in the avian brain. (A) GnRH-1 neurons originate outside the brain in the olfactory placode (OLF PLC) and migrate into the brain to the septum and preoptic area. (B and C) A major site where GnRH-1 neurons migrate during embryonic development occurs surrounding the nucleus of the hippocampal commissure (NHpC) in the septal region. (D) Approximately 73% of GnRH-1 neurons reside in the septum while terminal fields of GnRH-1 neurons occur in the organum vasculosum of the lamina terminalis (OVLT, shown in red) and subseptal organ (SSO, shown in green) in addition to their traditional terminal field in the external zone of the median eminence (ME). Scale bars = 300 µm. Other abbreviations: BO = olfactory bulb, BS = brainstem, CA = anterior commissure, TEL = telencephalon, TSM = tractus septopallio-mesencephalicus, VL = lateral ventricle. *Parts (B), (C), and (D) from Kuenzel and Golden (2006).*

of hippocampus (Goodson et al., 2004; Puelles et al., 2007). In the ventral region of the avian caudocentral septal division occur GnRH-1 neurons that are a continuation of the major group of GnRH-1 found in and about the nucleus of the hippocampal commissure (Kuenzel and Golden, 2006).

9.2.5.1.5 Circumventricular Organs Associated with the Septum: Lateral Septal Organ, Organum Vasculosum of the Lamina Terminalis, and Subseptal Organ

Circumventricular organs (CVOs) are found in the brain of all vertebrate classes. As the name implies, they occur adjacent to the ventricles of the brain in specific regions. Three CVOs are associated with the avian septum including the lateral septal organ (LSO), organum vasculosum of the lamina terminalis (OVLT), and subseptal organ (SSO). There are general characteristics that many CVOs possess, including specialized ependymal cells, a vascular area that has an incomplete blood–brain barrier and cerebrospinal fluid-contacting neurons (Vigh, 1971). Due to their known neuroendocrine function for sustained and integrated activities of vital importance to the survival of a given vertebrate species (Weindl, 1973), three CVOs that border the avian septum will be briefly discussed.

The avian LSO was first named (Kuenzel and van Tienhoven, 1982) and later characterized as having two components, a lateral and medial part (Kuenzel and Blähser, 1994;

Kuenzel et al., 1997). The medial LSO (LSOm) is located at the base of the lateral ventricle in the ventral portion of the lateral septum. It has cerebrospinal fluid-contacting neurons that contain and synthesize VIP, other neuron types, and specialized ependyma. The lateral component (LSOl) occupies the lateral aspect of the base of the lateral ventricle (Figure 9.5(D)), has layers of modified ependymal cells, vasoactive intestinal peptide receptors and lacks a complete blood–brain barrier (Kuenzel and Blähser, 1994; Kuenzel et al., 1997). Vasoactive intestinal peptide containing neurons in the avian (Silver et al., 1988; Wada et al., 2000) and reptilian (Foster et al., 1994; Foster and Soni, 1998) lateral septum have also been shown to contain opsin-like compounds, suggesting that those neurons or others in that organ may serve as encephalic photoreceptors involved in monitoring seasonal time by sensing exposure to daylight.

The OVLT is located near the rostral wall of the third ventricle, termed the lamina terminalis. On both sides of the beginning of the third ventricle is the OVLT, a highly vascular structure. In rodents, the OVLT is restricted to the anterior, ventral hypothalamic region and it is found near the suprachiasmatic nucleus (Duvernoy and Risold, 2007). In contrast, the OVLT of birds is more extensive and comprises a prechiasmatic segment located between the optic chiasma and base of the brain. The vascular OVLT continues dorsal on both sides of the anterior region of the third ventricle continues as a subcommissural segment and passes in front of and dorsal to the anterior commissure to form a precommisssural and supracommissural segment, respectively (Dellmann, 1964; Mikami, 1976). The avian OVLT therefore occupies a strategic position between the anterior roof of the diencephalon and floor of the septum along midline. In mammals, gonadotropin-releasing hormone (GnRH) neurons are found in the preoptic region adjacent to the OVLT and GnRH fibers are found in and about the OVLT (Foster and Younglai, 1991; Silverman et al., 1994). In the chick, a terminal field of GnRH-1 neurons has been observed throughout the entire extent of the OVLT (shown in red) and continues through the length of another CVO, the subseptal organ (shown in green; Figure 9.8D). Data suggest a large terminal field of GnRH-1 neurons occurs along the midline floor of the septal region where GnRH-1 hormone can be secreted into the cerebrospinal fluid of the third ventricle and/or into the capillaries of the CVOs (Kuenzel and Golden, 2006).

The subfornical organ (SFO) of mammals is situated at the meeting point of the two lateral and third ventricles and is suspended from the fornix (Miselis et al., 1979). A subseptal organ was described in birds and the name was suggested in place of the term subfornical organ due to lack of evidence that birds have a fornix (Legait and Legait, 1958). The subseptal organ has a finger-like projection into the dorsal region of the third ventricle and has a dense terminal field of GnRH-1 fibers (Figure 9.2; Walsh and Kuenzel, 1997) as well as a rostral and caudal extension along midline that continues following the caudal end of the OVLT as described previously. In mammals, the SFO is highly vascular and is an extremely sensitive brain site for the induction of water intake by angiotensin II (Miselis et al., 1979) due to the presence of angiotensin receptors in that organ (Mendelsohn et al., 1983). Similarly, the subseptal organ in birds is sensitive to angiotensin II (Takei, 1977; Massi et al., 1986) and has angiotensin II receptor subtypes in its structure (Schäfer et al., 1996).

9.2.5.1.6 Functional Considerations for the Septum

The septum has major connections with the hippocampus, amygdala, diencephalon, and brainstem. Functions attributed to this brain subpallial region include ingestive, defensive, and reproductive behaviors that are fundamental to sustainability of vertebrate species (Swanson, 2000). With respect to inputs from the hippocampus, food caching has been associated with the septum. Specifically, black-capped chickadees are known to display food-storing behavior, a seasonally related activity. A significant increase in septal as well as hippocampal volume occurred during the time of year storing behavior was at its peak (Shiflett et al., 2002). Another seasonal activity displayed by birds is reproductive behavior that usually occurs in the spring when day length increases. The septum plays a major role in courtship and aggressive behavior in a variety of avian species (Ramirez et al., 1988; Goodson, 1998; Goodson and Adkins-Regan, 1999; Panzica et al., 2001). Lesions of the septal region produced a facilitation of male courtship behavior and vocalization in ring doves (Cooper and Erickson, 1976) and facilitated both overt aggression and the number of simple, multipurpose songs in territorial field sparrows (Goodson et al., 1999). When brain sections are immunostained for arginine vasotocin (AVT), the lateral septum of male Japanese quail shows significantly greater immunostaining of AVT fibers when compared with females (Panzica et al., 2001). Similarly, AVT and galanin fibers in male chickens (Jurkevich et al., 1997; Klein et al., 2006) display increased density within the lateral septum. During both courtship and mating behavior between roosters and hens as well as agonistic behavior between two males, significantly greater amounts of Fos protein produced by the immediate early gene *c-fos* occurred in the lateral septum of males (Xie et al., 2010). Increased expression of the gene *c-fos* in neurons is a marker of activation of those cells.

The majority of neurons, GnRH-1 neurons, responsible for development and function of the gonads occur in the septum of birds (Kuenzel and Golden, 2006). It has been hypothesized for a number of years that activation of GnRH-1 neurons is thought to occur by neurons called encephalic photoreceptors that can sense photoperiod (Follett and Davies, 1975; Silver et al., 1988; Kuenzel,

1993; Sharp and Ciccone, 2005). The location of neurons serving as encephalic photoreceptors remains controversial. One possible site, as previously discussed, is in the LSO (Li and Kuenzel, 2008; Li et al., 2009). A second site is the mediobasal hypothalamus, where either neurons associated with thyroid hormone metabolism/opsin five (Yoshimura et al., 2003; Yasuo et al., 2003; Ono et al., 2009; Nakane et al., 2010) or neurons containing melatonin, dopamine, and melanopsin serve as the encephalic photoreceptors (Thayananuphat et al., 2007; Kang et al., 2007; El Halawani et al., 2009). Another candidate site is in and around the paraventricular nucleus, where neurons containing vertebrate ancient opsin occur (Halford et al., 2009).

Hodological studies in birds involving the septum have shown that not only is there a descending neuroendocrine system affecting hypothalamic function but also ascending pathways from key diencephalic structures back to the septum, suggesting that the downstream motor pathways have a number of feedback loops (Berk and Butler, 1981; Berk and Finkelstein, 1983; Atoji and Wild, 2004; Montagnese et al., 2004, 2008). Several hypothalamic structures with direct connections to the septum have been shown in previous studies to be involved with food intake and the regulation of the autonomic nervous system. The reciprocal connections of the septum to hypothalamic structures as well as the presence of the subseptal organ at the floor of the septum, shown to contain angiotensin II receptors, provides evidence that the septum is involved in the regulation of food and water intake, respectively. Indeed, there exists structural and functional evidence that the septum possesses a descending neuroendocrine and integration system involved with basic social and ingestive behaviors and functions.

9.3 COMPONENTS OF THE AUTONOMIC NERVOUS SYSTEM

The basic components of the ANS, including efferent pre- and postganglionic neuronal configurations of the sympathetic nervous system (SNS) and parasympathetic nervous system (PNS), neurotransmitters, receptors, and specific sites in the brain and spinal cord where preganglionic neurons originate can be found in the previous chapter addressing the avian ANS (Kuenzel, 2000). In addition, there are excellent reviews on this subject (Akester, 1979; Bubien-Waluszewska, 1981; Yasuda, 2002). This section includes solely the overall function and central structural components of the ANS in order to show sites where connectivity from subpallial structures occurs to affect the regulation of the ANS. Overall, the ANS is responsible for motor functions and secretions that occur automatically on a daily, seasonal, and annual basis. It involves the integration of sensory information such that smooth muscle, cardiac muscle, and secretory cells located in visceral organs provide the appropriate output to maintain homeostasis of bodily functions, such as heart and respiratory rate, blood pressure, osmotic and pH balance, body temperature particularly in homoiotherms, gastrointestinal movements, reproductive processes, circadian rhythms, and other essential circannual rhythmic functions. To regulate the output, two antagonistic systems are in place—the sympathetic and parasympathetic arms of the ANS.

9.3.1 Sympathetic Nervous System

Similar to mammals, a chain of ganglia exists on both sides of the vertebral column in the thoracolumbar region of the spinal cord of birds. A marked difference, however, exists in avian species. Most of the vertebrae are fused; therefore, it requires experience to dissect the entire spinal cord, spinal nerves, and ganglia associated with each segment of the spinal cord. More than one system of numbering the spinal nerves and ganglia exist due to the variable number of vertebrae among various avian species, as well as different methods that either number the spinal segments and nerves sequentially beginning with the cervical region and ending with the last coccygeal vertebra (Dubbeldam, 1993; Yasuda, 2002) or number the vertebrae, spinal segments, and their associated spinal nerves, dorsal root ganglia, and the chain of autonomic ganglia to a regional group of vertebrae (Nickel et al., 1977; Landmesser, 1978). The regional terms cervical, thoracic, lumbar, and sacral (or synsacral and coccygeal) nerves (and ganglia) have been used, but the transitional zones may be problematic to ascribe a ganglion or spinal nerve to the appropriate region when the synsacral bone is dissected to reveal the caudal spinal cord (Dubbeldam, 1993). Therefore, documentation with images is most helpful, particularly when referencing a specific segment, ganglion, or spinal nerve in a study.

Within each segment of the thoracolumbar region of the spinal cord is a nucleus that identifies the central nervous system origin of the SNS. The intermediomedial nucleus, previously termed the column of Terni, contains the preganglionic motor neurons of the SNS. The nucleus is located at midline of a cross-section of spinal cord, directly dorsal to the central canal (see Figure 9.5 in Kuenzel, 2000). The axonal processes of the neurons move laterally a short distance and innervate one of the autonomic ganglia. A major neurotransmitter released is acetylcholine (ACh), which binds to nicotinic receptors present on postganglionic neurons. The long postganglionic axons project to specific visceral organs and release primarily the neurotransmitter norepinephrine, which binds to subtypes of alpha- or beta-adrenergic receptors.

An autonomic ganglionated nerve unique to birds is Remak's nerve. It appears at the end of the duodenum, running parallel to the intestinal tract and ending at the cloaca. Remak's nerve plays a role in the regulation of gut motility

(Hodgkiss, 1984a,b). Microinjections into individual nerves within ganglia of Remak's nerve revealed four distinct morphological types of neurons. The function of each neuronal type remains unknown (Lunam and Smith, 1996).

9.3.2 Parasympathetic Nervous System

The PNS has a system divided into two sets of preganglionic neurons, one originating in the brain and a second set located in the sacral region of the spinal cord. Preganglionic neurons in the brain are found in motor nuclei of the oculomotor (III), facial (VII), glossopharyngeal (IX), and vagus (X) nerves (Akester, 1979; Dubbeldam, 1993). The cranial nerve that has a major impact on a diverse number of visceral organs regarding parasympathetic regulation of function is the vagus. Those in the sacral region have processes that form a pelvic plexus. In contrast to the SNS, the preganglionic neurons of the PNS project long processes to specific ganglia located within or adjacent to visceral organs or tissues. Similar to the SNS, the preganglionic neurons secrete the neurotransmitter ACh. Nicotinic receptors on postganglionic neurons bind ACh and, in turn, the major neurotransmitter released from postganglionic neurons is ACh, which binds to muscarinic receptors found within the targeted visceral organ.

9.4 FUNCTIONAL NEURAL PATHWAYS INVOLVING THE SUBPALLIUM AND ANS

Two behaviors exhibited by birds that are important to the survival of their species and their welfare are reproductive and ingestive behavior. Each of them to be expressed depends upon structures found in the subpallium and autonomic nervous system. This section attempts to show how each of the behaviors requires the subpallial, autonomic nervous, and neuroendocrine systems in order to regulate the essential ethophysiological processes required on a daily and/or seasonal basis.

9.4.1 Regulation of the Reproductive System

The proper function of the reproductive system depends upon an unusual developmental process. Unlike most neurons that develop and differentiate within the brain, gonadotropin-releasing hormone neurons type 1 (GnRH-1) originate outside of the brain and migrate into the developing organ. It was originally discovered in amphibians (Muske and Moore, 1988) and detailed data showed that GnRH-1 neurons in mammals migrate from the olfactory to preoptic and hypothalamic brain regions (Schwanzel-Fukuda and Pfaff, 1989; Wray et al., 1989). Similar data have been obtained for the embryonic chick (Murakami et al., 1991; Norgren and Lehman, 1991). It has been confirmed that the olfactory placode, outside of the brain, serves as the origin of GnRH-1 neurons in the chick (Figure 9.8(A)) and GnRH-1 precursors are specified through a mutual antagonism between retinoic acid and fibroblast growth factor (FGF), where FGF induces specification of GnRH-1 neurons (Sabado et al., 2012). Once inside of the brain in the olfactory region, the neurons migrate caudally toward the preoptic and hypothalamic area. In contrast to mammals, where the majority of GnRH-1 neurons take up residence in the preoptic area and anterior hypothalamus, including a population in the arcuate nucleus within the caudal mediobasal hypothalamus (Silverman et al., 1994), in the chick brain the majority of GnRH-1 neurons (73%) settle in the septal region of the subpallium (Kuenzel and Golden, 2006). A major group of GnRH-1 neurons occur surrounding the bed nucleus of the pallial commissure, currently renamed the nucleus of the hippocampal commissure (NHpC; Figure 9.8(B,C)). Indeed, developmental biologists have reported that within the septal region, a medium strip of the septum on either side of midline from the dorsal region down to the NHpC, called the septohippocampal septum, appears to have pallial-type neurons rather than the expected striatal and pallidal types using histogenic cell markers (Puelles et al., 2007; Abellán et al., 2010). The migrating GnRH-1 neurons from the pallial, olfactory bulb region could account for some of the pallial neurons found in this part of the septum (see Section 9.2.5).

The GnRH-1 neurons found in the septal and preoptic regions comprise the primary neuroendocrine system responsible for development and maintenance of the reproductive system and influence gender-specific reproductive behavior. A major portion of the neurons form a large terminal field in the median eminence, and their secretions stimulate the anterior pituitary gland to secrete luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In turn, the gonadotropins (LH and FSH) transported to the gonads cause the release of testosterone from the testes or estrogens from the ovaries.

In addition to the major population of GnRH-1 neurons that reside in the septal division of subpallium, another subpallial component, the extended amygdala, likewise impacts reproductive function. The medial extended amygdaloid complex (see Section 9.2.3 for more details) includes the medial bed nucleus of the stria terminalis (BSTM). The BSTM is sexually dimorphic, shown to be larger in males, is steroid-responsive and affects copulatory behavior in birds (Kiss et al., 1987; Voorhuis et al., 1988; Panzica et al., 1998; Viglietti-Panzica et al., 1992; Aste et al., 1998; Jurkevich et al., 1999). A subnucleus of the BSTM in chickens, the BSTM2 (ventromedial BSTM), functions in rooster appetitive sexual behavior (Xie et al., 2010, 2011). Importantly, vasotocin neurons in the BSTM project to the medial preoptic nucleus (Absil et al., 2002b). The medial preoptic nucleus (POM), similar to the BSTM, is sexually dimorphic (Viglietti-Panzica et al., 1986; Adkins-Regan and Watson, 1990). In male quail, the caudal POM was shown to be associated with consummatory sexual behavior, whereas the rostral area affected appetitive sexual behavior (Balthazart et al., 1998a; Balthazart and Ball, 2007).

A study in Japanese quail has included the mapping of an entire reproductive pathway from the POM down to the primary muscle in the cloaca responsible for the production of foam and transfer of semen from the cloaca of the male to that of the female during copulatory behavior (Wild and Balthazart, 2013). The pathway includes a projection from the POM to the intercollicular complex (ICo; Wild and Balthazart, 2013). Within the ICo was found a distinct, elongated nucleus, the dorsomedial nucleus (DM). The DM was shown to project to the caudal brainstem nucleus, called the nucleus retroambigualis (RAm; Wild et al., 1997; Wild and Balthazart, 2013). Anterograde tracing from the RAm showed a continuous projection from that caudal brainstem nucleus through the entire length of the spinal cord to the sacral region of spinal cord. The motor neurons in the ventral horn at that spinal cord level innervate the large cloacal sphincter muscle (mSC; Wild and Balthazart, 2013). The cloacal sphincter muscle has been shown responsible for the production of foam, which is transferred along with semen to the female during copulation to enhance male fertilization (Seiwert and Adkins-Regan, 1998).

Another pathway involving the autonomic nervous system has also been proposed, affecting avian reproductive function as well as dominance and defensive behavior. The key structure involved is the ICo, including a second structure enclosed within the ICo, the DM (described in the previous paragraph; Wild and Balthazart, 2013). An intriguing, earlier proposal was that the dorsomedial part of the ICo and the central gray (GCt) of avian species were comparable to the mammalian periaqueductal gray (PAG; Dubbeldam and den Boer-Visser, 2002). Of interest is that the mammalian PAG has been shown to be part of an emotional motor system (Holstege, 1992). The PAG concept of Dubbeldam and den Boer-Visser (2002) has been expanded and supported by additional data. It has been proposed that the elongated avian ICo containing the enclosed DM plus the dorsolateral nucleus (DL) that joins the GCt are equivalent to the mammalian PAG (Kingsbury et al., 2011). Within the elongated ICo and GCt of birds are distinct parts related to reproduction, particularly copulation and others related to dominance and defensive behavior. The GCt in birds has been shown to project to neurons in the column of Terni (the intermediomedial nucleus, pars commissurae dorsalis) that houses the preganglionic neurons of the sympathetic nervous system (Breazile and Hartwig, 1989). Therefore, the revived avian PAG concept (Kingsbury et al., 2011) provides a fertile ground for additional studies to refine and characterize this very interesting midbrain structure.

In summary, the septum, medial bed nucleus of the stria terminalis, medial preoptic nucleus, and their known connectivity with the neuroendocrine and autonomic nervous systems result in coordinated neural and endocrine hormonal output to help regulate this complex reproductive function of birds.

9.4.2 Regulation of Food Intake

Significant progress has been made in the neural regulation of food intake in mammals. A similar neural system appears to exist in avian species as well. A major signaling molecule, leptin, produced in adipose tissue was shown to play a major role in regulating body weight of mammals (Friedman and Halaas, 1998). The concentration of leptin found in the blood was shown to be proportional to the extent of adipose stores located in the periphery. Leptin appeared to be a metabolic signal that directly affected neural circuits in the central nervous system, particularly in the hypothalamus, that regulated food intake and energy homeostasis. A group of neuropeptides and receptors were found in the hypothalamus of mammals that played a key role in regulating appetite as well as energy expenditure in order to maintain body weight (Woods et al., 1998; Berthoud, 2002). Of interest is that some of the genes responsible for producing those critical neuropeptides and their receptors have been cloned in birds, suggesting strongly that the neural system is evolutionarily conserved.

A selected list of neuropeptides that have been shown to affect food intake and/or energy expenditure in birds is found in Table 9.1. Curiously, some of the peptides had different effects on feeding behavior in birds compared to mammals (indicated by footnotes). Even though the genes producing

TABLE 9.1 Neuropeptides Injected Centrally and Their Effect on Food Intake in Birds[1]

Orexigenic	No Effect	Anorexigenic

[3]*In mammals, the peptides increase food intake.*

leptin receptors have been cloned and sequenced in chickens and turkeys (Horev et al., 2000; Ohkubo et al., 2000; Richards and Poch, 2003; Liu et al., 2007), a controversy exists regarding the published sequence of its actual ligand. The consensus is that the leptin-like gene has yet to be cloned for any avian species. Regardless, there exists compelling evidence that an avian-like leptin molecule exists. A leptin gene has been cloned in amphibians; even though it has low amino acid sequence homology to mammalian leptin, a common feature among known leptin proteins is a highly conserved tertiary structure (Crespi and Denver, 2006). Administration of recombinant chicken or mammalian leptin proteins to birds reduced food intake, similar to leptin's effect in rats (Denbow et al., 2000; Lohmus et al., 2003; Dridi et al., 2005). Importantly, immunization against leptin in chickens resulted in increased food intake (Shi et al., 2006).

Key neuropeptides that have been identified in mammals for regulating feeding behavior and energy expenditure (Woods et al., 1998) have likewise been shown to play equivalent roles in birds. Figure 9.9 is a working model regulating food intake in avian species. The model is adapted from current data and concepts developed in mammals. Note that the schematic diagram, two transverse sections of chick brain (Figure 9.9), should be viewed as two parts. Figure 9.9(A) (left side of the brain) shows activity of the paraventricular nucleus (PVN), lateral hypothalamic area (LHy), infundibular nucleus (IN), and SNS when leptin-like signals in the blood are high. The right side of the brain (Figure 9.9(B)) shows activity of the PVN, LHy, IN, and PNS when plasma leptin-like signals are low. The following gives data supporting the concept that in mammals and birds high leptin-like signals (Figure 9.9(A), left side) result in decreased food intake and increased energy expenditure, whereas low leptin-like signals (Figure 9.9(B), right side) increase food intake and reduce energy expenditure.

Specifically, neuropeptide Y (NPY) has been shown to be one of the most potent orexigenic neuropeptides (Kuenzel et al., 1987). One of its locations in the diencephalon is the inferior hypothalamic (IH) and infundibular nucleus (Kuenzel and McMurtry, 1988; Walsh and Kuenzel, 1997); the latter nucleus is considered homologous to the arcuate nucleus, the major hypothalamic nucleus in mammals containing NPY neurons (Schwartz et al., 2000). Additionally, a melanocortin system comprising agouti-related peptide (AgRP) and α-melanocyte-stimulating hormone (α-MSH, a product of pro-opiomelanocortin [POMC] gene) are two other key peptides found within neurons of the mammalian arcuate nucleus regulating food intake (Woods et al., 1998; Cone, 1999; Schwartz et al., 2000). The melanocortin system has likewise been shown to occur in the infundibular nucleus of birds (Phillips-Singh et al., 2003). Similar to mammals, neurons in the avian infundibular nucleus co-expressed NPY and AgRP mRNA, and both NPY and AgRP mRNA were significantly increased by fasting (Boswell et al., 2002; Phillips-Singh et al., 2003). Importantly, AgRP administered centrally in birds increases food intake (Kawakami et al., 2000; Tachibana et al., 2001; Strader et al., 2003), whereas α-MSH inhibits feeding (Kawakami et al., 2000; Tachibana et al., 2001; refer to Table 9.1), similar to what has been found in mammals.

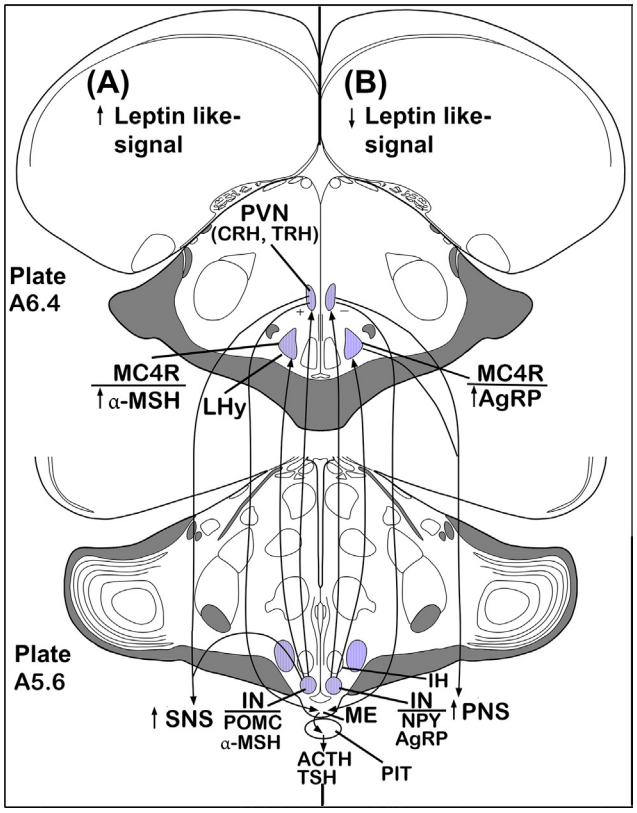

FIGURE 9.9 Two transverse sections of chick brain showing key hypothalamic structures regulating food intake and energy expenditure. (A) Left side of brain sections show activity of three hypothalamic structures, the infundibular (IN), lateral hypothalamic (LHy) and paraventricular (PVN) nuclei, when blood levels of leptin-like signals are high. Specific neurons found in the IN (homologous to the arcuate nucleus of mammals) containing pro-opiomelanocortin (POMC) and α-melanocyte stimulating hormone (α-MSH) are activated. The neurons in turn stimulate paraventricular (PVN) neurons containing corticotropin-releasing hormone (CRH) and thyroid-releasing hormone (TRH) to release their respective neuropeptides into the median eminence (ME). The peptides are transported to the anterior pituitary (PIT), causing the release of the hormones adrenocorticotropic hormone (ACTH) and thyroid-stimulating hormone (TSH) into the vasculature, effecting increased peripheral levels of corticosterone and thyroid hormones. The sympathetic nervous system (SNS) is activated. The increased α-MSH released into the LHy enable the peptide to effectively bind to melanocortin 4 receptors (MC4R). The overall effect is decreased food intake. (B) The right side of brain sections shows the effects of low levels of blood leptin-like signals. Neuropeptide Y (NPY) and agouti-related peptide (AgRP) containing neurons in the IN are activated that stimulate food intake. Additionally, they inhibit activity of CRH- and TRH-containing neurons in the PVN. The AgRP outcompetes α-MSH for MC4R binding sites in the LHy, thereby blocking α-MSH from inhibiting food intake. Additionally, the parasympathetic nervous system (PNS) is activated contributing to an enhanced food intake and decreased energy expenditure.

One additional component of the melanocortin system that is essential for the actions or signaling of its two key peptides, AgRP and α-MSH, is the identification of their respective receptors. In mammals, the main melanocortin receptor involved is the melanocortin 4 receptor (MC4R; Forbes et al., 2001). Two peptides, α-MSH and AgRP, compete for the same MC4R located on neurons in the lateral hypothalamic area. The peptide α-MSH is an agonist for the MC4R, whereas AgRP serves as an antagonist. When excess α-MSH is produced, the peptide out competes AgRP for binding sites, resulting in decreased food intake and increased catabolism. In contrast, excess AgRP will result in blocking available sites of the MC4R, resulting in elevated food intake and decreased energy expenditure (Cone, 2005). Importantly, birds likewise express the MC4R, which appears to be the key receptor regulating feeding behavior and energy balance based upon the use of an MC4R antagonist and a nonselective MC3-/MC4R agonist in ring doves (Strader et al., 2003). In chickens, the major melanocortin receptor type present in the brain implicated in the regulation of feeding is the MC4R (Takeuchi and Takahashi, 1998, 1999). The working model in birds (Figure 9.9) suggests that the regulation of food intake and energy expenditure in the two classes of vertebrates has similarities. Note, however, that it is a highly simplified model and requires experimental documentation, particularly for identification of the avian leptin-like molecule.

9.4.2.1 An Autonomic Pathway Regulating Food Intake and Energy Balance

The hypothalamic model regulating food intake and energy balance (Figure 9.9) no longer has a structure, the ventromedial hypothalamic nucleus (VMN)—previously termed the "satiety center" in publications for at least 60 years because lesions to that structure resulted in hyperphagia and obesity (Hetherington and Ranson, 1940). The arcuate nucleus has replaced it due to its sets of neuropeptide-containing neurons that either stimulate or inhibit feeding depending upon signals from peripheral organs, particularly lipid stores. In the rat as well as the chick brain, the VMN is positioned just anterior to the IN (arcuate nucleus) in the rostral-caudal plane. The VMN electrolytic lesions placed in experimental animal brains in past publications were large and most likely encroached upon the arcuate nucleus.

The model (Figure 9.9) has retained two neural structures, specifically the paraventricular nucleus and lateral hypothalamic area, which have been in feeding models over the past 50 years. In mammals, both show connectivity to the autonomic nervous system. The PVN projects to the central gray (GCt) and then to the intermediolateral (IML) cell column, where the preganglionic neurons of the SNS originate (Luiten et al., 1987). The PVN as well as the LHy project descending neuronal axons to the nucleus tractus solitarius (nTS) and to the dorsal motor nucleus of the vagus, which are key nuclei of the PNS (Luiten et al., 1987). Hence, a change in activity of SNS compared to the PNS, which are antagonistic, has significant effects on energy expenditure and therefore significantly impacts feeding behavior and homeostatic mechanisms regulating body weight. An energy sensor, adenosine monophosphate-activated protein kinase (AMPK), which is recognized as an important enzyme of a kinase-signaling cascade at the cellular level, stimulates energy-producing (catabolic) pathways (Hardie, 2004). The end result of AMPK activation is the stimulation of NPY/AgRP hypothalamic neurons, resulting in increased food intake and decreased energy expenditure. Coupled with AMPK is another type of sensor, a serine–threonine kinase called mammalian target of rapamycin (mTOR), which has the opposite effect of AMPK. When activated, the mTOR kinase pathway results in the stimulation of POMC-expressing neurons, causing the release of α-MSH and the subsequent reduction in food intake and an increase in energy expenditure (Cota et al., 2006). Utilizing antibodies to mTOR showed that this protein was found in both the PVN and arcuate nucleus with high abundance in arcuate NPY/AgRP neurons (Cota et al., 2006). An excellent review of possible mechanisms regulating appetite and energy expenditure in chickens, which incorporates AMPK and TOR signaling in a model that includes hypothalamic neurons impacting body weight, can be found in Richards and Proszkowiec-Weglarz (2007).

9.4.2.2 Poikilostasis or Shifts in Homeostasis: An Autonomic Hypothesis that May Explain the Regulation of Annual Cycles of Birds (and Perhaps a Consequence of Genetic Selection for Rapid Growth in Broilers and Turkeys)

In the last edition of *Sturkie's Avian Physiology*, the hypothesis of poikilostasis was introduced (Kuenzel, 2000). It was based upon the peptide distribution (Kuenzel and Blähser, 1994) and gene expression (Kuenzel et al., 1997) of the neuropeptide VIP mapped throughout the chick brain and a hypothesis related to a possible neural system regulating the annual cycle of domestic as well as wild avian species (Kuenzel and Blähser, 1993). The unique VIP distribution identified an avian circumventricular organ, the lateral septal organ, subpallial structures, and central components of the autonomic nervous system—a majority of which were previously grouped together and proposed to function as a visceral forebrain system in mammals (van der Kooy et al., 1984). The mammalian visceral forebrain system comprised the medial and lateral prefrontal cortex, paraventricular, arcuate, and posterolateral hypothalamic nuclei, bed nucleus of the stria terminalis, central nucleus of the amygdala, and nucleus tractus solitarius. It was hypothesized that the system influenced autonomic functions and

could override brainstem homeostatic mechanisms during periods of stress or emotional activity (van der Kooy et al., 1984). The poikilostasis hypothesis remains a viable one that perhaps can help explain the annual cycle of migratory birds, as well as the behavior and physiology of the modern broiler and turkey, which have been largely selected for growth rate and feed conversion.

Migratory birds, particularly those in temperate zones that migrate north each spring, need to shift from an anabolic state where rapid body weight gains are essential in order to deposit the necessary fat reserves to make the demanding migratory journey to the breeding grounds. Thereafter, a shift to a catabolic state occurs as birds enter a new phase of their annual cycle. Birds become territorial in order to attract and find a mate during the breeding season. The physiological and behavioral processes required for successful reproduction and the raising of young are metabolically demanding. Thereafter, birds undergo a major molt that continues their catabolic state, resulting in the utilization of considerable lipid reserves. A shift to an anabolic state then follows, resulting in increased food intake to prepare birds for a rigorous return migratory flight to the wintering grounds. Due to the marked changes in metabolic states that birds undergo, coupled with short time periods for each particular phase of their annual cycles, birds would unlikely be able to complete their seasonal life history requirements if set points for energy homeostasis were fixed throughout the year. Hence, shifts in homeostasis (poikilostasis) would allow the parasympathetic nervous system to dominate when anabolic processes were critical for rapid body weight gains; conversely, a shift to greater activity of the sympathetic arm of the ANS could occur when energy demands were high and sustained. The hypothesis of poikilostasis suggests that there exists in birds, and perhaps other vertebrate species, the capacity for dynamic shifts in the balance or set points of the ANS in order to successfully complete their annual cycles. The recent molecular models involving neural pathways, energy sensors, and the ability to integrate nutrient and hormonal signaling at the level of the hypothalamus may provide key markers for testing the validity of this hypothesis by focusing upon signals and processes associated with shifts in the balance of the ANS.

With the continued use of genetic selection programs in broilers as well as turkeys for increased growth rate and better feed conversion, the result has been a modern bird showing a high efficiency for the conversion of feed to a quality meat product. A cost, however, for managers of broiler and turkey breeders has been a feed restriction program that requires careful monitoring throughout the life span of birds in order to ensure that parent stock remain healthy and continue to produce an acceptable rate of fertilized eggs (Richards et al., 2010). Data over many years have shown that broilers compared to layers display increased food intake, less overall activity, and a lower basal metabolic rate. Data suggest an imbalance of the ANS, pointing to a physiological system with high parasympathetic and low sympathetic activity in meat-type birds. Due to the current advances in the understanding of the neural regulation of food intake, metabolic signals, energy homeostasis, and genes involved (Richards and Proszkowiec-Weglarz, 2007; Byerly et al., 2009; Yuan et al., 2009), the time may be appropriate to include an examination of genes affecting the ANS in order to develop an objective PNS/SNS ratio indicative of an effective balance between acceptable growth rate, lifetime welfare, and sustained reproductive output for birds selected as parent stock.

9.5 SUMMARY AND CONCLUSIONS

This chapter examined neural structures and functions that comprise five distinct regions in the subpallium of the avian forebrain (Figure 9.1), as well as the basic components of the ANS. Noteworthy is the evidence that the regions are evolutionarily conserved among vertebrates. Therefore, data obtained in mammalian species can be utilized to help discover the function of systems that have not been examined extensively in birds. Subpallial structures and regions are important as several have been shown to have connectivity to pallial (cortical-like) brain regions as well as to key hypothalamic and brainstem structures that are part of the neuroendocrine and autonomic nervous systems. Importantly, the latter two systems involve the production of hormones that can affect the physiology and behavior of organisms for hours, days, and even weeks—indicating processes regulating seasonal activities of birds.

Some of the functions associated with subpallial and ANS components include the neural regulation of feeding, reproductive, voluntary muscle, agonistic, and stress behaviors. Additional functions associated with the subpallium and ANS include reward, memory, and learning. It is hoped that the review will stimulate further reading and examination of the neural systems discussed as well as help suggest future experiments that can advance the understanding of the avian central nervous system, its neural pathways, and functions among various wild and domestic avian species.

Chapter 10

Blood

Colin G. Scanes
Department of Biological Sciences, University of Wisconsin, Milwaukee, WI, USA

10.1 INTRODUCTION

Blood consists of the following components:

- Plasma
- Formed elements, all containing nuclei
  - Erythrocytes
  - Leukocytes
  - Thrombocytes

Blood is critically important to the physiology of birds. The functions of blood include the following:

- Transportation of respiratory gases (oxygen and carbon dioxide), electrolytes, nutrients (e.g., glucose, amino acids, fatty acids), metabolites (e.g., lactate), waste compounds, hormones (from endocrine cell to target organ or tissue), heat, as well as some pathogens and toxicants are also transported via the blood stream
- Protection via antibodies, leukocytes, and thrombocytes
- Water and electrolyte homeostasis
- Clotting in the event of injury of blood vessels

Blood is more viscous than water, with the viscosity of chicken blood being 3.1 times greater than the viscosity of water; the viscosity of blood from domestic ducks and geese is 4.2 times greater than the viscosity of water (Sturkie, 1986). Moreover, the viscosity avian plasma is approximately 1.4 times greater than the viscosity of water (calculated from Sturkie, 1986 for chickens, ostriches, domestic ducks, and geese).

10.2 PLASMA

Table 10.1 summarizes mean concentrations of the constituents of plasma in birds. The osmotic pressure of avian plasma comes from the following (Peltonen and Sankari, 2011):

- Electrolytes: 95% (see Table 10.1)
- Glucose, amino acids, urea, and other organic molecules: 5%
- Proteins: 0.5% of colloid osmotic pressure

The circulating concentrations of electrolytes vary with physiological state. Venous plasma concentrations of sodium and plasma osmolarity are elevated by either dehydration or hyperthermia in chickens (Arad et al., 1983). Hyperthermia also results in elevated concentrations of chloride ions, blood urea nitrogen, and uric acid in chickens (Arad et al., 1983).

10.2.1 Circulating Electrolytes

The electrolytes are maintained within strict limits in view of their critical role in blood osmotic pressure and polarization/depolarization of nerve and muscle cells. The mean circulating concentrations of electrolytes such as sodium, potassium, calcium, and chloride across a large number of avian species are the summarized in Table 10.1 (additional materials can be found on the companion website http://booksite.elsevier.com/9780124071605/). There are shifts of the circulating concentrations of electrolytes with physiological state. For instance, acute heat stress is followed by decreases in plasma concentrations of sodium and potassium ions (chickens: Borges et al., 2004). Moreover, plasma concentrations of sodium are reduced with fasting and the concomitant reductions in metabolism (chickens: Christensen et al., 2012). There are differences in venous plasma concentrations of sodium and chloride between migratory and nonmigratory species of passeriform birds (Heatley et al., 2013).

Circulating concentrations of bicarbonate change with pCO_2 (see Section 10.4). For instance, there are decreases in plasma concentrations of bicarbonate ions due to panting associated with acute heat stress (chickens: Borges et al., 2004) and the hyperventilation with exercise (chickens: Gleeson and Brackenbury, 1984). Differences have been reported for venous plasma concentrations of bicarbonate between migratory and nonmigratory species of passeriform birds (Heatley et al., 2013).

10.2.2 Circulating Nutrients and Other Small Organic Molecules

The mean circulating concentrations of glucose, uric acid, and urea across a large number of avian species are summarized in Table 10.1.

10.2.2.1 Plasma Concentrations of Glucose

The plasma concentrations of glucose are more than double those in mammals (Table 10.1). Plasma concentrations of glucose are relatively refractory to physiological changes such as insulin administration or fasting. Plasma concentrations of lactate are increased in exercising birds, for example, increasing from 2.1 to 8.4 mM in chickens on a treadmill (Gleeson and Brackenbury, 1984).

10.2.2.2 Uric Acid and Urea

Nitrogenous waste is carried in the circulation in birds as both uric acid and urea. Plasma concentrations of uric acid and urea in birds are summarized in Table 10.1. It is widely assumed that the circulating concentrations of uric acid and urea are very similar in birds (Sturkie, 1986). However, this is only the case when expressed as mg/dL, not on a millimolar (mmol/L) basis. Circulating concentrations of nitrogenous waste are influenced by physiological state. For example, heat stress reduces circulating concentrations of urate (chickens: Lin et al., 2006).

TABLE 10.1 Mean Circulating Concentrations of Constituents in Avian Plasma

Parameter	Plasma Concentration
Protein (g/L) (100 species)	39.6 ± 0.74
Albumin (g/L) (63 species)	15.9 ± 0.55
Globulin (g/L) (55 species)	18.8 ± 0.96
Glucose (mM or mmol/L) (139 species)	15.4 ± 0.32
Sodium (mEquiv/L) (47 species)	152.5 ± 1.13
Chloride (mEquiv/L) (43 species)	112.6 ± 1.28
Calcium (mEquiv/L) (49 species)	2.56 ± 0.10
Potassium (mEquiv/L) (46 species)	3.21 ± 0.19
Uric acid (mM or mmol/L) (60 species)	0.50 ± 0.04
Blood urea nitrogen (mM or mmol/L) (43 species)	1.11 ± 0.09

For details of circulating concentration of serum/plasma constituents in individual avian species see Table 1 in the companion website (http://booksite.elsevier.com/9780124071605/).

10.2.2.3 Circulating Antioxidants

Antioxidants have a protective role, reducing damage from free radicals and the immune related respiratory burst. The major antioxidant in the plasma is uric acid with vitamin E and four carotenoids also being antioxidants. There are changes in circulating antioxidant capacity with stress and diet (Cohen et al., 2007, 2009).

10.2.3 Plasma Proteins

The mean circulating concentrations of protein, albumin, and globulin across a large number of avian species are summarized in Table 10.1. Table 10.2 summarizes the concentrations of prealbumin, albumin, α-globulin, β-globulin, and γ-globulin in representative avian species.

The colloidal osmotic pressure due to plasma proteins is much lower that exerted by electrolytes and small organic molecules, such as glucose, and is lower than that in mammals (Peltonen and Sankari, 2011). Based on electrophoretic analysis, the major proteins in serum are the following:

- Prealbumin (with thyroid hormone binding capacity and also known as transthyretin)
- Albumin (binding fatty acids, lipophilic hormones, etc.)
- Globulins (α, β, and γ)

In the avian embryo, the major embryonic plasma protein is α-fetoprotein. This α-fetoprotein binds metals. The α-fetoprotein has been isolated from chick embryo serum

TABLE 10.2 Concentrations of Plasma Proteins in Chickens and Wild Birds

Species	Prealbumin	Albumin	α-Globulin	β-Globulin	γ-Globulin	Reference
Black-fronted piping-guan (*Aburria jacutinga*)	3.4	27.3	4.8	6.8	1.5	Motta et al., 2013
Chicken[1]	Not reported but identified	15 17	4 8	8 12	15 9	Hasegawa et al., 2002 Peltonen and Sankari, 2011
St Vincent parrot (*Amazona guildingii*)	6	17.4	2.5	4.6	3.0	Deem et al., 2008
Red grouse (*Lagopus lagopus scoticus*)	1.7	19.7	17.9			Wilson and Wilson, 1978

[1]*Broiler breeder adults.*
Source: Peltonen and Sankari (2011).

but does not appear to bind steroid hormones, unlike its mammalian counterpart (Ido and Matsuno, 1982).

10.2.3.1 Extracellular Fluid Protein

Based on studies with suction blister fluids, the concentrations of proteins in extracellular fluids are about half those in plasma (Peltonen and Sankari, 2011).

10.2.3.2 Albumin

Albumin is synthesized in the liver (chicken: Fujii et al., 1996). The functions of albumin include providing a colloidal osmotic effect and facilitating transport of nutrients and lipophilic hormones. For instance, albumin binds to, transports, and distributes lipids, including fatty acids. In the presence of albumin, there is increased uptake of saturated fatty acids, such as palmitate, by chick embryo cardiac cells (Paris et al., 1978).

There are some changes in the plasma concentration of albumin with physiological state. For instance, induction of early molt by reduced photoperiod and feed withdrawal for 48 h results in reductions in albumin concentrations in the plasma but increases in globulin (chickens: Gildersleeve et al., 1983). There are marked diurnal rhythms of plasma concentrations of albumin (chickens: Gildersleeve et al., 1983). Moreover, plasma concentrations of albumin are decreased in laying females (Morgan, 1975).

10.2.3.3 Globulins

There are multiple proteins in the globulin grouping. Broadly, globulins can be divided into three categories based on electrophoretic mobility:

- Alpha globulins
  - α_1-globulins, including apolipoprotein A-I, which binds lipids (chicken: Roman et al., 2009) containing transcortin (discussed below) and retinol binding protein
  - α_2-globulins, including angiotensinogen (precursor for angiotensin I and II) and ceruloplasmin
- Beta-globulins (including plasminogen)
  - β_1-globulins
  - β_2-globulins, including transferrin in mammals but not in birds
- Gamma-globulin fraction, which is reported to contain transferrin in at least some birds (Torres-Medina et al., 1971) and the immunoglobulins (Ig), IgA, IgM, and IgY (equivalent to IgG in mammals).

Globulin concentrations are influenced by physiological state. For instance, induction of early molting, by reduced photoperiod and feed withdrawal, is accompanied by increases in plasma concentrations of total globulin (chickens: Gildersleeve et al., 1983). Serum concentrations of α_1-globulin decline during growth in male chickens (Peltonen and Sankari, 2011).

10.2.3.4 Specific Transporter Proteins

10.2.3.4.1 Ceruloplasmin

The principal circulating transporter protein that binds copper ions is ceruloplasmin. This glycoprotein is produced by the liver. Avian ceruloplasmin has been purified and partially characterized (chicken: Disilvestro and Harris, 1985; Calabrese et al., 1988; goose: Hilewicz-Grabska et al., 1988). Chicken ceruloplasmin binds five atoms of copper per molecule (Calabrese et al., 1988).

Plasma concentrations of ceruloplasmin are influenced by physiological and nutritional status. Copper status influences circulating concentrations of ceruloplasmin; these being depressed by copper deficiency (chicken: Baumgartner et al., 1978; Kaya et al., 2006) and elevated by dietary copper supplementation (chicken: Koh et al., 1996). Plasma concentrations of ceruloplasmin are also elevated acutely following injection of *Escherichia coli* endotoxin (chicken: Curtis and Butler, 1980; Lin et al., 2006) and by glucocorticoids (chicken: Lin et al., 2004). Circulating concentrations of ceruloplasmin are depressed in birds receiving dietary supplementation with 5-aminolevulinic acid, a precursor for porphyrin and then heme (chicken: Sato et al., 2012).

10.2.3.4.2 Insulin-Like Growth Factor Binding Proteins

Insulin-like growth factor 1 (IGF1) is transported in the plasma, predominantly bound to insulin-like growth factor binding proteins (IGFBPs). There are at least five IGFBPs in birds:

- IGFBP 1 (chicken: NCBI Reference Sequence: NM_001001294.1; turkey: NCBI Reference Sequence: XM_003204673.1; zebra finch (*Taeniopygia guttata*): NCBI Reference Sequence: XM_002192038.2)
- IGFBP 2 (chicken: GenBank: AJ544105.1; zebra finch (*Taeniopygia guttata*): NCBI Reference Sequence: XM_002191294.2) (Schoen et al., 1994)
- IGFBP 3 (chicken: NCBI Reference Sequence: NM_001101034.1)
- IGFBP 4 (chicken NCBI Reference Sequence: NM_204353.1)
- IGFBP 5 (chicken NCBI Reference Sequence: XM_422069.3).

10.2.3.4.3 Retinol-Binding Protein

Vitamin A is transported bound to retinol-binding protein (RBP), which can complex with prealbumin (chicken: Abe et al., 1975). Avian RBP has been purified and its crystal structure characterized (Zanotti et al., 2001). Transthyretin

also binds RBP (Eguchi et al., 2008). Synthesis of retinol binding protein by the liver is inhibited *in vivo* by vitamin E in the feed or *in vitro* by α-tocopherol in the incubation media (chicken: Zhou et al., 2012).

10.2.3.4.4 Transferrin

Transferrin transports iron (two molecules of iron for each molecule of transferrin) in the blood (reviewed in Lambert et al., 2005); in turn, at least some of the transferrin is bound to transferrin receptor. The circulating concentrations of iron are reported as ~2 μg/mL (chicken: Morgan, 1975; turkey: Huff et al., 2010). Iron that is bound to transferrin can be transferred to the other major iron binding protein, the yolk precursor phosvitin (Morgan, 1975).

The structure of avian transferrin has been reported (chicken: Guha Thakurta et al., 2003; Lambert et al., 2005). In addition to transporting iron, transferrin facilitates the uptake of ferrous iron during development of erythrocytes (chick embryo blood cells: van Bockxmeer and Morgan, 1982). Transferrin also binds a circulating enzyme, butyrylcholinesterase (chicken: Weitnauer et al., 1999).

Transferrin is synthesized by liver and secreted into the blood (chicken: Fujii et al., 1996). In birds, expression of the transferrin gene is restricted to the liver and oviduct (McKnight et al., 1980). The chicken transferrin receptor has been characterized based on the cDNA (chicken: Gerhardt et al., 1991). The transferrin receptor can induce programmed cell death or apoptosis (chicken: Ohno et al., 2008).

The circulating concentrations of transferrin and the transferrin receptor are reported as, respectively, 2.4 mg/mL (Morgan, 1975) and 1.2 μg/mL (chicken: Wiwanitkit et al., 2007). Plasma transferrin receptor concentrations reflect erythropoietic activity.

There are effects of physiology on circulating concentrations of transferrin. Circulating concentrations of transferrin are elevated by either estrogen or iron deficiency (chicken: McKnight et al., 1980). Hepatic expression of transferrin increased by estrogen and glucocorticoids (chicken: McKnight et al., 1980). Plasma concentrations of transferrin are also increased in chickens with a *Staphylococcus aureus* infection (Chamanza et al., 1999). Similarly, there is a strong tendency for plasma concentrations of transferrin receptor to be increased in birds infected with *Plasmodium gallinaceum*, the protozoan that causes malaria in poultry (chicken: Wiwanitkit et al., 2007).

10.2.3.4.5 Hormone Transport

Lipophilic hormones, including the steroid hormones, are transported in the plasma bound to proteins, including albumin and specific binding proteins. The rationale for lipophilic hormones having binding proteins in the circulation is to facilitate the distribution of the hormones throughout their target organ(s) (Richardson et al., 2005).

10.2.3.4.5.1 Sex Steroids Although a specific sex hormone-binding protein (SHBP) is found in amphibians, reptiles, and mammals, SHBP is missing from birds (Wingfield et al., 1984). This is confirmed in later reports (Breuner and Orchinik, 2009; Malisch and Breuner, 2010).

10.2.3.4.5.2 Thyroid Hormones Homologues of mammalian thyroxine-binding globulin are not present in birds (Schreiber and Richardson, 1997). Thyroid hormones bind to both albumin (Schreiber and Richardson, 1997) and transthyretin in birds as in all other vertebrate classes (Schreiber and Richardson, 1997; Richardson et al., 2005). Avian transthyretin has been purified as a 15 kDa protein (chicken: Eguchi et al., 2008). Transthyretin also binds retinol binding protein (Eguchi et al., 2008).

10.2.3.4.5.3 Corticosteroids Birds have a corticosteroid-binding globulin (CBG) or transcortin. This α_1-globulin binds and transports corticosterone in the plasma, for example, in the American kestrel (Whitman et al., 2011), chicken (Murakami, 1991), white crowned sparrow (Breuner and Orchinik, 2009), and zebra finch (Schmidt et al., 2010). CBG also binds cortisol, a major glucocorticoid in avian embryos (Schmidt et al., 2010). The concentration of CBG is decreased by stress, such as handling, in the American kestrel (Whitman et al., 2011).

10.2.3.5 Gamma Globulins

Gamma globulins include IgA, IgM, and IgY (equivalent to both IgE and IgG in mammals). In growing chickens, the concentrations of immunoglobulins are as follows (based on Klasing, 1998):

- Immunoglobulin A: 0.3 g/L
- Immunoglobulin M: 2.7 g/L
- Immunoglobulin Y: 5.5 g/L

The concentrations of IgY are reported to be markedly lower in laying hens (0.8 g/L) (adult female chickens: Cetin et al., 2010). This may be due to the transportation of circulating IgY into the yolk of the ovum.

10.2.3.6 Enzymes

There are multiple enzymes in the plasma of birds, including the following: alkaline phosphatase asparate aminotransferase, cholinesterase, creatine phosphotransferase, glutamic oxaloacetic transaminase (GOT), and lactic acid dehydrogenase (LDH). The activities of asparate aminotransferase and creatine phosphotransferase are most frequently determined in hematological studies.

The activity of enzymes is reported to be influenced by both physiology and the external environment. For instance, venous plasma alanine transaminase (SGPT or ALAT or SGPT) activity is elevated by either dehydration or hyperthermia (Arad

et al., 1983). Induction of early molt by reduced photoperiod and feed withdrawal for 48 h results in shifts in plasma components with reductions in glutamic pyruvic transaminase (GPT) and increases in alkaline phosphatase (Alk P), LDH, and GOT. Moreover, depressed plasma cholinesterase activity has been used as biomarker for exposure to organophosphates and carbamate and hence wildlife risk assessment. However, it is critically important to have baseline activity for the individual species of bird being investigated (Santos et al., 2012).

10.3 ERYTHROCYTES

Table 10.3 summarizes multiple erythrocyte characteristics including number, hematocrit, and erythrocyte size in wild birds and adult chicks.

10.3.1 Structure of the Erythrocyte

Avian erythrocytes are ovoid cells (Figure 10.1), with an average volume of 145 fL across multiple avian species with consistent sizes (see Table 10.3):

- Long diameter: approximately 12.5 µm
- Short diameter: 6.8 µm
- Thickness: 3.2 µm

The volume of erythrocytes declines during embryonic development from 170 fL at day 10 to 140 fL at day 18 (chicken: Tazawa et al., 2011). There is marked asymmetry, with a ratio of erythrocyte length to width of 1.7 µm in chickens and 1.8 µm across wild birds (Table 10.3).

There is a centrally located nucleus (long diameter approximately 6.5 µm, short diameter 2.8 µm). The avian erythrocyte differs from that in mammals by the presence of a nucleus and mitochondria and by being larger. The most abundant protein in erythrocytes is hemoglobin (Figure 10.1). Erythrocytes of wild birds contain more hemoglobin than those of chickens (Table 10.3). The nuclei of avian erythrocytes also contain hemoglobin (Davis, 1961). This is contiguous with cytoplasmic hemoglobin via pores in the nuclei membrane (Davis, 1961).

Microtubules stabilize the asymmetric structure of erythrocytes (Winckler and Solomon, 1991). These are composed of tubulin, with 95% of the tubulin from chicken erythrocytes being tubulin-βVI (Sharma et al., 2010). The erythrocyte anion transport protein (erythrocyte band 3) is the major transmembrane protein in the erythrocyte. It has two functions:

- An anchor for the intracellular cytoskeleton
- The key anion transporter exchanging bicarbonate (HCO_3^-) for chloride (Cl^-) ions

Another plasma membrane protein in the turkey erythrocyte is goblin, which is phosphorylated in the presence of β-adrenergic agonists (Alper et al., 1980). The fatty acid composition of the cell membrane of avian erythrocytes is modified by fatty acids in the diet (e.g., cockatiel; Heinze et al., 2012).

TABLE 10.3 Characteristics of Erythrocytes in Wild Birds (Excluding Poultry Species) and Chickens

Parameter	Wild Birds (Mean)	Chickens[1] (Mean)
Erythrocytes (10^6/µL)	3.33 (164 species)	3.2
Packed cell volume/ hematocrit (%)	44.0 (158 species)	44.0
Hemoglobin (%)	14.5 (134 species)	10.1
Erythrocyte volume (fL)	149.4 (81 species)	149.4
Erythrocyte length (µm)	12.5 (364 species)	12.2
Erythrocyte width (µm)	6.8 (362 species)	7.1
Ratio of erythrocyte length to width	1.844 (362 species)	1.718
Erythrocyte cross-sectional area[2] (µm²)	68.3 (362 species)	68.0
Erythrocyte hemoglobin (fg)	50.8 (23 species)	32

10.3.2 Erythrocyte Chromatin and Transcription

Chicken erythrocytes exhibit transcription (e.g., enolase; Toll-like receptors 3, 9, and 21; myxovirus resistance 1; Morera et al., 2011). Chromatin structure is critical in the control of DNA replication, repair, and transcription. It is reasonable to conclude that the chromatin is in a decondensed state (Morera et al., 2011). The 30 nm fiber is the first hierarchical level of chromatin folding, allowing transcription and access by regulatory factors but not DNA replication in chicken erythrocytes (Scheffer et al., 2011). There are also strong associations between linker histones and chromatin in chicken erythrocyte nuclei (Koutzamani et al., 2002).

The ratio of RNA to hemoglobin decreases rapidly in a linear manner, from approximately 240 µg per mg on day 3 to 35 µg per mg on day 6 (chicken: Baumann et al., 2003). Subsequently, the ratio of RNA to hemoglobin declines at a much slower rate, to less than 10 µg per mg at day 17 (chicken: Baumann et al., 2003). There are large reductions in the erythrocyte adenosine triphosphate (ATP) content, decreasing from a molar ratio of RNA to Hb from 6.8 (day 3) to 0.5 (day 17) (chicken: Baumann et al., 2003).

(B) Structure of avian erythrocyte showing cytoskeleton maintaining shape of the cell and supporting the nucleus. Marginal band of microtubules (blue) and membrane cytoskeleton (shown as cross-hatch) maintaining shape of the cell. Intermediate filaments (purple) support the nucleus. *(Based on Joseph-Silverstein and Cohen (1984); also see http://hermes.mbl.edu/BiologicalBulletin/MMER/COH/CohFig1.html (accessed 23.07.13.).)* (C) Electron microscopy of chicken bone marrow cells showing developing erythrocytes with electron dense hemoglobin (bar 5 μm). *Reproduced from Shini et al. (2008), with permission from Elsevier.*

10.3.3 Metabolism of Erythrocytes

Surprisingly, metabolism and expression of metabolic enzymes in avian erythrocyte has received relatively little attention. It has been assumed that glucose is the major substrate for energy needs of the erythrocyte. However, glucose fails to maintain erythrocyte ATP *in vitro* (chicken: Mathew et al., 1993). This is not unexpected in view of the very low active transport of glucose into avian erythrocytes. In contrast, glutamine was effective in maintaining erythrocyte ATP *in vitro* (chicken: Mathew et al., 1993). There is evidence that the avian erythrocyte employs the citric acid cycle based on older literature (chicken: Dajani and Orten, 1958). Moreover, chicken erythrocytes can use glycine as a substrate (Dajani and Orten, 1959). However, there was no detectable activity of TCA cycle enzymes in the pigeon erythrocyte (Kalomenopoulou and Beis, 1990). Metabolic enzyme activities (including hexokinase, phosphofructokinase, and pyruvate kinase) have been reported in pigeon erythrocytes (Kalomenopoulou and Beis, 1990). High activities for the following enzymes have been reported for erythrocytes from the little penguin (*Eudyptula minor*): triphosphate isomerase, lactate dehydrogenase, glyceraldehyde phosphate dehydrogenase, and phosphoglycerate kinase (Nicol et al., 1988). In the little penguin (*E. minor*) erythrocytes, about half of the glucose is metabolized to lactate (Nicol et al., 1988). There is a need to see studies on the

expression and its control of key metabolic genes by avian erythrocytes.

Erythrocytes have a high concentration of ATP in early embryonic development (e.g., 15 mmoles per liter at day 3 of incubation; chicken: Baumann et al., 2003). Erythrocytes from chick embryos also have significant levels of CTP and UTP (chicken: Baumann et al., 2003). In addition, erythrocytes from chick embryos contain another high energy compound, 2,3-bisphosphoglycerate (2,3-BPG) (chicken: Baumann et al., 2003). *In vitro*, ATP concentrations are depressed by hypoxia in erythrocytes from 10 day embryos (chicken: Baumann et al., 2003).

10.3.4 Number of Erythrocytes and Packed Cell Volume (Hematocrit)

Table 10.3 summarizes mean the packed cell volume (hematocrit) and erythrocyte concentrations across multiple avian species and a comparison with earlier data in chickens. Across avian species, hematocrit is reported to be inversely proportional to $\log_{10}$ body weight; declining from 52% on average in birds at 10 g to 40% in birds at 1 kg (Bishop and Butler, 1995). When erythrocytes are removed, the hematocrit declines as the plasma volume is more rapidly restored. Following removal of 30% of the blood, there is an almost immediate decrease in hematocrit and erythrocyte concentration (Japanese quail: Schindler et al., 1987).

When oxygen partial pressure is low, there is an increase in erythrocyte concentrations and hematocrit. For instance, hypoxia increases hematocrit (chickens and Japanese quail: Rosse and Waldmann, 1966). Similarly, following removal of 30% of the blood and the immediate decrease in erythrocyte concentration, there is then a rapid recovery with 72 h (Japanese quail: Schindler et al., 1987). Indicative of the acceleration of erythropoiesis, there are increases in the proportion of immature red blood cells, namely reticulocytes, in the blood and bone marrow (Japanese quail: Gildersleeve et al., 1985a,b; Schindler et al., 1987).

There are marked increases in the concentration of erythrocytes during embryonic development (chicken: Tazawa et al., 2011). These changes are illustrated in Figure 10.2. As might be expected, the concentration of erythrocytes is increased in response to high altitude (e.g., turkey embryos: Bagley et al., 1990). Similarly and not unexpectedly, hematocrit is reduced with copper deficiency (chicken: Baumgartner et al., 1978). In chickens, there appears to be a sex difference in hematocrit and erythrocyte number between breeding males and females (Table 10.4), perhaps due to the high concentrations of yolk precursors in the plasma of sexually adult females and/or direct effects of estrogens and/or androgens.

There are also decreases in erythrocyte concentrations caused by some toxicants, such as after *in ovo* administration of 1-(2-chlorophenyl)-1-(4-chlorophenyl)-2,2,2-trichloroethane

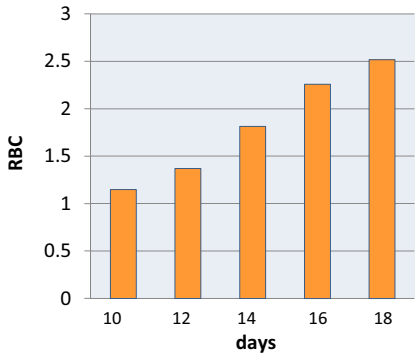

FIGURE 10.2 **Changes in erythrocyte numbers (10^6 per µL) during embryonic development of the chicken.** *Data from Tazawa et al. (2011).*

TABLE 10.4 Comparison of Erythrocyte Concentrations and Hematocrit in Male and Female Adult Chickens

Species	Erythrocyte Concentration (10^6/µL)	Hematocrit (%)
Male	3.6	42.9
Female	2.8	29.2

Source: Calculated from data summarized in Sturkie (1986).

o,p'-DDT (Japanese quail: Bryan et al., 1989). Chemicals such as acetophenylhydrazine and the organophosphorus pesticide foschlor reduce the circulating concentration of erythrocyte, thereby inducing anemia in birds (chickens: Coll and Ingram, 1978; Japanese quail: Gromysz-Kałkowska et al., 1985). Moreover, petroleum oil decreases packed cell volume (mallard ducks: Lee et al., 2012). In a meta-analysis of data from 37,000 broiler chickens, mycotoxin was demonstrated to depress hematocrit (Andretta et al., 2012).

10.3.5 Production of Erythrocytes

Avian erythrocytes are produced in the bone marrow. *In vitro*, embryonic marrow cells have been demonstrated as capable of developing into erythrocytes (e.g., Japanese quail: Brandon et al., 2000). The avian erythrocyte series can be summarized as follows (based on Williams, 1972):

1. Erythroblasts (cell proliferation) → Polychromatic erythroblasts (reduce cell volume with hemoglobin synthesis initiated)
2. Polychromatic erythroblasts → Reticulocytes (with further reduced cell volume but with hemoglobin synthesis)
3. Reticulocytes → mature erythrocytes (asymmetric elongated)

During the morphogenesis of mature erythrocytes, microtubules play a critical role in the development of the elongated

asymmetric shape (Winckler and Solomon, 1991). Thus, more rounded cells in the circulation represent immature erythrocytes/reticulocytes.

10.3.5.1 Erythropoietin

Evidence for an avian erythropoietin comes from the ability of chicken plasma to stimulate heme accumulation in chicken erythroid cells *in vitro*, with plasma from anemic chickens being more effective (Coll and Ingram, 1978). Moreover, *in vivo* the rate of erythropoiesis changes in a manner consistent with control by erythropoietin, being increased in anemia (chicken: Rosse and Waldmann, 1966) and depressed by polycythemia (Japanese quail: Rosse and Waldmann, 1966). During development of bone air sacs in the bones of posthatching pigeons, there are decreases in hemopoietic bone marrow as a percentage of body weight and increased distribution in the ulna, radius, femur, tibiotarsus, scapula, furcula, and the caudal vertebrae (Schepelmann, 1990).

Erythropoietin (EPO) acts by binding to the EPO receptor (EpoR). There is increased proliferation of avian erythroblasts with over-expression of EpoR (Mikulits et al., 2000). Moreover, iron repression of ferritin heavy chain (ferH) expression is prevented by overexpression of both EpoR and c-Kit, another cytokine growth factor receptor (Mikulits et al., 2000).

10.3.6 Lifespan of Erythrocytes

Despite having a nucleus, avian erythrocytes do not divide, failing to enter a new S phase (Williams, 1972). Bird erythrocytes have a very limited lifespan that is much less than in mammals (Brace and Atland, 1956; reviewed Beuchat and Chong, 1998), with all labeled cells disappearing in 42 days (ducks), 35 days (chickens, *Gallus gallus*) and 48 days (pigeons, *Columba livia*) (Rodman et al., 1957) and a mean survival time of 34 days in the (Japanese quail *Coturnix coturnix*: Nirmallan and Robinson, 1973).

The mean lifespan (± the standard error of mean) for four species of avian erythrocytes was calculated as 39.7 ± 3.3 days. In contrast, the longevity of mammalian erythrocytes is longer: 85.6 ± 10.5 days for 11 species (calculated from Röhme, 1981).

10.3.7 Hemoglobin

Hemoglobin binds to oxygen at the lungs and releases oxygen at the tissues. Avian hemoglobin has been purified (chicken: Matsuda and Takae, 1963), crystallized, and characterized, including x-ray analysis (e.g., bar-headed goose: greylag goose: Liang et al., 2001; ostrich: Sundaresan et al., 2009). As with mammals, hemoglobin is a tetrameric protein with four protein subunits, each attached to a ferrous iron-containing heme unit. The molecular basis of the greater oxygen affinity and a lower Bohr effect of early embryonic hemoglobin has been established (Chapman et al., 1980). ATP and other nucleotides are the major determinants of oxygen saturation (chicken: Baumann et al., 2003).

There are multiple forms of avian hemoglobin, with six forms in the chicken (four embryonic and two adult):

- Embryo major forms:
  - Hb P with π α globin and ϱ β
  - Hb P′
- Embryo minor forms:
  - Hb M α^D globin
  - Hb E α^A globin
- Adult major form: Hb A α^A globin
- Adult minor form: Hb D α^D globin

In the chicken, the relative contribution of two major embryonic hemoglobins peaks at 4 days of embryonic development and then decreases gradually. They are no longer detectable from 15 days. The two minor ones increase up to 6–7 days and then decrease, but they are still present in the blood at hatching (Cirotto et al., 1975). The shifts in composition of α-globin in hemoglobin in chick embryo blood are summarized in Figure 10.3.

The binding of oxygen to hemoglobin is markedly affected by organic phosphates in the avian erythrocyte. In most birds, it is thought that the major regulator is inositol pentaphosphate; however, in ostriches there is evidence that inositol tetrakisphosphate (inositol-P_4) plays a critical role (Sundaresan et al., 2009). Inositol hexakisphosphate (inositol-P_6) decreases the affinity of chicken or pigeon hemoglobin for oxygen (Vandecasserie et al., 1971). Similarly, inositol-P_5 lowers the oxygen affinity of hemoglobin (Isaacks et al., 1977).

Arteriovenous differences in the blood concentration of oxygen are constant in either resting or exercising birds, being independent of body mass (Bishop and Butler, 1995).

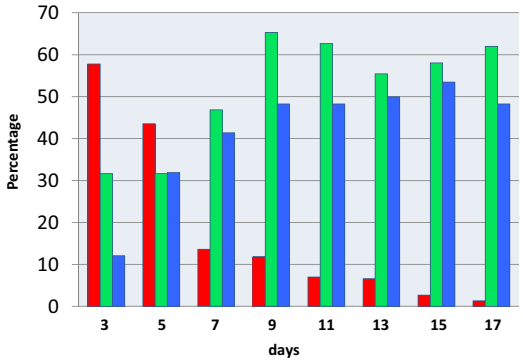

FIGURE 10.3 **Shifts in the proportion of α-globins during embryonic development of the chicken. Red: π-α-globin. Green: α-A-globin. Blue: α-D-globin.**

10.3.7.1 Hemoglobin Genes

In birds as in mammals, there are multiple hemoglobin genes: seven in the chicken (Reitman et al., 1993) and six in the zebra finch (Alev et al., 2009). These represent a small family of genes encoding α- and β-globins. The avian hemoglobin genes can be summarized as follows:

- Chicken π (Pi) α: homologous to duck π and orthologous to α1 in zebra finch
- Chicken αD: homologous to turkey, ostrich, and quail αD and orthologous to α2 in zebra finch
- Chicken αA: homologous to turkey, ostrich, and quail αA and orthologous to α3 in zebra finch
- Chicken ϱ (rho or P) β: possibly orthologous to β1 in zebra finch
- Chicken βH: possibly orthologous to β2 in zebra finch
- Chicken βA: homologous to turkey, duck, flamingo, condor, macaw, pigeon, and ostrich β major and orthologous to β3 in zebra finch
- Chicken β ε (epsilon or E): marked homologies to chicken ϱ

In adult zebra finches, hemoglobin consists of 74% α3 and 26% α2 and all β3 globin. In the embryo, hemoglobin consists of 28% α1, 55% α2, and 16% α3 and 44% β1, 33% β2, and 24% β3 (Alev et al., 2009).

The α-globin genes are located on chromosome 14 in the chicken. In embryonic erythrocytes, the region containing the multiple α-globin genes is located in a crown of DNA loops surrounding the nuclear matrix (Iarovaia et al., 2009).

10.3.7.2 Adaptations of Hemoglobin to Flight at High Altitudes

The structures of hemoglobin in birds that fly at high altitudes have increased affinity for oxygen (see Figure 10.4). For instance, there are subtle changes to the protein structure (single substitutions in α-globin) in both the bar-headed goose, a species that migrates across the Himalayas, and the Andean goose (Jessen et al., 1991). Similarly, the oxygen affinity of hemoglobin in driving birds, such as emperor penguins, is increased (Meir and Ponganis, 2009). This can be readily seen from the left shift in the O_2~Hb dissociation curve for the bar-headed goose and the emperor penguin compared with the domestic duck (and most other birds; see Figure 10.4).

10.3.7.3 Adaptations of Hemoglobin to Embryonic Development

There are marked changes in the affinity of hemoglobin for oxygen, with higher affinities earlier in development (see Figure 10.5). The molecular basis of the greater oxygen affinity and a lower Bohr effect of early embryonic hemoglobin has been established (Chapman et al., 1980).

10.3.7.4 Glycation of Hemoglobin

Despite elevated circulating concentrations of glucose, the percentage hemoglobin that is glycated is lower in most birds examined than in mammals (e.g., <2% in rooks (*Corvus frugilegus*) and mute swans (*Cygnus olor*) (Mikšik and Hodný, 1992; also reviewed in Beuchat and Chong, 1998). Even in hummingbirds, where plasma concentrations of glucose can be more than 40 mmol/L, glycated hemoglobin is within the mammalian range (3.5–5.0; Beuchat and Chong, 1998).

10.3.7.5 Hemoglobin and Nutrition

In birds, as might be expected considering their low iron availability, circulating concentrations of hemoglobin are reduced (Tako et al., 2010).

10.3.8 Carbonic Anhydrase

Carbonic anhydrase in erythrocytes catalyzes the reaction between carbon dioxide and water to yield carbonic acid.

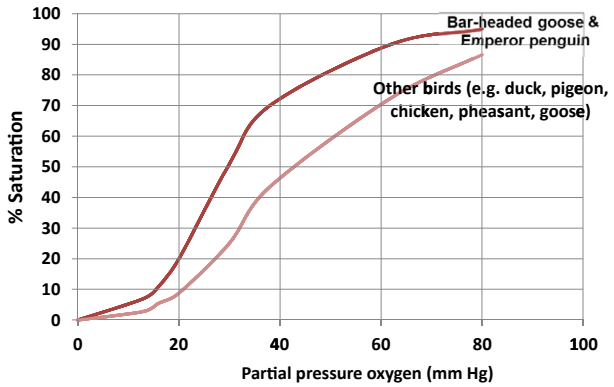

FIGURE 10.4 Oxygen dissociation curves for hemoglobin in avian erythrocytes. *Data calculated for pigeons, domestic ducks and geese, Mucovy ducks, chickens and red-necked pheasants from Christensen and Dill (1935) and for domestic goose, bar-headed geese, and emperor penguins from Meir and Ponganis (2009).*

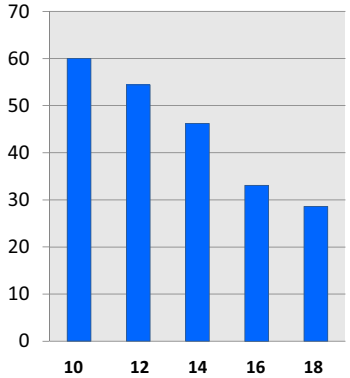

FIGURE 10.5 Changes in the oxygen affinity (p50) of chicken hemoglobin (*y*-axis) during the development (*x*-axis in days) of the chick embryo. *Data from Tazawa et al. (1976).*

This in turn forms bicarbonate (HCO_3^-) and protons (H^+) reversibly.

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+$$

Carbonic anhydrate (CA, EC 4.2.1.1) has been purified from avian erythrocytes (e.g., chicken: Bernstein and Schraer, 1972; ostrich: Ozensoy et al., 2005; pigeon: Ozensoy et al., 2011). Carbonic anhydrase activity is increased by β-adrenergic agonists based on studies with Japanese quail erythrocytes (Igbo et al., 1994). Moreover, hypoxia increases carbonic anhydrase activity in avian erythrocytes (Glombitza et al., 1996).

There are increases in the amount of carbonic anhydrase II (CAII) and the isoenzyme CAIII relative to hemoglobin as female chickens commences egg production (Nishita et al., 2011a,b). Ferrous iron increases the activity of carbonic anhydrase from avian erythrocytes (Wu et al., 2007).

10.3.9 Transporters

10.3.9.1 Anion Transporter

The key anion transporter exchanges bicarbonate (HCO_3^-) for chloride (Cl^-) ions. The transcripts for the anion transporter have been characterized in the chicken, with chicken erythroid cells expressing anion transport proteins (band 3) (Kim et al., 1988). The v-erbA oncogene suppresses expression of anion transport proteins (band 3) by chicken erythroid cells (Zenke et al., 1988).

10.3.9.2 Sodium and Potassium Transport

There is considerable movement of sodium and potassium across the erythrocyte plasma membrane. The flux of sodium ions across the plasma membrane of erythrocytes from turkeys is two- to three-fold that in humans (Palfrey and Greengard, 1981). The $Na^+/K^+/2Cl^-$ cotransporter in avian erythrocytes exhibits sensitivity to β-adrenergic agonists and to oxygen concentrations (reviewed in Gibson et al., 2000). Transport of potassium into chicken erythrocytes declines with age (Drew et al., 2002).

10.3.9.3 Glucose

Glucose entry into avian erythrocytes is low, being both nonsaturable and saturable carrier mediated; it can be inhibited by inhibited by cytochalasin (Simons, 1983a,b). The 3-0-methylglucose uptake by pigeon erythrocytes that can be inhibited by cytochalasin B is very low, as there are only about 200 copies of GLUT1 protein per erythrocyte (compared to 300,000 in humans) (Diamond and Carruthers, 1993). Chicken erythroblasts express two glucose transporters (GLUT), GLUT 1 and GLUT 3 (Mathew et al., 1994). During differentiation to erythrocytes, expression of GLUT 1 and GLUT 3 declines rapidly to very low levels (Mathew et al., 1994). Simple diffusion of monosaccharides is markedly greater in erythrocytes from chicken embryos than older birds (Ingermann et al., 1985).

10.3.9.4 Amino Acids and Urea

Amino acids are transported across the plasma membrane of the avian erythrocyte with, for instance, uptake by chicken erythrocytes of glycine, leucine, and lysine being sodium dependent (Somes et al., 1981; Lerner et al., 1984). Avian erythrocytes are reported to have little expression of urea transporter-B (Liu et al., 2011).

10.3.10 Hormonal Effects on Erythrocytes

Catecholamines enhance sodium transport via β-adrenergic receptors, activation of adenylate cyclase, and cyclic adenosine 3′,5′-monophosphate (cyclic 3′,5′-AMP) in turkey erythrocytes (Gardner et al., 1973; reviewed in Palfrey and Greengard, 1981). β-adrenergic agonists stimulate potassium influx into turkey erythrocytes (Furukawa et al., 1980).

There are at least three β- adrenergic receptors in the cell membrane of the avian erythrocyte—βtrunc, β3C, and β4C-receptors (turkey: Chen et al., 1994; Baker, 2010). The turkey has been used as a model for β-adrenergic receptors. These are functional, with β-adrenergic receptor agonists increasing adenylate cyclase activity (Stadel et al., 1982; Peters et al., 1984). Avian β-adrenergic receptors are desensitized by β-adrenergic receptor agonists and sensitized by β-adrenergic receptor antagonists due to structural changes (Stadel et al., 1982; Peters et al., 1984). Chick embryo erythrocytes have A2α adenosine receptors that also activate adenylate cyclase (Glombitza et al., 1996). There are progressive reductions in the erythrocyte responses to beta-adrenergic and A2 receptor agonists during embryonic development due to cGMP-inhibited phosphodiesterase 3 (Baumann et al., 1999).

There is also evidence for the effects of thyroid hormones on avian erythrocytes as erythrocytes from hypothyroid turkeys show lower sensitivity to β-adrenergic agonists (Furukawa et al., 1980).

10.3.11 Effect of Stressors

There are effects of stressors on the avian erythrocyte. For instance, exposure to crude oil is followed by degeneration of the erythrocyte mitochondria in herring gulls (*Larus argentatus*) and Atlantic puffins (*Fratercula arctica*) (Leighton, 1985). Avian erythrocytes exhibit marked increases in production of both hydrogen peroxide and superoxide *in vitro* in response to glucose or glucose 6-phosphate together with shifts in the oxygen dissociation curve for hemoglobin (Zhang et al., 2011). In contrast, the effects on either reactive oxygen species (ROS) or hemoglobin are not observed

with mammalian red blood cells (Zhang et al., 2011). Similarly, ROS are produced by mitochondria from avian erythrocytes, such as from quail or parrots (Montgomery et al., 2012). These effects may explain the shorter lifespan of avian erythrocytes.

10.3.12 Other Roles for the Avian Erythrocyte

It has been suggested that avian erythrocytes may have immune-like roles in addition to gas exchange (Morera et al., 2011).

10.4 BLOOD GASES

Table 10.5 summarizes arterial and venous pO_2, pCO_2, and pH in multiple species of resting birds. There is no change in arterial pO_2 during short-term flight (Butler et al., 1977), presumably due to the increased rate of respiration. Moreover, in chickens exercising on a treadmill, arterial pO_2 paradoxically increases (Gleeson and Brackenbury, 1984), again presumably due to increased respiration. The changes in venous pO_2 and pCO_2 during rapid growth and adult meat-type chickens are shown in Table 10.6. There is a decline in venous pO_2 during growth, presumably reflecting the requirements of metabolism.

Arterial pCO_2 is influenced by respiration, whereas venous pCO_2 reflects metabolism. For instance, pCO_2 is decreased in heat-stressed panting emus (Jones et al., 1983) and chickens running on a treadmill (Gleeson and Brackenbury, 1984). However, pCO_2 in venous plasma is increased during growth (Table 10.6) and reduced with fasting (young rapidly growing chickens: Christensen et al., 2012). These changes are presumed to reflect tissue metabolism.

10.5 LEUKOCYTES

There are five types of leukocytes: lymphocytes, heterophils (equivalent to neutrophils in mammals), basophils, eosinophils, and monocytes. Figure 10.6 shows the structure of avian leukocytes. Table 10.7 summarizes the concentrations of leukocytes and differential counts in both wild bird species and the domestic chicken. Klasing (1998) estimated that chickens produce 0.76 g leukocytes per kilogram per day. Leukocytes are found in the "buffy" layer when the hematocrit of avian blood is being determined.

10.5.1 Populations

Leukocyte numbers per unit volume of blood vary. Table 10.7 summarizes circulating concentrations of leukocytes in wild birds and chickens. Blood leukocyte concentrations and populations vary in birds, with a high ratio of heterophils to lymphocytes in *Accipitriformes* (63.1%:30.5%) and *Struthioniformes* (65.4%:26.0%) and low ratio in *Passeriformes* (19.6%:67.9%) (C.G. Scanes, unpublished observations).

A reciprocal relationship frequently exists between heterophil and lymphocyte concentrations. The stress hormone corticosterone increases heterophils and decreases lymphocytes in young chickens (see Figure 10.7; Gross and Siegel, 1983). This leads to large shifts in the heterophil/lymphocyte ratio (H/L) (Gross and Siegel, 1983). Similarly, stimulation of the adrenal cortical cells with adrenocorticotropic hormone is accompanied by changes in both increases in heterophils and decreases in lymphocytes in young chickens (Davison and Flack, 1981). There is a concomitant reduction in volume of heterophils with corticosterone administration in young chickens (Shini et al., 2008). The relationship between stress and leukocyte populations is further supported by the greater H/L ratio in injured Adélie penguins (Vleck et al., 2000); in young chickens exposed to stressors, such as atmospheric ammonia, intermittent electric shock (McFarlane and Curtis, 1989), and environmental heat stress (Borges et al., 2004); and in young turkeys after *E. coli* challenge together with transportation stress (Huff et al., 2008, 2010).

Marked changes in leukocyte populations have been reported in some birds in captivity, with an almost tripled proportion of heterophils with a concomitant decline in lymphocytes (Rufous-collared sparrows, *Zonotrichia capensis*: Ruiz et al., 2002). This may reflect an effect of stress.

There are also independent effects of environment on populations of different leukocytes. Circulating concentrations of leukocytes are depressed by 71.4% in blue-fronted Amazon parrots (*Amazona aestiva*) maintained in captivity compared to wild birds (Deem et al., 2005). This is due to decreases in both the percentage and number of heterophils (Deem et al., 2005). Although the percentage of lymphocytes is increased in blue-fronted Amazon parrots (*A. aestiva*) maintained in captivity, there is no change in the concentration (Deem et al., 2005). There are marked increases in total leukocyte numbers with botulism in black-faced spoonbills (*Platalea minor*; Chou et al., 2008). In a meta-analysis of studies on the effects of mycotoxins on chickens, Andretta et al. (2012) reported reductions in the concentrations of total leukocytes together with that of both heterophils and lymphocytes.

10.5.1.1 Number of Leukocytes

There are physiological shifts in both the total concentrations of leukocytes and in the relative proportion of heterophils and lymphocytes. Challenging chickens with the parasite *Plasmodium juxtanucleare* is accompanied by increases in the leukocyte concentration in the blood (Silveira et al., 2009).

Blood leukocyte populations are markedly influenced by stress. There are increases in heterophils and decreases in lymphocytes in young chickens receiving administration of exogenous corticosterone, the stress hormone (see Figure 10.7; Gross and Siegel, 1983). This leads to concomitant large shifts in the H/L ratio (Gross and Siegel, 1983). Similarly, stimulation of the adrenal cortical cells with adrenocorticotropic hormone is accompanied by changes in both increases in heterophils and decreases in lymphocytes in young chickens (Davison and Flack, 1981).

There is a concomitant reduction in volume of heterophils with corticosterone administration in young chickens (Shini et al., 2008). The relationship between stress and leukocyte populations is further supported by the greater H/L ratio in injured Adélie penguins (Vleck et al., 2000) and in young chickens exposed to stressors such as atmospheric ammonia, intermittent electric shock, environmental heat stress (McFarlane and Curtis, 1989) and lipopolysaccharide (LPS) (Shini et al., 2008). In response to intravenous cellulose microparticles, there are decreases in the percentage of heterophils and increases in eosinophils (chickens: Wang et al., 2003).

Changes in the leukocyte system were seen after poisoning with both chlorphenvinphos and foschlor, in the form of distinct neutrophilic leukocytosis and eosinopenia. A marked increase in the number of basophils was found after ingesting chlorphenvinphos, and a distinct increase in monocytes after ingesting both pesticides (Japanese quail: Gromysz-Kałkowska et al., 1985).

10.5.2 Heterophils

Heterophils are the major phagocytic leukocytes. They are presumed to be equivalent to the neutrophils in mammals.

10.5.2.1 Structure

Heterophils are the major polymorphonuclear leukocytes in birds (Figure 10.6). They have a diameter of 10–15 µm (Sturkie, 1986). Heterophils are weakly basophilic and pseudoeosinophic, staining brilliant red with Wright's stain (Sturkie, 1986). Electron microscopy studies of heterophils (duck and goose: Maxwell, 1973; chicken: Shini et al., 2008) reveal that avian heterophils have the following characteristics: The nuclei have two or three lobes. Mitochondria are sparse. There are two types of intracellular granules: dense and less dense small granules. The dense granules can be either oval or spherical, with diameters between 0.4 and 1.8 µm (ducks and geese: Maxwell, 1973).

Stressors, such as corticosterone or LPS, rapidly influence circulating heterophils; reducing cell size as indicated by cross-sectional area and increasing secretory granule diameter (chickens: Shini et al., 2008).

10.5.2.2 Function

Heterophils are the major phagocytic leukocytes in birds, with an analogous role to neutrophils in mammals (Figure 10.6; reviewed in Harmon, 1998). They are thought to have an important role in innate immune system, including mediating the acute inflammation response. Heterophils exhibit superior ability to monocytes, both to phagocytize and kill bacteria (chicken and turkey: Stabler et al., 1994).

Opsonization of bacteria enhances phagocytosis heterophils (Stabler et al., 1994). Heterophils release superoxide

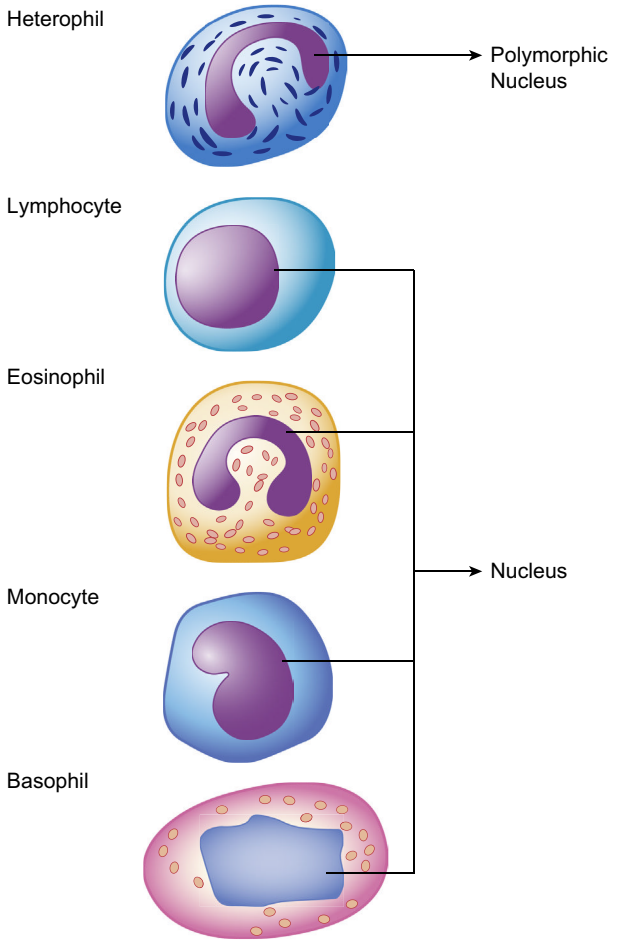

FIGURE 10.6 **Avian leukocytes.** (A) Schematic microscopic images of leukocytes.

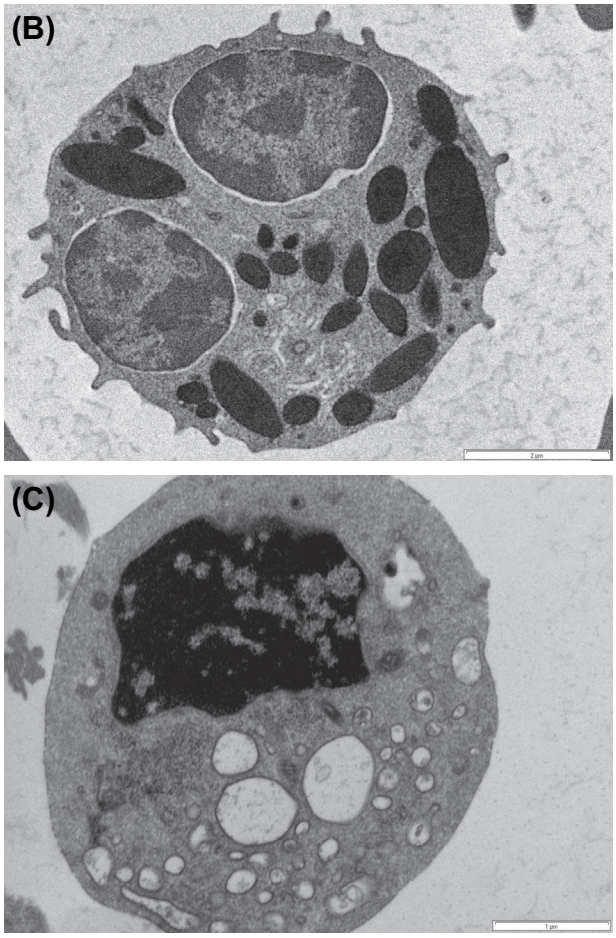

FIGURE 10.6—Cont'd, (B) Electron microscopy of heterophils from peripheral blood of chickens with large cytoplasmic granules (bar 2 µm). *(Reproduced from Shini et al. (2008), with permission from Elsevier.*

(chicken and turkey: Stabler et al., 1994). Chicken heterophils that are infected with bacteria, such as *Mycoplasma* gallisepticum, attract lymphocytes (Lam, 2002). Heterocytes have also been shown to phagocytize fungi, such as *Candida albicans* (ring doves (*Streptopelia risoria*); Terrón et al., 2003). The phagocytic activity of heterophils is increased following priming with interferon-gamma (chicken: Kogut et al., 2005). Interleukin-2 (IL-2) has marked effects on phagocytizing heterophils; increasing phagocytosis, bacteriocidal activity, and the expression of the inflammatory cytokine, IL-8 (chicken: Kogut et al., 2002, 2003). Avian heterocytes show decreases in phagocytic activity with age (ring doves (*S. risoria*): Terrón et al., 2004). Melatonin increases both phagocytic activity by heterophils and the percentage of ingested *C. albicans* killed while depressing superoxide anion levels (O_2^-; ring doves (*S. risoria*): Terrón et al., 2003). Aflatoxins decrease both the phagocytic and bactericidal activity of heterophils (chicken: Chang and Hamilton, 1979a).

Another aspect of the innate immune system are the granules in heterophils that contain β-defensins: gallinacins

TABLE 10.7 Mean Concentration of Thrombocytes and Leukocytes, Together with Differential Count, in Wild Birds (Excluding Poultry Species) and Chickens

Parameter	Wilds Birds (Mean)	Chicken (Mean)[1]
Thrombocytes (10^3/µL)	30.4 (14 species)	34.4
Leukocytes (10^3/µL)	16.1 (97 species)	25.5
Heterophils (%)	45.3 (80 species)	25.9
Lymphocytes (%)	45.5 (79 species)	57.6
Monocytes (%)	3.0 (77 species)	5.6
Eosinophils (%)	4.1 (77 species)	1.7
Basophils (%)	1.6 (77 species)	2.4

(Gal 1, Gal 1-α, and Gal 2), cathepsin, lysozyme, acid phosphatase, β-glucuronidase, and α-glucosidase (Harwig et al., 1994; also reviewed Harmon, 1998).

10.5.2.3 Number

Circulating concentrations of heterophils are increased by stresses (Figure 10.7) and by toxicants such as the herbicide paraquat (Japanese quail: Clark et al., 1988) and administration of organophosphate insecticides, either chlorphenvinphos or foschlor (Japanese quail: Gromysz-Kałkowska et al., 1985). Increases in the heterophil percentage have been also reported after removal of 30% of the blood volume (Japanese quail: Schindler et al., 1987). Chicken heterophils can be killed by some pathogens, such as *S. aureus* (Lowder et al., 2009).

10.5.2.4 Production

Heterophils are produced in the bone marrow. *In vitro*, embryonic marrow cells have been demonstrated to be capable of developing into heterophils (e.g., Japanese quail: Brandon et al., 2000).

10.5.3 Lymphocytes

Avian lymphocytes can be isolated using specific monoclonal antibodies, such as K55 monoclonal antibody, which binds chicken lymphocytes (Schmaier et al., 2011). There are B and T lymphocytes. T lymphocytes include the following (chicken: Gehad et al., 2002; Kushima et al., 2004):

- ($CD3^+$) T cells, T-helper cells ($CD4^+$)
- T-cytotoxic/suppressor cells ($CD8^+$)
- $CD3^+$ CD4- CD8- T cells

Chowdhury et al. (2005) reported that 17.5% of the lymphocytes in the blood of domestic turkeys are B lymphocytes, whereas 16% are $CD4^+$ and 16% are $CD8^+$.

10.5.3.1 Structure

Avian lymphocytes are weakly basophilic. Circulating avian lymphocytes have been characterized by electron microscopy studies (ducks and geese together with pigeons, turkeys, Japanese quail: Maxwell, 1974; also see Figure 10.6). The lymphocytes have a nonlobed nucleus with a high nuclear:cytoplasmic ratio.

Two types of lymphocytes have been reported in the circulation of birds: small and medium sized (Maxwell, 1974). In the small lymphocytes, the nuclei are pleomorphic in shape. The cytoplasm contains multiple mitochondria, Golgi apparatus, some endoplasmic reticulum, and a few granules. The small-sized lymphocytes have extensive pseudopodia. The medium-sized lymphocytes are oval with a spherical nucleus. They have relatively few intracellular organelles (mitochondria and endoplasmic reticulum) and a few pseudopodia.

There are shifts in ultrastructure with physiology. The stressor LPS rapidly reduces the cell size of circulating lymphocytes, as indicated by cell diameter or cross-sectional area (chickens: Shini et al., 2008).

10.5.3.2 Function

Lymphocytes play important roles in both humoral and cell mediate immunity. The IL-2 receptor alpha chain (CD25) is found on cell membranes of both $CD4^+$ and $CD8^+$ lymphocytes (chicken: Teng et al., 2006).

10.5.3.3 Number

Circulating concentrations of lymphocytes are decreased by stresses (as previously described for leukocyte populations) and toxicants, such as the herbicide paraquat (Clark et al., 1988).

10.5.4 Eosinophils

10.5.4.1 Structure

Avian eosinophils are oval granulocytes with considerable cytoplasm. The round granules stain red after the uptake of the stain or dye eosin. The nucleus has two lobes (i.e., bi-lobed) (Sturkie, 1986). Electron microscopy studies reveal that avian eosinophils have multiple dense granules (0.1–1.6 μm diameter) with crystalline cores (Maxwell and Siller, 1972).

10.5.4.2 Function

The function of avian eosinophils is not fully understood (Campbell, 1997; Campbell and Ellis, 2007).

10.5.4.3 Number

In a differential count, the percentage of eosinophils appears to be impacted by some stressors. Eosinophils are reported to be increased in some birds in captivity (Rufous-collared sparrows, *Z. capensis*: Ruiz et al., 2002). In contrast, the pesticides chlorphenvinphos and foschlor decrease eosinophil numbers (Japanese quail: Gromysz-Kałkowska et al., 1985).

10.5.5 Monocytes

10.5.5.1 Structure

Avian monocytes are oval cells with considerable cytoplasm. Electron microscopy reveals that avian monocytes have multiple small dense granules (0.1–1.6 μm diameter) with crystalline cores (Maxwell and Siller, 1972). They have kidney-shaped nuclei and extensive cytoplasm containing a well-developed Golgi apparatus, rough endoplasmic reticulum, microtubules, vesicles, and mitochondria (ducks and geese together with pigeons, turkeys, Japanese quail: Maxwell, 1974).

10.5.5.2 Function

The function of avian monocytes is not fully known. Monocytes produce nitric oxide (NO) in response to LPS challenge (chickens: Bowen et al., 2009) with, in turn, NO-inducing vasodilation. Expression of inducible NOS (iNOS) and hence the production of NO is stimulated by lipopolysaccharide in both monocytes and macrophages (chickens: Bowen et al., 2007).

The IL-2 receptor alpha chain (CD25) is found on cell membranes of monocytes (chicken: Teng et al., 2006). Chicken monocytes can exert a chemotaxic effect on heterophils and lymphocytes due to release of macrophage inflammatory protein (MIP)-1β (Lam, 2002). Opsonization of bacteria enhances phagocytosis by monocytes (Stabler et al., 1994). Aflatoxins decrease the phagocytic activity of monocytes (chicken: Chang and Hamilton, 1979b). The transformation of avian monocytes into very powerful phagocytic cells, the macrophage, is well documented (Grecchi et al., 1980).

10.5.5.3 Number

The effects of stress have been reported on monocytes as a percentage of total leukocytes, with increases after *E coli* challenge together with transportation stress (turkeys: Huff et al., 2010). Monocyte numbers are reduced initially after challenge with Gram-negative bacteria cell wall LPS, but then recover and increase (chickens: Gehad et al., 2002; Bowen et al., 2009). Pesticides, such as chlorphenvinphos and foschlor, increase monocyte numbers (Japanese quail: Gromysz-Kałkowska et al., 1985). In contrast, circulating concentrations of monocytes are decreased by the herbicide paraquat (Clark et al., 1988) and by the mycotoxicant aflatoxin (chicken: Chang and Hamilton, 1979b).

10.5.5.4 Production

Monocytes are produced in the bone marrow. *In vitro*, embryonic marrow cells have been reported as capable of developing into monocytes (e.g., Japanese quail: Brandon et al., 2000).

10.5.6 Basophils

10.5.6.1 Structure

The nuclei and cytoplasmic granules of basophils take up basic stains, such as hematoxylin, giving a pale purple appearance with a clear cytoplasm (Sturkie, 1986). The ultrastructure of avian basophils has been reported (ducks and geese: Maxwell, 1973). Basophils contain cytoplasmic granules (see Figure 10.6). These vary in diameter between 0.1 and 0.8 μm in ducks and geese and up to 1.0 μm in turkeys (Maxwell, 1973). The nuclei of basophils are reported as polymorphic (Sturkie, 1986) or nonlobulated (ducks and geese: Maxwell, 1973).

10.5.6.2 Function

The functions of avian basophils are not fully established.

10.5.6.3 Numbers

Parasites and toxicants influence basophil numbers. Challenging chickens with the parasite *P. juxtanucleare* is accompanied by increases in the basophil concentration in the blood (Silveira et al., 2009). The pesticide chlorphenvinphos increases basophil numbers (Japanese quail: Gromysz-Kałkowska et al., 1985).

10.6 THROMBOCYTES

Thrombocytes are the functional equivalent of platelets in mammals. Avian thrombocytes can be recognized by specific monoclonal antibodies for surface antigens (e.g., chicken: Horiuchi et al., 2004; guinea fowl: Bódi et al., 2009). Avian thrombocytes can be isolated using specific monoclonal antibodies such against chicken α_{2b} integrins 14 (Schmaier et al., 2011). Chicken thrombocytes express many of the genes specific for mammalian platelet formation (Schmaier et al., 2011). In view of their functions, some researchers suggest that thrombocytes should be considered as leukocytes (Seliger et al., 2012). Thrombocytes are found in the "buffy" layer when the hematocrit of avian blood is being determined.

10.6.1 Structure

Avian thrombocytes have the following characteristics (Japanese quail: Belleville et al., 1982):

- Cell diameter: 5.4 µm
- Nuclear diameter: 4.2 µm.

Avian thrombocytes can be confused with lymphocytes but are readily recognized by specific monoclonal antibodies for specific surface antigens (e.g., chicken: Horiuchi et al., 2004; guinea fowl: Bódi et al., 2009). The ultrastructure of the avian thrombocyte has been characterized (ducks, geese, pigeons, turkeys, Japanese quail: Maxwell, 1974). Avian thrombocytes have an irregular shape with multiple pseudopodia. Similarly, the nucleus is irregular in shape. There is more cytoplasm than is seen in small lymphocytes. There are multiple small mitochondria, an endoplasmic reticulum, prominent microtubules, and a few dense granules.

10.6.2 Function

Chicken thrombocytes, like mammalian platelets, release serotonin in response to either thrombin or collagen, but appear much less sensitive to bovine thrombin (Schmaier et al., 2011). Avian thrombocytes differ from mammalian platelets by their inability to form shear-resistant aggregates and their much lower levels of $\alpha(_2b)\beta_3$ integrin, a protein required for aggregate formation (Schmaier et al., 2011). Avian thrombocytes are activated by thrombin and adhere to fibrinogen as part of the process of blood clotting (Lacoste-Eleaume et al., 1994). Avian thrombocytes aggregate and induce hemostasis, a temporary stopping of blood flow (Grant and Zucker, 1973). Aggregation occurs in response to serotonin (Stiller et al., 1975). Avian thrombocytes differ from mammalian platelets by their inability to form shear-resistant aggregates and their much lower levels of $\alpha(_2b)\beta_3$ integrin, a protein required for aggregate formation (Schmaier et al., 2011).

There are avian homologs of the mammalian platelet proteins. For example, integrin GPIIb-IIIa is present on the surface of chicken thrombocytes (Lacoste-Eleaume et al., 1994).

Avian thrombocytes produce platelet-derived growth factor (PDGF). Expression of PDGF A and B-chain mRNA are, respectively, low and high in thrombocytes, but expression of both are increased further following exposure to type 1 collagen (Horiuchi et al., 2001, 2002). The PDGF is presumed to play a role in tissue repair. PDGF B-chain has been characterized from cDNA of the transcript from chicken thrombocytes (Horiuchi et al., 2002).

Avian thrombocytes, like mammalian platelets, release serotonin from intracellular granules in avian thrombocytes (Stiller et al., 1975). Serotonin is released in response to either thrombin or collagen but appear much less sensitive to bovine thrombin (chicken: Schmaier et al., 2011). The serotonin in turn induces vasoconstriction, aggregation of thrombocytes and blood clotting (Stiller et al., 1975; Lacoste-Eleaume et al., 1994; Chapman et al., 2008). Moreover, as with mammalian platelets, chicken thrombocytes release pro-inflammatory cytokines in response to lipopolysaccharide, a surrogate for pathogens. There are large increases in expression of IL-1β, IL-6, IL-8, and IL-12 together with interferon-α and cyclooxygenase in response to lipopolysaccharide, which is a surrogate for pathogens (Ferdous et al., 2008; Scott and Owens, 2008; St Paul et al., 2012). Toll-like receptors (TLR) recognize pathogens and are expressed by chicken thrombocytes. For example, TLR 2, 3, and 4, are expressed in response to lipopolysaccharide (St Paul et al., 2012).

Thrombocytes should also be considered as part of the innate immune system. For instance, avian thrombocytes are phagocytotic (Carlson et al., 1968) with bacteria but probably not protozoa (chicken: Chang and Hamilton, 1979c; DaMatta et al., 1998). Chicken thrombocytes have been reported exhibit increased phagocytosis in response to lipopolysaccharide (St Paul et al., 2012). Thrombocytes express the IgY Fc receptor (chicken: Viertlboeck et al., 2009). The IL-2 Receptor alpha chain (CD25) is found on cell membranes of thrombocytes, like monocytes, together with both $CD4^+$ and $CD8^+$ lymphocytes (chicken: Teng et al., 2006). There is increased release of nitrite from chicken thrombocytes in response to lipopolysaccharide and high expression of inducible nitric oxide synthase (St Paul et al., 2012).

10.6.3 Number

Table 10.7 summarizes thrombocyte concentrations in wild birds and poultry. The number of thrombocytes in the blood can be influenced by environmental factors. The circulating concentration of thrombocytes (thrombocytopenia) decreases with viral infection, such as by bursal disease virus in chickens (Lima et al., 2005). Moreover, there are marked changes in thrombocytes in chickens challenged with *P. juxtanucleare* to experimentally induce chicken malaria with infected and reduced numbers of thrombocytes (Silveira et al., 2009). Similarly, there are decreases in the number of thrombocytes following intravenous administration of cellulose microparticles (Wang et al., 2003). Thrombocyte numbers increase after challenge with LPS (chicken: Gehad et al., 2002). Pesticides can influence thrombocyte concentrations, being for instance increased by foschlor but decreased by chlorphenvinphos (Japanese quail: Gromysz-Kałkowska et al., 1985).

10.6.4 Production

Thrombocytes are produced from thromboblasts in the blood marrow. *In vitro*, embryonic marrow cells have been

demonstrated to be capable of developing into thrombocytes (e.g., Japanese quail: Brandon et al., 2000).

10.7 CLOTTING

Avian blood appears to clot more slowly than does mammalian blood (Japanese quail: Belleville et al., 1982). For instance, the whole blood clotting time is 38 min for Japanese quail compared 8 min for human blood (Belleville et al., 1982). Avian blood does not clot in responses to glass activation (Japanese quail: Belleville et al., 1982). Table 10.8 provides examples of clotting times in birds.

The overall scheme for clotting in birds is presumed to be the same as that in mammals (Figure 10.8). Fibrinogen is cleaved by the protease, thrombin, to fibrin, which then polymerized. Avian thrombin has been isolated (Japanese quail: Belleville et al., 1982). Prothrombin is activated to thrombin by a cascade of clotting factors.

10.8 AVIAN BLOOD MODELS

10.8.1 β-adrenergic Receptors

Erythrocytes from both turkeys and chickens have been employed as models for β-adrenergic receptor and adenylate cyclase for many years (turkey: Schramm et al., 1972; Bilezikian and Aurbach, 1973a,b; Oye and Sutherland, 1996). The fluxes of sodium ions across the plasma membrane of erythrocytes from turkeys is two- to three-fold that in humans (Palfrey and Greengard, 1981). Lines of chickens have been selected for high and low leucine uptake (Somes et al., 1981). These also have elevated glycine, lysine uptake, and the Na^+-K^+-ATPase activity

TABLE 10.8 Examples of Blood Coagulation Times

Test	Chicken[1,2]	Turkey[1]	Japanese Quail[3]	Hispaniolan Parrots (*Amazona ventralis*)[2]	Umbrella Cockatoos (*Cacatua alba*)[2]
Lee-White whole blood clotting (min)	52[1]	75	38	–	–
Capillary tube test (min)	78[1]	124	–	–	–
One-stage prothrombin test (sec)	15.9[1] (10.0[2])	16.9	10	10.0	10.0
Whole-blood thromboplastin test (sec)	16.9[1] (9.1[2])	19.5	(78[4])	10.3	–

[4]*Partial thromboplastin time.*

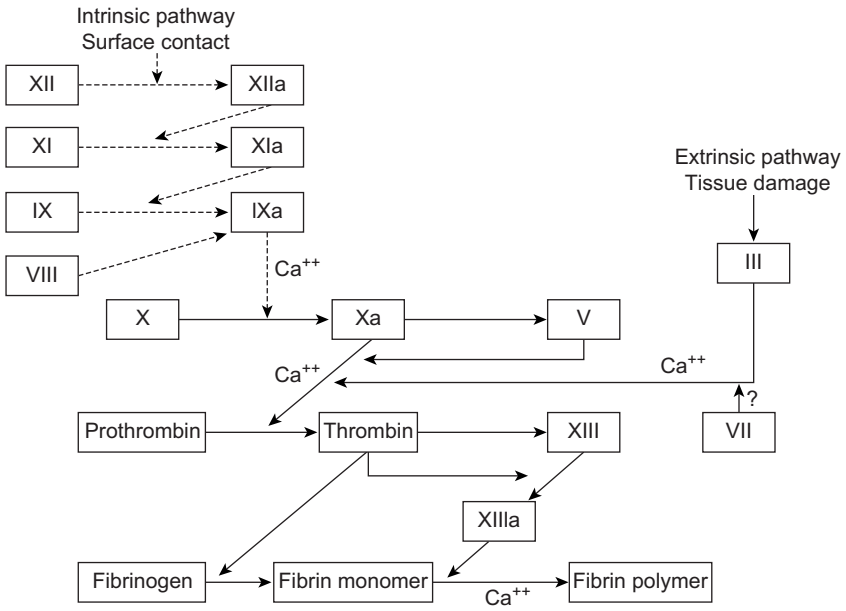

FIGURE 10.8 Cascade of coagulation of avian blood with a series of clotting factors.

(Somes et al., 1981; Lerner et al., 1982). Using a lysate of turkey erythrocytes, roles of protein kinases in the desensitization of β-adrenergic receptors has been demonstrated (Nambi et al., 1985). Adenylate cyclase is inhibited by calcium ions in turkey erythrocyte membranes (Demirel et al., 1998).

10.8.2 Transgenic Chickens

Transgenic chickens can produce desired proteins, such as human erythropoietin. Chickens producing human erythropoietin have been developed (Koo et al., 2010; Penno et al., 2010).

10.8.3 Avian IgY Antibodies

Chicken IgY antibodies are being used for immunoaffinity fractionation of human plasma due to their high avidity and specificity, low nonspecific binding, and ready source in eggs (Huang, and Fang, 2008).

10.8.4 Nutritional Models

10.8.4.1 Vitamin K

Historically, vitamin K was discovered based on nutritional studies in chicken (McCullem, 1957). This fat-soluble vitamin is critically important for the synthesis of proteins in the blood coagulation cascade.

10.8.4.2 Iron Availability

A model for nutritional studies for iron availability has been proposed using chickens together with the stable isotope ^{58}Fe (Tako et al., 2010).

Chapter 11

The Cardiovascular System

Edward M. Dzialowski and Dane A. Crossley II

Developmental Integrative Biology Research Cluster, Department of Biological Sciences, University of North Texas, Denton, TX, USA

11.1 INTRODUCTION

Birds have evolved a high-performance cardiovascular system to meet the rigorous demands of running, flying, swimming, or diving in a variety of environments, some of them extreme. Sustained high levels of activity in these environments place severe demands on the cardiovascular system to provide adequate delivery of oxygen to working vascular beds and to provide efficient removal of metabolic products. Furthermore, birds are endothermic organisms and the cardiovascular system plays a major role in conserving or removing body heat. The descriptions of the component parts of the circulatory system in this chapter illustrate that these transport requirements are met in a variety of ways in birds inhabiting particular environmental niches. This chapter describes the morphological and functional aspects of the avian heart (Section 11.2), circulatory hemodynamics (Section 11.3), and the vascular tree (Section 11.4). A common thread running through this discussion is that the component parts of the circulation must function in an integrated fashion to ensure tissue oxygen delivery matches tissue demands. This is accomplished through the integrative control of circulation by autoregulatory, humoral, and neural mechanisms (Section 11.5). Since the last edition of this book, a significant number of studies have examined the development of cardiovascular control in avian embryos (Section 11.5) which has expanded our understanding of this system throughout ontogeny. Finally, this chapter examines how the cardiovascular system functions within a complex animal interactsing in complex environments (Section 11.6).

Modern birds are derived from theropod dinosaurs (Padian and de Ricqles, 2009), whereas mammals have descended from a group of carnivorous reptiles, the cynodonts. These ancestral lines originated in the Triassic period more than 200 million years ago, so in evolutionary terms avian and mammalian stocks have been separated for a substantial period of time. As one might expect, significant differences in cardiovascular structure and function have arisen in the two groups since their separation, yet a number of similarities in their circulatory systems are also evident. Such similarities probably represent both the conservation of characteristics common to organisms ancestral to the two groups, a shared endothermic phenotype, and the results of convergent evolution once the stocks had divided.

However, our knowledge of cardiovascular structure and function is far more limited in birds than in mammals. In comparing the characteristics of the avian cardiovascular system with those of the mammalian circulation throughout this chapter, we have attempted to clarify the nature of the divergent and convergent features of this system in the two groups.

This review of the avian cardiovascular system encompasses the chapter from the previous edition of this volume (Whittow, 2000), which drew from a number of excellent previous reviews, including major works by Akester (1971), Jones and Johansen (1972), Bennett (1974), Baumel (1975), Akester (1979), Cabot and Cohen (1980), West et al. (1981), and Benzo (1986). This chapter has updated and extended these works and summarized recent contributions in additional areas, such as developments not previously covered.

11.2 HEART

11.2.1 Gross Structure and Function

11.2.1.1 Functional Anatomy

The avian heart, like that of the mammal, is a four-chambered, muscular fluid pump that intermittently pressurizes the central arteries, inducing blood flow to the capillary beds of both the systemic and pulmonary circulations. Functionally, these circuits lie in series with each other, and blood returns to the heart to be pressurized before entering either circuit. As in mammals, the right ventricle pressurizes the pulmonary circulation and the left ventricle pressurizes the systemic circulation. In each case, the pressure differential between the central mean arterial pressure and the central venous pressure drives blood flow (the cardiac output (CO))

Sturkie's Avian Physiology.

through the resistance to flow offered by the microvessels of the circulation. The left and right atria receive blood at central venous pressure before it enters the ventricles. In common with the atria of mammals, these chambers probably function more as blood reservoirs for their respective ventricles than as important "superchargers" for ventricular pressure. The resistance to blood flow, the peripheral resistance, is lower in the pulmonary than in the systemic circuit, so the right ventricle is required to generate less pressure than the left ventricle to produce the same volume flow rate. This difference in ventricular pressure is reflected in the gross anatomy of the ventricles, with the myocardium of the right ventricle being thinner than that of the more powerful left ventricle.

In birds, the heart is located in the cranial part of the common thoracoabdominal cavity, with its long axis slightly to the right of the midline. It is partly enclosed dorsally and laterally by the lobes of the liver. A very thin, but tough, fibrous pericardial sac encloses the heart. This sac contains a small volume of serous fluid that provides lubrication for the rhythmic motion of the cardiac contraction cycle. The pericardium is loosely attached to the dorsal surface of the sternum and the surrounding air sacs and more firmly to the liver. It is also attached, via the peritoneum of the hepatic peritoneal cavities, to the vertebral column. These attachments secure the apex of the heart within the median incisura of the liver and in the caudoventral axis of the thoracoabdominal cavity. The outer fibrous layer of the pericardial sac is continuous with the outer adventitial layer of the large central blood vessels. The pericardial membrane is relatively noncompliant and therefore strongly resists large, rapid increases in cardiac size that might be caused by volume overload of a heart chamber. The noncompliant nature of the pericardial sac may result in some degree of mechanical coupling between the ventricles via the contained incompressible lubricating fluid. For example, an increase in diastolic pressure in one ventricle may be transmitted to the other, increasing pressure and decreasing compliance.

11.2.1.2 Heart Size

In birds, heart mass scales with respect to body mass as $M_h = 0.014 M_b^{0.91}$ (Bishop and Butler, 1995). In mammals, the relationship is $M_h = 0.0058 M_b^{0.98}$ (Prothero, 1979), where M_h is heart mass and M_b is body mass. When compared with mammals, birds of a given body mass have a significantly heavier heart. This may be due to the high aerobic power input needed to sustain flapping flight. Furthermore, unlike mammals, in which heart mass is almost directly proportional to body mass, in birds the exponent denoting proportionality is significantly less than 1. This means that larger birds like swans, ducks, and geese tend to have proportionally smaller hearts in relation to their body mass than do smaller birds. Thus, heart mass represents about 1.1% of body mass for a bird such as the racing pigeon (421 g), compared with 0.8% for the 2.95 kg Pekin duck; this relationship is shown in Figure 11.1 (Grubb, 1983; Bishop and Butler, 1995). In a number of migrating species, the heart becomes hypertrophic before migration (see Section 11.6.1.2). Therefore, migrating birds may have the genetic potential to increase heart size, and therefore CO, through either seasonal humoral mechanisms or in the long term through natural selection. Hummingbirds have proportionally larger hearts than all other birds (shown separately in Figure 11.1), probably reflecting the high aerobic demands of hovering flight. For 25 species of hummingbirds, $M_h = 0.025 M_b^{0.95}$ (Hartman, 1961). In contrast, the ornate tinamou (*Nothoprocta ornata*) and Chilean tinamou (*Nothoprocta perdicaria*) have heart masses that represents 0.24% and 0.28% of body mass, respectively (Altimiras et al., 2013).

Heart mass as a fraction of body mass may also be age dependent. Prior to hatching, the ventricle of Pekin ducks (*Anas platyrhynchos*) represents about 0.4% of body mass and increases significantly upon hatching to 0.75% of body mass (Ream et al., 2013). This increase in heart mass coincides with an increase in aerobic capacity of the hatchling. Similar increases have been observed in the chicken and northern bobwhite quail (*Colinus virginianus*) after hatching (Dzialowski, unpublished data).

11.2.1.3 Cardiac Chambers

The avian heart has two completely divided atria and ventricles. These chambers are functionally equivalent to those of the mammalian heart, serving to distribute CO both to the systemic circulation and to the lungs. In life, the atria are rounded chambers, distended with blood during atrial diastole. In excised hearts, they may collapse, causing auricles to appear. The right atrium tends to be much larger than the left. The wall of the avian atria and ventricles, as in mammals, consists of endocardial, myocardial, and epicardial layers. The atrial walls are generally thin, although atrial muscle is arranged in thick bundles forming muscular arches. The right and left transverse arches are arranged at right angles to the dorsal longitudinal arch and the interatrial septum. The transverse arches branch into smaller bundles, which fuse with a circular muscle band (musculari basianularis atrii) at the ventral limits of the atria. Contraction of atrial muscle nearly empties the atria. In many species, the atria lack functional inflow valves, so that the importance of atrial contraction for ventricular filling may be slight.

The muscular architecture of the ventricles is more complex than that of the atria and includes a superficial layer, longitudinal muscle of the right ventricle, and sinuspiral and bulbospiral muscles. The left ventricle is cone-shaped and extends to the apex of the heart. Its right wall forms the interventricular septum. The free wall of the right ventricle is continuous with the outer portion of the wall of the

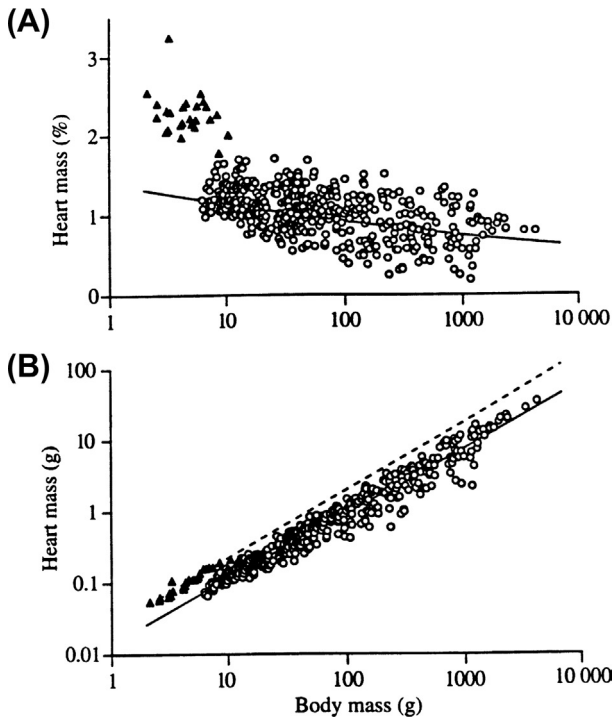

FIGURE 11.1 (A) Heart mass as a percentage of body mass. (B) Heart mass in grams, plotted against body mass (g) for 488 avian species, including 25 species of hummingbird. Hummingbird data are represented by the filled triangles and dashed line; all other species are represented by open circles and solid line. *From Bishop and Butler (1995).*

left ventricle and wraps around the right side of the heart to enclose a crescent-shaped cavity, which does not reach the apex of the heart. The muscular walls of the two ventricles are differentially developed, with the wall of the left ventricle being two to three times thicker than that of the right. In addition, the radius of curvature of the wall of the left ventricle is smaller than that of the right (Figure 11.2). This implies both a greater mechanical advantage for pressure generation in the left than in the right ventricle and, according to LaPlace's law, a smaller wall tension for a given left ventricular pressure increment. Therefore, contraction of the myocardial layers of the thick, smallradius wall of the left ventricle enables it to generate systolic pressures four to five times higher than those produced by the right ventricle, without rupturing. The larger radius of curvature and thinner free ventricular wall of the right ventricle reflects the lower systolic pressures generated by this chamber, made possible by the low vascular resistance of the avian lungs. Another consequence of this geometry is that relatively large changes in stroke volume can be made by small changes in the degree of shortening of right ventricular muscle fibers.

11.2.1.4 Valves

Blood entering the left ventricle from the left atrium on atrial systole passes through an orifice guarded by a membranous atrioventricular (AV) valve, similar in general structure to a mammalian AV valve. The valve forms a continuous membrane around the aperture. The valve is tricuspid, not bicuspid as it is in mammals, but in the avian heart the cusps of this valve are poorly defined. The anterior and posterior leaflets are small. The large aortic (medial) leaflet is connected to the bases of the left and noncoronary cusps of the adjacent aortic outflow valve by fibrous tissue. The free margin of the valve is well secured to the left ventricular endocardium by numerous inextensible chordae tendineae. This arrangement prevents valve eversion during ventricular systole.

Blood passing from the right atrium to the right ventricle enters through an orifice guarded by an AV valve that is structurally unique to birds. In pronounced contrast to the fibrous structure characteristic of the mammalian tricuspid valve, in birds the right AV valve consists of a single spiral flap of myocardium attached obliquely to the free wall of the right ventricle (Figure 11.3; Lu et al., 1993a). This spiral flap is apposed to a downward extension of the free wall of the right atrium. The atrial component of the valve extends toward the apex of the ventricle for a shorter distance than does the right ventricular flap. Most of the valve is made of ventricular myocardium and is bilaminar only in its upper portion. The mechanism of valve closure at the start of ventricular systole is unknown. It could be active, by contraction of the muscular flaps, or passive, by deflection of the ventricular flap by a brief backflow of blood at the start of ventricular systole.

The idea of valve closure depending at least partially on active muscular contraction is supported by evidence that at the cellular level both AV valves are closely approached by the electrical conducting system of the myocardium. A complete ring of Purkinje fibers encircles the right AV orifice and connects to the muscular AV valve (Lu et al., 1993a,b). An exception to this anatomical arrangement may be the penguin, in which Adams (1937) did not find a Purkinje

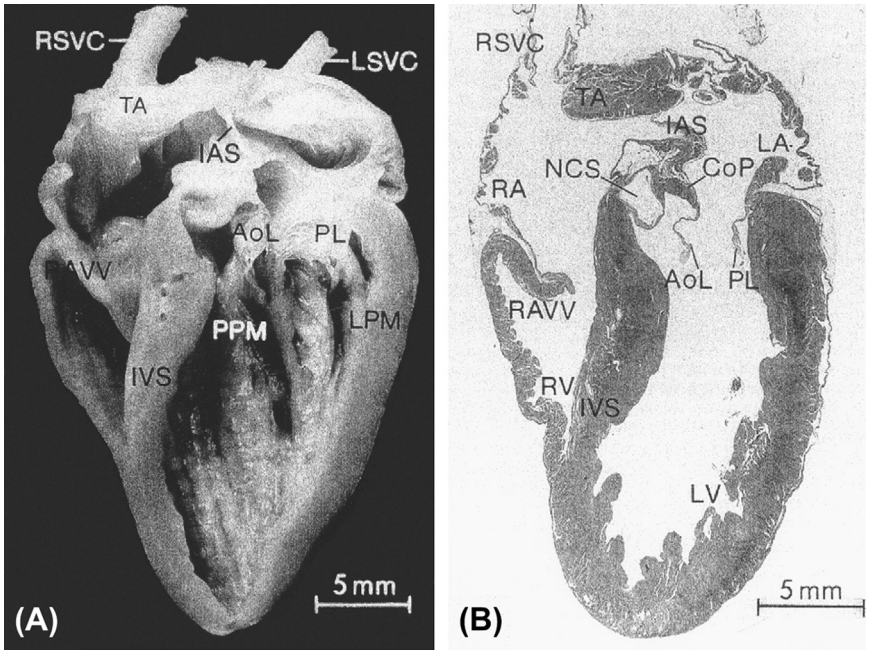

FIGURE 11.3 Anterior frontal views through the atria and ventricles of a chicken heart, showing both the right and left atrioventricular (AV) valves. (1993a).*

ring. The majority of studies, as summarized by Lu et al. (1993a,b), support the idea that both the atrial and ventricular muscular components of the right AV valve are excited to contract via the Purkinje system. However, Szabo et al. (1986) thought that there was an insulating layer of connective tissue between the Purkinje AV ring system and the left ventricular myocardium, suggesting that the muscle flap derived from the left ventricle may work passively. Definitive physiological experiments have not been performed to resolve this issue, but the balance of current evidence suggests that both portions of the valve are electrically activated before the ventricular myocardium to dynamically contract and close the AV orifice at the start of ventricular systole (Lu et al., 1993b). This is clearly very different from the closure mechanism in mammals, in which the leaflets of the tricuspid valve float up into the right AV orifice, moved by the AV pressure differential generated during ventricular systole itself.

The outflow valves from the right and left ventricles are, at first glance, more conventional (mammalian) in nature. The pulmonary outflow valve consists of three semilunar cusps. It prevents regurgitation from the pulmonary artery into the right ventricle, with the valvules closing as pressure in the ventricle falls below that in the pulmonary trunk on ventricular diastole. There are also three semilunar cusps in the aortic outflow valve, but they are much more rigid than those of the pulmonary outflow valve and are firmly attached to underlying myocardium. The cusps are linked by a ring of fibrous tissue that lies within a complete ring of underlying, circumferentially arranged, myocardial cells. The ring is completed by an arch of cardiac muscle that lies between the left coronary cusp of the aortic outflow valve and the aortic leaflet of the left AV valve, as shown in Figure 11.4 (Lu et al., 1993a). This anatomical arrangement contrasts with that in the mammalian heart, in which there is only connective tissue, not myocardium, between that part of the muscular ring lying between the aortic wall and the adjacent mitral valve; in mammals, the myocardial ring is incomplete. In the bird, however, this sphincter-like myocardial cylinder is potentially capable, on contraction, of constricting the left ventricular outflow tract. Lu et al. (1993a) proposed that the muscular ring could act as a sphincter controlling the rate of left ventricular outflow by modulating outflow resistance. Another attractive possibility is that muscular contraction of the myocardial ring could close the relatively rigid cusps of the aortic outflow valve. The middle bundle branch of the Purkinje system is connected to the arch of muscle, so its contraction may start relatively early in the cardiac cycle. Obviously, physiological studies are urgently needed to determine whether either of these intriguing mechanisms operates in the avian heart.

11.2.1.5 Coronary Circulation

Oxygenated blood destined to supply the avian myocardium via the right and left coronary arteries enters the right ventral

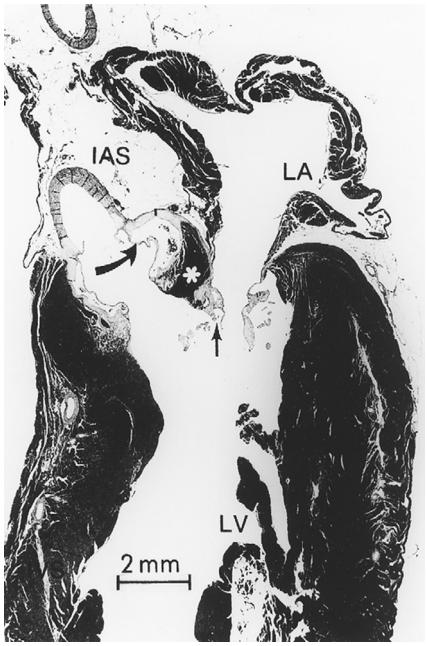

FIGURE 11.4 Photomicrograph of a histological section of the chicken heart, taken in a modified sagittal plane through the anterior column of the muscle arch, indicated by an asterisk. and left aortic sinuses, which lie immediately downstream from the cusps of the aortic outflow valve. Most birds have two entrances to the coronary circulation, although there is individual variation so that up to four openings have been observed. In chickens, the right ventral sinus leads into the right coronary artery, which then divides immediately into a superficial and a deep branch (Figure 11.5). The superficial branch follows the groove (coronary sulcus) between the right ventricle and atrium and supplies the cardiac muscle of both chambers. The larger deep branch supplies the ventral wall of the right ventricle, the dorsal walls of both atria, and the muscular right AV valve. In most species, the right coronary artery is dominant and also supplies the ventricular septum, the heart apex, and much of the left ventricular myocardium. The left coronary artery arises from the left aortic sinus and also has a superficial branch that follows the left coronary sulcus. Another superficial branch gives off atrial and ventricular tributaries, and a deep branch supplies the ventral myocardium of the left ventricle. It is not uncommon in chickens for the left coronary artery to be dominant, in which case it supplies almost all of the left ventricular myocardium and the heart apex. There are frequent anastomoses between the branches of the coronary arteries, particularly near the coronary sulcus.

Five groups of cardiac veins, with frequently anastomosing small tributaries, return venous blood from the myocardium into the right atrium via a coronary sinus. Small cardiac veins open directly into the atria and the right ventricle. This basic anatomical pattern of coronary circulation is seen in birds ranging from the chicken, duck, and pigeon (West et al., 1981) to the ostrich (Bezuidenhout, 1984).

The rate of perfusion of avian myocardium is high compared with perfusion rates of most other avian tissues, as shown in Figure 11.6 (see Section 11.4.2.3; Johansen, 1964; Jones et al., 1979; Ellerby et al., 2005). The constantly active cardiac muscle is perfused at a higher rate than resting skeletal muscle. During exercise in the guinea fowl, flow to the ventricles more than doubled (Ellerby et al., 2005). Presumably, as in mammals, the majority of avian coronary blood flow occurs in diastole, so coronary flow might be expected to increase if the diastolic interval is prolonged, provided arterial driving pressure does not fall.

Turkeys sometimes show a congestive cardiomyopathy that is presumed to be of viral origin, the so-called round heart disease. In this condition, systemic hypotension and low CO, caused by reduced left ventricular myocardial shortening, are probably the result of reduced subendocardial coronary perfusion rate (Einzig et al., 1980). Turkeys with round heart disease also show an altered electrocardiography pattern (see Section 11.2.3.4).

11.2.2 Cardiac Variables

The avian cardiovascular system is not merely a replica of the arrangement in mammals, despite similarities in performance between the two systems. Birds have larger hearts, bigger stroke volumes, lower heart rates, and higher COs than mammals of corresponding body mass (Grubb, 1983). In addition, in many avian species mean arterial pressure is higher than that found in mammals of comparable body mass (see Smith, 1994). CO, the product of stroke volume and heart rate, is of particular interest because it is a major determinant of the rate of oxygen delivery to tissues.

In resting birds, left ventricular stroke volume (V_s) was found to be almost directly proportional to body mass (M_b) (Grubb, 1983; Seymour and Blaylock, 2000). For nine species of birds ranging in body mass from 0.035 kg (budgerigar) to 37.5 kg (emu), Grubb found that $V_s = 1.72M_b^{0.97}$, where V_s is in milliliters and M_b is in kilograms. Seymour and Blaylock (2000) found a similar relationship in birds and $V_s = 0.99M_b^{1.03}$ in mammals. Heart rate (f_H, beats/min) at rest was found to be slower in larger birds: $f_H = 178.5M_b^{-0.282}$. CO (mL/kg/min) at rest, the product of stroke volume and heart rate, therefore scaled with the mass of the bird as $CO = 307.0M_b^{0.69}$. The corresponding relationship for mammalian cardiac output is $CO = 166M_b^{0.79}$ (Holt et al., 1968). These results show that birds have a proportionally larger CO compared with a mammal of the same body mass. In larger birds, resting heart rate is slower than in smaller birds. Bishop and Butler (1995) found that for 49 species the allometric

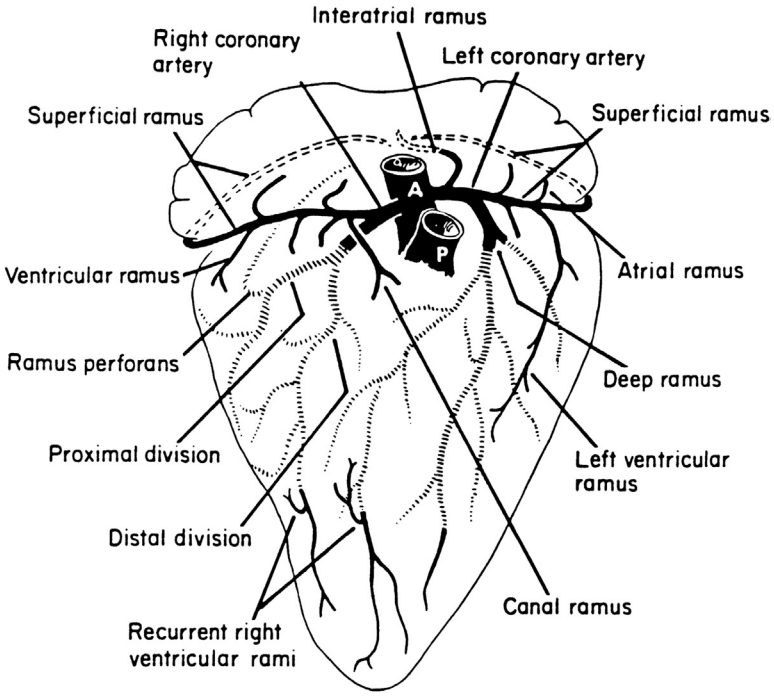

FIGURE 11.5 Arrangement of the coronary arteries of the chicken, *Gallus*, drawn from the cranioventral aspect. Solid black and dashed lines represent superficial portions of arteries. Cross-hatched lines represent deep arteries embedded in the myocardium of the ventral and right side of the interventricular septum. A, aorta; P, pulmonary trunk. *From West et al. (1981) with permission.*

relationship for heart rate at rest was $f_H = 125M_b^{-0.37}$, whereas for birds in flight it was $f_H = 480M_b^{-0.19}$. It is interesting that the heart rate–body mass relationship during flight has a shallower slope than in resting animals, indicating that larger species show a greater increase in heart rate in absolute terms in the transition from rest to flight (Figure 11.7). Bishop and Butler (1995) suggested that the body mass exponent of stroke volume in flight should be similar to that at rest ($M_b^{0.96}$), even though the absolute value of stroke volume may increase during flight. Therefore, in flight, it is predicted that CO will scale to body mass as the sum of the exponents for stroke volume and heart rate ($M_b^{0.77}$).

In flight, as at rest, larger species show lower coronary perfusion rates per mass of body tissue. It is likely that this reflects an optimization of the arterial oxygen supply at the tissue level, with the body mass exponent for CO being very similar to the exponent for mass-specific oxygen consumption. Thus, natural selection probably acts on CO to maintain the arteriovenous O_2 difference at a similar level across different avian species. Stroke volume is constrained by cardiac geometry such that, on theoretical grounds, V_s should be closely proportional to M_h and M_b (Schmidt-Nielsen, 1984; Astrand and Rodahl, 1986). Therefore, the lower mass-specific COs of larger avian species, matching their lower mass-specific $\dot{V}_{O_2}$ levels, are reflected in their lower heart rates.

11.2.3 Fine Structure and Cardiac Electrophysiology

11.2.3.1 Fine Structure

Histologically, the atria and ventricles are quite similar, consisting of an external layer, the epicardium, which is separated from an inner endocardium by the mass of heart muscle, and the myocardium. Ventricles are much thicker than the atria due to extensive proliferation of the myocardial layer. The epicardial and endocardial layers are morphologically similar, consisting of loose connective tissue and elastic fibers bordered by a single layer of squamous epithelial or endothelial cells, respectively. The atrial and ventricular septa have endocardial layers facing the lumens of their respective cavities, with myocardial cells between them. In the sparrow and stork, the atrial septum is very thin, in some regions consisting only of two apposed layers of endocardium.

The atrial and ventricular myocardia consist of striated muscle fibers, differing from those of mammals in three notable respects (Sommer and Johnson, 1969, 1970; Hirakow, 1970). First, striated muscle bands are prominent in mammalian cardiac muscle and are also present in bird hearts, with the exception of the M-band. In mammalian cardiac muscle, the M-band is a line of protein molecules connecting adjacent myosin filaments. The significance of the lack of an M-band on the contractile properties of avian

myocytes is unknown. Second, avian cardiac muscle fibers are much smaller in diameter than mammalian fibers and hence there are many more of them in similarly sized hearts. Avian myocardial cells are typically 2–7 μm in diameter compared with the 10–15 μm diameter of mammalian cells. Third, myocardial cells of all fish and reptiles, including avian species, lack transverse tubules (T-tubules), which are prominent in mammalian cardiac muscle. The membrane surrounding the muscle fibers (sarcolemma) consists of two parts—a cell membrane (plasmalemma) and an external layer interconnected with an interstitial network of collagenous fibers. In mammalian cardiac muscle, T-tubules form as invaginations of the plasmalemma, perpendicular to the long axis of the myofilaments. T-tubules lie next to, and form junctions with, sections of the sarcoplasmic reticulum (SR) (diads or triads, Figure 11.8). In mammals, the T-tubule system increases the surface area of the myocardial cells to the extent that the surface-to-volume ratio of a mouse cardiac cell (15 μm diameter) is the same as that of a finch (8 μm diameter). The finch and the mouse have similar cardiac frequencies (Bossen et al., 1978).

The connection between the SR and the plasmalemma occurs through "couplings". In birds, lacking a T-tubule system, these couplings occur at the surface of the cell (Figure 11.8). Couplings are affected by junctional processes that extend from the cytoplasmic face of the SR (junctional sarcoplasmic reticulum (JSR)) that are very closely apposed to the inner surface of the plasmalemma. Birds also possess an extended junctional sarcoplasmic reticulum (EJSR), which occurs in the region of the Z-bands, but it is anomalous. Although it resembles the JSR in most respects, the actual junctional processes may be separated from the plasmalemma by a cleft of several microns. EJSR is much less developed in chicken than in passerines (Sommer et al., 1991). Interestingly, the volume of JSR in mouse hearts and the total volume of JSR (20%) and EJSR (80%) in the finch are virtually identical (Bossen et al., 1978).

11.2.3.2 Excitation–Contraction Coupling

Excitation–contraction coupling describes how an electrical signal, the action potential (AP), traveling along the plasmalemma evokes calcium release from the SR in the region of the myofibrils, causing a change in actin–myosin interactions, which leads to muscle contraction. In cardiomyocytes, the transduction between the electrical signal and Ca^{2+} release from the JSR is effected by a transmitter, which is, in fact, calcium itself. In the first step of this process, the AP causes voltage-dependent Ca^{2+} channels to open in the sarcolemmal membrane through a conformational change in the channels. Ca^{2+} then enters the cell and diffuses to receptors on the junctional processes, where it acts as a transmitter, opening Ca^{2+}-dependent Ca^{2+} channels, which in turn release Ca^{2+} sequestered in the SR. This Ca^{2+}-induced Ca^{2+} release (CICR) is crucial for the physiological function of the bird heart, in which the EJSR, which is the majority of the junctional SR, is separated from the plasmalemma by several microns. Furthermore, CICR allows exquisitely fine

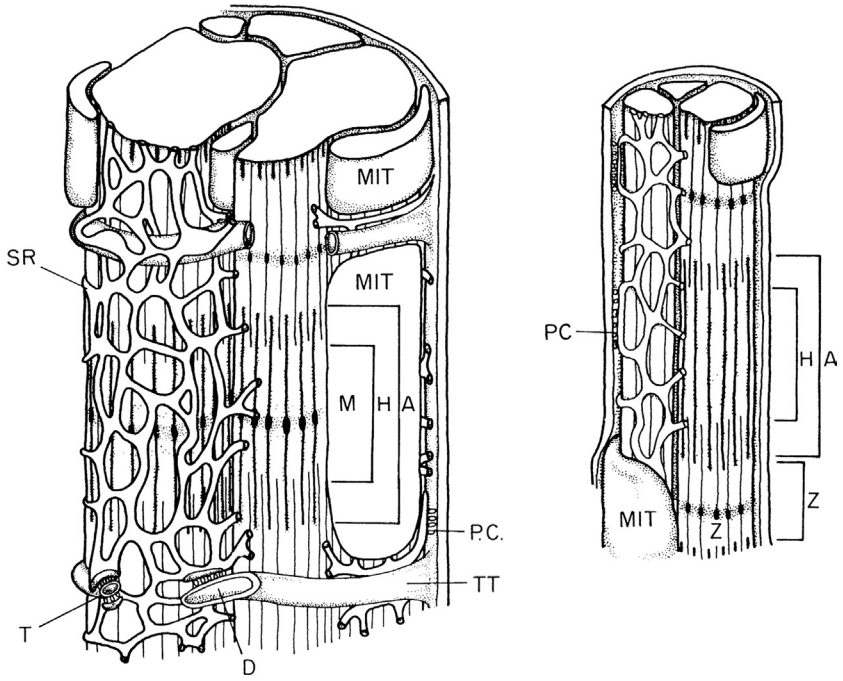

FIGURE 11.8 Comparison of mammalian (left) and avian (right) myocardial cells. The major distinguishing features of avian fibers are smaller cell diameters and absence of M bands and transverse (T)-tubules. regulation of force generation in myocytes. Relaxation of the myocytes is due to the uptake of Ca^{2+} into the SR and extrusion by Na^{+}/Ca^{2+} exchange. In cardiac muscle, contraction is "all or none". Force modulation must be done at the cellular level by regulating not only the amount of Ca^{2+} entering through the sarcolemma, but also its effect on Ca^{2+} release from the SR.

11.2.3.3 Conduction System

The cardiac conduction system of the avian heart consists of the sinoatrial (SA) node, AV node, AV Purkinje ring, His bundle, and three bundle branches (Figure 11.9). Histologically, three types of cells are associated with the conducting system. The first type, pacemaker cells (P-cells), are small and spherical in shape and are found in both the SA and AV nodes. P-cells have the property of repetitive spontaneous depolarization. Transitional cells (T-cells) are much smaller and have fewer microfibrils than cardiac muscle cells; their structure is intermediate between normal cardiac muscle cells and Purkinje fibers. The third type, Purkinje fibers, are large, elongated, brick-shaped cells containing few myofibrils. Many Purkinje cells, however, contain longitudinal fibers called intermediate filaments; these are part of the cytoskeleton, serving to maintain cell shape as the myocardium contracts. Purkinje cells may be up to five times the diameter of myocardial cells.

The SA node is located close to the opening of the venae cavae into the right atrium, although there is considerable species variation in birds. The SA node consists of P-cells and many T-cells and is enclosed in a loosely organized connective tissue sheath. The T-cells transmit impulses from the pacemaker to atrial muscle cells. The SA node is morphologically, and perhaps physiologically, diffuse in birds. The primary electrical pacemaker region appears to change position spontaneously within the node (Hill and Goldberg, 1980).

For normal cardiac function, all cardiac muscle fibers within a given cardiac chamber should contract more or less simultaneously, although it is essential that the atria contract before the ventricles. The wave of excitation initiated in the SA node is delayed at the AV node, allowing the atria to empty before ventricular contraction begins. The electrical impulse that initiates contraction spreads through the atria and ventricles at rates in excess of 1 m/s, whereas conduction through the AV node is two to three orders of magnitude slower. Spread of excitation through myocardial muscle occurs from one muscle cell to the next, as well as along specialized conducting pathways. Individual muscle cells are discrete entities, but they behave electrically as if they were all joined together to form a syncytium. This property results from low electrical resistance in parts of the cell membrane where cell apposition is very close. Junctional complexes, the intercalated disks, commonly join myocytes end-to-end in avian myocardium, occurring at right angles to the long axis of the myofibrils. Intercalated disks consist of two components, desmosomes, which mechanically couple the cells together, and nexuses, which couple cells electrically. A nexus may be viewed as an array of unit electrical resistors, with their number being inversely proportional to the electrical resistance between the cells (Sommer, 1983). Interestingly, there are few nexuses along the longitudinal axes of myocardial cells.

The speed at which the wave of electrical excitation propagates through the ventricles is enhanced by a specialized conducting system of Purkinje fibers, but whether a specialized conducting system also exists in the atria of birds is controversial. In the atrium, waves of electrical and contractile activity proceed in the same direction, from the SA to AV nodes, which may mean that a specialized conducting system is unnecessary here. However, both atria contain Purkinje cells, and these have been described both morphologically and physiologically as being organized to preferentially direct the wave of activation toward the AV node (Davies, 1930; Hill and Goldberg, 1980). The contrarian view is that because the Purkinje cells in the atria are mixed diffusely among the normal myocardial cells, then they may represent the remnants of an embryological anlage left over from the time when that anlage was building the ventricular conducting system (Sommer, 1983).

The atrial wave of excitation crosses to the ventricle through the AV node, which, in birds, is a somewhat controversial structure because many morphological investigations have failed to locate it, although its presence has been established in functional studies. In the chicken, the AV node is located in the right side of the base of the interatrial septum (Davies, 1930; Lu et al., 1993b; Ying et al., 1993), although in Indian fowl, *Pycnonotus cafer*, house sparrow, *Passer domesticus*, and in *Bubo bengalensis*, it is located in the left AV junction (Mathur, 1973). The His bundle and its three bundle branches of Purkinje cells arise from the AV node. The right and left bundle branches emerge from the septum to form a network in the subendocardium of the right and left ventricles, respectively, penetrating the myocardium along the tracts of the coronary arteries (periarterial Purkinje fibers).

An indication of the theropod ancestry of birds can be inferred from the conducting system of the heart. Birds, unlike mammals, possess an AV ring of Purkinje fibers on the right side of the heart, which runs up and around the right AV valve (Figure 11.10; also see Section 11.2.1.4). The middle bundle branch, after separating from the others, runs around the aorta and connects to the AV ring, forming a figure-eight (Lu et al., 1993b).

Purkinje cells conduct electrical impulses much faster than cardiac myocytes. In mammals, part of the reason for this high conduction speed is that Purkinje cells lack a T-tubule system. T-tubules increase the surface area of

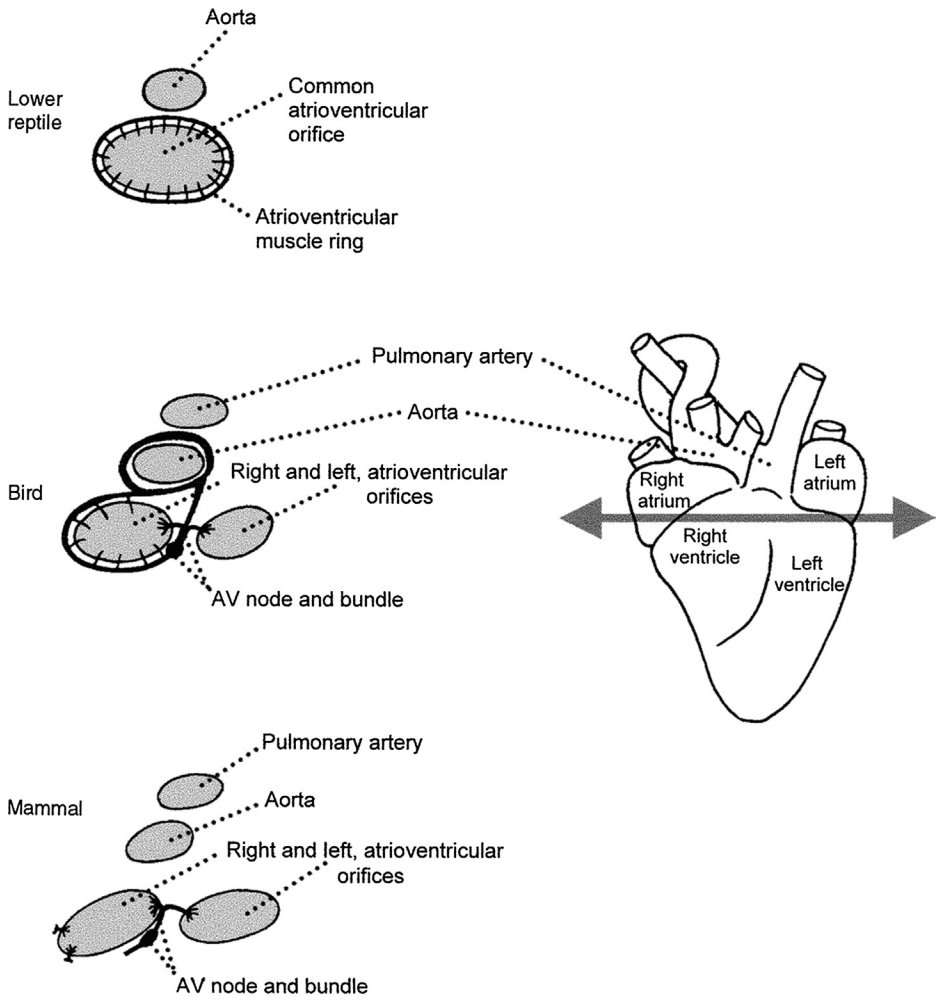

FIGURE 11.10 Diagram of specialized atrioventricular connections in lower reptiles, birds, and mammals as seen when looking into the ventricles after making a transverse section through the heart, as indicated on the diagram of the chicken heart on the righthand side. *From Davies (1930).*

the cell and therefore membrane capacitance (increasing the length of time a given amount of electrical charge will take to alter membrane potential); a high capacitance thus slows conduction velocity. However, in birds, there is no T-tubule system associated with either myocardial or Purkinje cells, yet the latter still conduct impulses at a faster rate. This is because conduction velocity varies directly with cell diameter and avian Purkinje cells are much larger than myocardial cells. Furthermore, a higher conduction velocity may be fostered in Purkinje cells by intermediate filaments, which serve to keep the cell round. Also, the electrical resistance between Purkinje cells is lower than that between myocardial cells because nexus size also increases with cell diameter, acting to further increase conduction velocity. Finally, in mammals with extremely large hearts (i.e., ungulates), the Purkinje cells within a bundle are tightly packed together and surrounded by an insulating membrane so that they behave electrically as a single fiber of a diameter equal to that of the whole bundle. Purkinje cells are likewise bundled in the avian heart, but whether this enhances conduction velocity is uncertain because the bundles lack a connective tissue sheath and are therefore not insulated from surrounding tissues.

11.2.3.4 Electrophysiology

The Purkinje fibers follow the coronary arteries and therefore take a relatively short course through the thick left myocardium. This accounts for the rapidity of arrival of the wave of excitation at a given point on the surface of the left ventricular wall in the avian heart (Lewis, 1916). The sequence of depolarization is, according to Kisch (1951): right ventricle apex, right ventricle base, left ventricle base, left ventricle apex. Moore (1965) mapped epicardial activation in the turkey and suggested that the apical third of the right ventricular epicardium is activated earliest, the upper basilar third is intermediate, and the pulmonary outflow tract is the last region activated in the whole heart. The anterior one-third

of the septal region and the middle region of the left ventricle are activated before the basilar regions, with the whole left ventricular epicardium being activated in 12.5 ms. Others have found somewhat different sequences of activation (Lewis, 1916; Mangold, 1919). Kisch's suggestion that the conducting system stimulates heart muscle only at places of direct contact between its terminal fibers and heart muscle and not along the entire course of the conducting system receives support from his own work (Kisch, 1951), showing that subendocardial muscle is activated about 20 ms later than the earliest activated subepicardial muscle, which in turn suggests short cuts of the conductive system to subepicardial muscle. However, Davies (1930), Lu et al. (1993b), and Kharin (2004) suggested that because the bundle branches lack a fibrous sheath, there will be early and widespread propagation of the impulse in the septal region and thence along the bundle to all parts of the ventricles. Kharin (2004) mapped activation patterns with 64 electrodes in the chicken ventricle and found earliest activation in both the right and left ventricle in a mosaic-like pattern. Repolarization of the ventricle follows a different pattern from that observed during depolarization (Kharin, 2004). Repolarization starts at the right ventricle apex and moves down to the left ventricle apex. This is then followed by repolarization of the left ventricle base and finally the right ventricle base.

The conducting system of the bird heart has been investigated by recording transmembrane potentials from cells in the heart of the chicken and turkey (Moore, 1965, 1967). The pacemaker cells of the SA node, in the absence of any extrinsic influences, set the heart rate. Cells that function as pacemakers show a characteristic slow depolarization during diastole, the steepness of the depolarization being related to the degree of automaticity inherent in the cell (the fastest cells to depolarize drive the slower cells), whereas cells not spontaneously active show a steady membrane potential during diastole (Figure 11.9). APs recorded from the junction of the left SA valve with the sinus venosus show diastolic depolarization (prepotentials) with a slow transition to the ascending phase of the actual AP (Figure 11.9), in contrast to the relatively more rapid rise of the AP recorded in the right SA valve itself, indicating that cells in the right SA valve are triggered by the pacemaker cells. The duration of APs recorded from ventricular muscle cells is longer than those recorded from atrial muscle cells (Figure 11.9). Purkinje fibers display a prominent sharp peak to their APs, which is followed by a distinct plateau, a feature not seen in APs from atrial or ventricular muscle cells. The duration of depolarization is also much longer in Purkinje fibers, although diastolic depolarizations have not been recorded from avian Purkinje fibers. The longer duration of the Purkinje APs as compared with those of ventricular myocytes indicates a long refractory period, which would tend to prevent extrasystole and possible fibrillation by assuring a concerted depolarization of the ventricular muscle (Moore, 1965).

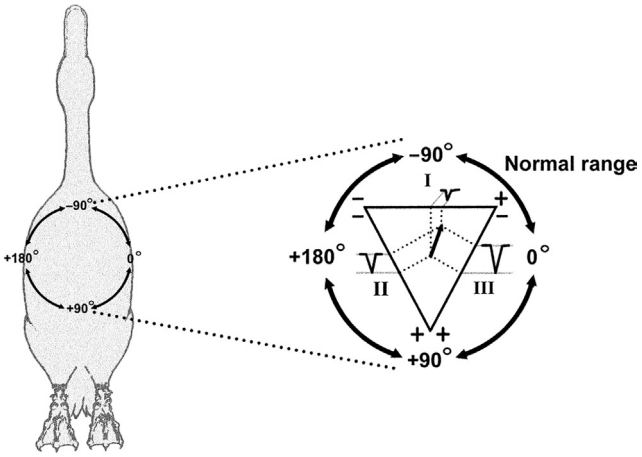

FIGURE 11.11 Relationship of the electrical axis of the heart to potentials recorded from the three standard leads (I, II, and III) as conceived by Einthoven. The duck is presented in ventral view on the left side of the figure. The electrical axis is upward and close to the midline. The arrow in the middle of Einthoven's triangle shows the direction of the axis, while the length represents its magnitude and degrees its orientation. The voltage changes seen at each lead (I, II, and III) are shown.

An electrocardiogram (ECG) shows the summed electrical activity of the heart. An ECG is usually recorded indirectly with electrodes placed on the body surface or just under the skin. (A direct ECG recording would be made by dividing the sternum and placing recording electrodes directly on the surface of the heart.) In birds, as in mammals, three standard leads (I–III) are used, following the model first conceived by Einthoven about 100 years ago. The body is a volume conductor of electricity and the waves of depolarization and repolarization that sweep across the heart can be reduced to a single electrical dipole. The dipole has magnitude (volts), direction, and sense (positive or negative), so it is a vector quantity. In Einthoven's concept, the cardiac vector is situated at the center of an equilateral triangle (Figure 11.11) formed by the bipolar lead connections. Lead I connects across the thorax from the right (negative electrode) to the left (positive electrode) wing bases. Lead II is recorded between right wing base (negative electrode) and left thigh (positive electrode). Lead III is connected between the left wing base (negative electrode) and the left thigh (positive electrode). The arrangement of these leads is such that, in humans and many other mammals, the polarity of the recorded signals is positive. In contrast, in birds, the polarity of the major component of the ECG (ventricular contraction) is negative (Figure 11.12).

There has been some controversy over what the typical avian ECG looks like (Figure 11.12). For instance, Kisch (1951) reported the presence of P, QRS, and T waves, whereas Mangold (1919) reported that the electrocardiogram of birds has no R component, but instead a deep S wave. Sturkie (1986) reported the presence of P, a dominant S, and T waves, a small R, but no Q wave. The status

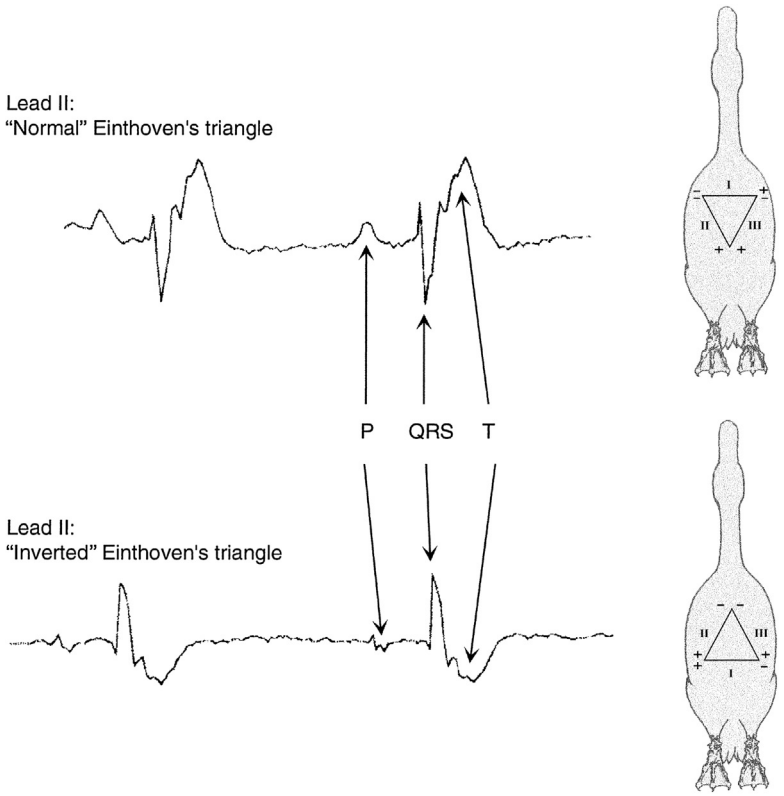

FIGURE 11.12 Upper electrocardiogram (ECG) trace: voltage recorded from lead II when the recording electrodes are placed in the conventional mammalian manner, on the right shoulder and left leg. Einthoven's triangle is shown on the duck on the upper right in ventral view. Lower ECG trace: voltage recorded from lead II when the recording electrodes are placed on the left shoulder and right leg. Einthoven's triangle is inverted as shown on the duck on the lower right in ventral view. The components of the ECG waveform are shown. P indicates atrial contraction, QRS is ventricular activation, and T represents ventricular depolarization. *From Liu et al. (unpublished data).*

of the Q wave has not been clarified by more recent work. There is general agreement that it is absent in the chicken (Goldberg and Bolnick, 1980; Liu and Li, 2005), small in the turkey (McKenzie et al., 1971), and prominent in some duck ECGs (Figure 11.12; Cinar et al., 1996). Aside from being useful in monitoring heart rate, the ECG can also be used to access the timing of the various phases of the cardiac cycle, because components of the ECG can be identified with atrial (P wave) and ventricular (QRS or RS) depolarization as well as repolarization of the ventricles (T wave). The duration of the P wave is the period of atrial depolarization and repolarization, whereas the P–R duration includes the conduction delay at the AV node. QRS or RS represents ventricular activation and the T wave is the period in which the heart is completely depolarized. QT or RT duration represents the duration of a complete cycle of activation and relaxation of the ventricle (Figure 11.12). Most of these intervals are fixed, so it is primarily the period between the T and P waves (i.e., interbeat interval), which shortens and lengthens with increases and decreases in heart rate, respectively. In fact, at very high heart rates, the T wave of one beat may come to overlie the P wave of the next.

Bipolar recording of the standard limb leads means that the cardiac vector is projected along the line between the two electrodes (Figure 11.11). When all leads are used, then it is possible to reconstruct the orientation of the cardiac vector or mean electrical axis (MEA) for any of the events of the cardiac cycle with respect to the plane of orientation of the leads. Standard leads lie in the frontal plane and, in mammals, the MEA of the QRS is oriented downward (inferiorly) and to the left (+60°). In contrast, the MEA of the QRS wave in the bird heart is close to −90°, being oriented along the long axis of the body and superior to the frontal plane. Hence, the QRS or RS wave is of negative polarity and barely represented in lead I, with the highest voltages being recorded by leads II or III (Figure 11.11). The mean electrical axes of the P and T waves can be calculated in a similar fashion. By using other cardiac leads in addition to the standard limb lead I, Szabuniewicz and McCrady (1967) were able to determine the MEAs of the QRS or RS, P, and T waves of the heart in the chicken, not only in the frontal plane (−77.1°) but also in the horizontal (+72.4°) and sagittal (−55.4°) planes.

The MEA of the ventricular depolarization phase is negative, whereas that for the repolarization phase is positive.

Therefore, the QRS or RS component deflects downward or negatively while the T wave is upright or positive (Figure 11.12). Obviously, the heart does not markedly change its position in the chest with each beat. The waves deflect in opposite directions because depolarization causes the ventricular myocardium to become negative and repolarization drives the myocardium positive. Also, the time courses of these waves are different. Repolarization is slower than depolarization, so the T wave is more spread out than the QRS or RS wave. In this context, it should be noted that when the ECG is recorded just for purposes of monitoring heart rate, using a single pair of leads (usually II), the RS wave is often presented as deflecting positively. This is achieved by reversing the polarity of the lead II bipolar electrodes (inverting Einthoven's triangle, Figure 11.12) and is done for artistic reasons.

Further interpretation of the ECG of birds is complicated by variability in electrode recording sites, anatomical differences between species, and the absence of a large bank of data such as has been accumulated for humans and, to a lesser extent, other mammals. In fact, it seems most unlikely that rigorous, detailed investigation of the ECG of birds will ever be used for clinical diagnosis. Boulianne et al. (1992) suggested that only diseases that cause a shift in position of the heart in the torso, and therefore alter the MEA, can be successfully diagnosed by two-dimensional electrocardiography. Round heart disease in chickens and turkeys produces such a shift; the mean RS axis in the frontal plane averages +70° compared with −85° in the normal bird (Hunsaker et al., 1971; also see Section 11.2.1.5).

11.3 GENERAL CIRCULATORY HEMODYNAMICS

The three major constituents of the pulmonary and systemic circulations are (1) the arteries or distributing vessels, (2) the capillaries or exchange vessels, and (3) the veins, which are storage vessels. Arterioles and venules are muscular vessels located upstream and downstream of the capillary beds, respectively. They are regulatory vessels, directly controlling blood flow distribution and indirectly controlling exchange of materials across capillary walls by adjustment of capillary pressure.

The major arteries bifurcate many times before the capillary beds; at each bifurcation, vascular resistance increases (McDonald, 1974). Volume flow in the parent and daughter vessels remains the same in the steady state, but flow velocity in the daughters falls to about 80% of that in the parent vessel. Therefore, the sum of the cross-sectional areas (πr^2, where r is internal radius) of both daughter vessels is greater than that of the parent vessel by about 25%. Hence, as the vessels divide, flow velocity falls; in the capillary circulation, flow velocity is exceptionally low. This allows adequate time for exchange of blood gases, nutrients, and metabolites with the surrounding cells.

Pressure, generated by cardiac contraction, drives blood flow around the circulation. Poiseuille's law relates volume flow ($\dot{Q}$) to the pressure drop ($P_1 - P_2$) along a tube of radius (r) and length (L) during steady flow, as follows:

$$\dot{Q} = (P_1 - P_2) \times \frac{\pi r^4}{8\mu L} \tag{11.1}$$

where μ is blood viscosity. Rearrangement of Eqn (11.1) hints at a somewhat more familiar form,

$$\frac{\pi r^4}{8\mu L} = \frac{P_1 - P_2}{\dot{Q}} \tag{11.2}$$

because the term on the left hand side of Eqn (11.2) is vascular resistance (R). Consequently,

$$R = \frac{P_1 - P_2}{\dot{Q}} \tag{11.3}$$

or, for the whole body, total peripheral resistance (TPR, kPa s/m^3),

$$\text{TPR} = \frac{\text{MAP} - \text{MVP}}{\text{CO}} \tag{11.4}$$

where MAP is mean arterial pressure (kPa), MVP is mean venous pressure (kPa), and CO is cardiac output (m^3/s). In order to compare animals of different sizes, it is common to express CO on a unit weight basis (i.e., m^3/s/kg).

Because the length (L) of any vascular channel is anatomically fixed while blood viscosity will only vary by 2–3 times, then vascular resistance is dominated by the radius of the vessels (Eqn (11.2)). Consequently, with a given pressure drop, halving vessel radius will reduce flow to one sixteenth, as shown in Figure 11.13, for a change in vessel radius from, for instance, two units (center profile) to one (left profile). This has important implications for the control of blood flow distribution.

Poiseuille's Law (Eqn (11.1)) applies to steady flow. However, in the major arteries, flow is highly pulsatile. In pulsatile flow, due to the inertia of the blood and high heartbeat frequencies, flow amplitude may no longer vary linearly with the pressure gradient. Nevertheless, the extent of the deviation from Poiseuille's law can be assessed from a nondimensional constant α (Womersley, 1957)

$$\alpha = r\sqrt{\frac{2\pi f\rho}{\mu}} \tag{11.5}$$

where r is radius, f is heart rate, ϱ is blood density, and μ is blood viscosity.

When $\alpha < 0.5$ for the fundamental frequency (i.e., heartbeat frequency), the phase lag is negligible and flow conforms approximately with that predicted by Poiseuille's equation. Calculations for the aorta of a duck give a value

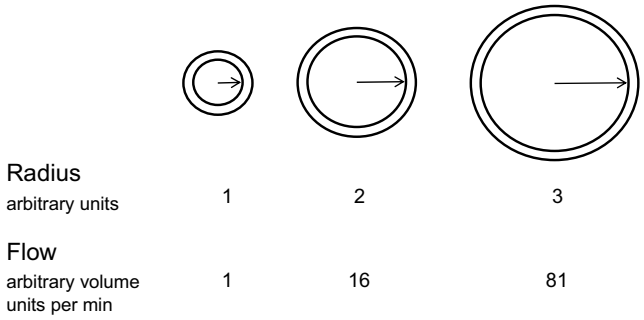

FIGURE 11.13 Effect of change in vessel radius as shown by the length of the arrow, on fluid flow with a constant driving pressure. Flow decreases in proportion to the fourth power of the decrease in radius. Radius dimensions and relative flow volumes are in arbitrary units.

for α of 6.0–7.0 for the fundamental frequency (about 3/s), so that estimation of flow by the Poiseuille formula is not reliable. However, it is obvious that for any given heart frequency, the value of α is directly dependent on the size of the vessel. Hence, in the femoral artery, α is certainly below 1, and flow will vary approximately linearly with the pressure gradient in this vessel. The vessels of the capillary circulation are small and α will be likewise, so application of Poiseuille's formula to this vascular bed would appear, superficially, to be most appropriate. Unfortunately blood viscosity, which can be regarded as a constant in larger vessels, may vary unpredictably in vessels of capillary size (Section 11.4.2). Therefore, caution is the watchword when applying steady flow formulations to flow driven by an oscillating pump. Even so, pulsatile flow has a mean, steady flow component and Pouseuille's law can be applied to this component, as in calculations of TPR (Eqn (11.4)).

Fourier analysis of pulsatile flow (and pressure) waveforms can be used to isolate the mean from the oscillatory components. The latter are resolved as a series of sinusoidal waves at the harmonics of the original waveform (the first harmonic is fundamental frequency (f); second harmonic is $2f$, …, nth harmonic is nf). If pressure and flow waveforms are recorded simultaneously, then dividing the oscillatory component of pressure by flow, at each harmonic, gives the vascular impedance. Consequently, vascular resistance (mean pressure divided by mean flow) can be considered as the impedance at zero frequency. The vascular impedance of any region of the circulatory system is thus determined by relating the corresponding frequency components of pressure and flow waves recorded simultaneously at that region. If pressure and flow are recorded at the input to the aorta, then aortic impedance is an expression not only of the characteristics of the whole systemic circulation but also of the afterload against which the left ventricle must work.

Pressure and flow recorded at the input to the arterial system start synchronously, yet peak flow velocity is reached before peak pressure. This rather anomalous situation is caused by the fact that the pulses travel through the arterial system. Therefore, for the pressure pulse, a positive gradient between an upstream and downstream point in an artery, established when the crest of the pressure wave traverses the upstream point, will reverse when the crest reaches the downstream point. Hence, the pressure gradient oscillates about a mean in all arterial vessels and flow will rise or fall or even reverse with these oscillations in the pressure gradient, although the presence of valves on the outflow tracts of the ventricles may limit the extent of reversal at the root of the aorta. Nevertheless, it is obvious that flow and pressure waves are not "in phase" and the extent of the phase difference, at each harmonic frequency, can be resolved by Fourier analysis.

The input impedance is presented (usually graphically, see Figures 11.14 and 11.15 in Section 11.4) as a set of terms of the values of modulus (|Z|) and phase (Φ) at each frequency obtained by Fourier analysis. Thus:

$$(|Z|) = \frac{\text{Pulsatile pressure}}{\text{Pulsatile flow}} \tag{11.6}$$

and

$$(\phi) = \text{Pressure phase} - \text{flow phase} \tag{11.7}$$

The phase of the impedance will be negative when the flow leads the pressure and positive when the pressure leads the flow.

11.4 THE VASCULAR TREE

11.4.1 Arterial System

11.4.1.1 Gross Anatomy

At least six pairs of aortic arches appear in the embryos of all vertebrates, recapitulating their aquatic ancestry. In birds, not all arches are present at one time and some are extremely transitory, such as the fifth pair of aortic arches, which make their appearance last. Only three arches persist in the adult, represented by the carotid artery (third arch), the aorta (fourth arch), and the pulmonary artery (sixth arch). In terrestrial vertebrates other than birds and mammals, both left and right branches of the fourth aortic arch are retained, whereas only the right persists in birds and the left in mammals. In some avian species, a remnant of the left aortic arch may remain as a solid core of cells; in a few others, such as the belted kingfisher (*Megaceryle alcyon*), the left arch remains patent and functional, although it loses its connection with the root of the aorta (Glenny, 1940). In an interesting series of experiments Stéphan (1949) demonstrated that ligation of the right aortic arch in the embryo causes the left to develop, as in mammals. This finding suggests that the retention or disappearance of aortic arches is dependent upon hemodynamic conditions, and it may be that the persistence of the right arch simply results from the unique development of the ventricular outflow tract in birds.

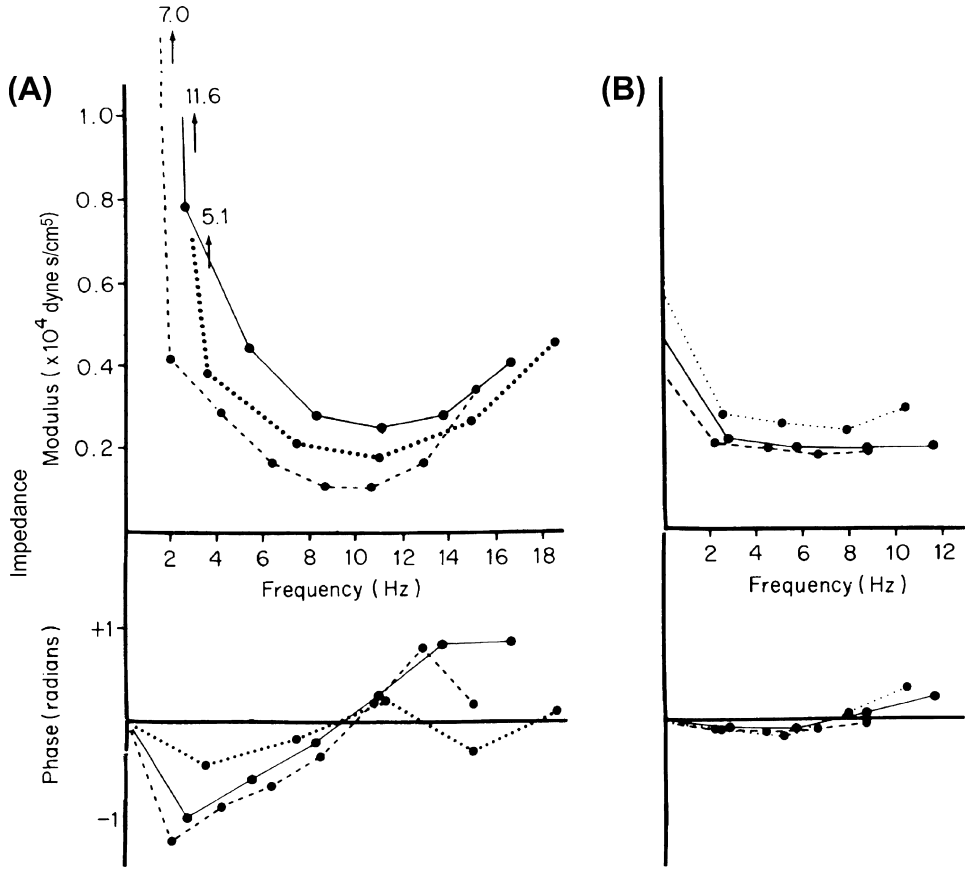

FIGURE 11.14 Impedance modulus and phase versus frequency graphs for aortic (A) and pulmonary (B) circulations in a duck. *From Langille and Jones (1975).*

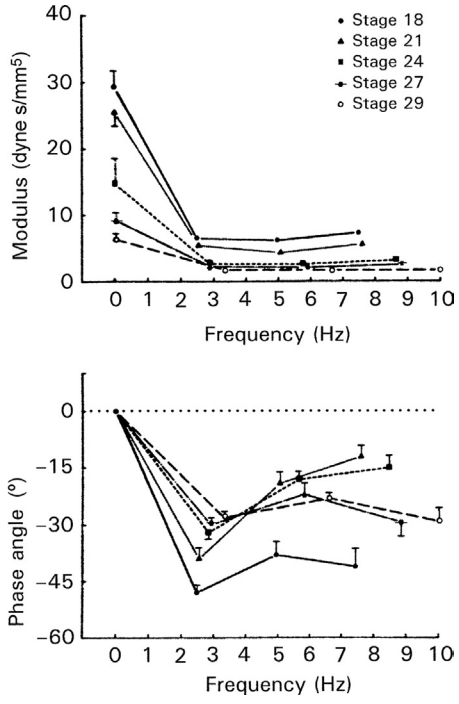

FIGURE 11.15 Impedance modulus (upper) and phase angle (lower) for chick embryos from stages 18–29. The identification key inset in the upper panel also applies to the lower panel. *From Zahka et al. (1989).*

The first major vascular bed supplied by the aorta is that of the heart. The coronary arteries, supplying the nutritional and respiratory circulation of heart muscle, arise from the ascending aorta close to the heart (Section 11.2.1.5). The ascending aorta then gives rise to two very large brachiocephalic trunks (Figure 11.16), supplying blood to the head, wings, and flight muscles. Each brachiocephalic vessel is usually larger in diameter than the continuation of the aorta, reflecting the higher blood flow rates in the brachiocephalics.

All arteries of the head and neck are branches of the carotid arteries. Surprising variation exists in the pattern of the carotid arteries close to the heart. The most common arrangement is two vessels of equal size running side by side (Figure 11.16). Other patterns include a single artery formed by fusion of both carotids (herons, bitterns, and kingfishers); a single vessel due to loss of the right (passerines) or left (plovers) carotid; or two arteries of unequal size (flamingos, sulfur-crested cockatoo).

Blood flow to the brain must not be interrupted, or impairment of brain function rapidly ensues. The carotid arteries lie in a groove in the base of the neck vertebrae close to the axis of rotation and are therefore protected from possible obstruction due to compression from neck movements. Other safety measures are provided by anastomoses between the carotid and vertebral arteries and,

at the base of the brain, by either an X-, I-, or H-shaped junction between the carotids. This intercarotid anastomosis has been found in all species of bird except those of the suborder Tyranni (Baumel and Gerchman, 1968). Birds do not possess a cerebral arterial circle of Willis comparable to that of mammals but, because the intercarotid anastomosis is relatively large in many cases, it may represent a more effective collateral circulation than the mammalian arterial circle. Blood to the wings and flight muscles is supplied by the subclavian arteries. Each subclavian divides into two branches, the brachial (wing) and pectoral (flight muscles).

The descending aorta runs caudally, ventral to the vertebral column, giving off paired intercostal and lumbar arteries. Blood is supplied to organs within the abdomen and legs by the following vessels, originating from the descending aorta (see Figure 11.16):

Celiac artery	Liver, spleen, glandular stomach, gizzard, intestine, pancreas
Cranial mesenteric artery	Most of intestine, pancreas
Renal arteries	Kidneys (anterior portion), testes
Femoral arteries	Legs
Ischiatic arteries	Middle and posterior portions of kidney and legs; uterine region of oviduct
Caudal mesenteric artery	Rectum and cloaca
Internal iliac arteries	Walls of pelvis; oviduct
Caudal artery	Tail, terminal branch of aorta

There are, in effect, three pairs of renal arteries in birds, one pair arising from the aorta and two from the ischiatic arteries. However, in the gray heron (*Ardea cinerea*), one pair of renal arteries arises from the femoral arteries instead of the ischiatics.

The ischiatic artery is the major vessel supplying the leg. At the level of the knee, it meets and joins the femoral artery to form the popliteal artery. This artery, passing into the lower leg, divides to form the anterior and posterior tibial arteries. In the tarsal region of the leg and in the axillary region of many birds, there are arteriovenous networks of vessels referred to as *rete mirabile*, particularly prominent in wading and aquatic birds (Midtgård, 1981). These structures serve as heat exchangers, because warm arterial blood is brought into close proximity to venous blood that has traversed the distal parts of the limbs and is therefore colder. The countercurrent arrangement of blood flow ensures that heat can be transferred from arterial to venous blood all along the length of the artery and vein apposed in the *rete*, thereby reducing heat loss to the environment by reducing the temperature of arterial blood flowing through peripheral thinner sections, such as the web of the foot or the wing.

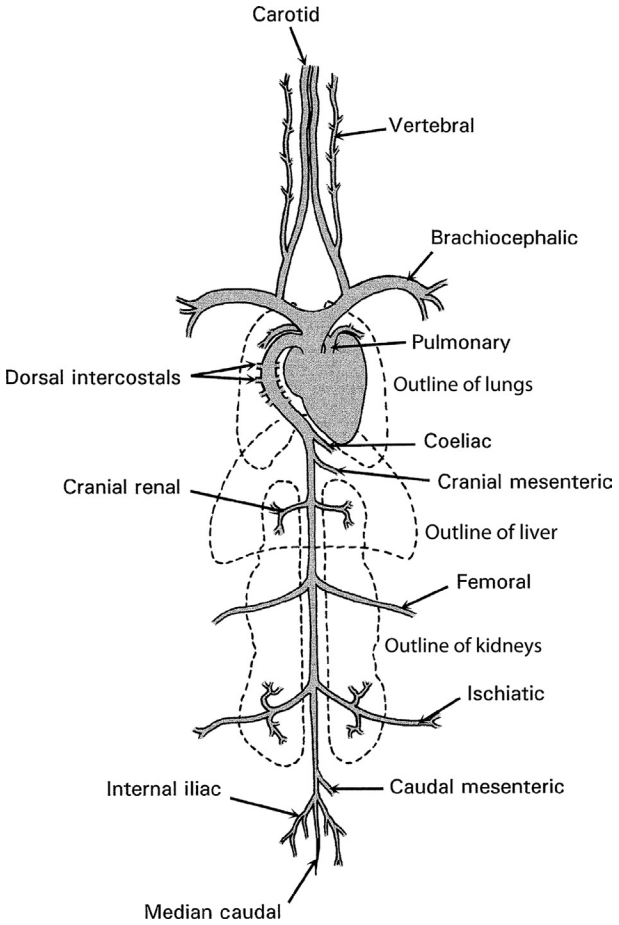

FIGURE 11.16 **The major systemic arteries in the bird.**

11.4.1.2 Functional Morphology of the Arterial Wall

The large arteries have two main functions. First, they serve as low-resistance conduits carrying blood to the arterioles for distribution to the peripheral vascular beds. Second, the whole arterial system serves as a pressure reservoir or *Windkessel*, accepting the volume of blood ejected by the heart and converting the highly pulsatile input into a steady flow of blood through the capillary beds. The *Windkessel* results from wall elasticity, particularly of those vessels close to the heart.

The central arterial vessels are elastic, whereas the more peripheral ones, certainly distal to the second order of branching, are muscular. In elastic arteries, the vast majority of the wall is made up of layers of smooth muscle embedded in elastin fibers, alternating with layers of collagen. One layer, composed of a combination of muscular, elastic, and collagen fibers, forms a single lamellar unit within the wall. Large numbers of concentric lamellar units make up the bulk of the wall of elastic arteries of pigeon, chicken, and the mute swan (*Cygnus olor*), as shown in Figure 11.17 (Bussow, 1973). Interestingly, the lamellar units do not

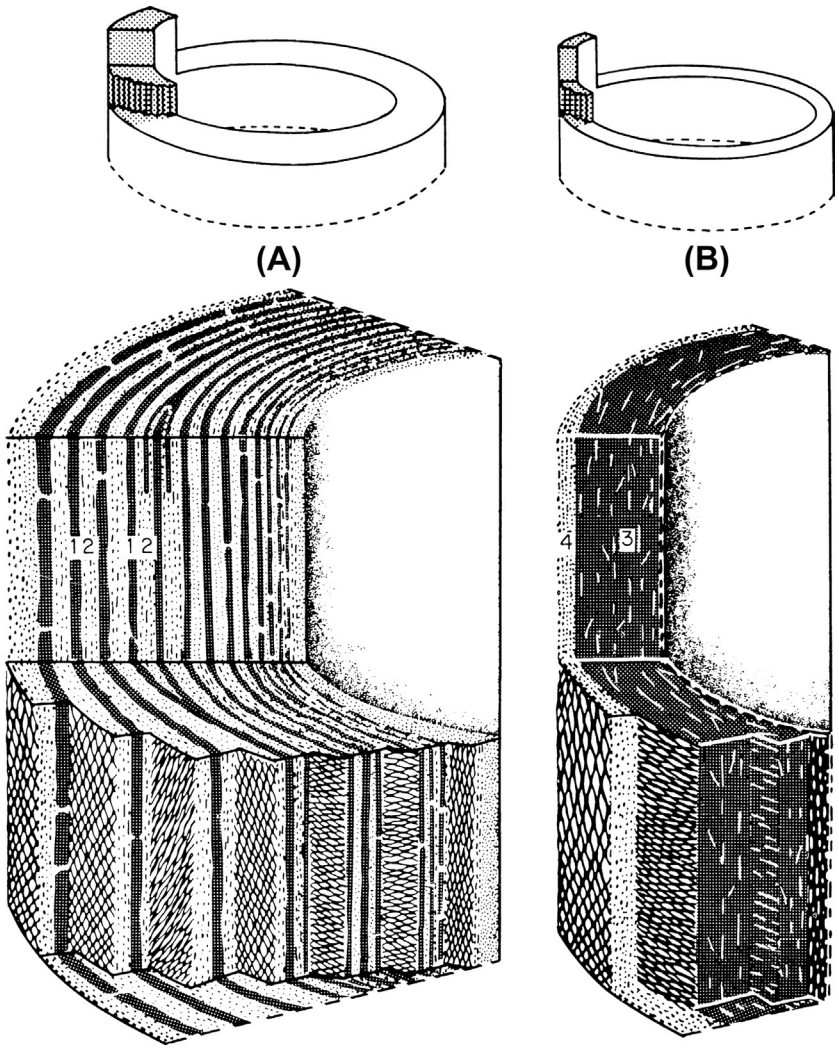

FIGURE 11.17 Schematic depiction of an elastic (A) and muscular (B) artery wall. (A) Wall structure of an avian elastic artery. The wall is composed of fragmented smooth muscle layers embedded in a fine network of elastic fibers (1) alternating with layers of collagen (2). (B) Wall structure of an avian muscular artery consisting of a thin intima, a media made up of smooth muscle cells and elastic fibers (3), and a thick adventitia with a well-defined elastica externa (4). Upper diagrams compare wall thickness of elastic and muscular arteries of similar lumen diameter. The wall of the elastic vessel is about three times as thick as that of a muscular vessel. *From Bussow (1973).*

form complete cylinders around the vessel. This is particularly obvious in vessels very close to the heart where an individual lamella may extend around only one quarter, at most, of the vessel circumference.

Wall structure of the muscular arteries is very different. Muscular vessels consist largely of circumferentially arranged smooth muscle cells with elastic fibers distributed, either singly or in bundles, as a wide-meshed plexus between the muscle cells (Hodges, 1974). The collagenous components are transferred to the outer layer of the wall. An interesting embellishment of the normal structure of muscular arteries occurs in the cranial mesenteric artery of the chicken and turkey (Ball et al., 1963). This vessel is invested by longitudinally arranged smooth muscle fibers, the thickness of this layer being approximately the same as that of the circumferentially oriented smooth muscle within the wall proper. The functional significance of the external muscle layer is unclear, but it may serve to shorten the vessel to accommodate changes in its position brought about by gut movements.

The elastic arteries include the aortic arch and its major branches, the thoracic aorta up to about the level of the celiac artery, and the extrapulmonary portions of the pulmonary arteries, whereas all branches of the abdominal aorta as well as the caudal portion of the aorta itself are muscular. In most regions of the arterial tree, the change from an elastic to a muscular wall occurs rather abruptly, usually at a branch site. An exception to this is the aorta itself. In the aorta, the elastic and muscular portions are separated by a segment of the vessel extending from the coeliac artery to the ischiatic arteries, whose wall structure fits neither description very well. Furthermore, in both the pigeon and turkey the wall in

this region is transversely asymmetric with a thick, muscular ventral wall and a thin elastic dorsal wall.

The arteries *in vivo* expand and recoil with every heartbeat, although this behavior is seldom mimicked *in vitro* during experiments designed to study vessel mechanics. Instead, the static rather than dynamic elastic behavior of the arterial wall is usually investigated. Essentially, a short length of excised blood vessel is inflated from a syringe and the pressure change induced by a given volume change is noted. These pressure–volume loops give an immediate and compelling view of how arterial elasticity changes with the degree of inflation.

Furthermore, by using blood vessels from different areas of the body, regional variations in elasticity are revealed. Pressure–volume loops are usually J-shaped, showing that the more a vessel is stretched the more resistant it becomes to further stretch (Figure 11.18; Speckmann and Ringer, 1966). The collagen fibers in the vessel wall inhibit expansion at high pressures, whereas the properties of elastin dominate the lower pressure limb of the curves. It is the compliance of elastin and the stiffness of collagen working in concert that allows uniform and smooth expansion of the vessel wall over a range of distending pressures without formation of aneurysms. In contrast, a wall in which the properties of extension remain constant across the range of distending pressures would be prone to aneurysm formation. Rubber has a straight rather than J-shaped response to distension and aneurysms always occur in the wall of cylindrical balloons when they are inflated.

When a blood vessel is inflated, more pressure is required to expand it than is recovered during recoil of the elastic walls. The ratio between the energy recovered in deflation to that expended in inflation is a measure of the resilience of that vessel (Figure 11.18). Surprisingly, resilience is similar for both thoracic (elastic) and abdominal (muscular) aortae of the turkey. Over the range of arterial pressures encountered in turkeys, resilience lies between 85% and 87%—values that are well above those of most mammals and approaching those obtained for invertebrate blood vessels. In one sense, the higher the resilience, the better because most of the energy cost of stretching elastic vessels with each cardiac ejection will be returned by elastic recoil on deflation. Unfortunately, if the resilience is too high, then the vessels may go into uncontrolled oscillations (resonance), particularly at the high repetition frequencies (heart rates) seen in many birds. Obviously, vascular engineering in birds is close to the edge.

Pressure–volume loops reveal characteristics specific to particular segments of whole vessels, whereas the properties of the materials making up a vessel wall are revealed by stress–strain curves (Figure 11.19(A)). Stress is the deforming force divided by the area of the vessel wall over which it is applied while strain is the ratio of the stretched radius to the unstretched radius of the vessel. Stress–strain curves for the ascending and descending aortae, the brachiocephalic arteries, and the thoracic aorta of the duck (*Anas*

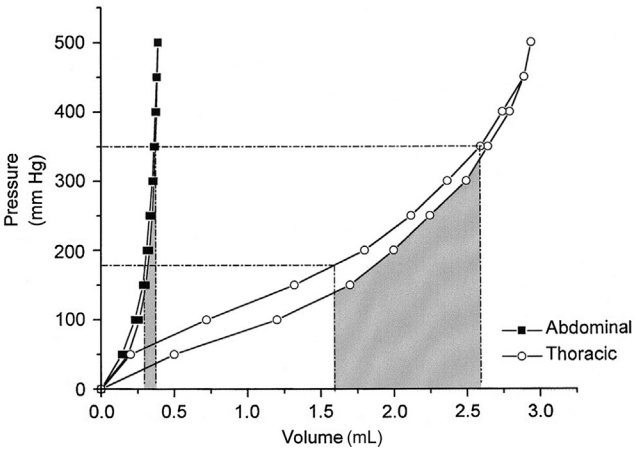

FIGURE 11.18 Typical pressure–volume loops for the abdominal and thoracic regions of the aorta in a turkey. For each loop, the upper curve is the inflation sequence and the lower curve the deflection sequence. Resilience of the vessel is obtained by dividing the area under the deflation sequence (shaded) by the area under the inflation sequence over the range of blood pressures recorded in turkeys. *From Speckmann and Ringer (1966).*

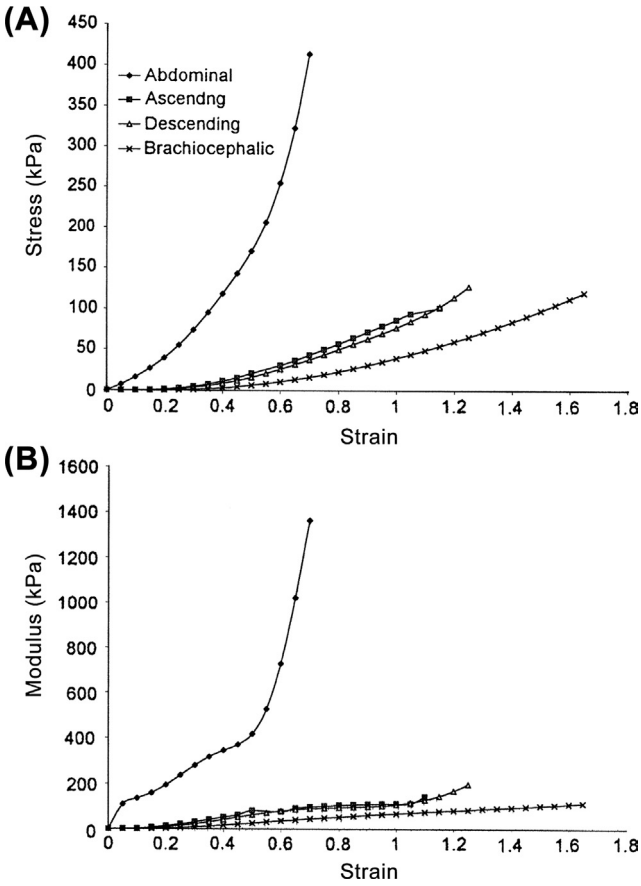

FIGURE 11.19 (A) Stress–strain curves for the blood vessel wall from four regions of the aorta in a duck (*A.platyrhynchos*). (B) The static elastic modulus of these vessels derived from data in A. *From Braun and Jones (unpublished data).*

platyrhynchos) are shown in Figure 11.19(A). The stress–strain relationship for the abdominal aorta lies to the left of that for the other, more central, vessels indicating that, as in the turkey (Figure 11.18), the abdominal aorta is stiffer than the other vessels—a finding that would be expected given that the abdominal portions of the aortae of duck and turkey have more collagen than do more central segments of this vessel.

The slope of the line of a stress–strain curve is the elastic modulus of the material making up the blood vessel wall, but, since the slopes for blood vessels are not linear, the elastic modulus is continually changing. The incremental elastic modulus describes the elastic modulus for a small increment in strain (Bergel, 1961). Incremental elastic moduli for the duck aorta, which are similar to those for the turkey aorta (Speckmann and Ringer, 1964), are shown in Figure 11.19(B). The moduli for the abdominal aorta are well above that for the thoracic, confirming that the former is stiffer than the latter. Nevertheless, these moduli are one to two orders of magnitude below those obtained from arteries in corresponding parts of the mammalian vascular tree. In mammals, the lamellar units in the wall form complete cylinders so that those laminae containing primarily collagen must be stretched to the same extent as the more distensible muscular laminae. Consequently, such rigid laminae are more important in determining the degree of extension of the wall. However, in birds, arterial lamellar units do not form complete cylinders, so there is some "series" coupling between the rigid and elastic components of the wall that allows more distensible laminae to be extended somewhat independently. Avian blood vessels have much thicker walls than mammalian vessels of the same diameter, thus compensating for their lower elastic modulus (Bussow, 1973).

11.4.1.3 Relationship between Arterial Pressure and Flow

Each heartbeat sends a pulse through the arterial system, which arrives later at sites more distal to the heart. The velocity at which the pulse wave travels is lowest in the most distensible vessels and increases in the stiffer peripheral vessels. In ducks, pulse wave velocity increases from 4.4 ± 0.8 m/s in the aortic arch to 11.7 ± 1.2 m/s in the abdominal aorta, with the major increase in velocity occurring in the thoracic aorta (Langille and Jones, 1975).

When the pulse transit time occupies a considerable proportion of each cardiac cycle, then significant phase changes occur between the pressure and flow pulses at different arterial sites. In ducks, the time taken for the pulse to travel from the heart to the distal end of the abdominal aorta is around 20 ms, which is about 5–10% of the cardiac cycle (Langille and Jones, 1975). Consequently, in ducks, there are marked changes in the waveform of the systemic pressure pulse as it travels through the arterial system (Figure 11.20). Both pulse amplitude and the contour of the pulse waveform are altered, with pulse pressure increasing by about 30%. This peaking of the pressure pulse results from a marked increase in the systolic portion, with little change in the diastolic portion (Figure 11.20).

Peaking of the pressure pulse is due to wave transmission effects, primarily wave reflections. All forms of wave motion can be reflected by physical changes in the system they are traveling through. When such changes occur within the arterial system, incident pressure and flow waves will be reflected back toward the heart. These physical changes can be discrete discontinuities, such as those due to arterial branching (McDonald, 1974) or continuous variations in wall compliance due to an increase in arterial stiffening toward the periphery (Langille and Jones, 1975, 1976). However, the major reflecting site seems to be the terminal vascular bed. From this site, pressure and flow pulse waves are reflected back toward the heart to interfere, destructively or constructively, with the incident wave generated by cardiac contraction. This interference means that pressure and flow waves recorded simultaneously at any one site in the arterial system will be quite unlike those recorded at another. In a reflectionless system, pressure and flow pulses sampled at any given site should look similar to those recorded anywhere else in the system.

An essential question concerns the nature of the termination that the peripheral vascular beds present to outgoing pressure and flow waves. Peripheral beds are closed terminations if they present a relatively large impedance to pulsatile flow; they are open if they present a relatively low impedance. In higher vertebrates, reflections produce large oscillations in peripheral pressures that drive small oscillatory flows through the terminal vascular beds (Figure 11.20), indicating a high terminal impedance (i.e., of the closed type). Hence, the pressure should be reflected at the closed end without a phase shift while, to satisfy the condition that high-pressure oscillations are required to drive low oscillatory flows through a high terminal impedance, the reflected flow wave should be inverted. That is, the reflected wave should be 180° out of phase with the incident wave. However, how much of the incident wave reaches the termination (because the incident pulse is attenuated, especially in the smaller vessels, as it propagates through the system) and how much of the reflected wave gets back to the heart (because its amplitude is also reduced by damping) is still a matter of speculation.

The reflection coefficient (that portion of the incident wave reflected by the terminal vascular beds) is extremely sensitive to the state of the peripheral vasculature. Under resting conditions, up to 80% of the incident wave may be reflected. Intense vasoconstriction occurring in ducks

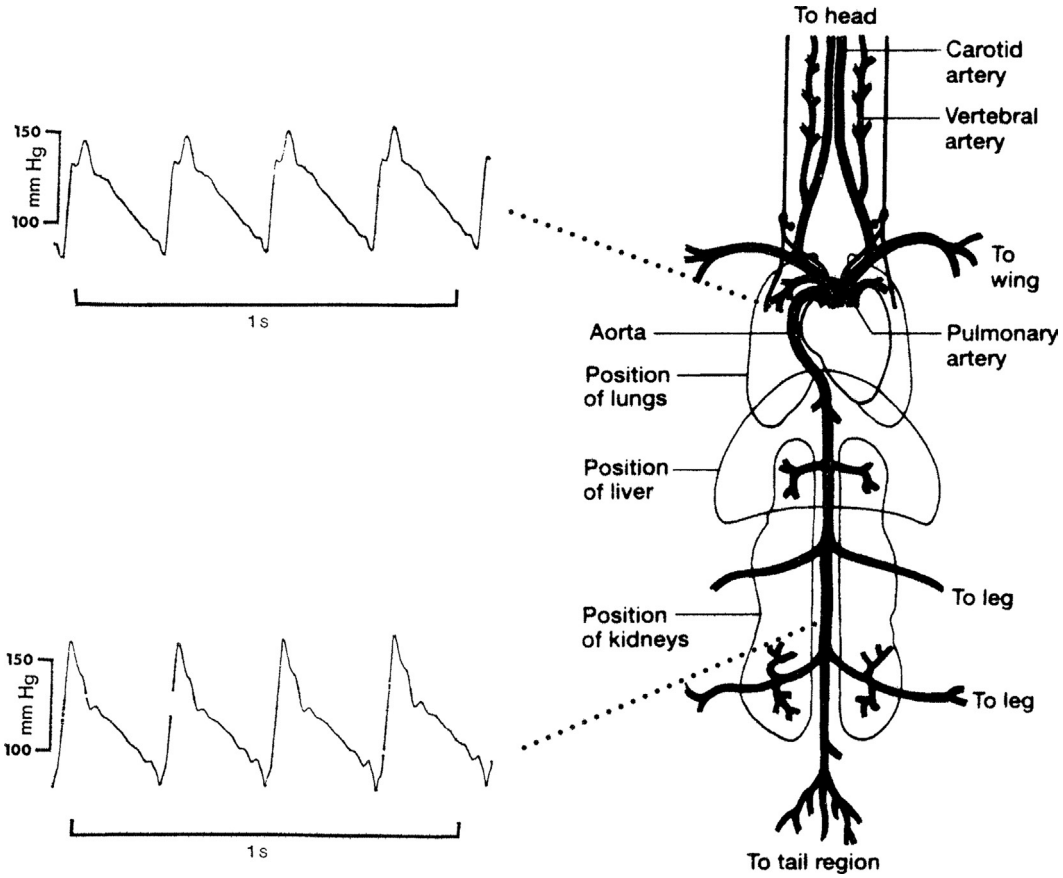

FIGURE 11.20 Diagrammatic representation of pressure waves recorded simultaneously in the proximal and distal aorta of a duck. Amplification and distortion of the pressure wave occurs during propagation along the aorta. *Modified from Langille and Jones (1975).*

during forced diving or when voluntarily diving birds are trapped underwater and unable to surface causes 100% of the incident wave to be reflected. In contrast, vasodilatation of peripheral vascular beds, occurring during exercise or hemorrhage, may reduce the reflection coefficient to zero.

Evaluation of wave propagation through the arterial system is complex, requiring harmonic analyses of pressure and flow waveforms. Fortunately, a simple conceptual analysis of the interaction of incident and reflected waves in the arterial tree is sufficient for the present purpose. For simplicity, consider a pressure wave displaying simple harmonic motion, as illustrated in Figure 11.21 (first harmonic). At the closed end of the system (terminal vascular beds), both incident and reflected pressure waves will be in phase and the waves will sum giving an antinode, evident as an enlarged pressure oscillation. The reflected wave is shown as 40% of the incident wave in Figure 11.21 so that the amplitude of the resultant compound wave will be 140% of the incident wave, as is shown by the wave envelope. Now, consider a point one-quarter wavelength back from the termination. The incident wave left here one-quarter of a cycle before it reached the closed end and the reflected wave takes another one-quarter cycle to return to this point,

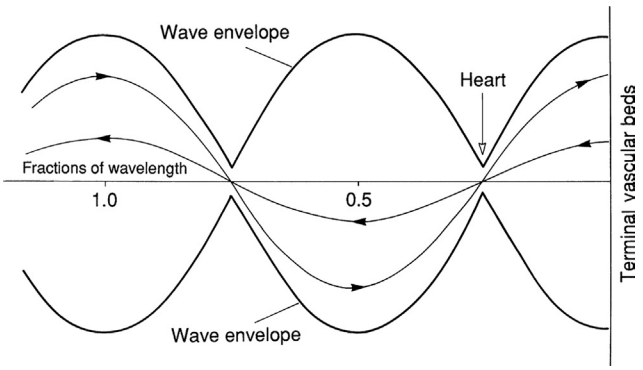

FIGURE 11.21 Interactions between incident and reflected pressure waves at a closed end (terminal vascular beds). For clarity, it is assumed that only 40% of the wave is reflected from the closed end (i.e., reflection coefficient = 0.4). The abscissa is marked in fractions of a wavelength. At the point of reflection, both waves are in phase and sum together. With reference to a point one-quarter wavelength away, the incident wave is 90° earlier and the reflected wave 90° later so that they are 180° out of phase and cancel. This point is a node and the only oscillation is the difference between the maximum amplitudes of the incident and reflected waves. For maximum benefits in terms of promoting cardiac efficiency the heart should be located at this point. The total excursion throughout the cycle is represented by the wave envelope (heavy outer lines). *Modified from McDonald (1974).*

so the incident and reflected waves are now 180° out of phase and destructive interference produces a node, evident as a decrease in pressure. Hence, the amplitude of the resultant wave is some 40% smaller (as shown by the wave envelope in Figure 11.21) than it would be in the absence of reflections.

The flow wave will also be reflected such that the incident and reflected waves are 180° out of phase at the termination but are in phase one-quarter cycle away from the terminal impedance. Hence, the flow waves will cancel one another at the termination and will sum at the heart. Therefore, highly oscillatory cardiac outflow is generated for less pulsatile pressure than would be the case in a nonreflecting system; the advantage of this is that more external cardiac work is available for any given level of cardiac oxygen consumption (Milnor, 1979).

The benefits of such reflections will be maximized when the heart is one-quarter wavelength upstream of the major reflecting site. In ducks, resting heart rate is 2–3 beats/s; therefore, even at the lowest pulse wave velocity (4 m/s), the major reflecting site would have to be located one-third or one-half meter from the heart—a most unlikely possibility. During exercise, however, heart frequency may double and the major reflecting site would now be 16–25 cm from the heart. Unfortunately, exercise is associated with vasodilation, which will reduce the reflection coefficient. In contrast, vasoconstriction during forced or voluntary diving, especially if the bird is trapped underwater, would accentuate reflections but heart frequency is now about 0.33 beats/s (or one beat every 3 s).

Consequently, obtaining the necessary balance between heart rate and reflection coefficient to maximize beneficial reflection effects seems unlikely. What then are the consequences of a mismatch between pulse wavelength and distance between the heart and major reflecting sites? Let us assume that Figure 11.21 describes the second and not the first harmonic of the pressure wave. In this case, the first harmonic will be 90°, not 180°, out of phase at the heart. This represents an antinode for the first harmonic which will add to systolic pressure, causing the heart to expend more energy. The heart will be located at a node for the second harmonic but at an antinode for the third (270° out of phase). As the first three harmonics contribute about 80–90% to the original pulse amplitude, then the net effect will be an increase in systolic pressure. In the duck, this is seen as a significant early systolic shoulder in the pressure pulse recorded in the aortic arch (Figure 11.20).

If the transit time of either pressure or flow waves through the arterial system becomes less than 5% of the cardiac cycle, then reflection effects on the shapes of these waves are not obvious. Nevertheless, reflections occur, but they are diffuse; the pressure wave bounces back and forth between the heart and periphery, until damped to extinction. In humans, atherosclerosis causes a loss of pressure pulse amplification as the pulse travels through the arterial system (O'Rourke et al., 1968); similar observations have been made in the turkey, *Meleagris* (Taylor, 1964), where atherosclerosis is very common (Ball et al., 1972; Manning and Middleton, 1972). Loss of pulse amplification in atherosclerosis results from a generalized stiffening of the major arteries, which acts to speed pulse wave propagation and thereby minimize wave transmission phenomena.

The hummingbird is among the smallest homeothermic vertebrates. Is it possible to predict the hemodynamics of the hummingbird from our knowledge of hemodynamics in the duck? Assuming pulse wave velocity is unaltered, then for similar conditions to hold in both hummingbird and duck, heart frequency (f_H) must increase in the same proportion as the linear dimension (L) of the animal decreases with reduction in body mass (M_b). For birds, the allometric equation relating f_H and M_b is $f_H = k_1 \cdot M_b^{-0.28}$ (Grubb, 1983; see Section 11.2.2), whreas $L = k_2 \cdot M_b^{-0.33}$ where k_1 and k_2 are constants.

According to this analysis, a hummingbird 400 times smaller than a duck will have a f_H 5.3 times higher but L will decrease nearly seven times. Even at the highest f_H reported for the giant hummingbird (*Patagona gigas*) of 1020 beats/min (Lasiewski et al., 1967), pulse transit time as a proportion of the cardiac interval will be considerably less than that in the duck and reflection effects on pulse wave shapes will probably not be obvious (Jones, 1991).

11.4.1.4 Vascular Impedance

While the complex pressure and flow waves recorded in avian arteries (Figure 11.22) are not directly comparable they, like all periodic signals, can be expressed as a sum of sinusoidal signals of ascending frequency (harmonics). These individual harmonics of pressure and flow are directly comparable (see McDonald, 1974). Comparison can be done most conveniently by determining vascular impedance versus frequency. Impedance modulus (amplitude of a pressure harmonic divided by amplitude of the flow harmonic of the same order) is the analog of vascular resistance that is applicable to pulsatile flows. Impedance phase is simply a measure of the degree to which pressure and flow oscillations are out of synchrony.

Figure 11.14(A) illustrates impedance versus frequency curves for the circulation supplied by the descending thoracic aorta of *Anas*, while Figure 11.14(B) illustrates the vascular impedance of the pulmonary circulation. Aortic impedance falls from the value at zero frequency, the peripheral resistance (Z_t), to settle at a steady value at high frequencies; this is an indication of the characteristic impedance (Z_o); (Figure 11.14(B)). Peripheral resistance and characteristic impedance are measures of arteriolar caliber and aortic distensibility respectively, uninfluenced by wave reflection effects. Often, the modulus and phase are not constant but fluctuate;

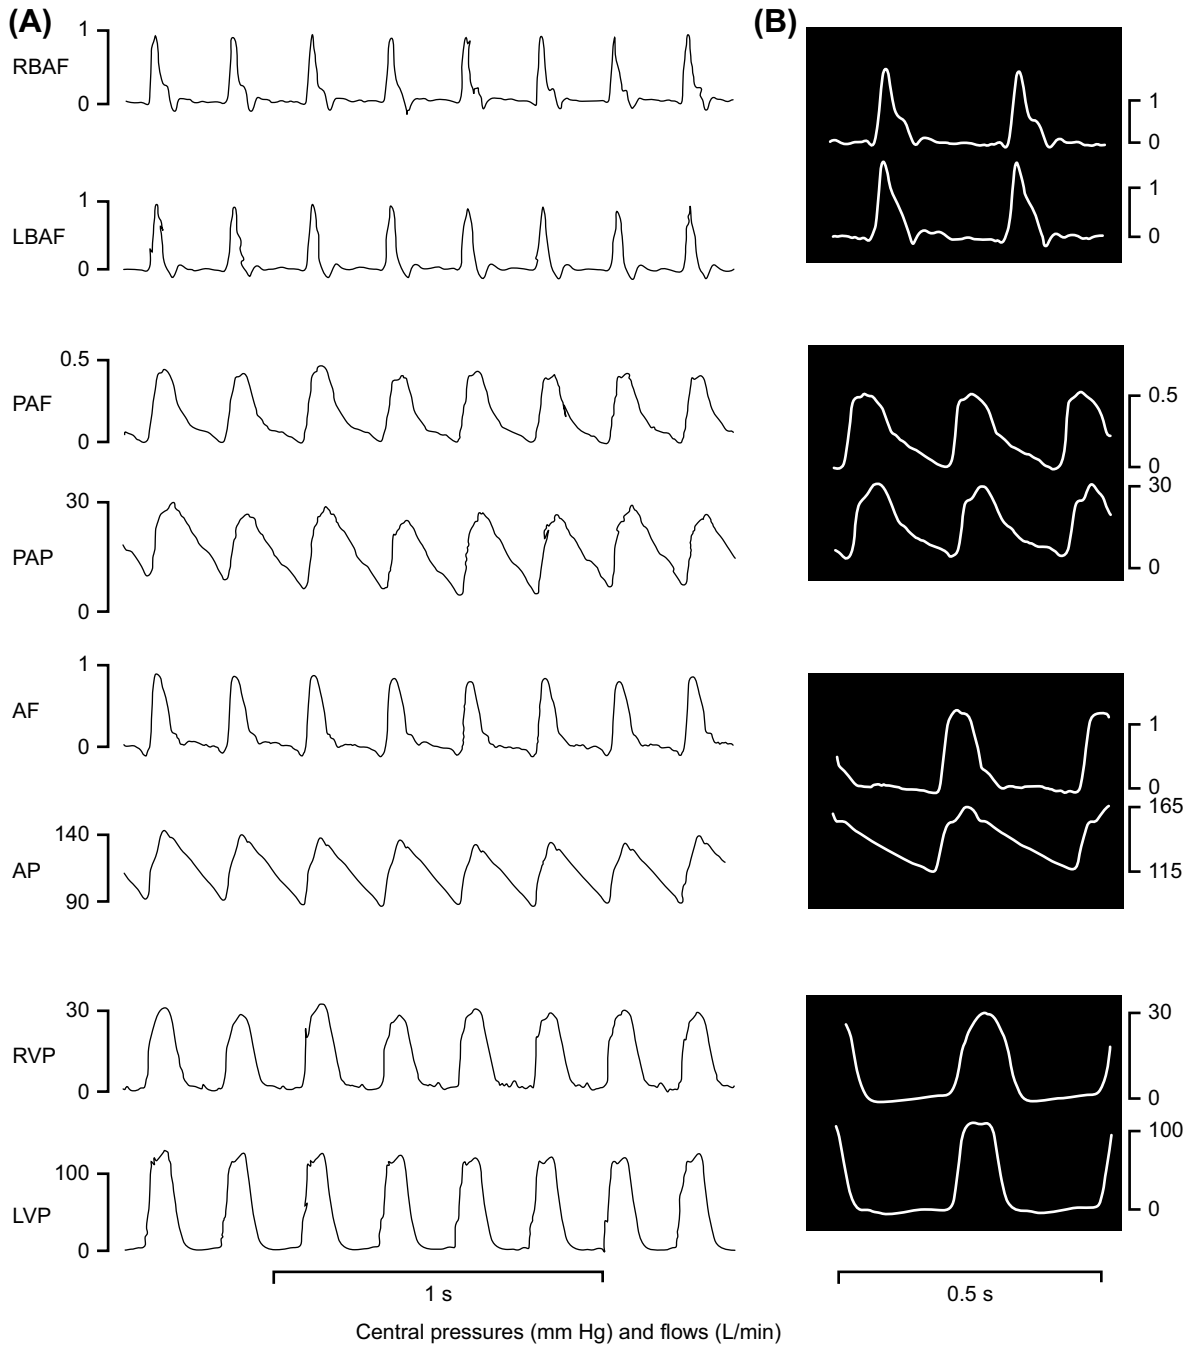

FIGURE 11.22 Pressures (mm Hg) and flows (L/min) recorded simultaneously in the arterial system of a duck. Traces, from top to bottom: RBAF, flow in right brachiocephalic artery; LBAF, flow in left brachiocephalic artery; PAF, pulmonary arterial flow; PAP, pulmonary arterial pressure; AF, aortic flow; AP, aortic pressure; RVP, right ventricular pressure; LVP, left ventricular pressure. Panels on right represent paired oscilloscope records of central pressures and flows. Traces match those on the left but each pair was recorded from a different animal. *From Langille and Jones (1975).*

these fluctuations are caused by wave reflection effects from peripheral vascular sites. A well-defined minimum in the impedance modulus of the aortic circulation, and a coincident rise in impedance phase from negative values (pressure lagging flow oscillations) to positive values (pressure leading flow oscillations), are characteristics of a wave reflecting system (Figure 11.14(A)). At the frequency of the impedance minimum (10 Hz), the circulation imposes minimal load for pulsatile flow on the heart (Figure 11.14(A)).

The reflection coefficient depends on the impedance mismatch between the terminal arteriolar bed and the supply artery and is given by the ratio

$$(Z_t - Z_o) / (Z_t + Z_o) \times 100$$

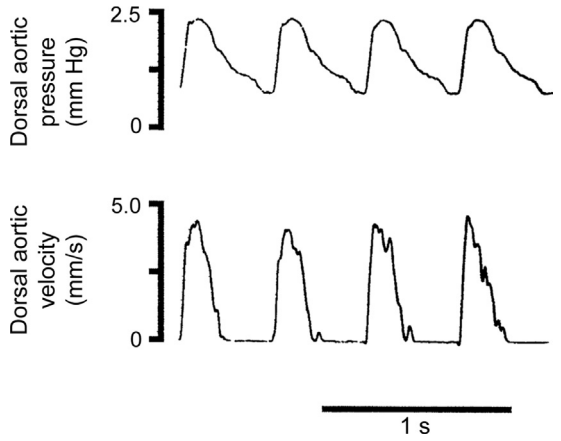

FIGURE 11.23 Dorsal aortic pressure and flow velocity recorded simultaneously from a stage 24 chick embryo. The pressure and flow waveforms are similar to those recorded from mature animals (see Figure 11.14) despite the absence of a semilunar valve apparatus. *From Zahka et al. (1989).*

For the aortic circulation, the reflection coefficient is high, being over 80%. However, in the pulmonary circulation, the absence of clear impedance minima suggests that this low-resistance circulation does not give rise to major reflections of the pulse wave. In fact, the reflection coefficient for the pulmonary circuit is only 25%.

Pulsatile pressure and flow are generated by the first, embryonic cardiac contractions. In stage 24, chick embryos pressure and flow waveforms resemble those recorded from mature animals, despite the absence of the semilunar valve apparatus in the heart (Figure 11.23; Zahka et al., 1989). Both peripheral resistance and vascular impedance modulus decrease with development through stages 18–29 (3–6 days, development; Figure 11.15). Over this period, mean dorsal aortic pressure and flow increase 13 and 10 times, respectively, with the increased flow being accommodated by the rapidly expanding arterial bed. The velocity of pulse wave propagation increases with developmental stage, from around 0.5 m/s at stage 18 to nearly 1 m/s at stage 24 (Yoshigi et al., 1997). Hence, pulse transit time will be a negligible fraction of the cardiac cycle (0.35–0.45 s) so that reflection effects will be unimportant. Even if this were not the case, reflection effects would be minimized in the later stages of embryonic development because of the marked decline in vascular resistance. Consequently, the fall in vascular impedance during embryonic development is due to the growth of a larger, more distensible, dorsal aorta in which elastic fibers first appear at stage 29 (Hughes, 1942).

11.4.2 Capillary Beds

11.4.2.1 Gas Exchange

Systemic capillaries form a vital functional interface between the blood and systemic tissues of birds. The pathway between erythrocytes in capillary blood and mitochondria in the surrounding tissue represents the last in a series of resistances in the oxygen transport pathway from the lungs. Oxygen and carbon dioxide move between the systemic capillary blood and the surrounding tissue mitochondria by simple diffusion. Therefore, the diffusion distance from erythrocyte to mitochondrion and the partitioning of diffusion resistance along this route is of immense physiological interest. The concept of a capillary domain, a volume of tissue whose oxygen demands could potentially be satisfied by diffusion from one capillary, was first expounded by August Krogh in 1914 and remains a valuable concept in understanding gas exchange in muscle tissue (Krogh, 1919). A simple explanation of the factors important in capillary blood–tissue gas exchange, based on this model, can be found in West (2008).

Studies on the systemic capillaries of birds, particularly those of flight muscle, have been dominated by two interesting themes: (1) the high workload of the avian pectoralis major muscle during flight, reflected in an increase in oxygen consumption of about five times that at rest (Butler et al., 1977), suggests that the functional anatomy of the pectoral muscle capillaries may reveal adaptations to both high tissue oxygen demand and mechanical tissue deformation during sarcomere shortening; and (2) some species fly at high altitudes (see Section 11.6). Therefore, there may be specific adaptations in capillary density or geometric arrangement that facilitates the delivery of oxygen to the working pectoralis muscle in the face of a relatively low P_{aO_2} (the pressure head for diffusion at the arterial end of systemic capillaries) caused by reduced atmospheric partial pressure of oxygen.

Three parameters may be considered in determining the capillarity of muscle. These are the number of capillaries per muscle fiber, the cross-sectional area of muscle fibers, and the geometrical arrangement of capillaries around each fiber (Snyder, 1990). Gray et al. (1983) found that sections of pure slow red muscle fibers from the anterior latissimus dorsi of chicken had 25% more capillaries per square millimeter than did sections of fast white fibers from the posterior part of this muscle. However, in six other species of birds ranging in mass from 11 g to 6.2 kg, there was no significant correlation between fiber diameter and capillary number per fiber in slow red fibers and fast white fibers of the anterior and posterior latissimus dorsi respectively. Thus, tissue capillary density decreased in muscle with larger fibers. Snyder (1990) estimated the maximum diffusion distance from capillary to mitochondrion in slow red fibers and fast white fibers of the gastrocnemius muscle to be on average 32.4 and 36.5 μm respectively. Torrella et al. (1999) found maximum diffusion distances ranging from 16.8 μm in the oxidative fibers of the mallard pectoralis to 34.4 μm in the glycolitic fibers of the mallard gastrocnemius. These are similar to the values obtained in mammals, suggesting that diffusion distance has been highly conserved in vertebrate

evolution. Increasing the number of capillaries per fiber appears to produce diminishing returns, such that beyond two capillaries per fiber there do not appear to be further measurable reductions in diffusion distance. In contrast to the situation in neonatal mammals, the capillary-to-fiber ratio in bird muscle appears to be fixed around hatching. Because the fibers hypertrophy during development, diffusion distances are shortest in newly hatched chicks—some 18 μm (Byers and Snyder, 1984).

The benefits conferred by reducing erythrocyte-to-mitochondrion diffusion distance depend on assumptions made about how the resistance to oxygen diffusion is distributed between source (blood) and sink (mitochondrion). It has been argued that the capillary-to-tissue interface represents the major resistance (Gayeski and Honig, 1986), in which case reducing the overall diffusion distance would be of limited effectiveness compared with increasing the area of this interface (see below).

Compared with the geometric arrangement in mammalian hind limb muscle, there are a larger number of capillary branches running perpendicular to the long axis of muscle fibers in pigeon pectoralis muscle (Mathieu-Costello, 1991, Figure 11.24). These branch from capillaries running parallel to the long axes of the muscle fibers. The branch points move closer together as the pectoralis muscle shortens on the power stroke, but the perpendicular orientation of the branches to the long axis of the muscle fibers does not change appreciably during contraction. The short segments of capillary parallel to the muscle fiber between these branches bow as the muscle shortens, but do not become particularly tortuous. The branches perpendicular to the long axis of the muscle fibers run around the circumference of the fibers; this arrangement, together with their high density, ensures that there is an effective envelope of capillary blood surrounding portions of the fibers. This results in very effective blood–tissue O_2 transfer (Ellis et al., 1983). Such an arrangement of capillary branches may compensate for the unfavorable rheological properties of avian blood compared with mammalian blood; these properties include relatively low red cell deformability and a low capillary hematocrit.

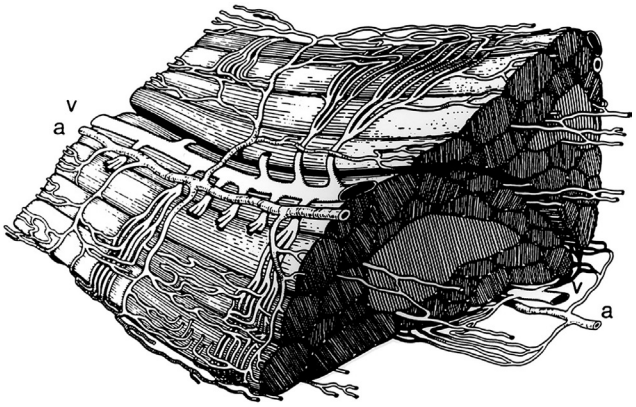

FIGURE 11.24 Schematic diagram illustrating the microvascular geometry in the pectoralis muscle of the pigeon. For clarity, the width and number of capillary branches running perpendicular to the long axis of the muscle fibers have been reduced. a, artery; v, vein. *Reprinted from Mathieu-Costello et al. (1994).*

Flying hummingbirds have the highest mass-specific metabolic rate of any vertebrate and hummingbird flight muscles have the highest oxygen demand of any vertebrate skeletal muscle. It would be expected, therefore, that the adaptations for effective gas exchange at the capillary level would be most obvious in these birds. These could include a reduced diffusion distance from the capillary to the mitochondria or possibly an increase in the capillary-to-fiber contact area. Increases in either of these factors would increase the flux of respiratory gases for a given drop in P_{O_2} across the capillary–mitochondrial diffusion distance. The ratio of capillary surface area to muscle fiber surface area is about twice as large in hummingbird flight muscle as in the rat soleus muscle, with similar mitochondrial density in the two muscles (Mathieu-Costello et al., 1992). Therefore, according to Fick's law, the rate of O_2 diffusion into the avian fiber would be about double that in the rat, all other factors being equal. This supports the idea that the large area of the capillary–muscle fiber interface in avian flight muscle plays an important role in enabling these muscles to maintain an extremely high oxygen usage during flight. The respiration rates of muscle mitochondria in working hummingbird flight muscle are about double those in the locomotor muscles of mammals. Interestingly, the size of this interface in the pectoralis muscle of the only actively flying mammal, the bat, is similar to that in hummingbird flight muscle.

The basic structure of the capillary network in the hummingbird is similar to that in pigeon flight muscle, although capillary density tends to be higher in the hummingbird. This results from the smaller cross-sectional area of the muscle fibers (one-half for aerobic and one-tenth for glycolytic) rather than from a greater number of capillaries surrounding each fiber (Mathieu-Costello et al., 1992). The smaller cross-sectional area of fibers may be an adaptation to reduce the diffusion distance from capillary blood to the mitochondria. However, some experimental and theoretical evidence shows that the main drop in P_{O_2} occurs across the resistance offered by the capillary–fiber interface and P_{O_2} then declines more slowly, largely because of myoglobin facilitated diffusion (Honig et al., 1991). Thus, a large contact area between capillary and fiber is probably a more important factor in effective oxygen delivery than a short path between capillary and mitochondrion. This is particularly true for flight muscle in both birds and bats where fiber myoglobin content, and therefore the potential for facilitated diffusion, is high. Interestingly, a comparison of actively flying and sedentary pigeons showed little effect

of flight conditioning on capillary–fiber relationships. Wild pigeons had a greater aerobic capacity than sedentary birds, achieved by a 30% greater cross-sectional area of aerobic fibers in the pectoralis together with a higher density of mitochondria. However, the capillary–fiber ratio was similar, as was capillary length–fiber volume at a given mitochondrial density (Mathieu-Costello et al., 1994). This finding is consistent with the results of Snyder and Coelho (1989), who caused hypertrophy of the right anterior latissimus dorsi of chickens by taping weights to the humerus. They found that the increased number of capillaries per fiber just matched fiber hypertrophy and concluded that muscle growth was the primary determinant of capillarity.

11.4.2.2 Microvascular Fluid Exchange

Capillary fluid balance is maintained by the dynamic interaction between hydrostatic and osmotic forces acting across the capillary wall, as first described by Starling over 100 years ago (Starling, 1896). Starling's original formulation has been modified and refined by Landis (1927) and Kedem and Katchalsky (1958), yielding the following equation to describe microvascular fluid exchange:

$$J_V = K_{FC}\left[(P_c - P_T) - \sigma_d\left(\pi_P - \pi_T\right)\right],$$

where J_V is net volume flow across the vascular wall, K_{FC} is capillary filtration coefficient, P_c and P_T are capillary and tissue fluid pressures, respectively, $(\pi_P - \pi_T)$ is colloid osmotic pressure (COP) difference between plasma (P) and tissue (T), and σ_d is the osmotic reflection coefficient.

In the steady state, the capillary blood pressure opposes the blood COP to maintain tissue fluid balance. Blood pressure exceeds COP at the arteriolar end of the capillary and is usually below COP at the venous end. Fluids are secreted at the arteriolar and absorbed at the venous ends of the capillary. Hence, for adequate fluid exchange, COP pressure must offset capillary pressure, the latter being a reflection of the arterial blood pressure (Landis and Pappenheimer, 1963). The value of the COP is determined by the concentrations and species of blood proteins as well as by cations held in the plasma by the Donnan effect of the proteins (Guyton et al., 1975). However, it is now clear that microvascular fluid exchange is a dynamic process in which extravascular forces, such as tissue fluid pressure, tissue COP, and the actual flow of lymph, can influence transcapillary fluid movement (Taylor and Townsley, 1987). In addition to heterogeneity of Starling forces in different areas of the microvascular beds, there is also the possibility that heterogeneity of capillary membrane permeability will also contribute to differences between global and local values of the Starling pressures (Michel, 1997). In the light of recent knowledge, the simplistic steady state view of secretion at the arteriolar end of the capillary and absorption at the venous end of the capillary can only be regarded as a transient phenomenon at best.

Studies on avian species have contributed little to this discussion although microvascular fluid exchange in birds presents some unique and interesting features. For instance, in turkey and duck, the ratio of protein concentration in the interstitial fluid to that in the blood is much lower than the ratio in mammals (Hargens et al., 1974). Hargens et al. (1974) have pointed out that the lower ratio in birds is correlated with a higher arterial blood pressure. Also, birds as a group seem to be highly resistant to hemorrhage, tolerating blood loss much better than mammals. Kovách and Balint (1969) have shown that increased hemorrhage tolerance becomes apparent only during prolonged bleeding because hemodilution continues in the pigeon through the period of blood loss, whereas in the rat no further hemodilution occurs after about 15–20 min of bleeding. Hemodilution is achieved by inflow of isotonic fluid with low protein content.

The restoration of blood volume results from absorption of tissue fluid across the capillary walls due to reduced capillary pressure. This fall in capillary pressure could be brought about by an increase in the ratio between precapillary and postcapillary resistances, as well as by changes in arterial and venous pressures during hemorrhage. Resistance changes across the capillaries seem to be the most important factor in rapid restoration of blood volume in ducks. Blockade of α-adrenergic receptors eliminates vasoconstriction in the skeletal muscle, which forms the major reserve of tissue fluid and leads to a greatly retarded restoration of blood volume (Djojosugito et al., 1968). Djojosugito et al. (1968) attribute the difference in ability to restore blood volume after hemorrhage in ducks and cats to a very pronounced reflex vasoconstriction in duck skeletal musculature and to a capillary surface area in ducks three to five times that in the cat, a condition that increases the rate of absorption of fluid into the vascular system (Folkow et al., 1966).

Many birds, such as the emu and ostrich, have extremely long necks, with the head being held a meter or more above the heart. Yet, the emu's resting mean arterial blood pressure (Grubb et al., 1983) does not differ from that of a pigeon (Butler et al., 1977). An exceptionally high blood pressure to overcome gravitational effects on circulation and to ensure flow to the head is not needed in these birds. In a fluid-filled system, the gravitational pressure of blood in the veins will counterbalance the gravitational pressure in the arteries of the neck, much like the loop of a siphon. In other words, it is no more difficult for blood to flow uphill than downhill in a system of closed tubes like the circulation. Overall circulatory flow around the body occurs due to a pressure difference between the aorta and right atrium, and it matters little what actual route the blood follows.

If pressure is measured in the cerebral circulation of a long-necked bird, this will be lower than that recorded in the aorta just outside the aortic valves by an amount sufficient to cause the required blood flow along the neck artery (a small difference) and by the gravitational effect due to the

height the head is held above the heart. If the head is held 1 m above the heart, pressure in the arteries of the head will be about 75 mm Hg less than at the heart. Consequently, in the cranial capillary beds, it is now possible that the hydrostatic pressure will be lower than the COP of the blood and fluid will be continuously removed from the interstitial spaces, with similar consequences to those following excessive alcohol consumption. However, because drunken ostriches are not a common sight, countermeasures such as markedly increased arterial blood pressure, decreased arteriolar resistance, or reduced blood COP must be in effect. It is now possible to obtain a ready supply of long-necked ostriches and emus, and it is hoped that these countermeasures can be subjected to empirical investigation.

11.4.2.3 Distribution of Blood Flow at Rest

The percentage of CO distributed to different organs is closely related to their aerobic metabolic activity and their size. The distribution of CO is ultimately determined by the relative resistance of systemic vascular beds that are arranged in parallel throughout the body. Vascular resistance, in turn, is determined by a variety of hormonal, autoregulatory, and neural control mechanisms (see Section 11.5). Values obtained by different investigators for relative blood flow (% CO) to various organs differ widely, probably reflecting differences in experimental technique, species, and resting conditions. Nevertheless, it is apparent from the limited data available that the heart, liver, kidneys, and intestines receive relatively large percentages of the total CO (Figure 11.6). The avian brain appears to receive about 3% of CO, similar to the proportion of CO going to the brain in a small mammal, such as the rat, at rest (Ollenberger and West, 1998).

By far the highest resting blood flows thus far measured in any avian organ (about 16 mL/min/g of wet tissue weight) are found in the spleen (Figure 11.25). This organ receives a disproportionately large percentage of total CO despite its small size (Figure 11.6). High tissue flow rates also have been found in the mammalian spleen; a flow of some 12 mL/min/g has been reported in conscious dogs (Grindlay et al., 1939). Such high rates are almost certainly related to the dual function of this organ: as a filter for aging erythrocytes, which are eliminated by the process of diapedesis; and as an organ of the reticuloendothelial system, in which the blood is cleaned by phagocytic reticuloendothelial cells as it passes through the splenic sinuses and pulp. Obviously, a high flow rate is needed for this dual filtration role to be effective. In contrast to splenic blood flow, the rate of cerebral blood flow in birds is an order of magnitude less. Blood flow to the whole brain and to individual cerebral regions ranges from 0.43 to just over 2 mL/min/g under normoxic conditions, as shown in Figure 11.25 (Bickler and Julian, 1992; Butler et al., 1988; Faraci and Fedde, 1986; Faraci et al., 1984; Grubb et al., 1977; Jones et al., 1979; Stephenson et al., 1994; Wolfenson et al., 1982; Ellerby et al., 2005). Both the heart and kidneys have relatively high rates of mass specific blood flow, reflecting the high oxygen demand of the contracting cardiac muscle and the activity of energy-dependent membrane pumps in renal tissue, respectively. Pectoral and gastrocnemius muscle, on the other hand, show relatively low perfusion rates at rest (Figure 11.25).

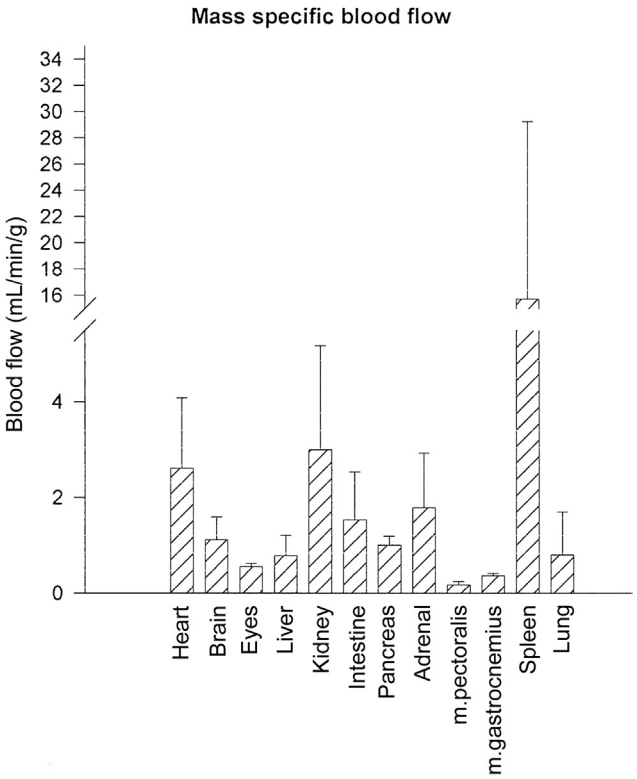

FIGURE 11.25 Mass-specific organ blood flow (mL/min/g) in birds at rest. Standard error bars are shown where appropriate. *Data from Butler et al. (1988) (tufted duck), Duchamp and Barre (1993) (muscovy duckling), Faraci et al. (1985) (Pekin duck), Jones et al. (1979) (Pekin and mallard), Stephenson et al. (1994) (Pekin duck), and Wolfenson et al. (1978) (chicken).*

11.4.3 Venous System

11.4.3.1 Functional Development of Venous System

The embryological development of the avian venous system follows a typical vertebrate pattern. At about the 15-somite stage of the avian embryo, paired cranial and caudal common cardinal veins develop from a vascular plexus in somatic mesoderm (Lillie, 1908; Sabin, 1917). The heart shifts caudally during embryonic development, and the cranial cardinal veins elongate to become the jugular veins. Subclavian veins, returning blood to the right side of the heart from

the pectoral region and the wings, arise as tributaries of the caudal cardinal veins (Ede, 1964). The adult avian venous system cranial to the heart differs in detail from the mammalian pattern in that there are two cranial (superior) venae cavae. The right jugular vein is much larger in diameter than the left, and there is an anastomosis between the jugular veins at the base of the head, allowing some blood draining from the left side of the head and neck to return to the heart in the larger right jugular vein.

Development of the venous system caudal to the heart is primarily concerned with the formation of the physiologically important renal and hepatic portal venous circulations (see below). Subcardinal veins, which develop along with the embryonic kidney (mesonephros), initially provide renal drainage into the caudal cardinal veins. Eventually, the anterior portions of the caudal cardinal veins disappear and the subcardinals form a connection with the ductus venosus; this connection becomes the caudal vena cava. The liver develops around the ductus venosus, which subdivides into a capillary bed, forming the hepatic portal circulation. The cranial portion of the ductus venosus becomes the hepatic vein and the caudal portion becomes the hepatic portal vein. Finally, the renal portal veins form a junction with the caudal vena cava via the common iliac veins and the caudal subcardinal veins are replaced by the caudal renal veins.

11.4.3.2 Capacitance Function

The walls of the veins in birds are, as in mammals, thinner than those of arteries; therefore, venous distension depends on a positive transmural pressure gradient. The three basic components of blood vessel walls—tunica intima, media, and externa—are present. The tunica media is composed of circumferential smooth muscle fibers. In larger veins, elastic laminae appear in the tunica externa, which makes up most of the wall tissue. Veins near the heart are frequently invested with cardiac muscle fibers that are apparently functional. The caudal vena cava of the mallard can occasionally be seen to contract at the same frequency as the sinus venosus.

As in mammals, the avian venous system does not necessarily represent a passive conduit returning blood to the heart. The thin, distensible walls of veins mean that these vessels are relatively compliant compared with arteries. As applied to blood vessels, compliance is the ratio of the change in vessel volume (ΔV) resulting from a change in transmural distending pressure (ΔP):

$$\text{Compliance} = \Delta V / \Delta P.$$

In mammals, the entire vascular system has a compliance of about 3 mL (blood) kg (body mass)/mm Hg. The compliance of the arterial vascular segment is only about 3% of that of the venous segment (Rothe, 1983). Therefore, despite the smaller vascular pressures in the venous side of the circulation, at any one time about 60–80% of blood volume is contained in the veins. They are therefore referred to as capacitance vessels. The capacity of the venous circulation can change either passively by changes in transmural pressure or actively by changes in the contractile state of venous smooth muscle. A reduced transmural pressure and therefore a passive elastic recoil of compliant veins, or a reduction in venous compliance by active contraction of smooth muscle in the venous walls, mediated by α-adrenergic receptors (Section 11.5.2.4), would both serve to reduce venous capacitance. This transfers blood toward the heart. All other things being equal, this would tend to increase atrial filling and therefore CO. The large veins of the domestic fowl are well innervated with adrenergic motor fibers (Bennett et al., 1974; Bennett and Malmfors, 1975b), and the density of this innervation suggests that there is active control of venous capacitance (Section 11.5.2.4), although to date there are no physiological studies in birds analogous to those of adrenergic effects on venous capacitance function in mammals (Vanhoutte and Leusen, 1969).

11.4.3.3 Physiological Role of Veins in Exercise and Submersion

Venous pressure in pigeons flying in a low-speed wind tunnel increased to 2.5 mm Hg from the resting value of 1.2 mm Hg (Butler et al., 1977). CO increased 4.4 times during flight, mainly accomplished by an increase in heart rate at a constant stroke volume. In flight, the increased pressure gradient from the venous end of capillaries to the right ventricle increases venous return, right heart filling, and CO via the Frank–Starling relationship. Venous pressure is determined by the relationship between venous volume and compliance, which is reduced as venous smooth muscle contracts and the vein walls stiffen. In mammals, the venous beds of the liver, spleen, and skin act as blood reservoirs that can actively reduce capacitance during exercise, thereby increasing venous pressure and volume of venous return to the heart (Rothe, 1983). Whether these venous vascular beds also constrict during flight exercise in birds is currently unknown.

Active venoconstriction may also be important in the cardiovascular adjustments to diving in birds. Djojosugito et al. (1969) provided indirect evidence that venous pressure increased during diving in ducks and this was confirmed by Langille (1983), whose results suggested that this was due to active venoconstriction. In the latter study, cardiac stroke volume fell if central venous pressure was held constant during diving. This suggests that reduced ventricular contractility, caused by an increase in vagal motor nerve activity to the heart, is normally counteracted during diving by increased venoconstriction-induced filling via the Frank–Starling mechanism (see Section 11.5.3.2.3).

11.4.3.4 Renal Portal System

In common with most other vertebrate groups, birds possess a renal portal circulation. Venous blood making its way back to the heart from the legs and the lower intestine of birds enters the kidneys through a renal portal system. Within the kidneys this blood mixes with postglomerular efferent arteriolar blood in peritubular sinuses that surround all nonmedullary nephron segments and eventually flows toward the renal veins. The physiological significance of the renal portal system is currently poorly understood. About 50–70% of total renal blood flow is contributed by the renal portal vein. However, this percentage is highly variable between animals and can change rapidly in the same individual for no apparent reason (Odlind, 1978). Part of the variability in flow can be attributed to the status of active, innervated renal portal valves within the iliac veins (Figures 11.26 and 11.27; Glahn et al., 1993). The valves receive dense reciprocal motor innervation from the parasympathetic and sympathetic divisions of the autonomic nervous system (see Section 11.5.2.3). Adrenergic stimulation produces relaxation of the smooth muscle of the valve, and cholinergic stimulation produces contraction. In contrast, smooth muscle of the renal portal vein itself shows a predominantly adrenergic contractile response typical of most vascular smooth muscle (Burrows et al., 1983). The distribution of vascular resistance within the portal system, governed by both the portal valve and the alternate, parallel venous pathways for blood returning to the heart (Figure 11.28) determine the volume flow of renal portal blood.

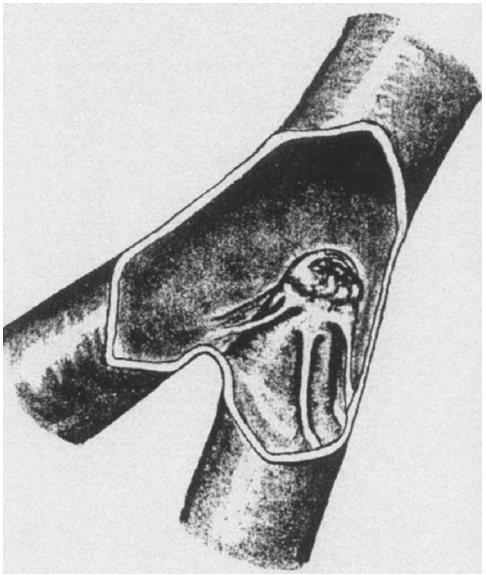

FIGURE 11.26 Illustration of a renal portal valve. The valve, composed of smooth muscle, is situated in the external iliac vein at the point where the efferent renal vein joins the iliac vein. The valve is anchored to the vein wall by muscular "tethers". *From Burrows et al. (1983).*

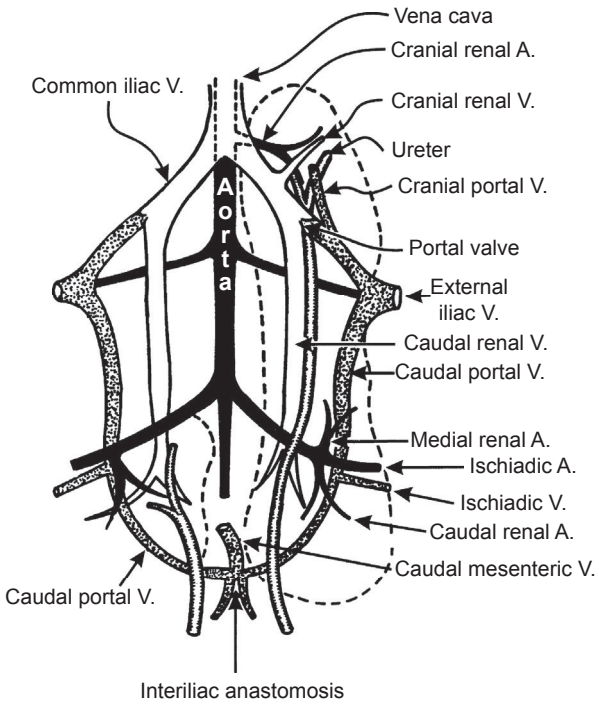

FIGURE 11.27 Ventral view of the avian kidneys with a simplified representation of the avian renal portal circulation and its connections to the systemic venous system. *From Wideman et al. (1992).*

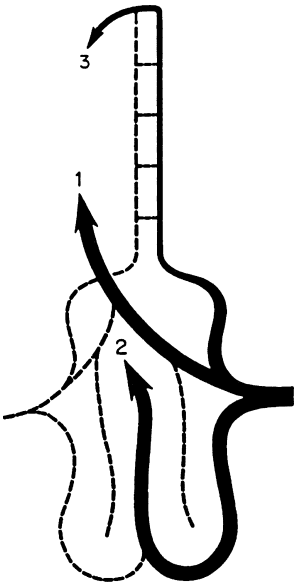

FIGURE 11.28 Three potential parallel shunt pathways in the renal portal circulation. (1) The renal portal valve is open under influence of its sympathetic motor innervation—venous blood flows from the external iliac vein through the patent valve into the common iliac vein, bypassing the kidney. (2 and 3) The renal portal valve is partially closed and resistance at the valve is high. Blood returning from the legs in the external iliac veins enters the cranial and caudal portal systems. *From Akester (1967).*

There are several options for a "packet" of venous blood returning from the legs in the external iliac veins (Figures 11.27 and 11.28): if the renal portal valve is open under the influence of sympathetic nervous system activation, blood can flow through the patent valve into the common iliac vein leading to the vena cava and directly back to the right side of the heart, bypassing the kidney. If the valve is partially closed due to parasympathetic stimulation and resistance at the valve is high, blood can alternatively enter the renal portal system by flowing into the cranial and caudal portal veins. Thus the portal veins are arranged functionally in parallel with the direct venous route provided by the common iliac vein and the vena cava. Blood entering the cranial and caudal portal systems eventually drains into the internal vertebral venous sinuses and caudal mesenteric veins respectively and makes its way back to the right side of the heart by this route. Anteriorly the caudal mesenteric vein connects with the portal system of the liver, providing another option for blood flow. The cranial and caudal portal veins are arranged in parallel with each other, and a "packet" of blood from the external iliac vein can enter one or the other, but not both. Therefore, variable fractions of venous blood derived from the legs, tail, and lower digestive tract can return directly to the right side of the heart (via the common iliac vein and vena cava) or enter the renal (cranial portal vein) or renal and hepatic portal systems (caudal portal vein) (Figure 11.28). The overall pattern of venous flow will depend on the distribution of vascular resistance within the portal system.

Several workers have tried to ascribe a functional significance to the renal portal system. This is a difficult task in the face of the possibility of neural, humoral, and local metabolic control all influencing the relative resistances offered by the portal veins and valve. Recent experimental evidence has resulted in the development of the portal compensation hypothesis, in which the parallel interconnecting veins described above are viewed as an anastomosing network, with the peritubular sinuses located in the renal cortex at its center. Therefore, the amount of portal blood flowing to the kidneys will depend on both the resistances and pressures in the parallel shunt pathways described above and resistance and pressure within the peritubular sinuses.

Blood flowing from the renal glomeruli also enters the sinuses and contributes to pressure within them (Wideman et al., 1991), so any reduction in renal arterial pressure below the autoregulatory range should promote inflow to the sinuses from the portal veins. It is known that if the portal system is intact, birds can maintain total renal blood flow in the face of a fall in renal arterial pressure to 40–50 mm Hg. Should arterial pressure fall, the glomerular vessels themselves can, by autoregulation, maintain glomerular filtration rate constant but only down to a minimum pressure of 70 mm Hg (Wideman et al., 1992). The wider autoregulatory range for total renal blood flow may be due partially to an autoregulatory buffering effect by the portal system. Experimentally reducing portal blood flow leads to a narrowing of the range of arterial pressures over which total renal blood flow is maintained constant (Wideman et al., 1992). There are regional differences in renal blood flow, with the anterior part of the kidney apparently receiving a greater contribution from the portal veins. This suggests that renal arterial flow is normally lower in the anterior kidney.

The functional significance of the portal system in the environmental physiology of birds may be related to salt loading and dehydration. Dantzler (1989) has proposed that under these conditions the adaptive response of the preglomerular arterial vessels of reptiliantype nephrons in the superficial renal cortex is to constrict, causing sustained cessation of filtration. Renal blood flow could be maintained under these conditions by a compensatory increase in portal flow, maintaining a nutritional blood supply to the cells of cortical nephrons (Wideman and Gregg, 1988).

11.4.4 Embryonic Shunts

The circulatory system of the developing avian embryo has a number of vascular shunts found only during the embryonic stages (Dzialowski et al., 2011). These vascular shunts allow systemic venous return entering the right atria to bypass the nonventilated lungs, providing a right-to-left shunt. The first major embryonic shunt in embryonic birds is through a pair of ductus arteriosi. In birds, these two embryonic vessels branch from the right and left pulmonary arteries and connect with the descending aorta (Figure 11.29). This arrangement is in contrast to the mammalian fetus that has a single ductus artertiosus connecting the pulmonary artery with the aorta in a position much closer to the heart and origin of these great vessels. During later stages of chicken embryonic development, White (1974) found that a large portion of venous return from the right anterior vena cava was shunted to the dorsal aorta through the paired ductus arteriosi. Tazawa and Takenaka (1985) estimated that the ductus shunt 84% of right ventricular output to the dorsal aorta. A large fraction of dorsal aorta blood flow goes to the umbilical arteries and the embryonic gas exchanger, the chorioallantoic membrane. Patency of the mammalian ductus during the fetal stage is maintained in part by the relaxing influence of prostaglandins. Interestingly, there is no vasodilatory response to prostaglandins in the avian ductus (Dzialowski and Greyner, 2008; Greyner and Dzialowski, 2008). This difference could be due to the fact that the maternal placenta is the source of circulating prostaglandins in the mammalian fetus.

A second shunt exists between the two atria of the heart which functions like the mammalian fetal foramen ovale. The avian right and left atria are connected by perforations or foramina in the wall separating the atria. The right atrium receives posterior venous return, which includes oxygenated blood from the embryonic gas exchanger, the chorioallantoic membrane (Figure 11.29; White, 1974). Tazawa and

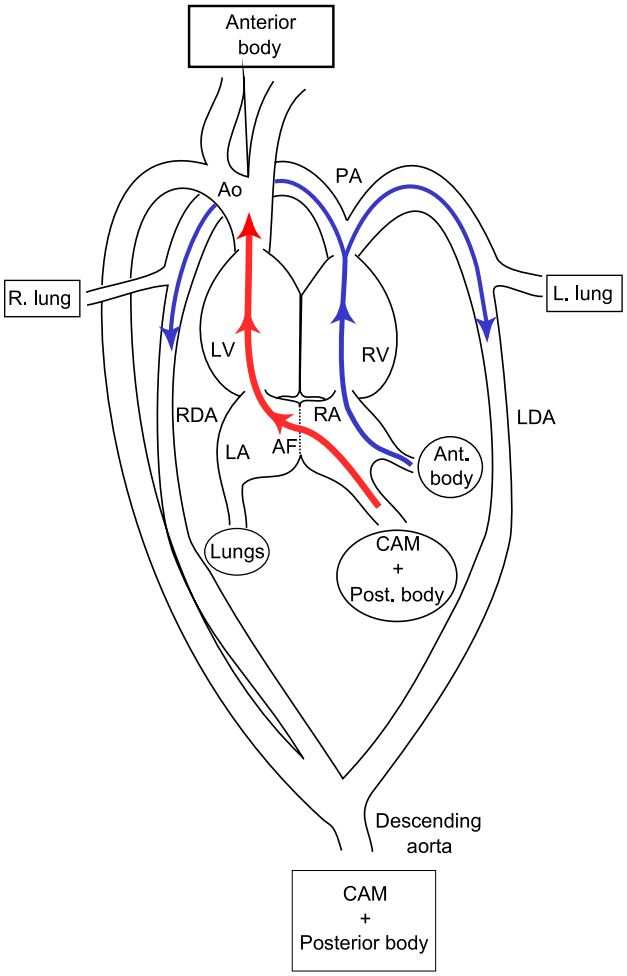

FIGURE 11.29 Embryonic circulation of a developing chicken embryo. The two right-to-left shunts are the left and right ductus arteriosi and the atrial foramina. PA, pulmonary artery; Ao, aorta; LDA, left ductus arteriosus; RDA, right ductus arteriosus; AF, atrial foramina; CAM, chorioallanotic membrane; RV, right ventricle; LV, left ventricle; LA, left atrium; RA, right atrium. *From Dzialowski et al. (2011).*

Takenaka (1985) estimate that 60% of this posterior venous return flows through the atrial foramina resulting in a right-to-left shunt. This shunt ensures oxygenated blood flows to the anterior portion of the embryo through the carotid and subclavian arteries.

Both vascular shunts discussed above must close upon hatching to ensure adequate oxygenation of blood in the lungs. The ductus arteriosus is an oxygen sensitive blood vessel that constricts in response to increases in oxygen (Greyner and Dzialowski, 2008; Agren et al., 2007). In the embryonic chicken, the strength of oxygen induced vasoconstriction increases during hatching. Using *in vitro* myography, the contractile strength of the ductus has been documented to triple between day 18 of incubation and external piping (Belanger et al., 2008). At the same time, arterial P_{O_2} in the hatchling increases from around 30–80 mm Hg (Tazawa et al., 2002). By the time of hatching, the chicken ductus arteriosi are functionally closed (Belanger et al., 2008). Closure of the atrial foramina appears to be caused by pressure changes in the left atrium that occur with hatching (Jaffee, 1965). The perforations appear to have in a valve-like manner, closing when the pressure in the left atrium is greater than the right atrium.

11.5 CONTROL OF THE CARDIOVASCULAR SYSTEM

11.5.1 Control Systems

Both the output of the heart and the resistance to blood flow in the vascular beds are subject to wide variations, depending on the type of activity in which animals are engaged and the intensity of that activity. CO varies in proportion to total body metabolic requirements while vascular resistance varies on a regional basis according to the blood flow requirements of different parts of the body. CO and resistance are both under the control of autoregulatory, humoral, hormonal, and neural influences. Arterial blood pressure is the product of CO and TPR and it is this pressure that produces the driving force to ensure adequate blood flow to the vascular beds. Blood pressure varies but over a proportionally narrower range than either CO or peripheral resistance. Investigations of the regulation of cardiovascular function have been driven by the broad assumption that blood pressure is maintained within sensible limits to ensure adequate tissue perfusion in the face of the variations in CO and peripheral resistance imposed by changes in the external environment or in activity levels.

The cardiovascular system is controlled by several integrated mechanisms operating over time scales ranging from less than a second to months or longer. The most rapid adjustments in CO and peripheral resistance, which may occur within the span of a few heartbeats, are reflexogenic and primarily function to maintain short-term homeostasis and to effect rapid cardiovascular responses to changes in the internal or external environments. Autoregulatory mechanisms acting within vascular beds to modify blood flow as a result of local changes in metabolites or other influences may operate on a time scale of seconds to minutes. Changes in humoral factors, such as levels of oxygen and carbon dioxide, pH, and metabolic products, can affect cardiovascular receptors or circulatory elements directly, producing changes in cardiac and vascular function directed toward correcting these disturbances on a time scale which may extend over long periods. An example of this is in birds undertaking extended migratory flights at high altitudes where inspired oxygen levels, and therefore blood oxygen levels, are much lower than at sea level. Circulating hormones can also affect both the peripheral circulation and the heart, and levels of many of these hormones in the blood may change depending on the activity state of the animal or on the time of year, as during molting or mating.

11.5.2 Control of Peripheral Blood Flow

Contraction of smooth muscle in the walls of arteries provides the means for varying vessel caliber, and the most effective location for altering blood flow by this means will be where the ratio of wall cross-sectional area to lumen area is maximal. The smallest arteries and arterioles possess the highest wall-to-lumen ratio, and it is here that the contraction of individual smooth muscle fibers, coordinated over the whole cross-section of the wall, will give the greatest change in resistance. The largest component of vascular resistance in the circulation is therefore set by the tone of the smooth muscles in the walls of these vessels. Arterial smooth muscle tone is subject to modulation by several mechanisms: (1) intraluminal pressure changes, leading to mechanical autoregulation of blood flow; (2) humoral factors including oxygen tension, levels of local metabolites, extracellular ion concentrations, locally released vasoactive agents, and circulating hormones and vasoactive agents; as well as (3) transmitters released from autonomic nerve terminals.

Smooth muscle fibers in the walls of veins are also influenced by these factors, providing mechanisms for adjusting compliance of the venous walls and thus some control of the rate of return to the heart of blood in the central venous pool. The influences of these regulatory factors on vascular function in birds are discussed in the following sections.

11.5.2.1 Mechanism of Vascular Reactivity

Regulation of smooth muscle contraction differs from skeletal muscle and involves activation of myosin light chain. Vascular smooth muscle contraction and relaxation are regulated by the phosphorylation and dephosphorylation state of the 20-kDa myosin light chain at Ser^{19} (MLC_{20}). In the phosphorylated state, smooth muscle contracts and produces vasoconstriction. Phosphorylation of MLC_{20} is mediated by Ca^{2+}-calmodulin-dependent MLC kinase (MLCK) that are activated by increased cytosolic Ca^{2+} due to Ca^{2+} release from sacroplasmic reticulum stores and extracellular Ca^{2+} entry through membrane bound Ca^{2+} channels (Ganitkevich et al., 2002; Somlyo and Somlyo, 2003; Webb, 2003). Relaxation occurs when myosin light chain phosphatase (MLCP) dephosphorylates MLC_{20}. Several G-protein coupled receptor agonists inhibit MLCP leading to an increase in MLC phosphorylation and contraction without changes in cytoplasmic Ca^{2+} concentration. The result is an increase in Ca^{2+} sensitization (Ganitkevich et al., 2002; Somlyo and Somlyo, 2003; Webb, 2003).

Inhibition of MLCP involves a number of pathways in mammals. MLCP activity is inhibited by the RhoA/Rho-kinase pathway by inactivation of MLCP through phosphorylation of the MLCP regulatory subunit, MYPT1. The second mechanism of MLCP inhibition in mammals is through phosphorylation of the smooth muscle-specific MLCP inhibitor protein CPI-17 (PKC potentiated inhibitor protein-17 kDa; Webb, 2003). Under physiological situations, Ca^{2+} release by the SR, Ca^{2+} influx, and Ca^{2+} sensitization act together to regulate vascular smooth muscle contraction. Their role in regulating avian smooth muscle contraction has only begun to be examined. The protein CPI-17 may not be involved in avian smooth muscle contraction because it was not detected in chicken smooth muscles from aorta, mesenteric artery, gizzard or small intestine (Kitazawa et al., 2004). Additionally, adult chicken arteries contract in response to PKC activation (Kitazawa et al., 2004). In contrast, the Rho kinase inhibitors Y-27632 and hydroxyfasudil produced marked impairment of vessel contractions in femoral artery and ductus arteriosus of chicken embryos and emu (Zoer et al., 2010; Greyner and Dzialowski, 2008; Dzialowski and Greyner, 2008). The role of these pathways in avian vascular smooth muscle contraction needs further study.

11.5.2.2 Autoregulation

Vascular tone within a region of the circulation can be defined as the average level of contraction of smooth muscle fibers in the blood vessel walls within that region. At a steady intraluminal pressure and in the absence of extrinsic influences, spontaneous contractions of individual smooth muscles occur at an intrinsic rate. In resistance vessels, the smooth muscle cells are arranged at a right angle to, or on a shallow helix around, the axis of flow, and the time-averaged tension generated by their contraction, in balance with the intraluminal pressure, will set vessel caliber and thus blood flow. An increase in arterial pressure will distend the vessel wall, increasing the caliber of the vessel and therefore reducing resistance to flow. As a result, blood flow through the vessel will increase. This wall distension also increases the frequency of contraction of the smooth muscles, and this increased vasomotion will then act to reduce the caliber of the vessel, increasing its resistance and restoring blood flow toward its original level. Conversely, a reduction in pressure will reduce wall tension, resulting in a decrease in the rate of smooth muscle spontaneous activity. This leads to vasodilation and an increase in blood flow to offset the effects of reduced perfusion pressure. These myogenic changes in vascular caliber thus provide a mechanism to autoregulate blood flow around a preferred level in the face of variations in tissue perfusion pressure. In most vascular beds, autoregulatory mechanisms are probably limited to the modulation of local blood flow to ensure even blood distribution, as, for example, in the kidney where this mechanism is important in maintaining glomerular flow rate in the face of alterations in arterial blood pressure. Throughout the body, local pressure-induced autoregulation will interact with locally released vasoactive agents and with neurogenically mediated vasomotion resulting from activation of autonomic

reflexes to provide balanced adjustments in regional peripheral blood flow.

11.5.2.3 Humoral Factors

Three broad classes of humoral factors affect blood flow in the peripheral vasculature. One class includes chemical factors such as P_{O_2}, P_{CO_2}, lactic acid and other metabolic byproducts, electrolyte concentrations, and pH, which act directly on myocytes. The second class of factors consists of vasoactive agents typically released from local vascular endothelial cells. This group includes nitric oxide, H_2S, prostaglandins, and endothelin; these factors act on smooth muscle cells by receptor-mediated mechanisms. The third class includes circulating vasoactive agents, also acting via receptor-coupled mechanisms to modify smooth muscle contraction.

11.5.2.3.1 Chemical Factors

If the metabolic rate of a tissue increases, as, for example, in skeletal muscle during exercise, regional blood flow will increase due partly to local vasodilation of resistance vessels and precapillary sphincters induced by an increase in the concentration of lactic acid and CO_2 and a fall in pH. Vasodilation under these circumstances is produced by alterations in Ca^{2+} flux and handling at the level of Ca^{2+} channels (Wray and Smith, 2004) and secondarily by direct chemical effects on the contractile apparatus of the vascular myocytes (Mellander and Johansson, 1968). Vasodilation may be further enhanced if local P_{O_2} falls or concentrations of extracellular ions such as K^+ increase. The resulting increase in blood flow is called functional hyperemia and serves to accelerate oxygen delivery to the muscle and to increase the clearance rate of tissue metabolites. During exercise, central arterial pressure may also rise (Butler, 1991; Saunders and Fedde, 1994) and local myogenic autoregulation would, as outlined in Section 11.5.2.2, attempt to limit the rise in blood flow; however in tissue operating at a high metabolic rate, this mechanism is to a large extent overridden by local chemical vasodilatory influences. Vasodilation due to tissue hypoxia and buildup of metabolites also occurs during periods of ischemia, for example, when blood flow to a vascular bed is occluded as shown in Figure 11.30. Upon release of the occlusion, blood flow rises transiently to several times the preocclusion rate, with the increase in flow proportional to the duration of the occlusion. This reactive hyperemia acts to restore tissue oxygen levels and to remove metabolic products accumulating during the period of occlusion. Local hypoxia also reduces the vasoconstrictor effects of norepinephrine applied exogenously or released from sympathetic nerve terminals in avian arteries *in vitro* (Gooden, 1980; see Section 11.5.2.3.2), and might therefore be expected to reduce the *in vivo* effectiveness of vasoconstriction mediated neurogenically or by circulating catecholamines in support of the hyperemic response. Local hypercapnia also produces vasodilation and, in the hind limb vascular bed of the duck, has an even stronger effect than hypoxia in inhibiting neurogenic or catecholamine-induced vasoconstriction (Lacombe and Jones, 1990).

11.5.2.3.2 Locally Released Vasoactive Agents

The endothelium-derived relaxing factor nitric oxide (NO) is a small, rapidly diffusible molecule released by enzymatic cleavage of L-arginine from vascular endothelial cells of mammals (see Umans and Levi, 1995 for review) and birds (Hasegawa et al., 1993). In both of these

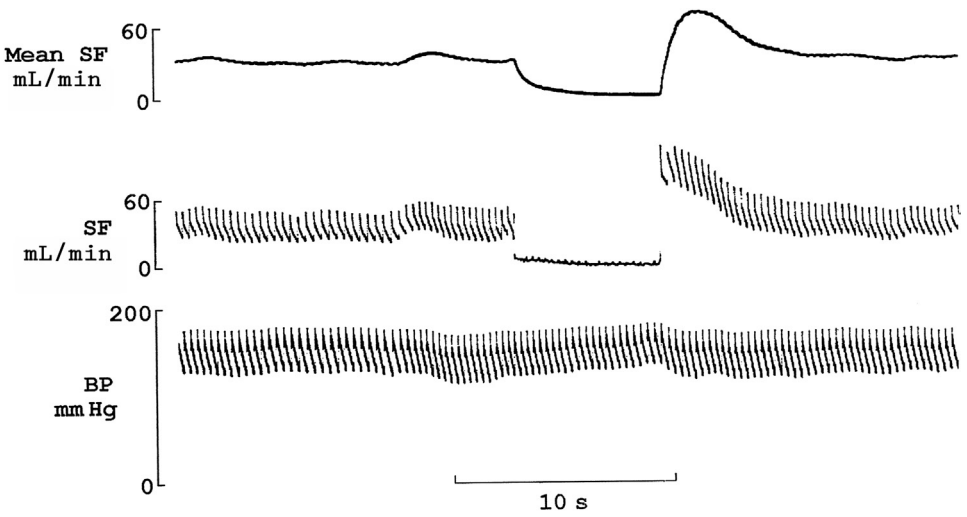

FIGURE 11.30 Change in pulsatile (SF) and mean (mean SF) blood flow in the sciatic artery of a duck in response to arterial occlusion. The period of occlusion is marked by zero flow. BP, arterial blood pressure. Note the hyperemia after the period of occlusion and the subsequent rapid return to the preocclusion flow rate with minimal change in pressure. *From Jones and Johansen (1972).*

vertebrate classes this molecule exerts a powerful vasodilatory effect by relaxing precontracted vascular smooth muscle. The release of NO as a result of acetylcholine (ACh) stimulation of endothelial cells thus provides part of the explanation for the vasodilatory effects of ACh in the circulation (Furchgott and Zawadzki, 1980). In the *in vitro* aorta of the fowl, ACh acting at muscarinic receptors on endothelial cells provokes release of NO which then produces local vasodilation (Hasegawa and Nishimura, 1991; Jarrett et al., 2013). Nitric oxide can produce relaxation through activation of soluble guanylate cyclase which increases levels of cGMP. This in turn activates a cGMP-dependent protein kinase which decreases intracellular Ca^{2+}.

Another factor provoking release of NO from avian vascular endothelial cells is angiotensin II (AII); the vasodilation produced by NO release has been proposed to cause the transient depressor effects on arterial blood pressure observed in some birds immediately after systemic injection of AII (Stallone et al., 1990; Hasegawa et al., 1993; Takei and Hasegawa, 1990). Mechanical stimuli such as flow-induced shear stress (see Section 11.5.2) may also elicit release of NO from endothelial cells in the vasculature of birds. This effect has been reported for mammalian vasculature (Umans and Levi, 1995); given that blood flow rates in birds are generally higher than those in mammals of comparable body size, such a mechanism could provide additional local adjustment of the degree of vasodilation within a vascular bed to match the immediate flow requirements of that bed.

Other locally released vasoactive agents, such as endothelin and H_2S, are important in adjusting regional blood flow in birds. Endothelin is the most potent vasoconstrictor known in mammals (Inagami et al., 1995). In chickens, endothelin has been shown to produce contractions of femoral, mesenteric, and pulmonary arteries in the embryonic stages (Moonen and Villamor, 2011; Villamor et al., 2002) and pulmonary arteries from adults (Martinez-Lemus et al., 2003). In hatchling chickens, endothelin produced contraction at low doses and relaxation at higher doses (Moonen and Villamor, 2011). Moonen and Villamor (2011) suggest that contraction may be mediated by ET_A receptors and at higher doses ET_B receptors. Receptors for this peptide have been demonstrated on avian cardiac myocytes and their activation causes an increase in contractile force (Kohmoto et al., 1993; Hassanpour et al., 2010). Recently, locally released H_2S has been found to be potentially important in regulating vessel tone. It produces both vasorelaxation and vasoconstriction in systemic vessels. Vasorelaxation by H_2S is proposed to act through K_{ATP} channels and cGMP levels in a fashion similar to NO (biological roles are reviewed in Kolluru et al., 2013). H_2S mediated vasoconstriction in the mammalian aorta is mediated by downregulation of cAMP (Lim et al., 2008). In the one study looking at the Pekin duck aorta, H_2S constricted the unstimulated aorta and produced a weak relaxation followed by constriction in the preconstricted vessel (Dombkowski et al., 2005). As with many of these pathways, further research is needed to determine the potential role of H_2S in regulating vessel tone in the avian system.

11.5.2.3.3 Circulating Agents

Circulating catecholamines have powerful effects on all elements of the circulation in birds. The catecholamines epinephrine (EPI) and norepinephrine (NE) are released into the circulation from adrenal chromaffin cells and have direct effects on vascular smooth muscle. Significant amounts of NE are also released into the circulation by activation of the sympathetic nervous system (discussed in Section 11.5.2.4 below). A number of peptides which have vasoactive effects on mammalian vasculature are also present in avian plasma, but the specific actions of most of these peptides on the avian vasculature have not been investigated in detail. Of these peptides, the most extensively studied in birds with respect to vasomotion are AII and avian antidiuretic hormone.

Circulating NE levels in conscious ducks and fowl at rest are in the range of 3–5 nM (Lacombe and Jones, 1990; Kamimura et al., 1995), whereas the resting plasma level of EPI is about half the value for NE (Lacombe and Jones, 1990), as illustrated in Figure 11.31(A). EPI appears to be released solely from the adrenal glands since removal of these glands eliminates EPI from the plasma (Lacombe and Jones, 1990). The loss of adrenal glands does not, however, markedly affect the resting level of circulating NE, which must therefore be due to spill over into the plasma of NE released from sympathetic nerve terminals by autonomic efferent activity. Circulating levels of both EPI and NE vary under different physiological conditions. For example, plasma catecholamines can increase by factors ranging from 2 to >1000 in ducks during involuntary submersion, with end dive levels being proportional to dive length as shown in Figure 11.31(B) (Huang et al., 1974; Hudson and Jones, 1982; Lacombe and Jones, 1990).

Both NE and EPI produce vasomotion in avian vascular smooth muscle, acting via α- and β-adrenergic receptors (Bolton and Bowman, 1969). NE, injected intravenously into conscious ducks, produces vasoconstriction throughout the body. This vasoconstriction causes an increase in blood pressure produced by the collective effect of increases in resistance to flow in individual vascular beds in the body, illustrated in Figure 11.32, by increased resistance in the hind limb vascular bed. These vascular responses to NE are primarily mediated by α-adrenergic receptors (Butler et al., 1986; Wilson and West, 1986; Bolton and Bowman, 1969). Activation of α-adrenoceptors on vascular smooth

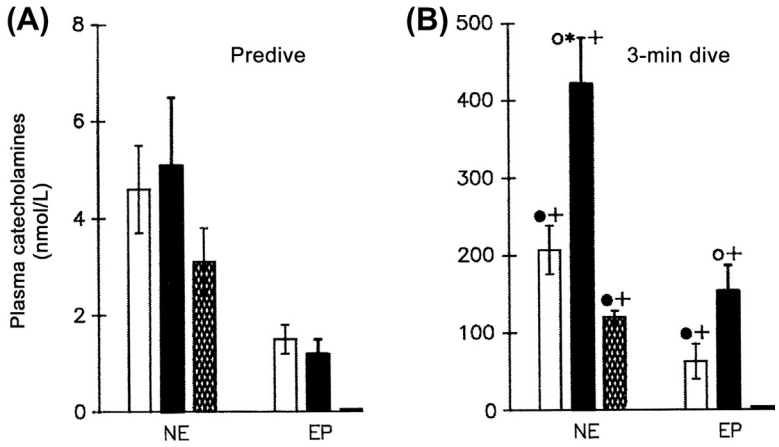

FIGURE 11.31 Plasma levels of norepinephrine (NE) and epinephrine (EP) in intact (open bars), sham-operated (filled bars), and adrenalectomized (cross-hatched bars) ducks (A) before and (B) at the 3 min point during forced submergence. The open circles indicate significant differences from intact ducks; closed circles, differences from sham-operated animals; asterisks, differences from adrenalectomized animals; plus signs, differences from predive value. Adrenalectomy eliminated EP but not NE from the plasma. Note ordinate scale change in B. *From Lacombe and Jones (1990).*

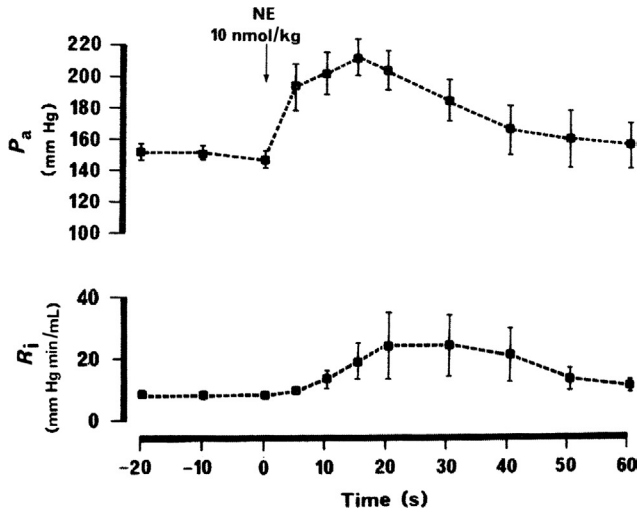

FIGURE 11.32 Responses of mean arterial blood pressure (P_a) and resistance to blood flow in the ischiatic artery (R_i) of an adult duck to a bolus intravenous injection of norepinephrine (NE, at arrow). The R_i values for each data point were calculated from the corresponding P_a and ischiatic blood flow values. *Modified from Wilson and West (1986).*

muscle acts through second-messenger systems to mobilize internal Ca^{2+} stores and to open membrane calcium channels, thus increasing intracellular Ca^{2+} concentration and activating the actin–myosin contractile apparatus (see Webb, 2003; Section 11.5.2.1). Norepinephrine can also have a vasodilatory effect on the vasculature of birds, mediated through β-adrenergic receptors; however, this effect is only apparent systemically after pharmacological blockade of α-adrenoceptors (Butler et al., 1986). β-adrenergic vasodilation in the avian vasculature also works by activating intracellular second messengers, converting the actin–myosin complex to an inactive form to promote relaxation. Combined α- and β-adrenergic blockade appears to eliminate all direct effects of NE on bird vascular smooth muscle. The overall effects of NE on peripheral resistance therefore depend on the relative abundance of α- and β-receptors in individual vascular beds. Epinephrine also acts on adrenoceptors of vascular smooth muscle but binds to α-receptors with a higher affinity than to the β subtype, so exerts a stronger vasoconstrictive effect for the same receptor density than does NE.

Avian AII is similar to the corresponding mammalian peptide in its structure and in the biochemical pathway of its production (see reviews by Wilson, 1989; Henderson and Deacon, 1993). Renin, released from the juxtaglomerular cells lining glomerular afferent arterioles in the kidney, produces the peptide angiotensin I by hydrolysis of angiotensinogen, a plasma α-globulin. Angiotensin-converting enzyme, which has been identified in circulating plasma and fixed in the walls of blood vessels in birds (Henderson and Deacon, 1993), then cleaves angiotensin I to produce AII. A number of stimuli such as systemic hypotension, hypovolemia, decreased plasma or distal tubule ion concentrations (particularly Na^+), or the activation of juxtaglomerular β-receptors causes renin to be secreted into the plasma. This promotes an increase in circulating angiotensin I, making it available for conversion to AII. AII affects circulatory function at several levels, evoking responses in both the central nervous system and the peripheral vasculature. These responses are aimed at the conservation of water and electrolytes in order to counter the original renin secreting stimulus.

Within the central nervous system, AII acts on receptors of some hypothalamic neurons to promote drinking behavior (Evered and Fitzsimons, 1981). In the periphery, exogenous or endogenous AII produces either an increase in systemic arterial blood pressure or a biphasic hypotensive–-hypertensive response, depending on species. In ducks (Wilson and West, 1986; Butler et al., 1986) and pigeons

(Evered and Fitzsimons, 1981), systemic injections of AII produced dose-dependent increases in arterial blood pressure. Butler et al. (1986) and Wilson and West (1986) proposed that this response was due to vasoconstriction resulting from AII mediated release of NE from sympathetic nerve terminals and enhanced EPI and NE release from the adrenal glands; in their experiments, α- and β-adrenergic blockade eliminated the pressor effects of AII injection. Indeed, Moore et al. (1981) maintained that AII has no direct vasoconstrictor effects on arterial smooth muscle in the fowl. Wilson (1989), in a review of the renin–angiotensin system in birds, ascribed AII-induced vasoconstriction entirely to the effects of elevated catecholamine secretion.

In fowl and quail systemic circuits, AII injections produce a rapid, transient hypotension followed by a prolonged rise in arterial blood pressure (Nakamura et al., 1982; Takei and Hasegawa, 1990). The hypertensive phase of this response is mediated by adrenergic mechanisms, as in the duck and pigeon, but the transient hypotensive phase appears to be an indirect AII effect on vascular endothelial cells, working via the local release of NO from these cells, as described in Section 11.5.2.3.2. *In vitro* isometric tension studies on the abdominal aorta of embryonic and adult chicken have shown AII induces a vasorelaxation that is inhibited by L-NAME and eliminated by removal of endothelium (Nishimura et al., 2003).

Arginine vasotocin (AVT), released from the posterior pituitary into the circulation under conditions of osmotic or hypovolemic challenge, is the avian homolog of the mammalian antidiuretic hormone arginine vasopressin. However, the effects on avian vasculature of increased endogenous AVT levels after salt loading or hemorrhage are not well understood, nor are the vasomotor effects of systemic AVT injections. In mammals, arginine vasopressin produces vasoconstriction in systemic arterioles and in glomerular afferent arterioles, both serving to facilitate antidiuresis. In birds, AVT also induces vasoconstriction of afferent glomerular arterioles (see Braun, 1982 for review), but its effects on the rest of the circulation are controversial. Several studies have reported no cardiovascular consequences of AVT injection, maintaining that the avian vasculature is not sensitive to this peptide even at doses many times greater than "physiological" levels (Simon-Oppermann et al., 1988; Robinzon et al., 1988). In contrast, Wilson and West (1986) in ducks and chickens and Brummermann and Simon (1990) in ducks found that systemic injections of AVT produced hypotension accompanied by tachycardia. The latter authors proposed that AVT directly relaxes vascular smooth muscle, producing a fall in arterial blood pressure which then evokes a baroreflex-mediated tachycardia. However, Robinzon et al. (1993) found in fowl that the direction of AVT-mediated vascular responses depended on the dose and method of application. Low doses given slowly by intravenous infusion produced hypertension similar to the mammalian response to arginine vasopressin, whereas bolus intravenous doses produced the hypotensive responses reported in other avian studies. Robinzon et al. (1993) therefore proposed that AVT acts primarily via modulation of vascular caliber but that the degree and direction of vasomotion was not uniform in beds throughout the body. Although there appears to be consensus that AVT does have direct vascular effects in birds, the understanding of its specific actions must await further studies on isolated vascular beds *in situ* and on blood vessels *in vitro*.

11.5.2.4 Neural Control

All parts of the systemic and pulmonary vascular trees, except capillary beds, are innervated by the autonomic nervous system. This innervation constitutes the final common pathway for rapid and flexible control by the central nervous system of regional distribution of CO. Autonomic outflow to the vasculature is governed by a variety of reflexogenic inputs from visceral or somatic receptors relayed through brainstem and spinal cord pathways, and is also subject to influences originating at suprabulbar levels of the central nervous system. However, the degree of vasomotion produced in any region of the vasculature for a given intensity of autonomic drive will depend on the densities of effector terminals and postjunctional receptors in that region.

The location of autonomic terminals within the vascular wall is different in arteries and veins. Nerve fibers and terminals in the walls of arteries are, with some exceptions, limited to the tunica adventitia, extending as far as the outer elastic lamina marking the border between the adventitia and the tunica media (Bennett and Malmfors, 1970). In this respect, the innervation pattern of avian arteries is similar to that in mammals (see Hirst and Edwards, 1989 for a review of mammalian arterial innervation). In contrast to the arterial innervation pattern, nerve fibers and terminals in avian systemic veins are commonly apposed to smooth muscle in the tunica media, as well as being located in the adventitia (Bennett and Malmfors, 1970), and in this regard also birds are similar to mammals (see Shepherd and Vanhoutte, 1975 for a review of the innervation of mammalian veins).

In addition to intramural nerve fibers and terminals, large and small nerves course over the outer surfaces of both arteries and veins, and some vessels are completely surrounded by plexi of nerve fibers. Furthermore, throughout the body nerves generally accompany blood vessels, running parallel with the vessels to form neurovascular bundles. These close associations between blood vessels and nerves have an important consequence for experimental investigations of neurogenic vasomotion. In assessing the effectiveness of neural control of vascular resistance in particular beds, electrical stimulation of autonomic nerves is commonly employed. However, some neural pathways to these beds may be interrupted if supply vessels to the beds

are manipulated or sectioned (for example, to insert a blood flow probe) between the stimulus site and the expected site of vasomotion.

11.5.2.4.1 Systemic Arterial Innervation

The aorta from its origin to the junction with the celiac artery, the proximal brachiocephalic trunks, and the most proximal parts of the common carotid arteries are elastic vessels (see Section 11.4.1.2), having relatively little smooth muscle and thus a correspondingly sparse vasomotor innervation (Bennett and Malmfors, 1970; Bennett, 1971). The aorta, especially close to its root and adjacent to the root of the pulmonary trunk, has numerous small cells in the adventitia that contain catecholamines (Bennett, 1971). These cells occur singly or in clusters, appear to be similar to amine-containing cells of the carotid body, and are innervated by branches of the vagus nerve. Although these cells may be a source of locally released catecholamines, it has also been suggested that these cells may constitute chemoreceptive aortic bodies (Bennett, 1971; Tcheng and Fu, 1962) similar to those found at the homologous site in mammals. In addition, the adventitia of the aortic arch is innervated by afferent vagal fibers with nerve terminals transducing wall stretch and thus signaling an index of central arterial blood pressure; these constitute the only systemic arterial baroreceptors in birds (Jones, 1973).

The transition from elastic to muscular wall structure occurs in the arterial tree distal to the branching points of major distribution arteries from the great vessels. This transition also marks an increase in the density of innervation of the arterial wall, as shown in the photograph of a branch of the posterior mesenteric artery of the fowl in Figure 11.33.

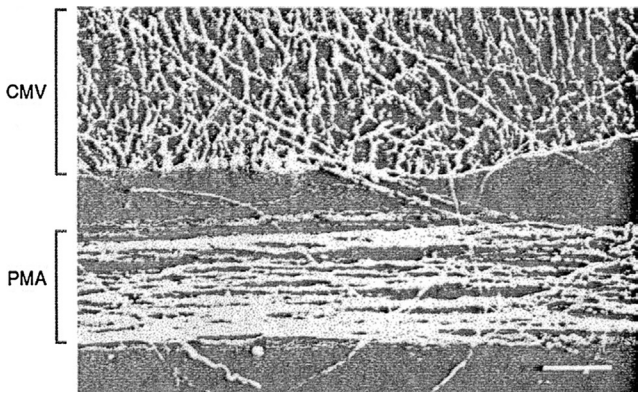

FIGURE 11.33 Adrenergic innervation patterns of a distal branch of the posterior mesenteric artery (PMA) and the coccygeomesenteric vein (CMV) of the chicken. The vessels run side by side with their long axes aligned from left to right in the photograph. Aldehyde fluorescence histochemistry shows that adrenergic nerve fibers and terminals are present in both vessels; in the artery, they run parallel to the vessel axis and are more dense than in the vein. The horizontal bar represents 100 µm. *Modified from Bennett and Malmfors (1970).*

In some arteries such as the ischiatic, varicose fibers can be seen in the media as well as at the medial–adventitial border (Bennett and Malmfors, 1970). Of the large muscular arteries, the common carotids appear to be the most heavily innervated (Bennett and Malmfors, 1970). Given that these arteries convey the majority of blood flow to the avian brain, this density of innervation possibly reflects a requirement for greater autonomic control of cephalic blood flow than in other beds. Vasomotor innervation of the smaller branches of arteries within individual vascular beds supplied by the large arteries has not been systematically described but in all beds muscular arterioles, which constitute the resistance vessels responsible for 70–80% of TPR, are densely innervated (Folkow et al., 1966; Bennett and Malmfors, 1970).

The density of innervation of different regions of the arterial tree is variable among bird species; this variation has important consequences for differences in regional neurogenic control of blood flow among species. Large arteries supplying hind limb muscles in ducks, for instance, are more densely innervated than those in turkeys, and this difference is correlated functionally with an enhanced capability in the duck to generate and maintain neurogenically mediated intense peripheral vasoconstriction (Folkow et al., 1966). These authors proposed that this was a general physiological adaptation in diving birds, enabling the redistribution of blood flow away from those peripheral vascular beds able to withstand periods of ischemia and toward the central circulation, thus conserving blood oxygen for ischemia-sensitive heart and brain tissue.

Electrical stimulation of the sympathetic innervation of a vascular bed evokes increases in vascular resistance in that bed, mimicking the effect of elevated vasoconstrictor outflow from the central nervous system. As illustrated in Figure 11.34, graded increases in stimulation frequency evoke proportionally larger increases in peripheral resistance in the hind limb vascular bed of the duck, producing

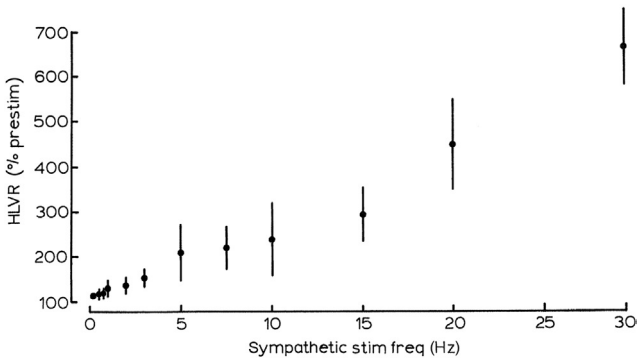

FIGURE 11.34 Relationship between frequency of electrical stimulation of the sympathetic innervation of the hind limb and vascular resistance of this bed (HLVR) in a duck. HLVR for each data point was calculated from the corresponding arterial pressure and ischiatic artery flow. Increases in HLVR are expressed in percentages relative to the prestimulus value. *From Smith (unpublished data).*

a maximal increase of up to 7 times the prestimulus resistance value at a stimulation frequency of 30 Hz. In contrast, stimulus frequencies of less than 10 Hz are required to produce a maximal increase in resistance in the cat hind limb (Folkow, 1952). The hind limb vascular bed in the duck thus requires a greater degree of sympathetic drive than that of the cat to achieve the same order of increase in resistance to flow. This may reflect differences in the distribution of sympathetic terminals to the arteries in this bed in the two species. In support of this, Bennett and Malmfors (1970) noted that the pattern of adrenergic innervation of small intramuscular arteries in birds was not markedly different from that in mammals, but observed a higher terminal density in larger arteries of avians relative to mammals.

Some regions of the avian arterial vasculature have specialized wall structures and unusual innervation patterns, possibly reflecting enhanced capabilities for regional control of blood flow. The anterior mesenteric artery in several species of birds has, in addition to the normal circular smooth muscle in the media, an outer layer of longitudinal smooth muscle in the adventitia (Bolton, 1969; Bennett and Malmfors, 1970; Bell, 1969; Ball et al., 1963; see Section 11.4.1.2). Adrenergic fibers and varicose terminals are found at the adventitial–medial border in this as in other arteries, but these elements also extend into the longitudinal muscle itself, aligned in the direction of the muscle fibers. Longitudinal muscle of this vessel also receives cholinergic innervation (Bolton, 1967; Bell, 1969; Bennett and Malmfors, 1970), although this does not extend to the inner circular muscle (Bell, 1969). Adrenergic nerve stimulation produces contraction of the circular muscle which is mimicked and blocked by α-adrenergic agonists and antagonists, respectively (Bolton, 1969; Bell, 1969; Gooden, 1980). The longitudinal muscle is, however, relaxed by adrenergic nerve stimulation, acting through β-adrenergic receptors (Bolton, 1969; Bell, 1969). Stimulation of cholinergic nerve fibers in an *in vitro* preparation of a segment of the vessel caused the longitudinal muscle to contract, shortening the whole segment. This did not, however, markedly affect resistance to flow through the vessel but in the shortened state adrenergic vasoconstrictor responses of the circular muscle were found to be exaggerated (Bell, 1969). The cholinergic innervation of longitudinal muscle has thus been proposed to potentiate adrenergically mediated control of blood flow, possibly as an adaptation for rapid adjustment of intestinal blood flow during stress (Bell, 1969). The fact that increased sympathetic drive to this vessel has a relaxing effect on the longitudinal muscle as well as a constricting effect on the circular muscle would facilitate the effects of cholinergic input in shortening the vessel segment. Cholinergic input may also help adjust blood flow more precisely when the length of the anterior mesenteric artery changes during gross intestinal movements associated with digestion.

Coronary arteries also possess an outer coat of longitudinal muscle, but adrenergic innervation of this muscle layer is very sparse. In these arteries, the majority of adrenergic nerve fibers and terminals are found at the adventitiomedial border, as in other arteries (Bennett and Malmfors, 1970). There are no reports of cholinergic innervation of the coronary arteries of birds. Cerebral arteries are, however, dually innervated by adrenergic and cholinergic fibers (Tagawa et al., 1979). Adrenergic varicosities are located in the adventitia near the border with the media throughout the cerebral circulation, in common with most other arteries of the body. Cholinergic fibers as well are located in the tunica adventitia but occur less frequently than adrenergic terminals (Tagawa et al., 1979). It is presumed that, since cerebral arteries have no smooth muscle in the adventitia, neurotransmitters released from both types of terminals diffuse into the media to act on muscle fibers there. Tagawa et al. (1979) also reported that, as in mammals, some of the cholinergic innervation of avian cerebral arteries appears to originate from central neurons, especially in the diencephalon, as well as from peripheral neurons. Studies in mammals have shown that the functional significance of reflexogenic vasomotion in overall control of cerebral blood flow is relatively minor compared with neurogenic control of blood flow in other vascular beds in the body; intracerebral blood distribution is influenced mainly by local and possibly circulating humoral factors (Kontos, 1981). This is likely to be true also in birds; Stephenson et al. (1994) estimated that neurogenic contributions to changes in cerebral blood flow in ducks during diving were minor.

11.5.2.4.2 Systemic Venous Innervation

Large veins in birds are more densely innervated than those in mammals. The density of noradrenergic innervation of the chicken caudal vena cava is graded, increasing in portions of the vessel more distal to the heart (Bennett, 1974; Bennett et al., 1974). The caudal vena cava has an outer coat of longitudinal muscle as well as an inner circular layer and both layers receive adrenergic innervation, with the orientation of the terminals and fibers following the direction of the muscle fibers in each layer (Bennett, 1974). There is also a sparse cholinergic innervation of this vessel. The superior venae cavae also have two muscle layers, with a similar adrenergic innervation pattern to the caudal vena cava (Bennett and Malmfors, 1970). The walls of the pectoral, subclavian, celiac, and jugular veins contain both circular and longitudinal smooth muscle, and the innervation of these vessels is through a plexus of varicose fibers and terminals located primarily between the inner and outer muscle layers. Other veins, such as the coccygeomesenteric vein, have primarily circular muscle, innervated in the pattern illustrated in Figure 11.33.

Functionally, adrenergic vasomotion appears to be preeminent in veins. Vasomotion of the caudal vena cava and other major veins is mediated primarily by α-adrenergic receptors producing vasoconstriction when activated; no functional β-adrenergic receptors are present (Bennett and Malmfors, 1974). Responses of venous smooth muscle to cholinergic nerve stimulation are weak and variable and probably do not contribute directly to neurogenic control of wall compliance; however, ACh released from cholinergic nerve terminals can modulate the release of NE from local adrenergic nerve terminals and thus may provide fine adjustments of adrenergically generated venomotor tone.

Sympathetically mediated contraction of smooth muscle in the major veins serves to decrease wall compliance and vessel diameter, thus providing a reflexogenic mechanism for reducing the volume of the central venous pool and increasing return of blood to the heart, as discussed in Section 11.4.3.2. Langille (1983) proposed that reflexogenic venoconstriction was responsible for the increased central venous pressure observed in ducks during involuntary submersion. This response may function to aid venous return to the heart to help maintain stroke volume in the face of a reduction in cardiac contractility, which may develop during diving (Djojosugito et al., 1969; Langille, 1983).

The renal portal valves, located bilaterally where the external iliac veins join the junction of the caudal vena cava with the caudal renal veins, are unique to birds. These valves (Figure 11.26) are in the form of sphincters of smooth muscle which can close off the direct route for blood flow from the external iliac veins to the caudal vena cava. Closure increases renal portal blood flow, venous blood from the external iliac vein being then partially redirected into the renal capillaries and thence to the caudal vena cava, as discussed in Section 11.4.3.4. The renal portal valve is heavily innervated by both adrenergic and cholinergic nerve fibers (Akester and Mann, 1969; Bennett and Malmfors, 1970) with reciprocal effects on the smooth muscle of the valve. Adrenergic nerve stimulation and sympathomimetic agents induce relaxation, mediated by β-adrenergic receptors, while cholinergic nerve stimulation and cholinomimetic agents produce contraction via muscarinic receptors (Bennett and Malmfors, 1975a; Sturkie et al., 1978). The importance of this valve in the control of venous blood distribution in the renal portal system has been the subject of some debate (Akester, 1967; Section 11.4.3.4). Functional studies of the avian kidney *in situ* by Glahn et al. (1993) have shown that the status of the renal portal valve affects total renal blood flow by altering the amount of flow in the renal portal system. In conditions of lowered arterial blood pressure in which renal arterial perfusion is below the range of autoregulation of glomerular blood flow, closure of the renal portal valve raises renal portal blood flow to compensate total renal blood flow (Glahn et al., 1993). Neural control of the renal portal valve may thus form a component of the suite of reflexogenic responses to hypotension or hypovolemia.

11.5.2.4.3 Pulmonary Vessel Innervation

Adrenergic innervation of the pulmonary artery in the fowl consists mostly of fibers with few varicose nerve terminals. Fibers and nerve terminals form a plexus at the adventitiomedial border of the artery, with some projections into the circular smooth muscle of the media. There is also smooth muscle oriented longitudinally in the adventitia, but innervation of this is very sparse (Bennett and Malmfors, 1970; Bennett, 1971). Some intrapulmonary arterial branches have dense adrenergic plexi occurring in short segments along their length (Bennett and Malmfors, 1970), which may help to redistribute blood flow to selected gas exchange areas within the lung to optimize local ventilation–perfusion ratios (Hebb, 1969).

The pulmonary veins proximal to the left atrium are very densely innervated with adrenergic nerve fibers and terminals, the density of this innervation being markedly greater than in the pulmonary arteries (Bennett, 1971). Abundant terminal varicosities and nerve fibers are located in a plexus at the adventitiomedial border, with some penetration into the media (Bennett, 1971; Bennett and Malmfors, 1970). There is also longitudinal smooth muscle present in the adventitia, with adrenergic terminals between the muscle fibers (Bennett, 1971; Bennett and Malmfors, 1970). The density of innervation of the longitudinal smooth muscle is reduced close to the left atrium, increasing distally along the vessel until the bifurcation to the lungs. At this junction, there is an abrupt decrease in density of innervation of the entire vessel wall, and within the lungs the major branches of the pulmonary veins are very sparsely innervated. Smaller branches of these vessels appear to have no innervation (Bennett, 1971).

11.5.2.4.4 Autonomic Pathways

The cell bodies of adrenergic postganglionic vasoconstrictor neurons innervating the vasculature are located in paired paravertebral ganglion chains, in prevertebral ganglia and, in some cases, in small ganglia scattered throughout the viscera. Cells in the superior cervical ganglion (representing a fusion of the two most cranial cervical ganglia) innervate blood vessels of the head, including those of the salt and salivary glands, via cephalic extensions anastomosing with several cranial nerves (Bennett, 1974). In birds, pairs of sympathetic ganglia are associated with the cervical vertebrae and cells in these ganglia innervate blood vessels of the neck. The presence of cervical paravertebral ganglia in birds constitutes a major difference in the organization of the sympathetic nervous system between this vertebrate group and mammals. In the caudal part of the neck, in the

thorax, and in the wings of birds the vasculature is innervated by neurons in the thoracic paravertebral ganglion chain. Sympathetic fibers reach wing vessels primarily through the brachial plexus. Some thoracic postganglionic neurons also contribute sympathetic fibers to the greater splanchnic nerves innervating anterior abdominal viscera via the celiac plexus (Bennett, 1971).

Vertebrae of the lumbar, sacral, and coccygeal spine are fused to form the synsacrum in birds. The paravertebral ganglion chains from each side in this region are fused in the midline at about the level of the sixth coccygeal segment in avian species so far examined, and this combined sympathetic trunk continues caudally to the pygostyle (Pick, 1970; Akester, 1979; Benzo, 1986). Axons from postganglionic neurons in this part of the sympathetic nervous system innervate abdominal and pelvic viscera via the lesser splanchnic nerves and aortic plexus, the hypogastric plexus, the pelvic plexus, and the cloacal plexus. Some sympathetic postganglionic somata are also located in prevertebral ganglia within these plexi. In addition, lumbosacral sympathetic neurons contribute vasoconstrictor axons to the hind limbs via the lumbosacral plexus (Benzo, 1986; Bennett, 1974).

Sympathetic preganglionic cell bodies that synapse on the postganglionic vasoconstrictor neurons are located in and near a bilateral column of neurons, the column of Terni, in the gray matter near the central canal of the spinal cord (see Section 11.5.3.2). All preganglionic axons innervating postganglionic neurons in the cervical sympathetic chain exit the spinal cord through ventral nerve roots of cranial thoracic segments; there are apparently no connections between the cervical spinal nerve roots and the sympathetic ganglia in the neck (Bennett, 1974; Akester, 1979; Pick, 1970). Although no detailed analysis has been done of the segmental locations of spinal preganglionic neurons projecting to postganglionic vasoconstrictor neurons innervating the thoracic, abdominal, pelvic, and limb regions, it is likely that the locations of these neurons follows the mammalian plan. That is, axons of preganglionic neurons in a particular spinal segment emerge from the cord in the ventral root of that segment to innervate postganglionic neurons in ganglia at that level or within one or two segments rostral or caudal to the exit site (see Gabella, 1976 for review).

Parasympathetic postganglionic neurons innervating the vascular smooth muscle of such organs as salt glands and salivary glands in the head of birds are located in autonomic ganglia near or embedded in the organs (Ash et al., 1969). Cell bodies of preganglionic neurons innervating parasympathetic postganglionic vasodilator neurons associated with structures in the head are located in the oculomotor, facial, glossopharyngeal, and vagal nuclei in the brainstem and course to peripheral ganglia via the respective cranial nerves associated with these nuclei (Akester, 1979). Postganglionic cholinergic nerve fibers innervating arteries and veins of the body originate from the somata of neurons located in plexuses associated with blood vessels themselves or, for vessels of the abdominal viscera, in prevertebral ganglia containing a mixture of adrenergic and cholinergic postganglionic neurons (Bennett and Malmfors, 1970; Bennett, 1974). The location of cells of origin of preganglionic axons innervating the postganglionic neurons producing vasodilation in the viscera and skeletal muscle has not been determined in detail. However, in birds the parasympathetic outflow is organized in cranial and sacral tracts as it is in mammals. It would therefore be expected that preganglionic neuronal somata responsible for vasodilation in thoracic and anterior abdominal viscera and skeletal muscle in the upper part of the body are located in medullary vagal motor nuclei, with their axons running to postganglionic neurons via the vagus nerves. Similarly, vasodilation of posterior abdominal and pelvic viscera and skeletal muscle of the lower part of the body is likely to be mediated by preganglionic neurons with their somata located at sacral levels of the spinal cord and their axons innervating postganglionic neurons via the abdominal and pelvic autonomic nerves.

11.5.3 Control of the Heart

11.5.3.1 Catecholamine Effects on the Heart

Both NE and EPI are present in circulating plasma of birds (see Section 11.5.2.3.3 for discussion), and these amines have cardiac effects which include an increase in the rate of pacemaker depolarization (DeSantis et al., 1975; Bolton and Bowman, 1969) and augmented force of myocardial contraction (DeSantis et al., 1975; Bennett and Malmfors, 1974; Bolton, 1967; Bolton and Bowman, 1969). In isolated heart preparations and in myocardial strips *in vitro*, NE has been found to be as effective as, or more potent than, equimolar EPI in producing inotropic and chronotropic augmentation. This is in marked contrast to the condition in the mammalian heart, in which EPI is the more potent stimulant (Gilman et al., 1990). In whole-animal experiments on birds, intravenously injected boluses of NE and EPI augment CO by transiently increasing both rate and force of contraction, contributing along with peripheral vasoconstriction to catecholamine-mediated hypertension (Wilson and Butler, 1983; Wilson and West, 1986; Bolton and Bowman, 1969; Butler et al., 1986). In the avian as in the mammalian heart, catecholamines appear to act primarily via β-adrenergic receptors on myocardial and pacemaker cells (Bolton and Bowman, 1969; Butler et al., 1986; Bolton, 1967).

11.5.3.2 Neural Control

The anatomical organization of the innervation of the heart in birds has been studied for more than 100 years, first by gross dissection and then with a variety of nerve-specific

stains (see for example Ábrahám, 1969; Hirsch, 1970; Pick, 1970), but these techniques have not allowed the patterns of cardiac sympathetic and parasympathetic innervation to be anatomically differentiated. This is a factor of major importance in determining the mechanisms involved in neural control of the heart. It is only recently, with the advent of histochemical techniques specific for adrenergic and cholinergic neurotransmitters or enzymes in the catabolic and anabolic pathways of these transmitters, that the patterns of dual, function-specific cardiac innervation have begun to be explored. The most well-established histochemical method for determining the peripheral distribution of adrenergic nerves is that developed by Falck (1962) to render catecholamines brightly fluorescent under ultraviolet illumination in the light microscope. This sensitive technique shows cell bodies, axons, and nerve terminal varicosities, and most of the descriptions of adrenergic innervation of the heart are based on the use of this technique in whole-mounts or sections of atrial and ventricular tissue. Histochemical assays for the presence of acetylcholinesterase (AChE), based on those developed by Koelle and others (reviewed by Koelle, 1963), have been used to determine the distribution of parasympathetic innervation of the heart. There are also more recent immunohistochemical techniques available for identifying enzymes in the biochemical pathways synthesizing neurotransmitters; specifically, antibodies directed against dopamine β-hydroxylase and tyrosine hydroxylase (NE synthesis) and choline acetyltransferase (ACh synthesis) are commercially available. These techniques, however, have yet to be applied to the avian heart.

Interpretation of the results of studies using transmitter-specific histological techniques to determine patterns of autonomic innervation of the cardiovascular system rests on two major assumptions: (1) that the primary neurotransmitter released by the terminals of sympathetic postganglionic neurons is NE, and (2) that released by parasympathetic terminals is ACh. Functional studies in bird hearts largely support this assumption. However, work on peripheral autonomic anatomy and function in a wide range of vertebrates has emphasized the diversity of autonomic neurotransmitters and neuromodulators in addition to the classic transmitters utilized by this system (see Nilsson and Holmgren, 1994; Armour and Ardell, 1994; Furness and Costa, 1987), so some caution must be exercised in this area. In the following discussion of the innervation of the avian heart, results from studies using neurotransmitter-specific techniques are emphasized.

11.5.3.2.1 Sympathetic Innervation

11.5.3.2.1.1 Anatomy Postganglionic sympathetic nerve fibers arising from neuronal somata extrinsic to the heart form part of an intracardiac nerve plexus distributed throughout all four cardiac chambers. The adrenergic innervation of the proximal part of the venae cavae appears to be continuous with the intracardiac plexus associated with the right atrium (Bennett and Malmfors, 1970). Sympathetic nerve fibers form a network over the epicardial surface of the right atrium, with some fibers penetrating into the thin atrial wall to lie adjacent to bundles of myocardial cells and others passing through the wall to the subendocardium (Smith, 1971a). The overall appearance of the plexus is that of a three dimensional latticework of fibers extending from the epicardium through the wall to the subendocardium, with varying concentrations of smooth (nonvaricose) and varicose nerve fibers and nerve endings in different regions of the atrial myocardium.

Bennett and Malmfors (1970) reported that the most densely innervated region of the heart was the external wall of the right atrium; furthermore, within this area the region adjacent to the confluence of the venae cavae with the wall contained the highest density of fibers and terminals. These authors referred to this area as the "sinu-atrial node", presumably by analogy with the corresponding sharply defined SA node of the mammalian heart. There is, however, some evidence that the cells in the primary pacemaker site in the right atrium of the bird heart may have a functional organization different from that in the mammalian heart, in the area of the junction of the sinus venosus with the SA valves (Moore, 1965; see Section 11.2.3.3). These valves are present in birds but are only represented by a vestigial flap in mammals. A large number of the nerve fibers in this area of the avian heart were varicose, running among the myocardial cells and aligned with the longitudinal axes of these cells. Another area with a high density of adrenergic terminals was in the right atrial wall near the AV border, an area corresponding to the AV node (Bennett and Malmfors, 1970; Section 11.2.3.3). Many nerve varicosities were also associated with blood vessels in the right atrial wall.

Bogusch (1974), (osmium stain) reported in the fowl that the specialized cells of the pacemaker areas and conducting system in the right atrium are well innervated by nerve fibers with frequent varicosities and some bare nerve endings. In contrast, Yousuf (1965), (silver stain) found no investment of nerve fibers into the SA node region and few in the AV node in the sparrow heart. This disparity could be due to a species difference or to a relative lack of sensitivity of the silver stain; in any case, neither technique is neurotransmitter specific, nor as sensitive as the amine fluorescence technique. Full details of the sympathetic innervation of the conducting tissues of the right atrium are still not clear. A combination of immunohistochemical localization of dopamine hydroxylase or tyrosine hydroxylase in nerve terminals and standard histological processing for visualizing pacemaker cells and atrial Purkinje fibers would address this problem.

A small number of strongly fluorescent cell bodies are present in the right atrium and in the walls of some parts of the vasculature after processing for amine related

fluorescence. These cells are, however, not associated with intracardiac ganglia (Bennett and Malmfors, 1970) and probably represent small, intensely fluorescent cells or so-called paraganglion cells (Eranko and Eranko, 1977) of as yet uncertain function. There are, however, some fluorescent nerve endings around the cell bodies of nonfluorescent ganglion cells (Bennett and Malmfors, 1970), suggesting some form of sympathetic modulation of the activity of intrinsic cardiac neurons.

The right AV valve has a central layer of connective tissue between two layers of cardiac muscle (Section 11.2.1.4), and nerve bundles have been observed in association with this connective tissue (Smith, 1971a). In this study, several general nerve stains as well as a cholinesterase-specific stain were used, but unfortunately no details are given regarding the specificity of staining of the valvular innervation. However, Bennett and Malmfors (1970) have shown that this valve is innervated by adrenergic nerve fibers with few terminals, arranged in a loose plexus in the leaves of the valve. These observations suggest the existence of some degree of neural control of this valve, possibly by both sympathetic and parasympathetic limbs of the autonomic nervous system.

Adrenergic innervation in the left atrium is less dense than in the right atrium, but more dense than in the ventricles. Adrenergic fibers and terminals of the left atrial cardiac plexus, while distributed in a three-dimensional pattern similar to that in the right atrium, appear to be more evenly spread throughout the left atrial wall with little variation in density. In addition, the interatrial septum also receives adrenergic innervation as an extension of the epicardial plexus (Akester, 1971; Akester et al., 1969). The distal portion of the left AV valve has a fibroelastic structure, while more proximally cardiac muscle is associated with the fibrous skeleton (Section 11.2.1.4). Smith (1971a) has described a fine network of nerve fibers, continuous with the left atrial subendocardial plexus, investing the fibroelastic portion of this valve; no mention of an innervation of the muscular portion of the valve was made in this study. The staining technique used was again not transmitter specific, so the left AV valve may be under sympathetic or parasympathetic influence, or both, or the innervation observed may be afferent. However, regarding the latter possibility, Smith (1971a) stated that no simple or specialized nerve endings typical of sensory receptors were observed in or near the left AV valve.

The avian ventricles are relatively sparsely innervated compared with the atria, but even so are more densely innervated than are the ventricles of the hearts of mammals (Smith, 1971b). Akester et al. (1969) and Akester (1971) reported adrenergic innervation of the interventricular septum, and Bennett and Malmfors (1970) observed that innervation of this region was denser than that in the rest of the ventricle walls. Although these authors did not determine the intraseptal targets of innervation, it is possible that some of these axons may innervate intraseptal Purkinje cells since bare nerve endings have been observed close to these cells (Akester, 1971). Regarding the innervation of the pulmonary and aortic valves, Smith (1971a) reported that they were sparsely innervated in comparison with the left AV valve. Fibers in the pulmonary and aortic valves comprise a plexus arranged to form a widely spaced lattice in the basal parts of the valve leaflets.

In birds, the sympathetic cardiac nerves arise from the most rostral ganglia of the thorax and the most caudal cervical ganglia, but there is some variation in detail among different accounts (see Cabot and Cohen, 1980 for summary). Macdonald and Cohen (1970) and Cabot and Cohen (1980) describe the right sympathetic cardiac nerve in the pigeon as a single trunk formed by the anastomosis of postganglionic nerves arising from the three most caudal cervical ganglia. These ganglia are associated with spinal nerves contributing to the brachial plexus; the most caudal ganglion of this group is thus associated with the last spinal segment contributing to the brachial plexus. This description closely follows that of Malinovsky (1962) in the pigeon. In the chicken, however, the origin of the right cardiac sympathetic nerve is limited to the first thoracic paravertebral ganglion (as defined by its location caudal to the head of the first rib; Pick, 1970; Tummons and Sturkie, 1969; see Figure 11.35).

There has been some controversy over the nomenclature of avian sympathetic ganglia. Birds have a sympathetic ganglion associated with each cervical spinal segment (Gabella, 1976; Pick, 1970) and this observation, as well as variations in opinion on numeration of the ribs in the bird, has made it difficult to be precise about the terminology for the most caudal ganglion contributing to the cardiac nerve.

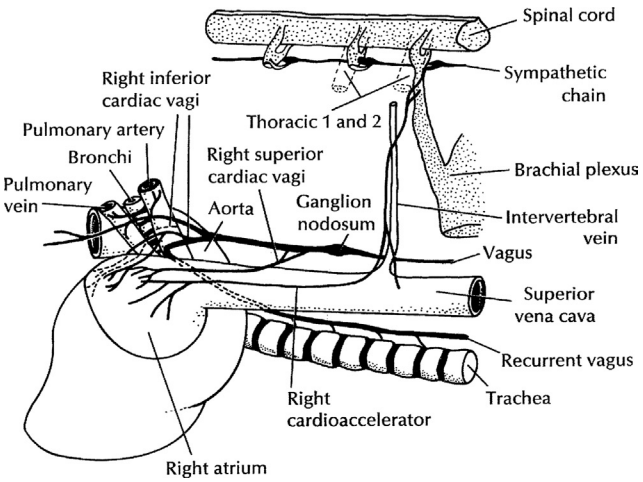

FIGURE 11.35 Schematic representation of the sympathetic innervation of the chicken heart on the right side. In this species, the cardiac sympathetic nerve originates from the first thoracic paravertebral ganglion. *Modified from Tummons and Sturkie (1969).*

Malinovsky (1962) holds that this is the first thoracic ganglion, because it lies between the heads of the first and second ribs. However, Macdonald and Cohen (1970) have sided with earlier authors in noting that the first rib should not be considered to mark the first thoracic segment because this rib is reduced in size and does not form part of the ribcage proper. As Cabot and Cohen (1980) have pointed out, the issue of terminology is not critical when considering functional aspects of cardiac sympathetic outflow to the bird heart, but may become important when attempting to draw conclusions about the homology of this pathway with the sympathetic innervation of the mammalian heart. Mammals have no cervical paravertebral ganglion chain, and postganglionic neurons efferent to the heart in this vertebrate class are located in the middle cervical ganglion and the stellate ganglion, with the latter being formed by the condensation of the caudal cervical and first thoracic ganglia. This arrangement has no parallel in birds.

Regardless of the number of ganglia contributing to the right cardiac sympathetic nerve, the course of this nerve to the heart appears to follow the same general pattern in all avian species so far examined. The nerve courses toward the heart in conjunction with a small vertebral vein arising from the lateral aspect of the vertebral column between the last cervical and first thoracic spinal segments. The vessel and nerve merge with the apical pleura of the lung and run together between the pleural fascia. At the ventral surface of the pleura close to the junction of the vertebral vein with the superior vena cava, the nerve turns caudally along the vena cava toward the heart, there forming two rami. The medial ramus divides further and its fascicles enter the cardiac plexus to distribute within the right atrial wall. The lateral ramus joins the right vagus nerve in the vicinity of the right pulmonary artery (Pick, 1970; Cabot and Cohen, 1980; Tummons and Sturkie, 1969; Cabot and Cohen, 1977a; Macdonald and Cohen, 1970; Malinovsky, 1962). The ganglionic origin of the left sympathetic cardiac nerve is similar to that of the right, arising in the chicken from paravertebral ganglion 14 (first thoracic) and in the pigeon by anastomosis of postganglionic branches from ganglia 12–14 (Cabot and Cohen, 1980). In the pigeon, the largest branch contributing to the left sympathetic cardiac nerve arises from ganglion 14, as on the right side. In its path to the heart, the left cardiac nerve in the pigeon divides into two or more fascicles that run in parallel for a short distance then recombine before reaching the superior vena cava. This nerve ramifies again as it runs caudally along the vena cava toward the heart, and the individual rami merge with the cardiac plexus of the left atrium.

The general locations of the cells of origin of the sympathetic postganglionic axons to the avian heart and the intraspinal locations of the cardiac sympathetic preganglionic neurons have been worked out in greatest detail in the pigeon, by Cabot and Cohen and their coworkers. These workers used a combination of degeneration, neuroanatomical tracing, and electrophysiological stimulation and recording techniques. Macdonald and Cohen (1970) undertook a series of neuronal degeneration studies in order to determine the ganglionic distribution of the somata of postganglionic neurons supplying axons to the heart. After section of the right or left cardiac sympathetic nerve in the thorax, the greatest number of degenerating neurons was found in ganglion 14, with lesser numbers in ganglia 12 and 13; no degenerating neurons were observed in ganglia rostral or caudal to this level. Postganglionic cells of origin of fibers in the cardiac sympathetic nerves were thus located bilaterally in the same sympathetic ganglia, which give rise to the postganglionic nerves constituting the cardiac nerve. In experiments in which the ganglia themselves or the interganglionic sympathetic trunks were stimulated electrically, Macdonald and Cohen (1970) obtained positive cardiac chronotropic responses of short latency from ganglia 12 to 16, occasional longer-latency responses from ganglia 17 and 18, and none from ganglia caudal to 18. Experiments in which stimulation of ganglia was combined with sections of the sympathetic trunk above and below the stimulation site confirmed these results. These data were interpreted to mean that preganglionic axons originating in the spinal cord as caudally as the 16th segment converged on postganglionic cardiac neurons in ganglia 12–14. The longer latency cardiac responses to stimulation of ganglia 17 and 18 were attributed to sympathetic activation of the adrenal glands and consequent release of catecholamines into the bloodstream; nerves arising from ganglia 17 and 18 were observed to join the splanchnic nerves, branches of which innervate the adrenal medulla.

Avian sympathetic preganglionic neurons innervating the heart are located in the same area of the spinal gray matter as those innervating the blood vessels, near the midline dorsal and lateral to the central canal, and extending rostrocaudally throughout segments 14–21. Most of the preganglionic neurons are confined to a distinct cell column in the midline, the column of Terni, a nucleus peculiar to the avian spinal cord (Huber, 1936; Cabot and Cohen, 1980). This cell column is the probable homolog of the mammalian intermediolateral cell column. Leonard and Cohen (1975), in a study of the cytoarchitecture of the pigeon spinal gray, reported that the rostral and caudal extents of this nucleus were indistinct due to small clusters of cells which extended into the regions between segments 13 and 14 and caudal to segment 21. Neurotracer studies using retrograde transport of horseradish peroxidase have shown that spinal preganglionic neurons efferent to the postganglionic cells in ganglion 14 of the pigeon are present from the caudal portion of segment 14 to the rostral part of segment 17 (Cabot and Cohen, 1977a). This finding provides strong anatomical support for the earlier

conclusion of Macdonald and Cohen (1970), reached on the basis of functional and degeneration studies, that spinal preganglionic inputs to cardiac postganglionic neurons originate from segments 14 to 16, with some inputs possibly coming from segment 17.

The protocol used by Cabot and Cohen (1977a) did not label cardiac preganglionic neurons specifically. In a more recent study of the intraspinal circuitry involved in sympathetic control of the heart, the region of the spinal cord containing cardiac preganglionic motor neurons has been more precisely mapped by Cabot et al. (1991b). In this study, preganglionic neurons associated with ganglion 14 in the pigeon were labeled using fragment C of tetanus toxin (a nontoxic moiety which is retrogradely transported by axons), injected into sympathetic ganglion 14. These experiments confirmed the location of preganglionic neurons in the column of Terni and also demonstrated labeling of neurons lateral to this nucleus (Figure 11.36) in an area which, in the mammalian spinal cord, is occupied by sympathetic preganglionic neurons of the nucleus intercalatus spinalis (Petras and Cummings, 1972), a term that Cabot et al. (1991b) have applied to the corresponding area in the pigeon spinal cord. Their results show that cardiac neurons in the spinal cord are not confined to the column of Terni. No studies have yet been done to label cardiac postganglionic sympathetic neurons in the bird which innervate specific regions of the heart, but this will be a necessary further step in order to determine the intraspinal locations of groups of neurons controlling cardiac functions such as rate and contractility. A potentially useful approach to this problem would be localized injections of a retrograde neuroanatomical tracer such as fragment C of tetanus toxin or pseudorabies virus into specific regions of the heart. This tracer would then be transported retrogradely and transsynaptically so that both cardiac postganglionic neurons and the spinal preganglionic neurons afferent to them could be visualized. This approach has proven advantageous in studies of cardiac autonomic pathways in mammals (Strack et al., 1988).

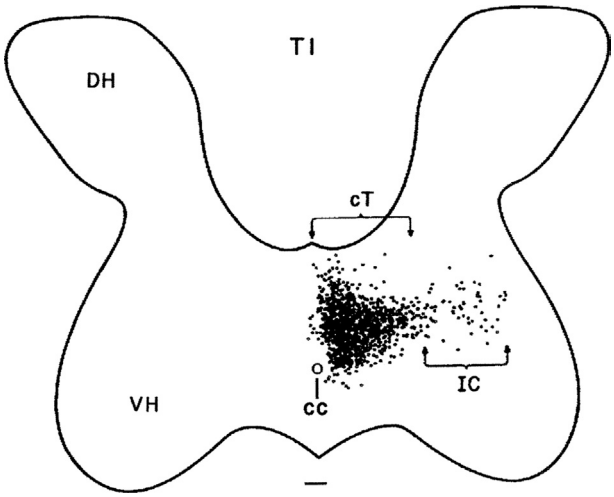

FIGURE 11.36 Mediolateral distribution of cell bodies of spinal preganglionic neurons labeled in the first thoracic segment (T1) of the spinal cord by an injection of a retrograde neurotracer (fragment C of tetanus toxin) into the right paravertebral ganglion 14 of the pigeon. The largest root of the cardiac sympathetic nerve in the pigeon arises from this ganglion. The diagram shows labeled neurons concentrated in the column of Terni (cT, large cluster of dots closest to the central canal (cc)), along with a lesser concentration of cells located more laterally in the nucleus intercalatus spinalis (IC). Although preganglionic neurons innervating the heart were not labeled specifically in this experiment, their cell bodies will be among the labeled population. Abbreviations: DH, dorsal horn; VH, ventral horn. Horizontal scale bar represents 50 µm. *Reprinted from Cabot et al. (1991b).*

The descending projections from higher centers in the central nervous system to sympathetic preganglionic neurons controlling the heart have not in general been delineated in birds. However Cabot et al. (1982), in a series of anatomical studies in the pigeon, determined that the overall pattern of projections to spinal preganglionic neurons is very similar to that found in mammals, and this anatomical data corroborates the results of earlier brain stimulation studies in the bird. In particular, Cabot et al. (1982) have shown anatomically that avian preganglionic neurons receive direct projections from diencephalic and medullary areas which, when electrically stimulated, provoke cardioaugmentation (Macdonald and Cohen, 1973; Folkow and Rubenstein, 1965; Kotilainen and Putkonen, 1974; Feigl and Folkow, 1963).

11.5.3.2.1.2 Sympathetic Control Electrical activation of intramural adrenergic nerves in the avian heart produces augmented force of contraction and cardioacceleration. Bolton and Raper (1966) and Bolton (1967) first demonstrated sympathetically mediated augmentation of force of contraction of electrically paced strips of *in vitro* left ventricle from the fowl heart. In these studies, field stimulation excited both cholinergic and adrenergic nerves, and sympathetically mediated augmentatory effects were then pharmacologically isolated by the application of atropine to eliminate parasympathetic inhibitory effects. After muscarinic blockade, the increased contractile force produced by field stimulation was attributed to activation of adrenergic nerves since this effect could then be blocked by β-adrenergic antagonists. These data provided the first evidence in birds that the sympathetic nervous system can have a positive inotropic effect directly on ventricular myocardial cells.

Similar field stimulation experiments on left and right atria *in vitro* have shown that activation of intramural sympathetic nerves has powerful effects on these chambers. In the left atrium of the fowl heart, increased force of contraction of myocytes resulted from sympathetic nerve activation. These positive inotropic effects were blocked by β-adrenergic antagonists (Koch-Weser, 1971; Bennett and Malmfors, 1974, 1975b). The right atrium *in vitro* responds

to field stimulation of intramural sympathetic nerves with an increase in force of contraction and rate of pacemaker discharge, with both effects mediated by β-adrenergic receptors (Pappano and Loffelholz, 1974).

In the isolated chicken heart perfused *in vitro* by Langendorff's method, stimulation of the attached right cardiac sympathetic nerve produces positive chronotropic effects (heart rate increased from 186 to 292 beats/min; Sturkie and Poorvin, 1973). The basal heart rate of this isolated preparation, supplied with (presumably) adequate oxygen in the perfusate at 40 °C, might be expected to be similar to that of the *in situ* chicken heart after bilateral section of the vagus and cardiac sympathetic nerves ("decentralized" state), but this was not the case. The mean rate of *in situ* decentralized hearts was in the range of 235–285 beats/min (Tummons and Sturkie, 1968, 1969). Under these conditions, stimulation of the peripheral stump of the right cardiac sympathetic nerve increased heart rate to 345 beats/min, an increase of 48%. By comparison, stimulation of the right cardiac nerve stump attached to isolated hearts *in vitro* produced a mean heart rate of 292 beats/min. That is, maximal sympathetic stimulation in this preparation could only raise heart rate to a level equivalent to the basal rate of the decentralized heart *in situ*. However, even though basal heart rate was different in these preparations, the proportional increase in rate during sympathetic stimulation was the same in both cases. Thus sympathetically mediated chronotropic effects in the isolated heart may, in relative terms, reflect the capabilities of this control system in the *in vivo* heart.

In a beating heart *in vivo*, stimulation of the cardiac sympathetic nerves produces cardioacceleration. Tummons and Sturkie (1968), in the unanesthetized chicken, showed that either cardiac sympathetic nerve could produce this effect when stimulated: activation of the right nerve increased heart rate by 48% above the prestimulation value, while activation of the nerve on the left side increased heart rate by 32%. In the pigeon, however, Macdonald and Cohen (1970) found that only the right cardiac nerve mediated cardioacceleration when stimulated (Figure 11.37, top panel), whereas stimulation of the left cardiac nerve altered the appearance of the T wave of the electrocardiogram without a chronotropic effect (bottom panel, Figure 11.37). Such functional asymmetry in cardiac control has also been reported for the mammalian heart (Randall, 1994).

In the right atrium the role of the dense adrenergic innervation of the SA area (see Section 11.5.3.2.1) in controlling heart rate is obvious and a number of studies have shown that adjustments of heart rate *in vivo* are made by the sympathetic nervous system under a variety of physiological conditions. Furthermore, the anatomical evidence for widespread cardiac innervation and the data cited above for sympathetic influences on myocardial contractility in the atria and ventricles implies that the sympathetic nervous system can also produce both global and regional enhancement of contractility. Two important functional consequence of this arrangement are that (1) different patterns of sympathetic outflow from the central nervous system to individual chambers of the heart provide the means for augmenting regional contractility differentially to match the chambers' pumping actions to the hydraulic impedances into which they are working; and (2) the output of each chamber can be controlled independently of pumping rate. However, to understand the function of this control system more thoroughly it is necessary to establish whether different populations of pre and postganglionic sympathetic neurons do in fact innervate different cardiac regions and whether such subpopulations may be differentially activated through reflexes driven by receptors in specific cardiac or vascular reflexogenic zones. Such an analysis is complicated by the location, remote from the heart, of cells of origin of the postganglionic sympathetic axons innervating the cardiac chambers, in contrast to the intracardiac locations of the postganglionic parasympathetic neurons.

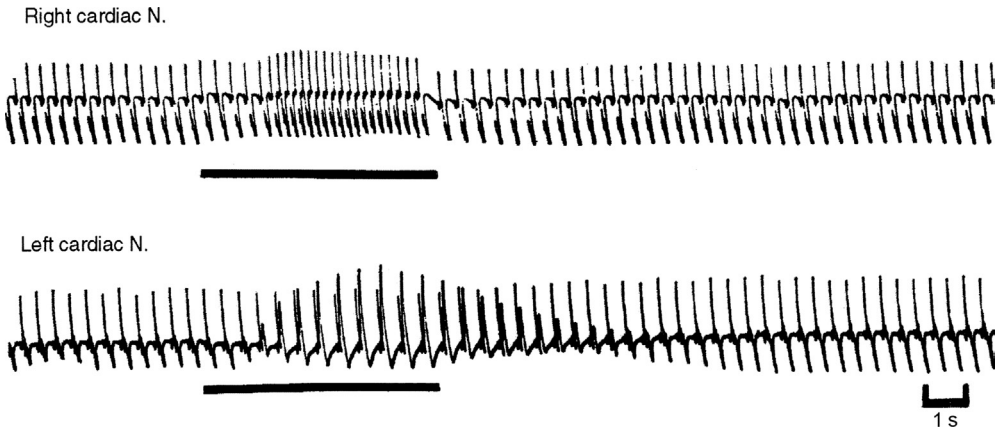

FIGURE 11.37 Electrocardiograms showing heart rate responses in the pigeon to electrical stimulation of the right (top) and left (bottom) cardiac sympathetic nerves. The duration of the stimulus train delivered to each nerve is indicated by the length of the solid bars under the traces. *From Macdonald and Cohen (1970).*

Most studies of sympathetic control of cardiac function have affirmed the role of NE as the transmitter released by avian postganglionic terminals on the myocardium. However, the bird heart contains EPI as well as NE (Sturkie and Poorvin, 1973; DeSantis et al., 1975; data summarized in Holzbauer and Sharman, 1972). It has been suggested that, in other organs such as the rectum of the fowl, adrenergic terminals may release EPI (Komori et al., 1979). In the isolated chicken heart, DeSantis et al. (1975) proposed that both EPI and NE may act as sympathetic neurotransmitters, on the basis of two main lines of evidence. First, sympathetic nerve stimulation, infusion of tyramine (a compound provoking the release of endogenous amines from sympathetic nerve terminals) or depolarization of intracardiac nerve terminals with a potassium-enriched perfusate all produced elevated NE and EPI efflux from the heart. Second, exogenously applied NE and EPI were equipotent in augmenting cardiac rate and strength of contraction. These authors also treated hearts with 6-hydroxydopamine to destroy sympathetic nerve endings and found that this reduced the intracardiac concentrations of both EPI and NE to very low levels. But DeSantis et al. (1975) did not perform the critical experiment of determining the effect of chemical sympathectomy on release of catecholamines during cardiac nerve stimulation. Sturkie and Poorvin (1973), on the other hand, concluded that even though they and other workers had identified stores of both EPI and NE in the heart, only NE appeared to be released during sympathetic nerve stimulation. These authors concluded that EPI was sequestered in nonneuronal stores and would not, therefore, be involved in neurogenic control of the myocardium. Currently, the most widely accepted view is that NE is the primary sympathetic neurotransmitter in the avian heart, as in the mammalian heart.

Autonomic tone is usually taken to mean the level of spontaneous and ongoing activity in autonomic nerves to the heart under basal or resting conditions (i.e., when the animal is not actively moving or engaged in major physiological responses to its environment). Because monitoring spontaneous nerve activity is technically difficult in any preparation other than the acutely anesthetized animal instrumented for nerve recording, the level of basal heart rate is usually taken as the major indicator of cardiac autonomic tone as rate is easily measured under a variety of conditions in the whole animal. An added complication in analyzing tonic autonomic drive to the heart is that both autonomic limbs can strongly affect rate. Because rate is driven in opposite directions by parasympathetic and sympathetic inputs, the chronotropic effects of tonic activity in one limb can only be accurately assessed in the absence of influences from the other limb. Autonomic inputs to the heart can be selectively ablated by a variety of means including surgical section of the vagus or cardiac sympathetic nerves, chemical sympathectomy (by pretreatment with agents which destroy adrenergic nerve terminals or by adrenergic blockade), blockade of cardiac vagal effects with atropine, or a combination of these methods.

The level of sympathetic tone to the heart can be quantified by determining the change from basal heart rate produced by any of the above methods for functional sympathectomy after vagal influences on the heart are removed. Widely varying levels of sympathetic tone have been reported among bird species and even among different studies of the same species. A portion of this variability is likely due to the use of anesthetics. Baseline heart rate itself will change as a consequence of general anesthesia, and anesthetics will also have a blunting effect on autonomic control of the heart (Vatner and Braunwald, 1975; Brill and Jones, 1981; Lumb and Jones, 1984). Therefore, the most accurate assessment of cardiac sympathetic tone would be made in awake, spontaneously breathing animals in a quiescent state after vagal influences on the heart have been eliminated.

Johansen and Reite (1964) investigated the level of autonomic tone to the heart in both awake ducks and those under general anesthesia; the authors did not differentiate between these states in reporting their data, claiming that this made no difference to the outcome of the experiments. In vagotomized ducks in this study, β-adrenergic blockade produced a large fall in heart rate, implying the existence of strong resting sympathetic tone. Tummons and Sturkie (1969) reported that, in awake chickens at 6 days after recovery from surgical division of the cardiac sympathetic nerves, heart rate was about 16% less than that in intact animals. In anaesthetized ducks, Kobinger and Oda (1969), using pharmacological agents to inhibit sympathetic function at central and peripheral levels of the nervous system, also found evidence for significant sympathetic tone to the heart. On the central side, they showed that clonidine mediated depression of vasopressor areas in the medulla, including the sympathetic cardiomotor area, led to a reduction in heart rate. On the peripheral side, depletion of NE from peripheral sympathetic terminals with reserpine, or prevention of NE release from these terminals, also significantly reduced cardiac rate. None of these experiments was done with accompanying vagal blockade. In contrast to the results of Kobinger and Oda (1969), Folkow et al. (1967) found no significant change in heart rate after β-adrenergic blockade in the same species. However, a complicating factor in the latter study was that the agent used (an experimental β-blocker then under development) was acknowledged by the authors to have a partial β-agonist effect, which may have offset any effects of β-blockade on basal heart rate. Butler and Jones (1968, 1971) reported no significant change in heart rate in unanesthetized ducks after β-blockade with propranolol, an agent free of intrinsic β-agonist effects. In awake chickens, Butler (1967) found that β-blockade with the vagi intact produced a significant fall in heart rate to 75% of the control rate. β-blockade after vagotomy produced less of an effect,

reducing heart rate to 82% of the level in animals with intact vagi. These results show that significant sympathetic tone is present in the chicken, reinforcing the contention that the level of this tone can only be accurately assessed in the absence of parasympathetic input to the heart. However, the results of Butler (1967) contrast with those of Tummons and Sturkie (1970), who found that sectioning the sympathetic nerve produced a fall of about 16% in heart rate from the level before nerve section, while vagotomy produced a rise of about the same proportion. Combined vagotomy and sympathetic nerve section resulted in a heart rate not significantly different from that in intact animals. The authors therefore concluded that, in resting intact animals, the balance between tonic sympathetic and parasympathetic inputs to the heart maintained rate at the same level as the intrinsic rate in animals after cardiac decentralization. It is clear from the foregoing discussion that further studies of tonic sympathetic drive to the heart must be rigorous in taking both the state of anesthesia and the level of concomitant parasympathetic drive into account.

An electrophysiological analysis of the compound AP of the right cardiac nerve in the pigeon has shown that axons in this nerve can be categorized into two groups separable by conduction velocity, as shown in Figure 11.38 (Cabot and Cohen, 1977a). Fibers of the more slowly conducting group (range 0.4–2 m/s) were shown to mediate sympathetic cardioacceleration. The range of conduction velocities of these axons lies within that of unmyelinated sympathetic postganglionic fibers known to innervate the viscera (Gabella, 1976), and morphological analysis of the pigeon right cardiac nerve confirms that 67% of axons in this nerve are unmyelinated (Macdonald and Cohen, 1970). The faster-conducting group of fibers in this nerve (range 2–5.6 m/s) are likely to be myelinated axons. These make up the remaining 33% of the total number of axons and probably represent so-called sympathetic afferent fibers (Malliani et al., 1979) with receptor endings in the heart, great vessels, or lungs. Afferent fibers in cardiac nerves have been shown to participate in cardiopressor reflexes in the pigeon (Cabot and Cohen, 1977b).

11.5.3.2.2 Parasympathetic Innervation

11.5.3.2.2.1 Anatomy Efferent neurons with their cell bodies in the heart form the final common pathway for parasympathetic control of cardiac function. These postganglionic neurons receive synaptic inputs from terminals of preganglionic neurons with their somata in the brainstem and their axons coursing to the heart in the vagus nerves. It is generally accepted that parasympathetic efferent neurons in the heart are cholinergic, releasing ACh at their myocardial terminals; this neurotransmitter acts to modify myocardial function through postjunctional muscarinic receptors. Indeed, most of the anatomical studies of parasympathetic

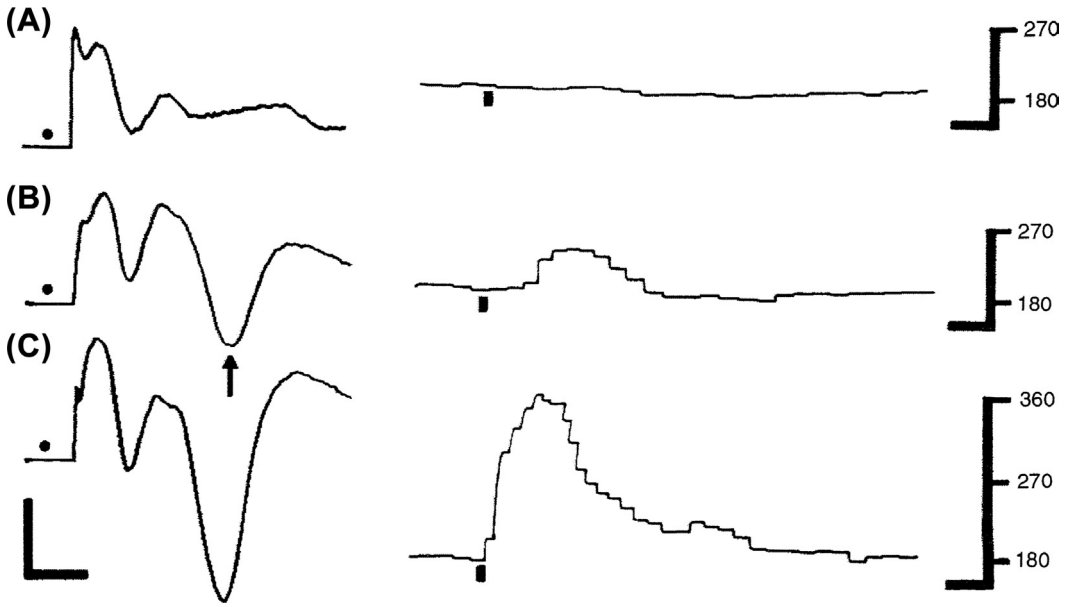

FIGURE 11.38 Correlation between components of the compound action potentials evoked by graded electrical stimulation of the right cardiac sympathetic nerve and chronotropic responses of the heart in the pigeon. The traces on the left represent the compound action potential at three intensities of stimulation increasing from A to C (round dots associated with each trace indicate the start of the stimulation, which consisted of a 200 ms train of 50 Hz pulses). For these traces the vertical calibration bar represents 100 μV and the horizontal bar represents 5 ms. The traces on the right represent beat-by-beat ratemeter recordings showing heart rate responses produced by the same stimuli (filled squares under each trace) which evoke the nerve responses on the left. The calibration bars to the right of each trace indicate heart rate in beats/min. For these traces the horizontal bar represents 1 s. The onset of the component of the compound action potential indicating conduction of cardioaccelerator fibers is indicated by the arrow in trace B; this component strengthens with increased stimulus intensity in trace C, as does the degree of cardioacceleration. *Reprinted from Cabot and Cohen (1977a).*

innervation of the heart have used a histochemical reaction indicating the presence of AChE as a marker to determine the distribution of cholinergic fibers and terminals of the cardiac plexus, as well as the locations of intracardiac neurons. Cabot and Cohen (1980) have extensively reviewed the cholinergic innervation of the heart, so a brief synopsis of that review and the contributions of later workers are combined below.

In all avian species so far examined, all four cardiac chambers receive AChE-positive innervation (Hirsch, 1963; Yousuf, 1965; Smith, 1971a,b; Akester and Akester, 1971; Mathur and Mathur, 1974; Rickenbacher and Müller, 1979; Kirby et al., 1987). Smith (1971a,b), in studies of the innervation pattern in the chicken heart, determined that cholinergic nerves, nerve fibers, and terminals formed a subepicardial ground plexus throughout the atria and ventricles, penetrating into the myocardium. Some fibers were observed to run all the way to the endocardial region, where they contributed to a subendocardial plexus that was also distributed throughout the atria and ventricles. In many avian species, the overall intracardiac distribution of cholinergic innervation parallels the distribution of adrenergic fibers and terminals (Bennett and Malmfors, 1970). The right atrium has been a particular focus for anatomical studies of cholinergic innervation in view of the location of the primary pacemaker in this chamber and the vagally mediated inhibition of pacemaker node discharge rate. Yousuf (1965) noted in the sparrow heart that the region around the SA node was the first part of the heart to receive extrinsic cholinergic innervation during embryological development and observed that, in later developmental stages, this area and the right atrial wall near the AV node were heavily innervated. However, no nerve fibers were observed to enter the SA node area proper, and only a few fibers were present among the AV nodal cells. This pattern has also been observed in the pigeon heart (Mathur and Mathur, 1974). However, Gossrau (as summarized in Akester, 1971) reported that in pigeon, chaffinch, and canary hearts, the pacemaker region had a dense AChE-positive innervation, while in duck and chicken this area was sparsely innervated. Differences among these studies may be partly species dependent, although the contrasting results of Mathur and Mathur (1974) and Gossrau in the pigeon heart may be due to differences in the techniques used. Bogusch (1974) observed a dense cholinergic innervation pattern around subepicardial Purkinje fibers of the fowl right atrium but noted that the density of this innervation decreased as the conducting fibers approached the AV border. In this study, multiple nerve terminals were only loosely associated with Purkinje fibers, leaving some doubt as to the nature of the neuroeffector–tissue relationship in cholinergic control of conduction in the atrium. SA valve remnants have also been reported to be the targets of cholinergic innervation in the bird heart (Akester, 1971; Mathur and Mathur, 1974).

Cholinergic innervation of the left atrium and the ventricles has been less extensively studied than that of the right atrium, but the general pattern of subepicardial and subendocardial plexi with individual nerve fibers and terminals extending into the myocardium, as described by Smith (1971b), appears to hold. Extensive cholinergic innervation has been described in the interatrial and interventricular septa (Akester, 1971), the right AV valve leaflets (Akester, 1971; Mathur and Mathur, 1974), and the left AV valve. Here, the AChE-positive nerve fibers enter the basal half of the valve from the subendocardial plexus (Smith, 1971a). The cholinergic innervation of the avian chordate tendineae is controversial: Smith (1971b) reported no nerve fibers present in chordae tendineae of the chicken heart, whereas Mathur and Mathur (1974) found in the pigeon heart that these structures were innervated. The function of such innervation is obscure because the chordae tendineae contain no actively contracting tissue, serving only to anchor the papillary muscles to the aortic valve leaflets. It is most likely that the nerve fibers observed in these structures are efferents en route to either the valves or the papillary muscle, but some fibers may subserve an afferent function.

The adventitia of coronary arteries associated with all chambers of the bird heart is innervated by cholinergic nerve fibers (Hirsch, 1963; Akester, 1971; Smith, 1971a) but the origin of this innervation is not known. Cholinergic fibers innervating coronary arteries may originate from postganglionic parasympathetic neurons within the heart or may possibly be extrinsic sympathetic cholinergic fibers; in either case, this innervation probably functions to increase coronary blood flow by promoting vasodilation.

In development of the chick heart, Rickenbacher and Müller (1979) determined that cell bodies of intracardiac neurons, clustered into ganglia, first developed in the left ventricle, then a large group of ganglia became evident around the coronary sulcus and the ventral surface of the ventricles and, lastly, ganglia developed in association with the dorsal atrial walls.

In the adult avian heart, ganglia are located primarily in the subepicardial plexus, usually in association with plexus nerves and frequently near the branch points of these nerves. The somata of intracardiac neurons have been characterized as multipolar (possessing more than two processes; Smith, 1971b; Yousuf, 1965), but these observations are limited to the hearts of only two species (chicken and sparrow, respectively). No morphological data exists on the variation of somatic dimensions or on the length or specific projection targets of the processes of intracardiac neurons in any avian species.

Histochemical reactions for AChE have been the primary tool used in analyzing the distribution of intracardiac neurons in the bird heart, and there seems little doubt that these techniques allow visualization of most if not all of these neurons. Such anatomical data, along with evidence from

the functional studies cited below, supports the contention that the phenotype of avian intracardiac neurons is cholinergic. However, AChE has been detected in some nonneuronal elements associated with the nervous system (see review by Fibiger, 1982) and demonstration of the presence of this enzyme in neuronal somata in the heart, although necessary, may not be a sufficient criterion for designating these cells cholinergic. In the central nervous system the most widely accepted indicator of cholinergic function is the presence of choline acetyltransferase (ChAT), an enzyme in the pathway for ACh synthesis (Fibiger, 1982). Reliable antibodies directed against ChAT are now commercially available and have begun to be applied to the mammalian peripheral autonomic nervous system. A similar application of ChAT immunohistochemical techniques to the avian heart would help verify the assumption that intracardiac neurons in this vertebrate group are in fact of cholinergic phenotype.

In their analysis of the distribution of the intracardiac ganglia during development, Rickenbacher and Müller (1979) found that the right ventricle wall contained about half of the total number of ganglia, the right atrium about one-fifth, the left ventricle about one-sixth, and the left atrium possessed the fewest ganglia. In the adult bird heart, no quantitative studies of regional neuron distribution have been done to date, so the absolute number of neurons associated with each chamber is not known. However, the general pattern of distribution of intracardiac neurons in the adult heart has been established (see Cabot and Cohen, 1980 for review). Ganglia containing variable numbers of neurons are present on both dorsal and ventral aspects of the left and right atria and ventricles (Yousuf, 1965; Smith, 1971a,b; Rickenbacher and Müller, 1979; Kirby et al., 1987; reviewed by Cabot and Cohen, 1980). Smith (1971b) has reported that a larger proportion of the total number of intracardiac ganglia is found in the ventricles of bird hearts than is the case in mammalian ventricles. Ganglia have been observed near but not within the SA node region (Yousuf, 1965; Smith, 1971b). Yousuf (1965) reported that some neurons in the sulcus terminalis appeared to send projections in the direction of the nodal tissue. The AV nodal region was also reported to be devoid of ganglia (Yousuf, 1965; Smith, 1971b; Mathur and Mathur, 1974) but this region and the AV bundle appeared to be innervated by axons from ganglion neurons in the nearby AV sulcus (Yousuf, 1965). Smith (1971b) described high concentrations of ganglia within the dorsal right atrial wall near the ostia of the superior and inferior venae cavae, near the roots of the pulmonary veins on the dorsal aspect of the left atrium, within the dorsal portion of the AV groove, and clustered around the roots of the pulmonary artery and aorta. In the ventricles, neurons are located in a scattered pattern reaching from the AV groove to the apex on the ventral surface (Smith, 1971b; Rickenbacher and Müller, 1979). There are also numerous ganglia associated with nerves accompanying atrial and ventricular coronary arteries (Mathur and Mathur, 1974; Smith, 1971b).

Studies in the mammalian heart have shown that a number of neuropeptides are colocalized in axons, terminals, and somata of cholinergic intracardiac neurons, as well as in preganglionic terminals contacting these neurons (Steele et al., 1994, 1996). Peptides constitute an important class of neuromodulators in the peripheral autonomic nervous system, and their presence in specific combinations in some peripheral neurons has been proposed to chemically code subpopulations of these neurons for specific functions such as vasomotion or control of muscle cell contractility. In the bird heart, substance P and vasoactive intestinal peptide have been found in intracardiac neurons and their terminals, while somatostatin is present in intracardiac terminals but not in cell bodies (Corvetti et al., 1988). These neuropeptides have been shown to exert powerful modulatory effects on mammalian intracardiac neuronal activity and cardiodynamics (Armour et al., 1993) and their presence in the bird heart indicates that they may play a prominent role in modulation of ganglionic and neuroeffector transmission in this vertebrate group. This constitutes a promising but as yet unexplored area for the comparative study of mechanisms of neural control of the heart.

The course of the avian vagus nerve and its cardiac branches has been described for a number of species (see Pick, 1970; Jones and Johansen, 1972; Cabot and Cohen, 1980 for reviews). The latter review points out that descriptions of the course and major branches of this nerve are consistent among species so a general summary of the avian vagal cardiac innervation will be given here, based on the comprehensive reports of Malinovsky (1962) and Cohen et al. (1970) in the pigeon and the reviews cited above. Inside the cranium, the peripheral trunks of the vagus and glossopharyngeal nerves originate bilaterally from large ganglia composed of a fusion of the proximal ganglion of the glossopharyngeal nerve and the jugular ganglion of the vagus nerve. The trunks of these nerves emerge together from the skull through the jugular foramen, and immediately outside the foramen an anastomosis (of Staderini) connects the vagal trunk to the petrosal ganglion of the glossopharyngeal nerve. The vagal trunk continues caudad in the neck along the dorsomedial aspect of the internal jugular vein, passing over the cervical spinal nerves on their ventral sides. No major vagal branches arise from the trunk along its cervical portion, although Malinovsky (1962) described occasional small anastomoses with the nearby cervical sympathetic trunk. At the level of the thoracic inlet the nodose (alternatively termed distal vagal) ganglia are present as spindle-shaped enlargements of the vagal trunks, as shown in Figure 11.39. Several afferent nerves carrying the axons of receptors important in the control of cardiovascular and respiratory functions arise from each nodose ganglion. Along the length of this

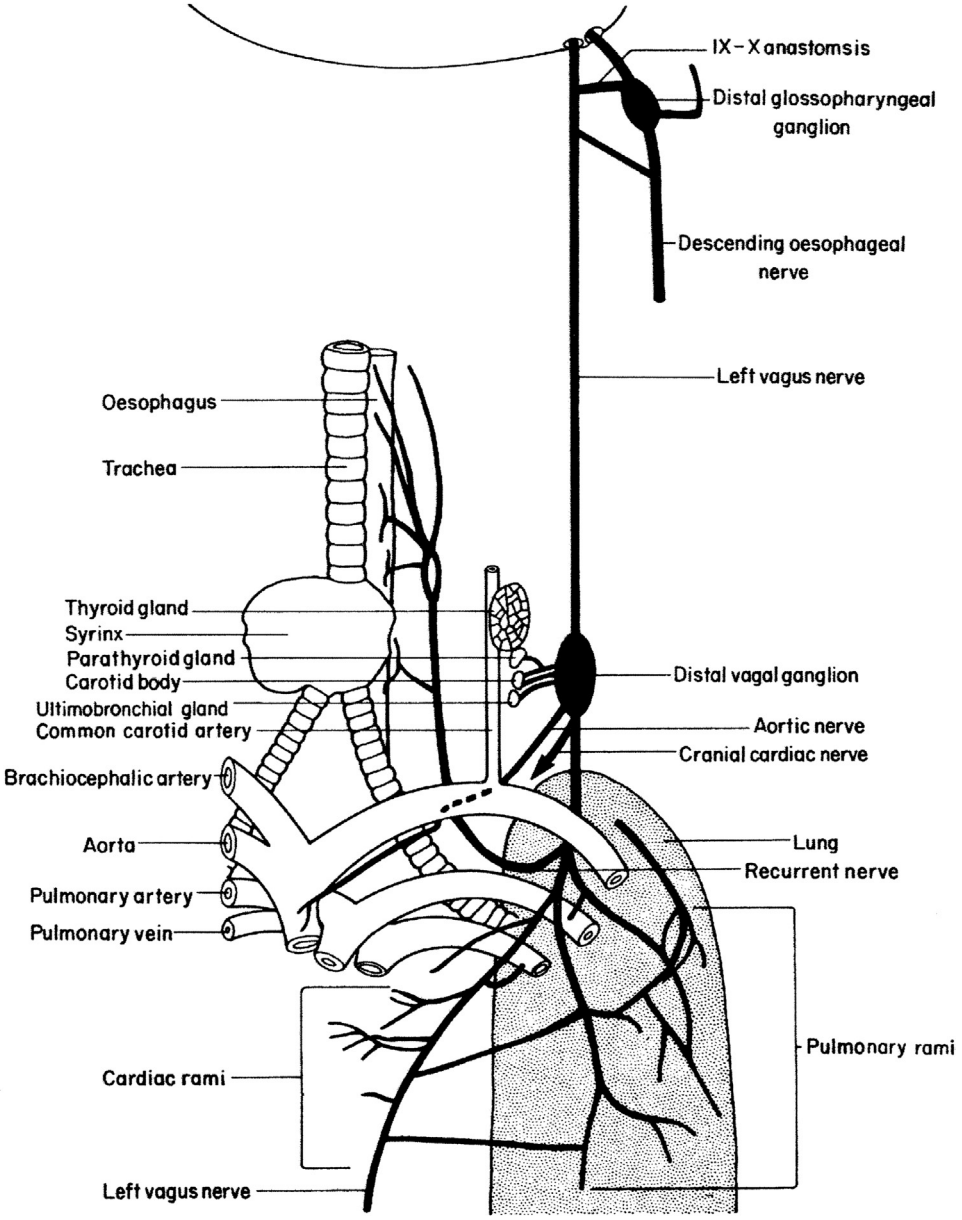

FIGURE 11.39 Schematic diagram depicting a ventral view of the pathway of the left vagus nerve in the area of the upper thorax of the duck. Details of the vagal innervation of the carotid body, ultimobranchial, thyroid, and parathyroid glands, and the aorta are illustrated. *From Jones and Johansen (1972).*

ganglion, branches arise which extend medially to innervate the thyroid, parathyroid and ultimobranchial glands, and the carotid body (Figure 11.39).

The latter structure constitutes the primary locus for peripheral chemoreceptors sensing arterial oxygen and carbon dioxide tensions and pH in the bird (Jones and Purves, 1970; see Section 11.5.4.1). Branches exiting from the caudal portion of the nodose ganglion course to the root of the aorta. On the right side, Nonidez (1935) reported two such branches in the chick, which he designated depressor and accessory depressor nerves by analogy with the mammalian condition. Nonidez (1935) reported no equivalent nerve on the left side, but in other species nerves from the nodose ganglion coursing to the aortic root (designated aortic nerves) have been reported to be present bilaterally (Jones and Purves, 1970; Jones, 1973; Cohen et al., 1970; Jones et al., 1983; Smith and Jones, 1990, 1992; summarized by Smith, 1994; see Figure 11.39). These nerves ramify into a plexus in the aortic wall. Jones (1973) first demonstrated that the aortic nerves carried arterial blood pressure information centripetally and that aortic baroreceptors were involved in regulating and maintaining arterial blood pressure in the duck.

A few millimeters caudal to the nodose ganglion the vagal trunk splits, as shown in Figure 11.40, to form several

major divisions as it approaches the pulmonary artery. Two of these circumscribe the pulmonary artery, rejoin, and continue as the main vagal trunk en route to the abdominal cavity while a third forms the recurrent laryngeal nerve, coursing craniad along the trachea; no cardiac vagal branches arise from this nerve. Another major vagal branch courses to the heart to enter the dorsal cardiac plexus (Jones and Johansen, 1972; shown in Figure 11.39). The remaining vagal branches form part of the pulmonary innervation, running to the lungs along the pulmonary arteries. The main vagal trunk, after reforming caudal to the pulmonary artery, passes ventral to the ipsilateral bronchus and over the dorsal surface of the heart. From this portion of the trunk a variable number of smaller branches arise and enter the cardiac plexus. On the right side, these branches enter the heart near the SA and AV nodes and at the caval ostia; on both the left and right sides of the heart vagal branches also enter the cardiac plexus in the vicinity of the AV groove. That the cardiac nerves described here constitute the major efferent vagal innervation of the heart has been confirmed by functional studies in which electrical stimulation of the vagal trunk was combined with surgical section of the trunk and the various cardiac branches (Cohen et al., 1970). Caudal to the origin of the most inferior cardiac branches, the left and right vagal trunks pass ventral to the pulmonary veins where both turn medially, coming to lie in close approximation as they course to the abdominal viscera (Figure 11.40).

The location in the central nervous system of cells of origin of vagal cardioinhibitory fibers in birds has been investigated by a variety of anatomical and physiological techniques. The extent of the medullary regions containing vagal preganglionic motor neurons innervating pharyngeal structures and thoracic and abdominal viscera was originally defined anatomically by determining the extent of

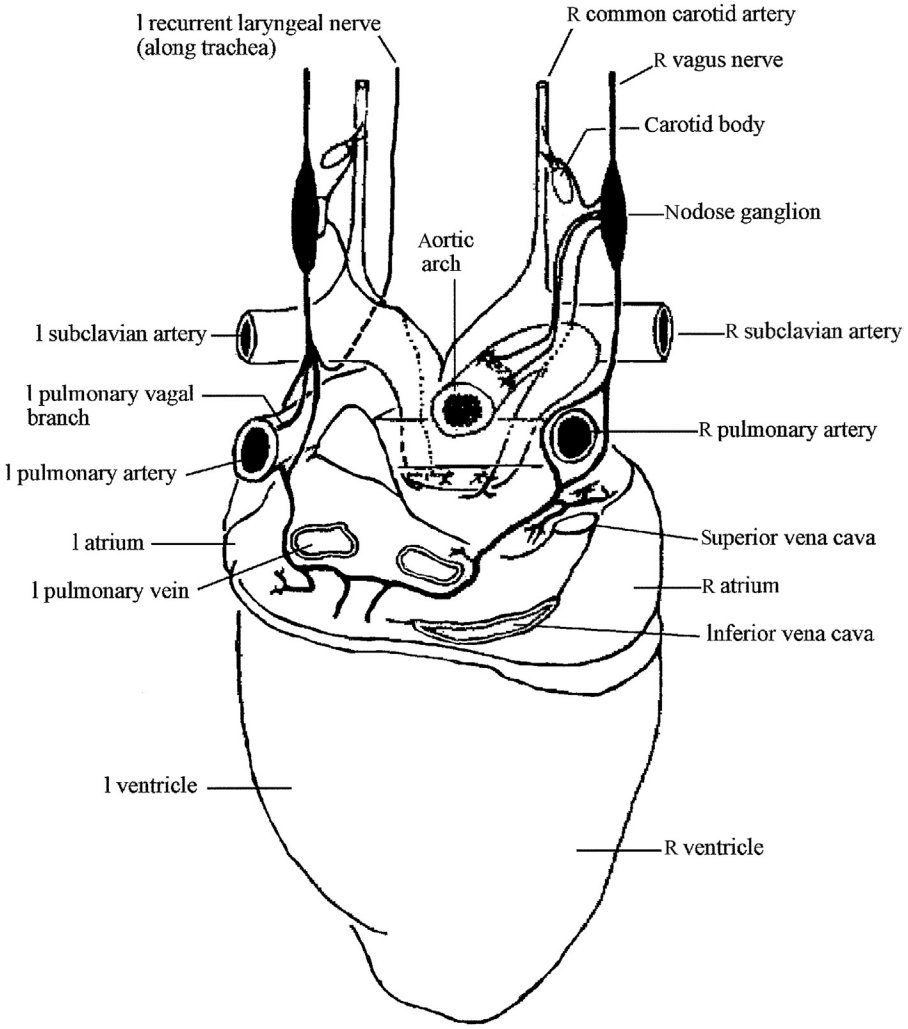

FIGURE 11.40 Schematic diagram to illustrate a dorsal view of the generalized vagal innervation of the avian heart. Note the pathways of the vagal branches as these nerves split close to the pulmonary arteries. For clarity the right pulmonary and right recurrent laryngeal branches are not shown and the right pulmonary vein, depicted next to the left, is not labeled (r, right; l, left). *Modified from Cabot and Cohen (1980).*

retrograde degeneration of neuronal somata after section of the cervical vagus nerve (Cohen et al., 1970) and by retrograde labeling of vagal neurons with neurotracers applied to the peripheral vagus nerve (Katz and Karten, 1979, 1983a,b, 1985; Cabot et al., 1991a). Cohen et al. (1970), working in the pigeon, described three major subdivisions of the dorsal motor nucleus of the vagus nerve (DMV) based on cytoarchitectonic and morphological criteria. The principal medullary location of neurons showing signs of degeneration after section of the cardiac vagal branches was in a region extending from the obex to the rostral pole of the DMV, with the highest density of degenerating cells in an area between 0.6 and 0.8 mm rostral to the obex. At this rostrocaudal level, these cells were primarily located in the most ventral region of the DMV. The results of these experiments suggested that the central arrangement of vagal cardioinhibitory neurons in birds was different than the mammalian condition; in mammals the primary locus for these neurons is the nucleus ambiguus, ventrolateral to the DMV (reviewed by Hopkins, 1987).

In the pigeon, focal electrical stimulation of the regions of the DMV shown anatomically to contain cell bodies of putative cardioinhibitory neurons produced short-latency decreases in heart rate; this response is shown in Figure 11.41 (Cohen and Schnall, 1970). The response was rapid, occurring within one or two cardiac cycles after the start of stimulation, suggesting that cardioinhibitory preganglionic cell bodies were being directly stimulated. If stimulation was continued, complete AV blockade could be produced in some animals; a depressor response invariably occurred secondary to all negative chronotropic responses (Figure 11.41). There was no lateral asymmetry in this response: stimulating in the DMV on either side produced similar cardioinhibitory responses. The cardiac effects produced by central stimulation could be mimicked by stimulating the vagal trunks in the neck or at the thoracic inlet (Cohen and Schnall, 1970). Field potential and single-unit recordings made in the pigeon DMV during stimulation of the vagal trunk provided further confirmation that the cell bodies of a large number of cardioinhibitory neurons were located in the central zone of the DMV rostral to the obex (Schwaber and Cohen, 1978b).

Schwaber and Cohen (1978a), in an electrophysiological study of the vagus nerves, found that when the cervical vagus was stimulated at progressively greater intensities the onset of bradycardia coincided with the elicitation of a specific component of the compound AP (B1 wave, Figure 11.42). This component was generated by the activation of a group of vagal axons conducting in the velocity range of 8–14 m/s. When the vagus nerve was stimulated with sufficient intensity to evoke both the A and B1 components (trace B of Figure 11.42) and a polarizing voltage was applied to the nerve to block the A but not the B1 component, the cardioinhibitory response was maintained. This led the authors to conclude that fibers in the vagus nerve responsible for generating the B1 component of the compound AP were responsible for cardioinhibition. This was confirmed in experiments in which field potential and single-unit activity were mapped in the DMV in correlation with synchronous compound APs recorded from the vagus nerve during stimulation of this nerve (Schwaber

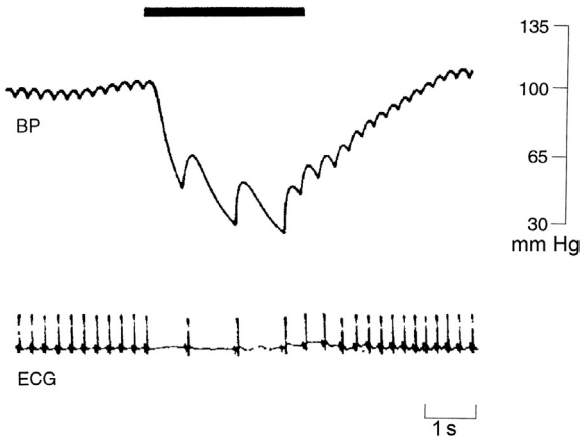

FIGURE 11.41 Arterial blood pressure (BP) and cardiac chronotropic (ECG) responses to focal electrical stimulation in the area of the dorsal motor nucleus of the vagus nerve in the pigeon. The duration of the stimulus train (50 Hz pulses) is shown by the solid horizontal bar above the traces. *From Cohen and Schnall (1970).*

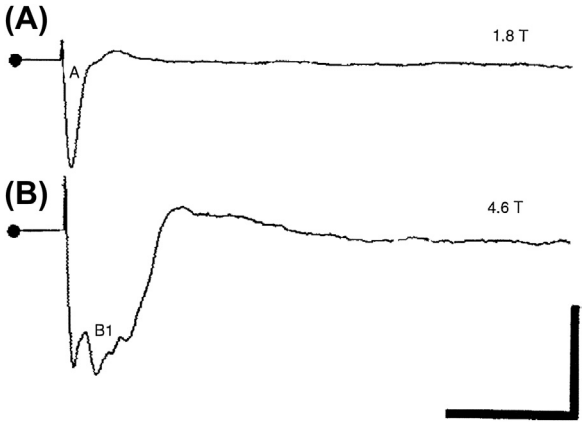

FIGURE 11.42 Compound action potentials evoked in the right vagus nerve by electrical stimulation at the midcervical level in the pigeon. Responses to stimuli of two intensities are shown. (A) Stimulation at 1.8 times the intensity which just evokes a response (threshold intensity, T) produces a short-latency component labeled the A wave, representing the fastest conducting fibers in the vagus (start of stimulus is indicated by the dot at the left side of trace). No change in heart rate is associated with the activation of this group of fibers. (B) Stimulation at 4.6 times the threshold intensity evokes responses in an additional, more slowly conducting group of fibers; this component of the compound action potential is labeled the B1 wave. The fibers responsible for this component conduct in the range of 8–14 m/s and when activated produce bradycardia. The vertical bar represents 250 μV; the horizontal bar represents 5 ms. *From Schwaber and Cohen (1978a).*

and Cohen, 1978b). In these experiments, stimulus-evoked activation of the B1 component in the vagus nerve produced the shortest latency, highest amplitude responses in the region of the DMV, which had been shown in previous studies to contain the somata of putative cardioinhibitory neurons. In addition to the evidence from stimulus-evoked potentials, recordings of spontaneously active single units in the DMV rostral to the obex in awake, paralyzed pigeons demonstrated rhythmic discharge patterns phase-locked to mechanical events in the cardiac cycle (Gold and Cohen, 1984). These authors also showed that single-unit neuronal activity in this area was decreased or eliminated by external conditioning stimuli (light flash, foot shock) which caused heart rate to increase (see Section 11.5.5).

The above anatomical and physiological evidence, taken together, indicates that in the avian brain preganglionic vagal cardioinhibitory neurons are located in the ventrolateral region of the DMV rostral to the obex. However, a more recent reexamination of the question of the location of these neurons was undertaken by Cabot et al. (1991a), using a new and more sensitive method for retrograde neuroanatomical tracing. These authors injected small volumes of the binding fragment of tetanus toxin into selected regions of the pigeon heart. This neurotracer was taken up by local nerve fibers and terminals at the injection site and transported retrogradely to label the somata of vagal preganglionic cardiac neurons in the medulla by two possible routes, both giving similar end results. The first of these was via direct uptake of neurotracer by fibers or terminals of the preganglionic neurons running through or close to the injection sites in the heart; in this case, the tracer would be transported directly back to the cell bodies. The second route was via transsynaptic transport. Fibers and terminals of postganglionic intracardiac neurons took up the neurotracer from the injection sites, and upon traveling to the somata and other processes of these neurons, the tracer would then cross synaptic clefts to the preganglionic terminals contacting the postganglionic cells. From these terminals, the tracer was transported to the somata of the preganglionic neurons. After intracardiac injection of the tracer, labeling of preganglionic vagal neurons was found in two locations in the medulla (Figure 11.43). The majority of label was found in neurons located ventrolateral to the DMV, in a site homologous to the nucleus ambiguus of the mammalian brainstem; these neurons were clustered within 0.5 mm of the obex as shown in the bottom panel of Figure 11.43. A smaller number of labeled neurons were found in more rostral sections in an area bordering the ventrolateral margin of the DMV (top panel of Figure 11.43), in close proximity to the region delineated in the degeneration studies of Cohen et al. (1970) and just ventral to the area described in the functional studies of Schwaber and Cohen (1978a,b). The results of Cabot et al. (1991a) have forced a reevaluation of the central organization of neurons controlling the

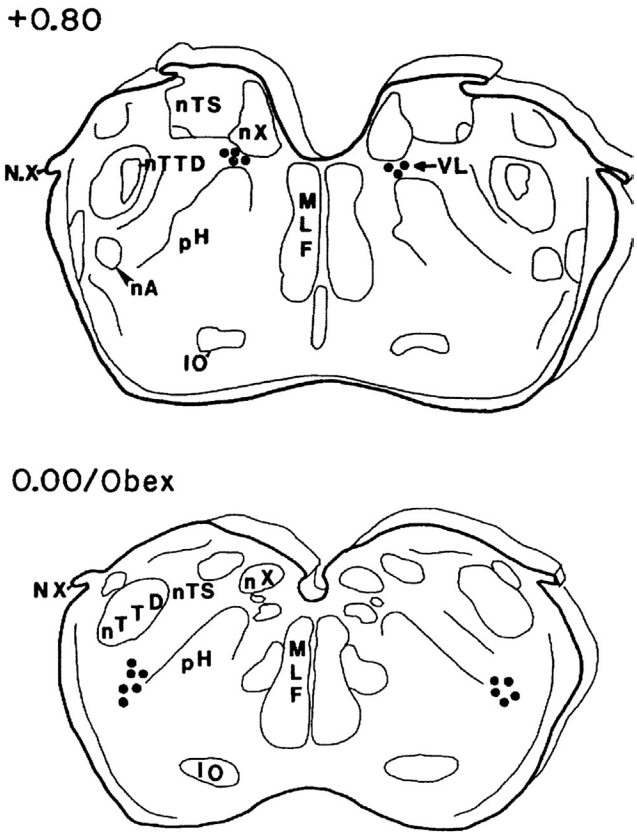

FIGURE 11.43 Outline drawings of transverse sections of the pigeon medulla in the region of the obex, depicting the location of vagal preganglionic neurons labeled by retrograde transport of tetanus toxin binding fragment C injected into the heart. See text for explanation. The top panel shows a section cut 0.8 mm rostral to the obex, with labeled neurons (filled circles) located just ventral to the dorsal motor nucleus of the vagus (nX) in the nucleus ventrolateralis (VL). The bottom panel, representing a section taken at the level of the obex, shows additional labeled neurons in an area of the medulla which may be the avian homolog of the mammalian nucleus ambiguus (nA), ventrolateral to nX. Abbreviations: IO, inferior olivary nucleus; MLF, medial longitudinal fasciculus; nTS, nucleus and tractus solitarius; nTTD, nucleus and tractus trigemini descendens; NX, vagal nerve rootlet; pH, plexus of Horsley. *Reprinted from Cabot et al. (1991a).*

avian heart, indicating that this organization has much more in common with the mammalian condition than was previously believed. However, these anatomical data have not been confirmed by physiological studies. In addition, it still remains for the membrane and firing properties of vagal cardioinhibitory preganglionic neurons to be investigated to determine if there are functionally discrete subpopulations within this group of neurons and, if so, whether there is any correlation between the functional properties of neurons and their potential roles in controlling specific aspects of cardiodynamic function.

Little is known of the nature and origins of inputs to medullary vagal cardiomotor neurons in birds. Berk and Smith (1994) have shown in the pigeon that peptide

containing projections to these neurons arise from the area of the nucleus of the tractus solitarius (NTS). The NTS is one target for afferent information from visceral receptors carried in the vagus, glossopharyngeal, and other cranial nerves, and such peptidergic projections from the NTS to cardiomotor neurons may represent an important viscero-visceral reflex pathway, as has been described in mammals (Loewy and Spyer, 1990). In addition to inputs of peripheral origin, there is an extensive pattern of projections to the DMV from structures located more rostrally in the brain. Berk and Finkelstein (1983) and Berk (1987) demonstrated projections from the bed nucleus of the stria terminalis, the ventral paleostriatum, and the medial and lateral hypothalamus to the DMV. These forebrain inputs thus represent potential pathways through which central nervous control of cardiac function may be exerted in the interests of homeostasis, as well as providing pathways for neutrally mediated alterations in cardiac function which may be required during exercise, feeding or other behaviors, or in response to changes in the external environment. In addition, Cohen and coworkers have explored the central anatomical pathways mediating conditioned responses which target medullary cardiomotor neurons in birds (see Section 11.5.5). These cardiomotor neurons therefore integrate information from visceral and other receptors and from higher levels of the central nervous system to control cardiodynamics, but our knowledge of the integrative mechanisms involved is scant at present.

11.5.3.2.2.2 Parasympathetic Control Acetylcholine acts in the bird heart to depress atrial and ventricular myocyte contractility, rate of discharge of pacemaker tissue, and rate of conduction through the specialized conductive tissues. ACh, released from preganglionic terminals, activates excitatory nicotinic receptors on the membranes of postganglionic neurons in the heart and these neurons in turn release ACh from their effector terminals to inhibit cardiac functions. Intrinsic postganglionic parasympathetic neurons release the majority of ACh which overflows from the isolated heart during vagal nerve stimulation. Only a small fraction of the total amount of ACh recovered in these experiments is released from vagal preganglionic terminals, as shown by a large reduction in vagally evoked ACh release after treatment of the isolated heart preparation to prevent release of the neurotransmitter from postganglionic terminals (Loffelholz et al., 1984).

ACh has different effects on the cell membrane conductances and thus on contractile properties of myocytes in the avian atria and ventricles. Inoue et al. (1983), using intracellular electrode techniques *in vitro*, investigated the effects of ACh on membrane ion conductances of atrial and ventricular myocytes to determine how these might differ. They found that, in ventricular muscle cells, ACh reduced the force of contraction, diminishing both amplitude and time course of the AP, but did not change either resting membrane potential or whole-cell resistance. On the other hand, in atrial myocytes, ACh hyperpolarized the membrane and reduced whole-cell resistance (implying an increase in steady-state ionic conductance) as well as causing a reduction in amplitude and time course of the AP. ACh binds to muscarinic receptors on myocyte membranes, and the authors found that this induced similar decreases in calcium-dependent sodium currents in the two types of cells. However, atrial myocytes exhibited in addition a muscarinically mediated increase in an outward potassium current, which accounted for the hyperpolarization and reduction in resistance induced by ACh; this mechanism was not present in ventricular myocytes. These differences in response to ACh imply that the same neurotransmitter can differentially control atrial and ventricular contractility.

There are several subtypes of muscarinic receptor present in the mammalian heart (see Deighton et al., 1990 for review) and some of these receptor subtypes are also present in the avian heart. The majority of muscarinic receptors on mammalian myocardial cells are of the M_2 subtype (Deighton et al., 1990; Jeck et al., 1988), and this subtype is believed to mediate complex intracellular mechanisms, leading to the inhibition of myocyte functions, which are ultimately responsible for the parasympathetic control of the heart. In a comparison of muscarinic receptor types in the chicken and guinea pig hearts, Jeck et al. (1988) found that receptors of the M_1 subtype predominated in the myocardium of the chicken while the most prevalent type in the guinea pig heart was the M_2 subtype, as found in other studies of the mammalian heart. Detailed analyses of the muscarinic receptor subtypes present in the hearts of other avian species have not been conducted, but if the results of Jeck et al. (1988) in the chicken represent the general avian situation, there are likely to be major differences in receptor-mediated intracellular mechanisms of mucarinic inhibition of myocyte function between birds and mammals.

In avian atrial tissue *in vitro*, and in atria in whole *in situ* or isolated hearts, it is widely accepted that ACh has a strong negative inotropic effect (Jeck et al., 1988; review by Sturkie, 1986), but studies of specific cholinergic effects on ventricular inotropy have been few in the bird. Avian ventricular tissue has a higher density of cholinergic innervation than does that of mammals as outlined above and a higher proportion of the total number of intracardiac neurons is associated with the ventricles of the avian than the mammalian heart (see above, and Smith, 1971b). On the basis of early anatomical evidence suggesting a high density of cholinergic innervation of the ventricular myocytes in birds, Bolton and Raper (1966) compared responses of strips of the right ventricle of fowl and guinea pig hearts *in vitro* to endogenously released and exogenously applied ACh. Field stimulation of electrically paced ventricular strips produced a strong decrease in force of contraction

of fowl ventricular tissue, while guinea pig ventricular tissue responded with an increase in force. Atropine, blocking muscarinic receptors, eliminated the negative inotropic response of the fowl ventricle to stimulation, and a strongly positive response was then observed; however, atropine had no effect on the response of the guinea pig ventricle to stimulation. The authors proposed that the fowl heart has a capacity for effective parasympathetic inhibition of ventricular inotropy, mediated by intracardiac release of ACh. Furthermore, blockade of this response unmasked a stimulus-evoked increase in force of contraction which the authors determined was the result of release of NE from sympathetic nerve terminals. They concluded that, in contrast with the mammalian condition, the fowl right ventricle was innervated by both the sympathetic and parasympathetic limbs of the autonomic nervous system. Subsequent *in vitro* work has confirmed these observations (Bolton, 1967; Biegon et al., 1980; Biegon and Pappano, 1980).

The first experimental approach used to explore general questions of parasympathetic efferent control of the avian heart, dating from the early part of the 1900s, was to examine the effects of exogenously applied ACh on the activity of pacemaker cells in the right atrium (reviewed by Jones and Johansen, 1972; Cabot and Cohen, 1980). More detailed characterization of this system has resulted from investigations carried out by Loffelholz and co-workers, and others. In the *in vitro* right atrium, ACh release provoked by field stimulation and by stimulation of the attached right vagus nerve produced a fall in pacemaker discharge rate (Pappano and Loffelholz, 1974; Pappano, 1976; Brehm et al., 1992). This chronotropic effect was blocked by atropine but not by the ganglionic blocker hexamethonium, so it must have been mediated by direct release of ACh from postganglionic parasympathetic neurons in the atrial wall (Pappano and Loffelholz, 1974). On the other hand, hexamethonium in the absence of atropine blocked all effects of electrical stimulation of the attached vagal stump. Vagally mediated bradycardia therefore occurred as a result of the synaptic activation of intracardiac postganglionic neurons by preganglionic terminals. As with cholinergic control of the inotropic state of the atrial and ventricular myocardium discussed above, control of pacemaker rate operates via the synaptic relay of impulses from pre- to postganglionic neurons within intracardiac ganglia.

11.5.3.2.2.2.1 Dromotropic Effects There have been no studies of the direct effects of ACh on the rate of impulse conduction through the specialized conducting cells of the avian heart and few studies of the overall parasympathetic control of this function. There are technical difficulties in identifying the locations of conducting tissues in a viable *in vitro* preparation of cardiac tissue, so work on this intriguing problem in birds has largely been conducted on hearts *in situ*. In the chicken, Goldberg et al. (1983) showed that AV conduction time could be significantly prolonged by stimulation of either vagus nerve; there was no bilateral asymmetry in this response. However, in order to unmask this dromotropic effect the heart was paced through electrodes attached to the SA node, both to control heart rate and to prevent shifts in pacemaker position during vagal nerve stimulation. Bogusch (1974), using anatomical techniques, identified cholinergic fibers and terminals in the region of conducting cells near the AV border and proposed a functional role for this innervation but the study of Goldberg et al. (1983) appears to be the only physiological confirmation of this role in the bird (also see Section 11.2.3.3).

11.5.3.2.2.2.2 Chronotropic Effects The study of vagal control of heart rate in birds has a long history going back to the recognition in the last eighteenth century that activation of the vagus nerves could produce large reductions in heart rate and, in some cases, arrest the heart (see Cabot and Cohen, 1980 for a summary of early work). As these reviewers have pointed out, the nature of vagally mediated bradycardia has been intensively reinvestigated using recently developed techniques in a variety of avian species (Johansen and Reite, 1964; Bopelet, 1974; Peterson and Nightingale, 1976; Langille, 1983; Lindmar et al., 1983; Goldberg et al., 1983; Lang and Levy, 1989; Butler and Jones, 1968; Cohen and Schnall, 1970; Jones and Purves, 1970; and others). The negative chronotropic effects of ACh in the pharmacological studies cited above are paralleled by the effects of electrical stimulation of the vagus nerves. Several preparations have been used to assess the chronotropic consequences of vagal stimulation. These include *in vitro* atrial tissue, isolated beating hearts with attached vagal stumps, open-thorax anesthetized preparations, and anesthetized or awake animals in which only the vagi in the cervical region were exposed. Vagal control of the heart is apparently very robust in all of these preparations and each type of preparation yields results which complement the findings obtained from the others.

Examples of stimulus-induced bradycardia obtained in pigeon are shown in Figure 11.44. The peripheral cut ends of the right (top panel) and left (bottom panel) cervical vagus nerves were stimulated with trains of pulses at a frequency of 50 Hz. In each case the contralateral vagus nerve was intact. In these examples the intensity of stimulation used was capable of arresting the heart. A close parallel to the negative chronotropic effect of peripheral vagal nerve stimulation can be produced by focal electrical stimulation in the medulla (Cohen and Schnall, 1970) where anatomical studies (see above) have shown that cardiac vagal preganglionic neurons are located.

The effectiveness of the left and right vagi in controlling heart rate has been shown by some workers to be equivalent, while other workers have found strong bilateral asymmetry in this system. Bopelet (1974), Peterson and Nightingale (1976), and Goldberg et al. (1983) reported no difference in the chronotropic response of the fowl heart to electrical stimulation of left and right vagus nerves. In the same

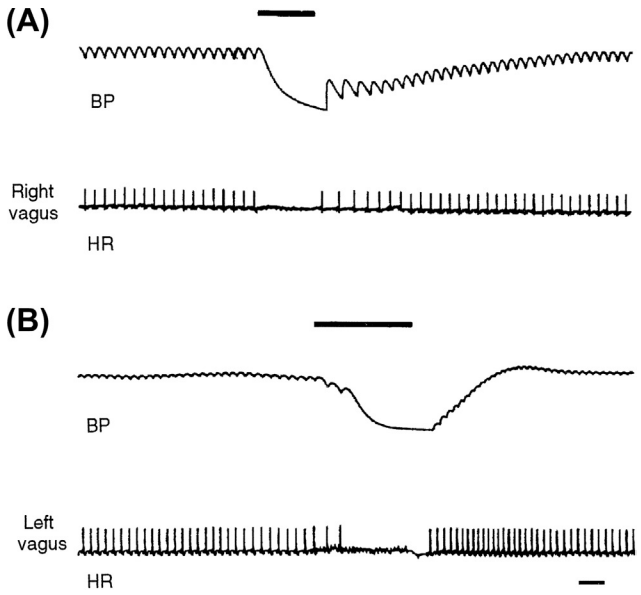

FIGURE 11.44 Effects of stimulating the right (A) and left (B) vagus nerves on heart rate (HR) and arterial blood pressure (BP) in two pigeons. The nerves were exposed in the neck and stimulated with 50 Hz trains of pulses (stimulus duration indicated by the horizontal bars above the BP traces). Horizontal bar below the bottom trace represents 1 s. *From Cohen and Schnall (1970).*

species, however, Sturkie (1986) and Lang and Levy (1989) reported that the right vagus was more effective in altering heart rate than was the left. Johansen and Reite (1964), in ducks and seagulls, Jones and Purves (1970) in ducks, and Cohen and Schnall (1970) in pigeons, all reported a similar asymmetrical response to electrical stimulation of the vagus nerves. Furthermore, in a systematic study of vagal control of heart rate in the duck, Butler and Jones (1968) showed by means of cold blockade of the vagi in the neck and by unilateral and bilateral section of these nerves that vagal dominance could change sides over time. However, these authors did not stimulate the peripheral cut ends of the vagi after nerve section, so it is not known whether the origin of this bilateral asymmetry was within the central nervous system or at the heart.

Lindmar et al. (1983) have quantified the amounts of ACh released in the isolated chicken heart by stimulation of the attached left and right vagal stumps in an attempt to determine if there were bilateral differences in the intracardiac connections of these nerves. If fibers from each vagus innervated approximately the same number of postganglionic intracardiac neurons, the amount of ACh released by stimulation of either nerve alone would be expected to be similar, and this was in fact found to be the case. If there were no overlap in the populations of intracardiac neurons innervated by each vagus, then the sum of ACh released by unilateral stimulation of each nerve should be the same as that released by simultaneous bilateral nerve stimulation. However, Lindmar et al. (1983) found that the sum of ACh released by separate nerve stimulation was significantly greater than that released by bilateral stimulation, indicating that a large proportion of intracardiac neurons must have been bilaterally innervated. In these experiments it was not possible to separate the responses of postganglionic neurons innervating the pacemaker tissue from the responses of neurons subserving other functions, but if it is assumed that the overall pattern of bilateral innervation found by Lindmar et al. (1983) can be applied to the specific subpopulation of neurons controlling heart rate, then this pool of neurons may be controlled by preganglionic fibers running in either nerve. There would thus be little reason to expect that side-to-side shifts in vagal dominance result from factors acting to change the relative intracardiac influences of these nerves. This line of reasoning supports the notion that changes in the pattern of activity of vagal preganglionic neurons in the medulla may be responsible for spontaneous shifts in the dominant vagus nerve. Such central nervous factors might be investigated using the approach of Gold and Cohen (1984) to simultaneously record spontaneous activity from neurons in medullary vagal complexes on both sides.

11.5.3.2.2.2.3 Inotropic Effects Despite the evidence cited above for strong negative inotropic effects of endogenously released or exogenously applied ACh in the avian heart *in vitro*, the inotropic effects of vagal stimulation on *in situ* hearts is controversial. Folkow and Yonce (1967) unmasked a strong reduction in one index of left ventricular contractility, that of peak left ventricular chamber pressure, in the duck heart in response to vagal nerve stimulation when heart rate was kept constant by electrical pacing. These authors also found that CO declined with vagal stimulation during pacing. Because vagal stimulation was shown not to affect peripheral resistance in this study, the fall in CO must have been caused by a decrease in stroke volume. Although contractile force was not measured directly, the authors attributed both the fall in left ventricular pressure and in CO to a vagally mediated decrease in ventricular contractility. That this effect was neurally mediated was demonstrated by the elimination of the effects of vagal stimulation after atropine was administered intravenously. Furnival et al. (1973), using another index of ventricular contractility, that of maximum rate of change of left ventricular pressure, reported results contrary to those of Folkow and Yonce (1967). In their comparative study of the responses of ventricular contractility to vagal stimulation in the dog, duck, and toad, Furnival et al. (1973) reported that only the amphibian heart displayed a significant reduction in contractility. These authors proposed that the ventricles of the ducks in the experiments of Folkow and Yonce (1967) had been subject to very high end-diastolic pressures as a consequence of the experimental protocol, were probably in failure as a result of this treatment, and thus responded abnormally to vagal stimulation. Yet Lang and Levy (1989), using the same index of ventricular contractility in the chicken as that

employed by Furnival et al. (1973) in the duck, concluded that vagal stimulation could produce decreases of more than 50% in contractile force (Figure 11.45). Furthermore, the inotropic responses to vagal stimulation in the chicken heart reported by Lang and Levy (1989) were considerably more powerful than those that could be obtained in mammalian hearts.

The controversy surrounding this issue likely hinges on problems inherent in the methods used to evaluate ventricular contractility. Resolution of this issue will only be possible when more direct indices of contractility, such as direct attachment of Walton-Brodie type force gauges to the ventricular walls, estimation of beat-by-beat ejection fraction, or the measurement of CO in combination with ventricular and systemic pressures for calculating stroke work, are employed.

11.5.3.2.2.2.4 Tonic Parasympathetic Activity Studies of tonic parasympathetic restraint of heart rate in several bird species have shown that this, like sympathetic tone, varies over a wide range. The factors discussed in Section 11.5.3.2.1, which affect the evaluation of sympathetic tone (state of anesthesia, presence or absence of tone from the other autonomic limb), apply equally to the analysis of vagal tone, and the protocols used in studies of the extent of vagal restraint will therefore influence the way in which the results of these studies are interpreted. In a study by Johansen and Reite (1964) in awake or anesthetized ducks with intact sympathetic cardiac innervation, section of one vagus nerve (right or left) produced no change in heart rate; the chronotropic response to subsequent section of the remaining vagus was an increase in heart rate up to 65% above that in intact or unilaterally vagotomized animals. These results imply the presence of strong tonic vagal restraint of the heart; however, the authors found that after bilateral vagotomy, β-blockade revealed a high degree of sympathetic tone to the heart. Since the authors did not perform the converse experiment of β-blockade prior to bilateral vagotomy in this study, neither the balance between parasympathetic and sympathetic tone nor the actual degree of parasympathetic restraint on the heart could be ascertained. In unanesthetized ducks, Butler and Jones (1968), using a combination of cold block and section of the cervical vagi, showed that mean resting heart rate rose about 180% over the rate prior to these manipulations. In another study by the same authors, pharmacological blockade of the parasympathetic nervous system with atropine caused mean heart rate to increase to about 150% over the control value in awake ducks (Butler and Jones, 1971). In both of these studies the sympathetic nervous system was functional during evaluations of parasympathetic tone. In chickens Butler (1967) found that heart rate increased to 138% over the control value after bilateral vagal nerve section; in contrast to this, Bopelet (1974) reported an increase of only 8%, and Peterson and Nightingale (1976) found no change in rate in chickens after bilateral vagotomy. Sympathetic influence on the heart had not been eliminated in any of these studies. Sturkie and co-workers (reviewed by Sturkie, 1986) addressed the problem of evaluating parasympathetic tone to the heart by examining the effects of pharmacological or surgical vagotomy in the absence of sympathetic cardiac influences in the chicken using the rationale discussed in Section 11.5.3.2.1. They found that the net restraining effect of tonic parasympathetic activity on the chicken heart was the equivalent of a 20% reduction in heart rate from the rate of the completely decentralized heart. This estimate of vagal tone is substantially lower than the estimates of other workers in chickens (Butler, 1967) or in ducks (Johansen and Reite, 1964; Butler and Jones, 1968, 1971) in which the sympathetic cardiac innervation was functional. The degree of parasympathetic restraint on the heart in the latter studies may have been exaggerated by the presence of ongoing sympathetic drive after the lifting of vagal influence.

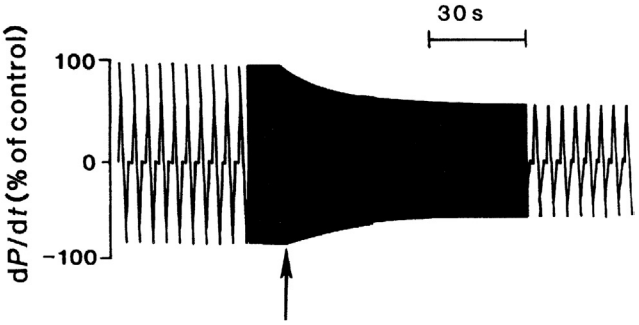

FIGURE 11.45 Effect of stimulation of the right vagus nerve on the rate of change of left ventricular pressure (d*P*/d*t*) in the chicken heart. Vagally induced changes in this variable represent an index of changes in ventricular contractility. The trace depicts the electrically analyzed first derivative of left ventricular chamber pressure; the amplitude of each peak thus represents the maximum rate of change of the corresponding ventricular pressure pulse. The trace was obtained at two speeds; the segment on the left side was recorded at a high chart speed to show the rate of pressure change of individual pulses prior to vagal stimulation. Just before stimulation was started (at the arrow) the chart speed was reduced to display the response to the first part of an 80s stimulus train (frequency, 20 Hz); the 30s time bar over the trace applies to this segment. On the right the recorder was returned to a high speed to display the rate of change of individual pressure pulses once the response to vagal stimulation had reached a plateau. *From Lang and Levy (1989).*

11.5.3.2.3 Control of CO

The volume of blood pumped by either the left or right ventricle per unit time is termed CO. The total volume of blood pumped by the heart per unit time is therefore twice the CO, since the outputs of both sides of the heart must be exactly matched over time. CO, usually expressed in units of mL/min, is the product of the rate of contraction of the heart (beats/min) and the volume pumped during each beat, or stroke volume (mL). Rate and stroke volume are determined by factors which may be intrinsic or extrinsic to the heart. Intrinsic factors include atrial pacemaker cell activity and

contractile properties of the cardiac muscle fibers. Extrinsic factors affecting rate and stroke volume include autonomic nervous activity and levels of circulating cardiotropic hormones. CO over a given time period will thus be determined by the complex interplay of these intrinsic and extrinsic factors. Some of these have been discussed in previous sections, and references will be made to them as necessary.

11.5.3.2.3.1 Role of Heart Rate in Control of CO The basal level of heart rate in the absence of external influences is primarily determined by the inherent membrane properties of the pacemaker cells of the SA node (Section 11.2.3). The rate of depolarization, and thus the rate of discharge of APs in these cells, is set by the ion conductances through their membranes (particularly K^+), but this process is itself partly dependent on physical factors such as the concentrations of extracellular ions and temperature. Under most circumstances these physical factors are kept within fairly narrow limits by homeostatic mechanisms and should therefore not affect heart rate substantially.

The interaction of the sympathetic and parasympathetic branches of the autonomic nervous system controls heart rate in a complex, nonlinear manner. Part of this complexity arises from the fact that the full chronotropic effects of vagal stimulation on heart rate occur within a few heartbeats whereas it may take up to 30 s for the full expression of the cardiac response to sympathetic stimulation (Figure 11.46). Consequently, the most rapid changes in heart rate appear to be dominated by the parasympathetic system. The major reason for the nonlinearity is that the degree of parasympathetic–sympathetic interaction at the heart may be changed by increasing output of one of these limbs.

The relationship of heart rate to bilateral stimulation of the distal cut ends of the vagus and cardiac sympathetic nerves of the duck *A. platyrhynchos* is illustrated in Figure 11.47 (Furilla and Jones, 1987b). In this figure, 100% represents the frequency of stimulation above which no further changes in heart rate occurred. The heart rate resulting from a given level of vagal and sympathetic stimulation was plotted on perspective graph paper and the surface was drawn, by eye, to encompass all heart rates obtained in the stimulation experiments. Area B represents complete cardiac denervation and area E maximal vagosympathetic stimulation. The effects of varying the intensity of sympathetic stimulation at minimal and maximal vagal activity are represented by the lines A–B and D–E, respectively. Similarly, the effects of varying the intensity of vagal stimulation at minimal and maximal sympathetic activity are represented by the lines B–D and A–E, respectively.

Increasing sympathetic activation at zero vagal activity causes heart rate to rise over 200 beats/min (B to A) while increasing sympathetic drive at maximal vagal activation only increases heart rate by 50 beats/min (D to E). Similarly, increasing vagal activation causes heart rate to fall by more than 200 beats/min at zero sympathetic activity (B to D) and by nearly 400 beats/min at maximal sympathetic activity (A to E). Obviously, the greater the vagal drive, the more this input is able to occlude sympathetic effects on the heart, accounting for the nonlinearity in the interplay between the two branches of the autonomic nervous system at the cardiac pacemaker. This increased parasympathetic

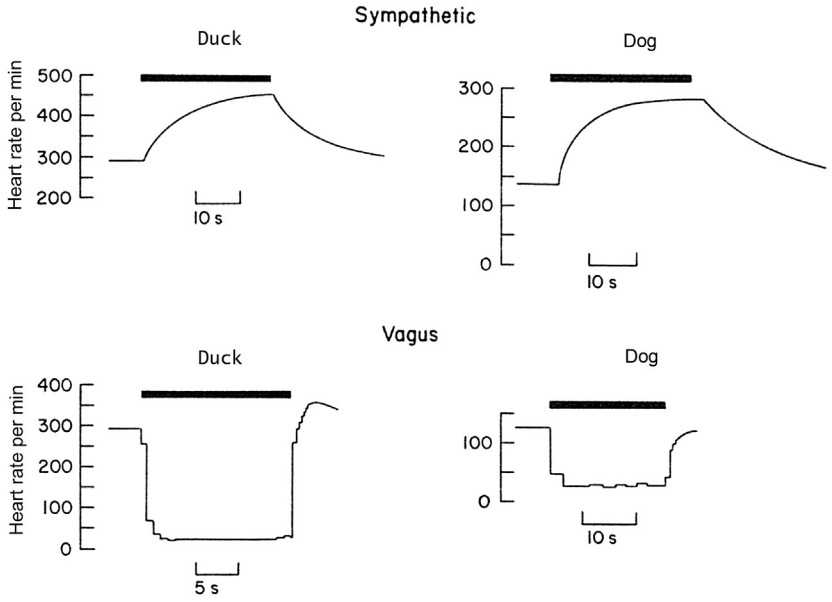

FIGURE 11.46 Comparison of time courses of changes in heart rate evoked by bilateral stimulation of cardiac sympathetic nerves (top panels) and vagus nerves (bottom panels) in a duck (left-hand traces) and dog (right-hand traces). In each panel the thick horizontal bar represents the duration of the stimulus. *Modified from Furilla and Jones (1987a).*

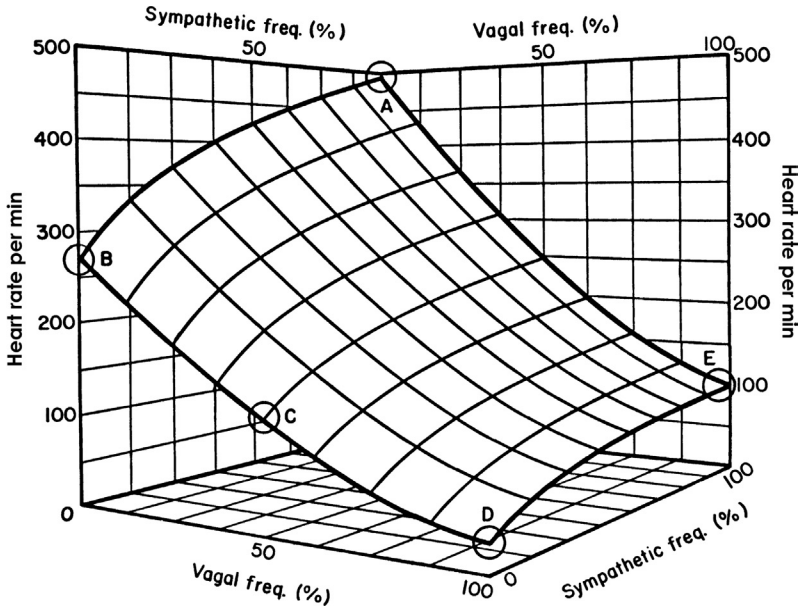

FIGURE 11.47 The relationship of heart rate to bilateral stimulation of the distal cut ends of the vagus and cardiac sympathetic nerves of the Pekin duck. "One-hundred percent" represents the frequency of stimulation above which no further changes in heart rate occurred with increases in stimulation frequency. The heart rate caused by a given level of vagal and sympathetic stimulation was plotted on "perspective" graph paper and the surface was drawn, by eye, to encompass all heart rates obtained in the stimulation experiments. See the text for an explanation of points A–E. *From Furilla and Jones (1987a).*

effectiveness in cardiac control is termed accentuated antagonism and may be mediated through two mechanisms. First, in response to sympathetic stimulation above a certain threshold, there is a cholinergically mediated reduction in prejunctional release of NE. Second, the magnitude of the postjunctional response to a given level of sympathetic stimulation is attenuated by ACh (Levy, 1971).

Short-term heart rate fluctuations are caused by the continued tug-of-war between the two branches of the autonomic nervous system at the pacemaker. This interplay may overlie long-term changes in heart rate caused, for instance, by changes in levels of circulating hormones. The normal homeostatic processes tend to reduce variability and maintain constancy of internal physiological functions, and short-term fluctuations in heart rate are usually seen as perturbations away from the norm. If a series of cardiac intervals is recorded from an animal, the duration of intervals within the series appears quite irregular with apparently random fluctuations occurring all the time. Whether these fluctuations are truly random or patterned, in the latter case providing evidence for chaotic control of heart rate (Denton et al., 1990; Goldberger et al., 1990), is a matter of some controversy. The strongest evidence for chaotic control of heart rate may lie in the morphology of the nerves innervating the heart. The nerves divide repeatedly, like the branching of a tree which is an intrinsically fractal structure. Hence, if the anatomy is fractal, then why should the day-to-day workings of the system not be fractal as well? (Goldberger, cited in Pool, 1989; Goldberger, 1991).

In any event, it is clear that, rather than maintaining a homeostatic steady state, heart rate fluctuates considerably, even when recorded over short time periods (Figure 11.48(A)). The interbeat intervals form a time series which can be transformed into the frequency domain by Fourier analysis, revealing the presence of periodic components within the series. The square of the absolute value of the Fourier transform yields the power spectrum of the heart rate variability (PS/HRV) (Kamath and Fallen, 1993).

The PS/HRV of an intact, resting, duck (*Aythya affinis*) is shown in Figure 11.48(B)(i). This plot reveals a respiratory sinus arrhythmia as a single major peak at the respiratory frequency. This is a manifestation of respiratory modulation of cardiac parasympathetic activity (Shah et al., 2010; the response to sympathetic heart stimulation is too slow to significantly affect heart rate at a high frequency). Blockade of the sympathetic nervous system with a β-antagonist tends to increase heart rate variability although the amplitude of the high-frequency components are reduced (Figure 11.48(B)(ii)), while parasympathetic blockade with atropine gives a regular, unvarying heart rate (Figure 11.48(B)(iii)). This confirms that short-term heart rate control is dominated by the parasympathetic nervous system in *A. affinis*. Similar control of heart rate variability has been found in hatchling emu (*Dromaius novaehollandiae*) (Shah et al., 2010).

The PS/HRV is a quantifier of autonomic responsiveness (Saul, 1990) and allows evaluation of cardiovascular regulation in birds over long time courses and during many types of activities. Also, the influence of other periodic functions

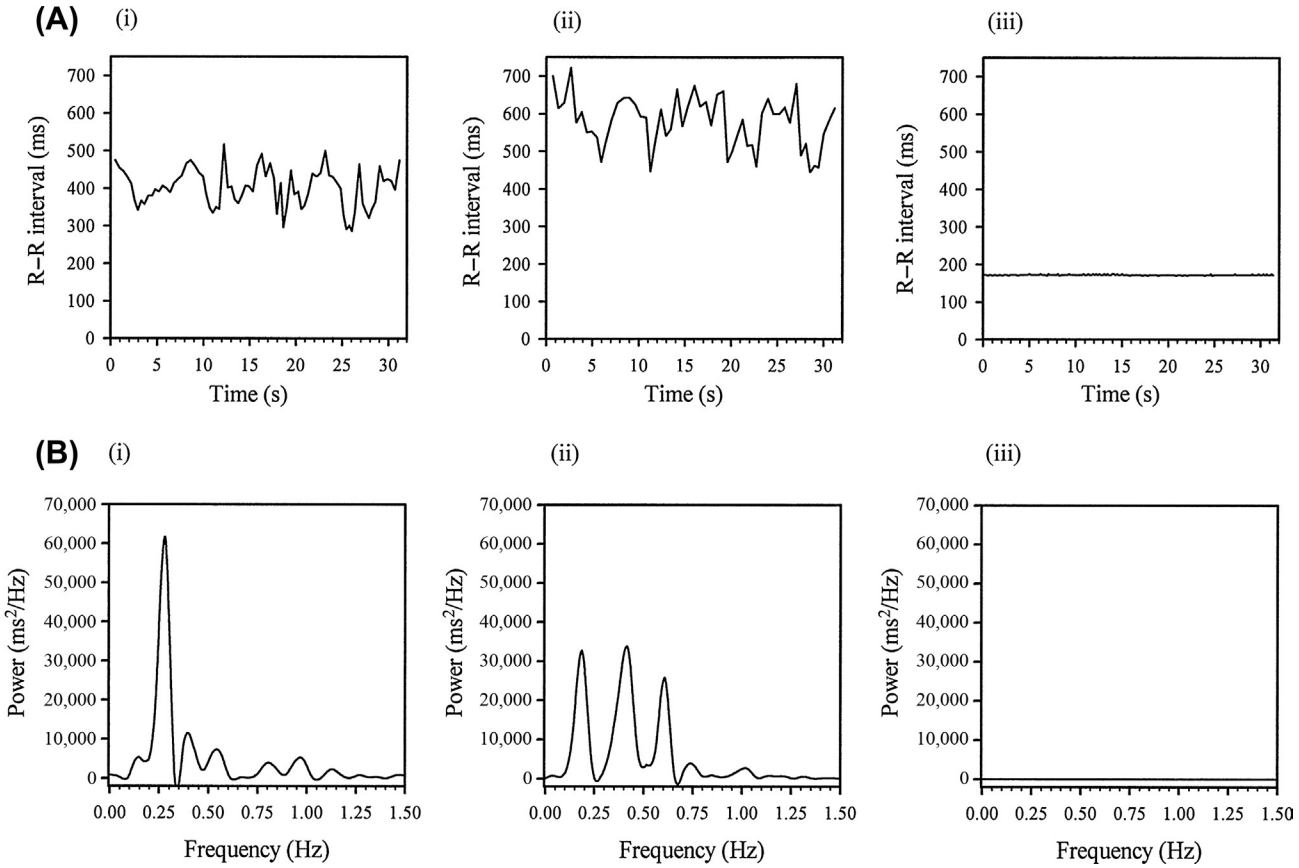

FIGURE 11.48 (A) 30s duration time series of interbeat intervals (R–R intervals) recorded by radiotelemetry from a duck (*Aythya affinis*) while the animal was resting quietly on the water surface. (i) Control; (ii) after sympathetic nervous system blockade with Nadolol (a β-adrenergic antagonist); and (iii) after parasympathetic nervous system blockade with the muscarinic antagonist atropine. (B) Power spectra of heart rate variability derived from the time series shown in (A). (i) Control; (ii) after Nadolol blockade; and (iii) after atropine blockade. Because the time series were too short to adequately display extremely low-frequency components, these components were removed with a high-pass filter from the power spectra. *From McPhail et al. (unpublished data).*

such as arterial blood pressure and vasomotor fluctuations on PS/HRV can be evaluated using this technique. Telemetric recording of heart rate, combined with frequency analysis of cardiac function, will open new doors for studying control of physiological processes in unrestrained, active birds.

11.5.3.2.3.2 Role of Stroke Volume in Control of CO Stroke volume, like heart rate, is dependent upon factors intrinsic and extrinsic to the heart. As all myocytes within the heart contract during each beat, the primary intrinsic factors which determine stroke volume are the inherent contractile properties of each muscle fiber and the resting lengths of all the fibers. The amount of force developed during contraction by a cardiac muscle fiber at a specified precontraction length is properly termed *contractility*, but this term has also been used more loosely to describe the collective contractile properties of all muscle fibers associated with one chamber of the heart. A major problem in quantifying contractility is that the force developed by a single cardiac muscle fiber is difficult to measure in working hearts. Consequently a number of indirect indices have been developed to estimate this variable. These include measuring cardiac outflow volume over time to calculate stroke volume; recording the ventricular peak systolic pressure developed against a fixed afterload or into a constant arterial pressure; and measuring the rate of rise of ventricular pressure during systole. The major assumption in all of these methods is that the measured variable reflects the contractility of all muscle fibers integrated over the dimensions of the whole chamber. However, the variety of indices of contractility used by investigators under different experimental conditions has made it difficult to compare estimates across studies. The direct measurement of volume flow from the ventricle would appear to give the most reliable index of cardiac contractility, being independent of the complicating effects of changing arterial or ventricular pressures. This measurement is also among the most difficult to make, requiring highly invasive procedures to place the appropriate instrumentation.

By analogy with the contraction of skeletal muscle, the amount of force developed by a contracting cardiac muscle

fiber depends upon its precontraction length ("preload"). This principle was first applied to the heart by Otto Frank (summarized in Rushmer, 1976), who showed that, within limits, the greater the preload on ventricular muscle in diastole, the more tension was developed during the next systole. This length–tension relationship was further investigated by Ernest Starling and coworkers, who demonstrated that the amount of blood ejected by the left ventricle during systole was proportional to the volume of blood in the ventricle at the end of the diastolic filling phase of the cardiac cycle. These concepts have been combined into the Frank–Starling relationship to describe the intrinsic responses of ventricular stroke volume to changes in cardiac venous return, expressed graphically in Figure 11.49. Elevated contractility of each muscle fiber in the ventricle is evoked by increasing the preload on all of the fibers by increasing the volume of blood filling the ventricle before each beat; this is reflected in an overall increase in ventricular stroke volume. The curve designated A in Figure 11.49 is termed a ventricular function curve. The relationship embodied in this curve demonstrates an autoregulatory feature of cardiac function known as heterometric regulation: a change in the resting fiber length (heterometry) results in a change in contractility in the same direction. This regulatory mechanism is an intrinsic property of cardiac muscle. The consequence of this mechanism for the overall function of the heart is that, if all other conditions remain constant, CO will be determined by venous return. An increase in venous return to the left ventricle via the left atrium will result in greater end-diastolic stretch of the ventricle walls and an increase in stroke volume at the next beat; conversely, stroke volume will be reduced if cardiac return falls. In short, the heart "pumps what it gets" if all other factors are unchanging.

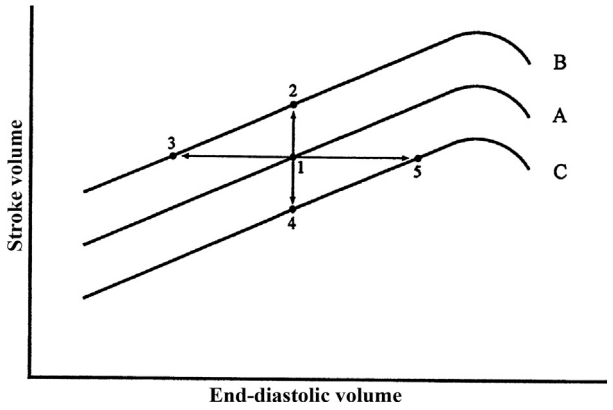

FIGURE 11.49 Idealized graphical representation of the Frank–Starling relationship for cardiac ventricular muscle. (A) Intrinsic ventricular function curve depicting the relationship between end-diastolic volume (representing degree of stretch of muscle fibers) and stroke volume (index of contractility) in the absence of extrinsic influences. The curve peaks and begins to decline at high end-diastolic volumes because resting sarcomere length is maximal here. (B and C) Factors extrinsic to the heart that alter inotropic function of cardiac muscle reset the ventricular function curve to operate over different ranges of stroke volume, independent of end-diastolic volume or initial fiber length. (B) Elevated cardiac sympathetic drive or circulating catecholamines have positive inotropic effects, resetting the curve toward higher stroke volumes. (C) Elevated vagal drive has negative inotropic effects, resetting the curve toward lower stroke volumes. Points 1 through 5 are the operating points assumed for the text discussion of the effects of extrinsic factors on ventricular function.

Cardiac contractility is influenced by extrinsic factors in addition to the intrinsic Frank–Starling mechanism. Circulating hormones such as EPI and the autonomic neurotransmitters NE and ACh (see Sections 11.5.3.1 and 11.5.3.2) directly affect the contractility of cardiac muscle fibers. These extrinsic factors are superimposed on the intrinsic autoregulatory factors governing stroke volume and can shift the whole ventricular function curve (curve A in Figure 11.49) toward higher (curve B) or lower (curve C) stroke volumes at the same resting muscle fiber length or degree of ventricular filling. This type of regulation of stroke volume is referred to as homeometric regulation, to emphasize the fact that changes in contractility can occur independent of resting fiber length. An increase in sympathetic drive to the heart or an increase in the level of circulating catecholamines will increase ventricular inotropic function homeometrically; thus a greater stroke volume will result from the same degree of cardiac filling, as indicated in Figure 11.49 by the arrow from point 1 on curve A to point 2 on curve B. Another way to consider this is that after such a shift in the curve a much smaller end-diastolic volume will give the same stroke volume (arrow from point 1 to point 3). On the other hand, elevated vagal drive to the heart of birds can decrease the contractility of ventricular muscle and will shift the ventricular function curve toward a lower stroke volume (curve C in Figure 11.49). At the new operating point, the same degree of preload will result in a lower stroke volume (arrow from point 1 to point 4); alternatively, a much larger end-diastolic volume will be required to maintain the same stroke volume (arrow from point 1 to point 5).

The arterial pressure against which the ventricle pumps ("afterload") is a major extrinsic factor in determining the magnitude of stroke volume. The pressure generated during the isometric phase of ventricular contraction is a function of the contractility of the muscle fibers, and when chamber pressure exceeds that in the aorta the valves open and blood is ejected from the ventricle during the isotonic phase. If the preload on the ventricle is increased by elevating the arterial blood pressure without a change in contractility or end diastolic volume, stroke volume of subsequent beats will be reduced because more energy will be required to raise chamber pressure above the new level of arterial pressure. Initially, this will leave a larger fraction of the previous end-diastolic volume still in the chamber at the end of systole, resulting in an increased level of resting tension on the muscle fibers during the next filling phase. This increased tension, according to the Frank–Starling mechanism, will quickly result in increased contractility during subsequent

beats, restoring stroke volume by heterometric regulation in the face of the increased arterial pressure.

In many species of birds, CO is adjusted to match perfusion requirements of the tissues in a variety of conditions, such as during exercise, hypoxia, or submersion (see Section 11.6). These adjustments appear to be made primarily through alterations in heart rate, with stroke volume remaining relatively unchanged. Changes in CO during exercise are driven by increased heart rate in ducks (Bech and Nomoto, 1982; Kiley et al., 1985), geese (Fedde et al., 1989), and turkeys (Boulianne et al., 1993a,b). However, in the emu (Grubb et al., 1983) and the chicken (Barnas et al., 1985) stroke volume may increase by up to 100% during exercise, contributing significantly to elevated CO. Reflex changes in CO mediated by systemic arterial baroreceptor input also appear to operate via alterations in heart rate, leaving stroke volume relatively unchanged (Section 11.5.4.2). In summary, during exercise, hypoxia, or submersion, birds display significant changes in heart rate, arterial blood pressure, and venous return from the resting condition. In the transition from the resting condition to these altered states, stroke volume also varies. However, in most of the species examined so far, stroke volume returns to values close to those at rest after a short period of initial adjustment. This indicates that intrinsic autoregulation of CO has the potential to play an important role in the maintenance of stroke volume in the face of large-scale circulatory adjustments.

11.5.4 Reflexes Controlling the Circulation

11.5.4.1 Chemoreflexes

In birds, reflex adjustments of CO and vascular caliber are generated by chemoreflexes in response to changes in levels of oxygen, carbon dioxide, and pH in the cerebrospinal fluid and in arterial blood. Receptors sensitive to CO_2 in cerebrospinal fluid are present in the avian central nervous system (Jones et al., 1982), but no detailed studies of the location or transduction properties of these receptors have been done in birds. However, if these receptors are similar to those found in mammals, they may be located at or near the surface of the ventrolateral medulla (reviewed by Schlaefke, 1981). Arterial chemoreceptors in birds are located primarily in the carotid bodies, bilateral structures lying caudal to the thyroid gland, and close to the ultimobranchial gland and nodose ganglia of the vagus nerves and the carotid artery (from which they are supplied with blood) (Figure 11.39; Adams, 1958; Jones and Purves, 1970; Kameda, 2002). The carotid bodies are innervated by the vagus and the recurrent laryngeal nerves (Kameda, 2002). Chemoreceptors have also been reported in aortic bodies associated with the roots of the great vessels in several species of birds (Tcheng et al., 1963; Ito et al., 1999).

The discharge characteristics of arterial chemoreceptors in response to changes in arterial P_{CO_2} (P_{aCO_2}), P_{O_2} (P_{aO_2}) and arterial pH (pH_a) have been studied in the duck and chicken. Receptor discharge rate increases proportionally with P_{aCO_2} and in inverse proportion to P_{aO_2} (Bouverot and Leitner, 1972; Bamford and Jones, 1976; Nye and Powell, 1984; Hempleman et al., 1992). Discharge sensitivities to changes in P_{aCO_2} and P_{aO_2} have been quantified by Hempleman et al. (1992) for carotid body chemoreceptors in the duck. When P_{aO_2} was maintained at a normoxic level (near 100 mm Hg) mean chemoreceptor sensitivity to step changes in P_{aCO_2} (produced by changing the fraction of CO_2 in the air breathed by the bird) was $+0.20$ impulses/s mm Hg/P_{aCO_2}. Hypoxia (P_{aO_2} 56 mm Hg) potentiated chemoreceptor discharge in response to altered P_{aCO_2} (Figure 11.50). In this condition, the same step changes in P_{aCO_2} as given in normoxia resulted in a sensitivity of $+0.32$ impulses/s mm Hg/P_{aCO_2}. In the absence of CO_2 in the inspired air, step changes in P_{aO_2} from the normoxic level to about half this level resulted in a mean sensitivity of about -0.10 impulses/s mm Hg/P_{aO_2}. Carotid body chemoreceptors are thus about twice as sensitive to changes in absolute levels of arterial CO_2 as to O_2. Some of the chemoreceptors sampled in this study were also sensitive to the rate of change of O_2 and CO_2 in the blood, indicating that proportional and rate-related information on arterial blood gas status are both transmitted to the central nervous system. However, the maximum rate of change of discharge of most rate-sensitive chemoreceptors was in the lower frequency range of physiologically occurring blood gas oscillations. Therefore, only relatively low

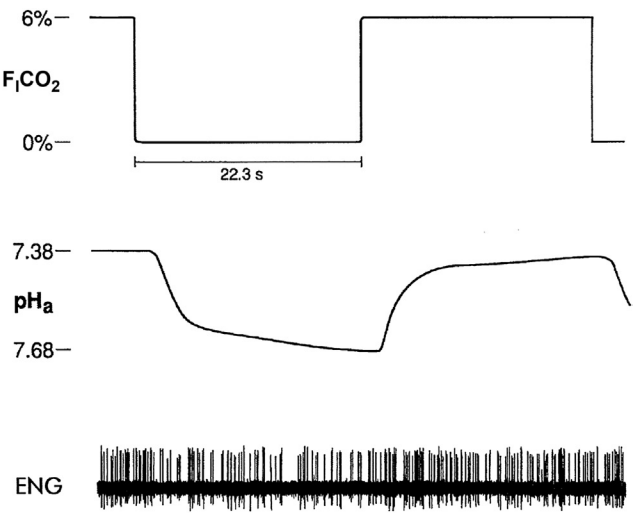

FIGURE 11.50 Single-fiber arterial chemoreceptor response recorded from vagal slip (bottom trace, electroneurogram (ENG)) to step changes in inspired CO_2 level (top trace, fraction of CO_2 in inspired gas F_{ICO_2}) during hypoxia (10% O_2 in inspired gas) in a duck. Arterial pH (middle trace (pH_a)) also changes in step with inspired CO_2. Chemoreceptor discharge is sensitive to the level of CO_2 and pH_a and to rate of change of these variables. *Reprinted from Hempleman et al. (1992).*

frequencies of blood gas oscillation, such as those occurring at rest or during low-intensity activities, will be faithfully transduced. At higher oscillation frequencies, such as those occurring during panting or high-intensity exercise, chemoreceptor inputs to the central nervous system probably represent mean blood gas levels averaged over several oscillatory cycles.

Arterial chemoreceptors are spontaneously active at normoxic and normocapnic blood gas levels in birds and these receptors have been proposed to play an important role in setting the level of eupneic ventilation under these conditions (Bouverot and Leitner, 1972). However, the role of arterial chemoreceptors in reflex control of the avian circulation is less clear. Analyses of the circulatory effects of chemoreceptor activation are complicated by parallel changes in ventilation. During apneic asphyxia in ducks, blood oxygen tension falls, CO_2 tension rises, and carotid body chemoreceptors become progressively more strongly stimulated; this input plays a major role in initiating and maintaining an intense bradycardia (Jones and Purves, 1970; Butler and Taylor, 1973). However, if blood gases in spontaneously breathing ducks are artificially adjusted to mimic the hypoxic and hypercapnic levels achieved during apneic asphyxia, chemoreflex drive acts to increase ventilation, leading to elevated drive from pulmonary receptors. In this state, there is little or no change in heart rate (Butler and Taylor, 1973, 1983). When the rise in ventilation (and thus the elevation in pulmonary receptor input) is prevented by controlling tidal volume and respiratory frequency during hypoxic hypercapnia in paralyzed but unanesthetized animals, heart rate falls to a level midway between that in normoxic, normocapnic animals and that obtained at end-dive (Butler and Taylor, 1973, 1983). This effect is illustrated in Figure 11.51. Subsequent cessation of respiration by stopping the ventilator pump then results in the full expression of chemoreceptor mediated bradycardia: heart rate falls to the same level as at end-dive (Butler and Taylor, 1973, 1983). These experiments show that in ducks, as in mammals, the cardiovascular responses to strong arterial chemoreceptor stimulation during spontaneous breathing are masked by elevated ventilatory drive. Butler and Taylor (1983) have suggested that pulmonary receptors activated by increased ventilation contribute to occlusion of the cardiac chemoreflex.

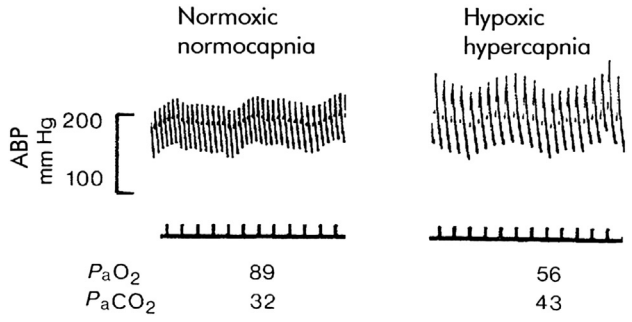

FIGURE 11.51 Effect of systemic hypoxic hypercapnia on heart rate and blood pressure in mallard duck. The animal was artificially ventilated after spontaneous respiratory movements were suppressed with intravenous pancuronium bromide. (Left panel, upper trace) Arterial blood pressure and heart rate during ventilation with air; systemic arterial blood gas values are shown at bottom. (Right panel) When blood gas values were adjusted to match those at end of 1 min submersion by altering CO_2 and O_2 levels in inspired gas, heart rate decreased as a result of arterial chemoreflex activation. In both panels the ticks on the bars under the pressure traces indicate 1 s intervals. *Reprinted from Butler and Taylor (1973).*

Input from peripheral arterial chemoreceptors can reflexly alter peripheral vascular resistance but the general role of chemoreceptors in control of the vasculature has not been established. Indirect evidence for chemoreflex effects on the vasculature comes from a study by Bouverot et al. (1979), who showed a trend toward increased peripheral resistance in carotid body-intact ducks subjected to arterial hypoxia while breathing spontaneously. The same stimulus in animals after denervation of the carotid bodies led to a 40% fall in peripheral resistance, indicating a potential role for these chemoreceptors in generating the vascular response to hypoxia. As with cardiac responses to carotid body stimulation, elevated ventilation during hypoxia may mask the full extent of reflexogenic vasoconstriction. In the study by Bouverot et al. (1979), no attempt was made to evaluate this interaction by controlling ventilation.

It is clear that the full role of arterial chemoreflexes in circulatory control has yet to be defined in birds. Elevated carotid body input can result in both ventilatory and cardiac responses, and both of these responses are important in maintaining oxygen delivery to and CO_2 washout from working tissues. Further experiments are necessary to establish the relative importance of these limbs of the chemoreflex in matching ventilation with perfusion to cope with changes in internal and external levels of these gases.

11.5.4.2 Baroreflexes

Arterial blood pressure provides the driving force for perfusion of the systemic vascular beds and must therefore be maintained within limits that ensure optimal tissue blood flow under a variety of physiological conditions. Blood pressure in birds is maintained by the baroreflex, a mechanism employing negative feedback (see reviews by Bagshaw, 1985; Smith, 1994). Adjustments in blood pressure produced by the baroreflex are driven by afferent signals from arterial baroreceptors. These are mechanoreceptors with their receptor endings embedded in connective tissue of the arterial wall, where they sense changes in arterial pressure as variations in wall tension. An increase in intraarterial pressure results in an increase in circumference of the vessel wall, which in turn stretches baroreceptor endings to increase their frequency of discharge of APs. Arterial baroreceptors in birds are located primarily in the walls

of the aorta close to the left ventricular valves (Jones, 1973). Their axons course to the brainstem via aortic nerves which arise from the nodose ganglia of the vagus (Nonidez, 1935). In the few studies of avian baroreceptor function done to date, discharge characteristics in response to changes in blood pressure appear to be similar to those of mammalian high threshold, slowly adapting baroreceptors (Jones, 1969, 1973). Spontaneous baroreceptor impulse generation is phase locked to mechanical events in systole of the cardiac cycle, as shown in Figure 11.52. Baroreceptors are also sensitive to the rate of rise of the pressure pulse. It thus appears that baroreceptors are capable of transmitting information on cardiac rate, peak systolic pressure, and the slope of the aortic pressure waveform (which may in turn reflect cardiac contractility) to the central nervous system.

Mean arterial blood pressures of resting birds are higher than those recorded in mammals of equivalent body weight at rest; indeed, mean resting pressures may exceed 150 mm Hg in some avian species (Altman and Dittmer, 1971). Avian baroreceptor discharge occurs at resting levels of blood pressure in birds (Jones, 1969, 1973), so it is likely that the baroreflex is tonically active at these pressures. Changes in blood pressure sensed at the receptors are represented to the baroreflex circuitry in the central nervous system by changes in baroreceptor afferent discharge frequency. The baroreflex acts to adjust pressure in a direction opposite to that of the initial pressure change. This reflex operates through both peripheral vascular and cardiac effectors to return blood pressure toward a set level after disturbances. Pressure is thus maintained within fairly narrow limits over time to ensure a constant pressure head for tissue perfusion. Little is known of the central nervous mechanisms involved in blood pressure regulation in birds. Inhibition of NMDA receptors by ketamine attenuated the pressor response in the pigeon suggesting a role for the vagal nerve as in mammals (Lucitti and Hedrick, 2006). It is assumed that the basic organization of central components of the baroreflex is similar to the arrangement in mammals (Lucitti and Hedrick, 2006).

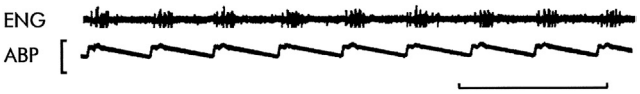

FIGURE 11.52 Relationship between baroreceptor discharge (upper trace, electoneurogram (ENG)), recorded from peripheral cut end of aortic nerve, and blood pressure (lower trace (ABP)), recorded from a brachiocephalic artery in an anesthetized duck. Baroreceptor discharge is synchronous with systolic peak pressure. ABP scale bar represents a pressure span from 100 to 200 mm Hg. *From Jones (1973).*

The primary cardiovascular response to changes in blood pressure is a baroreflex-mediated change in CO, seen in Figure 11.53(A) as a rapid fall in heart rate in response to a pharmacologically induced pressure increase. Such reflex responses are completely abolished by bilateral section of the aortic nerves (Figure 11.53(B)). The sensitivity of the blood pressure–heart rate relationship ranges from

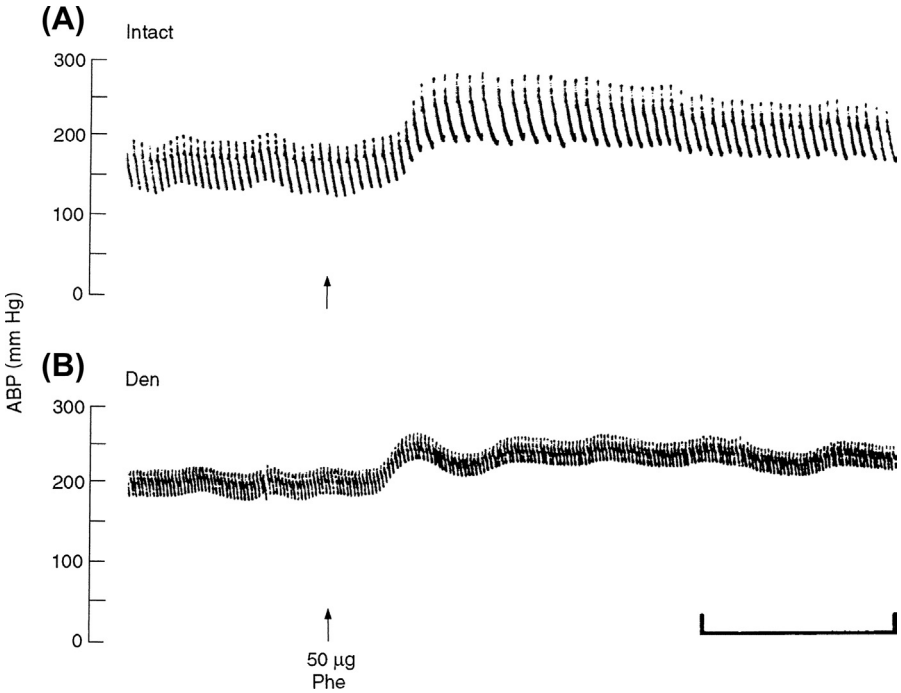

FIGURE 11.53 Heart rate responses to increased arterial blood pressure (ABP) induced by bolus intravenous doses of phenylephrine (Phe, injected at arrows) in the same duck (A) before and (B) after barodenervation by section of aortic nerves. Baroreflex-mediated bradycardia was eliminated by denervation of baroreceptors. Note increased preinjection blood pressure and heart rate in barodenervated animals, indicating a degree of baroreflex-mediated restraint on cardiovascular system in baroreceptor intact animal. *From Smith (unpublished data).*

−0.5 to −3.13 beats/min/mm Hg, depending on species and method of evaluation (chickens, Bagshaw and Cox, 1986; ducks, Smith and Jones, 1990, 1992; Millard, 1980; pigeons, Lucitti and Hedrick, 2006; see Smith, 1994 for further discussion). The baroreflex-mediated effects of changing pressure at the receptors can be mimicked by electrical stimulation of the central cut end of an aortic nerve in an animal in which both aortic nerves are sectioned. This method was used by Smith and Jones (1992) to explore the dynamic role of baroreceptors in controlling the circulation. Stimulation of the aortic nerve in barodenervated animals evokes a decrease in arterial blood pressure in proportion to the stimulus frequency when stimulus current is set just above threshold for a response (Figure 11.54, closed circles). This response works primarily through a fall in CO, mediated by decreased heart rate with no change in stroke volume (Smith and Jones, 1992). This response follows the same pattern as the baroreflex-mediated response to pharmacologically induced pressure changes in baroreceptor-intact birds; that is, in both intact and denervated animal's baroreflex activation was expressed primarily through changes in heart rate. However, the baroreflex can engage peripheral vasomotion as well as cardiac responses: in barodenervated animals, stimulation of the aortic nerve with a current intensity several times the threshold level produced decreases in peripheral resistance as well as in heart rate (Smith and Jones, 1992). These data suggest that when relatively small disturbances in pressure occur they will be compensated by adjusting CO, but larger changes in pressure will be corrected by a combination of cardiac and peripheral vascular adjustments.

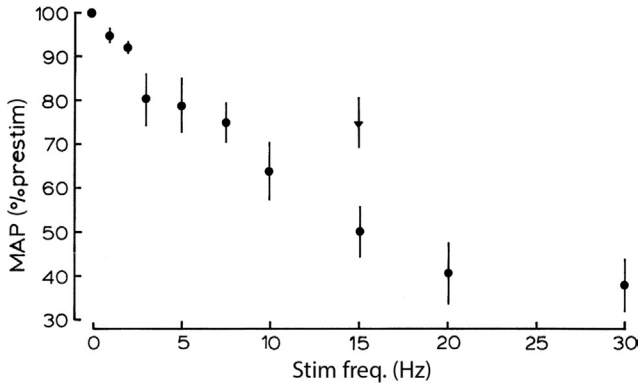

FIGURE 11.54 Normalized responses of mean arterial blood pressure (MAP) to electrical stimulation of aortic nerve in awake ducks spontaneously breathing air (P_{aO_2}: 88 mm Hg, P_{aCO_2}: 26 mm Hg; closed circles) or a hypoxic hypercapnic gas mixture (P_{aO_2}: 62 mm Hg, P_{aCO_2}: 44 mm Hg; triangle). Pressure response at each frequency of nerve stimulation is expressed as a percentage change in MAP relative to MAP just prior to stimulation. Loading the chemoreceptors attenuated the depressor effect of aortic nerve stimulation at 15 Hz. Error bars represent: 1 S.E.M. for five trials in normoxic conditions and three trials during hypoxic hypercapnia in three animals. Stimulus pulse duration and amplitude were constant within each trial. *From Smith (unpublished data).*

The effectiveness of baroreflex control of the circulation can be modified by interaction with other reflexes, such as the chemoreflex, which may be concurrently engaged. In an effort to determine the cause of an apparent reduction in baroreflex function observed during submersion in ducks (Jones et al., 1983; Millard, 1980), Smith and Jones (1992) stimulated the aortic nerve in barodenervated ducks before and during periods of elevated chemoreceptor drive. Stimulation of chemoreceptors was accomplished by ventilating animals with a gas mixture which simulated the hypoxic and hypercapnic blood gas values observed at the end of 2 min of submersion; this significantly decreased the capability of aortic nerve stimulation to affect mean arterial pressure. This is shown in Figure 11.54 by a 50% decrease in the pressure response to aortic nerve stimulation at a frequency of 15 Hz during hypoxic hypercapnia (triangle), compared with the responses during air breathing (closed circles). That this occlusive response was due to chemoreceptor activation was further demonstrated by the attenuation of baroreflex function during perfusion of one vascularly isolated carotid body with venous blood in otherwise normoxic, normocapnic animals which were spontaneously breathing (Smith and Jones, 1992). It therefore appears that the chemoreceptor drive that develops after the first minute of submersion (Jones and Purves, 1970) is at least partly responsible for the attenuation of baroreflex control of cardiovascular variables which occurs during this period.

11.5.4.3 Reflexes from Cardiac Receptors

Small nerve terminals in the shape of simple knobs, plates or rings as well as straight or spirally wound nerve endings have been observed in anatomical studies of avian atria and ventricles (Ábrahám, 1969; also see review by Jones and Milsom, 1982), but bird hearts do not appear to have the complex and highly developed sensory receptor endings present in large numbers in mammalian hearts. Few functional studies of avian cardiac receptors and their reflexogenic effects have been done so far. Jones (1969) established in the duck that some afferent fibers in the cervical vagus had receptor endings associated with the heart, responding to punctate stimulation near the AV junction and discharging spontaneously in patterns which were phase-locked to mechanical events in the cardiac cycle. In the chicken, Estavillo and Burger (1973a,b) found that a majority of cardiac receptors with their cell bodies in the nodose ganglia had receptive fields located in the left ventricle near the aortic valves. Discharge patterns of these receptors were either phase-locked to the cardiac cycle or were irregular and apparently unrelated to mechanical events in the cycle. The discharge of receptors of both types could be modulated by varying inspired CO_2 and pH_a independently or together. In this study, the discharge rate of phasically firing cardiac receptors was proportional to arterial blood

pressure over a wide pressure range, and this relationship was reset toward lower discharge rates at increased CO_2 levels, as shown in Figure 11.55. Bilateral section of the middle cardiac nerve, carrying the axons of cardiac receptors in the chicken, produced an immediate rise in arterial blood pressure (Estavillo, 1978; Estavillo et al., 1990) reminiscent of that produced in ducks after section of the aortic nerve (Figure 11.53).

Avian cardiac receptors have been proposed to contribute to blood pressure regulation and to the control of ventilation, providing sensory feedback on intracardiac pressures and volumes. Such feedback may be modulated by changes in the levels of P_{aCO_2} and pH_a (Estavillo and Burger, 1973b; Estavillo et al., 1990). In the latter study, bilateral section of the middle cardiac nerve considerably blunted the increase in ventilation elicited by systemic hypercapnia, in addition to promoting elevated blood pressure.

Birds exhibit a Bezold–Jarisch reflex similar to mammals. It manifests in ducks as a fall in heart rate and arterial blood pressure when cardiac receptors are stimulated (Blix et al., 1976; Jones et al., 1980). Blix et al. (1976) proposed, on the basis of pharmacological stimulation of cardiac receptors, that this reflex contributed to the generation and maintenance of the cardiac chronotropic response to submersion. In a reexamination of this issue, Jones et al. (1980) loaded and unloaded the cardiac receptors by altering left ventricular pressure to provide more realistic physiological stimulation of these receptors before and during submersion. The results of this study failed to confirm a link between cardiac receptor activation and diving bradycardia.

There is as yet insufficient evidence to determine the overall function of reflexes driven by inputs from cardiac receptors. Although these receptors can influence blood pressure and ventilation, they do not appear to have a primary role in pressure or ventilatory regulation. However, they may mediate some of the dynamic interactions between respiratory and circulatory systems, thus helping to correct ventilation–perfusion mismatches that can develop during exercise or in adverse environmental conditions.

11.5.4.4 Reflex Cardiovascular Effects from Skeletal Muscle Afferents

Reflex mediated changes in arterial blood pressure, heart rate, and other cardiovascular variables accompany exercise, hypoxia, and hypoxic hypercapnia in birds. In several studies designed to deduce the respective roles of peripheral arterial chemoreceptors, chemosensitive areas of the central nervous system and arterial baroreceptors in these cardiovascular responses, it has been suggested that inputs from these receptor groups do not account for all of the changes observed. Thus inputs from other receptor type must also be involved. In mammals there is a significant reflexogenic increase in mean arterial blood pressure induced by skeletal muscle activity; receptors for this response appear to be intramuscular terminals of group III afferent fibers (small myelinated fibers) and group IV fibers (unmyelinated or C-fibers) coursing in somatic nerves (see Coote, 1975 for review). Kiley et al. (1979) implicated muscle afferents in the cardiovascular responses to exercise in ducks, and Lillo and Jones (1983) proposed that somatic muscle afferents in ducks were at least partly responsible for those portions of the cardiac and vascular responses in hypoxic hypercapnia and ischemia which were independent of chemoreceptor activation. Furthermore, Solomon and Adamson (1997) demonstrated that ducks express an "exercise pressor" reflex similar to that in mammals. This effect consists of an increase in mean arterial pressure (largely due to elevation of diastolic pressure) induced by and sustained during static contraction of a large hind limb muscle, the gastrocnemius (Figure 11.56(A)). The authors concluded that this was a reflex effect since section of the sciatic nerve carrying

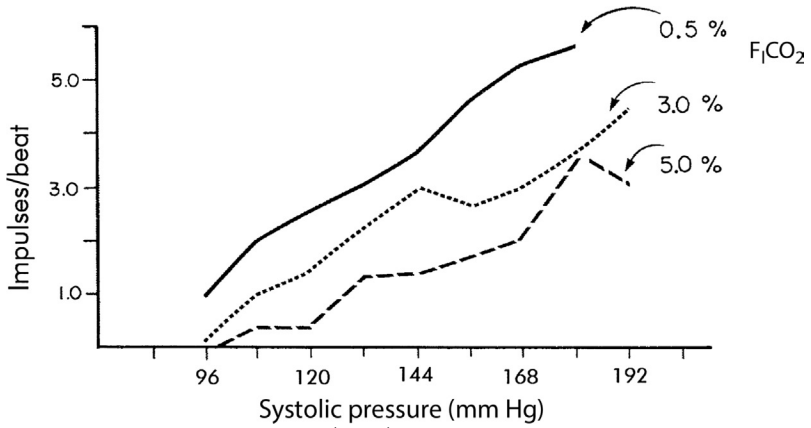

FIGURE 11.55 Modulatory effect of changes in inspired CO_2 (F_{ICO_2}) on the relationship between discharge rate of cardiac mechanoreceptors (impulses per heartbeat) and arterial blood pressure (systolic pressure) in chicken. Curves were obtained by plotting receptor discharge rate at a given blood pressure over a range of pressures produced by bolus intravenous injections of mecholylchloride or epinephrine. Progressive increases in F_{ICO_2} displaced the receptor discharge–blood pressure relationship to progressively lower discharge rates. *From Estavillo and Burger (1973b).*

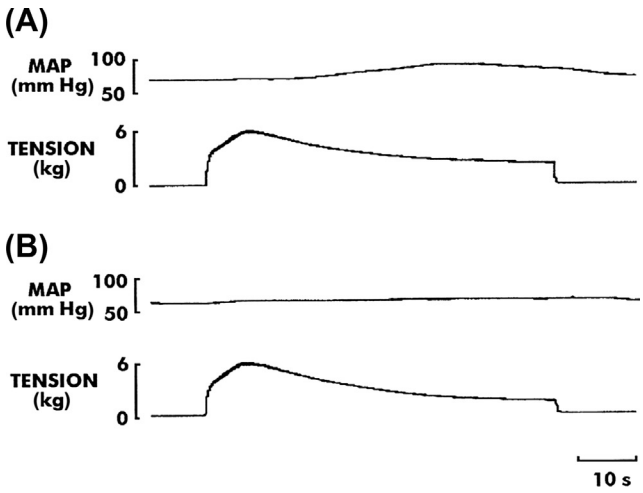

FIGURE 11.56 Pressor effect (upper traces in each panel, mean arterial blood pressure (MAP)) of static contraction of gastrocnemius muscle (lower traces in each panel (tension)) induced by electrical stimulation of sciatic nerve in anesthetized chicken. (A) MAP increases during static muscle contraction when sciatic nerve–spinal cord connection is intact. (B) No change in MAP during static muscle contraction after section of sciatic nerve. Afferent limb of pressoreflex originates within gastrocnemius muscle. *From Solomon and Adamson (1997).*

afferent fibers from the muscle to the spinal cord eliminated the pressor response to muscle contraction (Figure 11.56(B)). Whether the intramuscular receptors involved in these responses were sensing mechanical events related to muscle contraction or chemical signals resulting from intramuscular metabolite buildup as the primary physiological stimulus for this reflex was not clear from this study. The authors acknowledged that receptors sensing either modality, or both, could be driving reflex changes in pressure. The studies done to date on reflex effects of activating skeletal muscle afferents suggest that direct sensory feedback from exercising or hypoxically stressed muscle to the neural circuitry controlling the circulation could be involved in initiating or intensifying cardiovascular responses to muscle activity. Such a mechanism would serve to increase the perfusion of working muscle, but the full contribution of these reflexes remains to be determined.

11.5.5 Integrative Neural Control

As discussed in the previous sections, the major reflexes controlling cardiovascular function are the chemoreflex, the baroreflex, and reflexes driven by receptors within the heart and skeletal muscle. Under some conditions these reflexes may interact, as in the case of chemoreflex occlusion of the baroreflex detailed in Section 11.5.4.2. Furthermore, there are a number of other reflexes which can affect the circulation as part of more global homeostatic control systems, such as those regulating temperature and ventilation. All reflexes influencing the circulation do so through the final common pathways of the autonomic nervous system innervating the heart and vasculature, and several of these reflexes may be engaged at the same time during physiological challenges to the animal. Integrative control of the circulation by the nervous system therefore operates through complex interactions among cardiovascular and other reflexes, but the nature of these interactions is still incompletely understood in any vertebrate group. This large-scale integration makes investigation of the properties of any one reflex a considerable challenge, particularly in unanesthetized animals. One approach to this problem is to ensure that only afferents specific to the reflex in question are stimulated, while activation of afferents associated with other reflexes is prevented. However even this may not be enough to prevent complications in analysis since efferent activity associated with one reflex, and the consequences of this activity, can produce secondary activation of other reflexes. A case in point is the activation of pulmonary reflexes consequent to an increase in ventilation driven by primary stimulation of the arterial chemoreflex. The design of further studies of avian cardiovascular reflexes embedded in complex control systems must therefore take into account the integrative nature of these systems.

A single neurally mediated response, such as a change in heart rate, involving the stimulation of one or more afferent or efferent pathways by a frequently induced or naturally performed behavior, may be subject to habituation or conditioning. Habitation refers to a decrement in the response (not due to sensory adaptation or motor fatigue) resulting from repeated presentations of a single triggering stimulus. In contrast, conditioning involves the animal learning a relationship between two different stimuli. In classical conditioning (Pavlov, 1927) a conditioned and an unconditioned stimulus are presented with little temporal dissociation between them.

The animal learns the relation between these stimuli so that after the initial trials the reflex response can then be evoked by presenting only the conditioned stimulus. A reflex, once conditioned, will anticipate, augment, and have similar effects as the unconditioned reflex.

Cohen and his collaborators have developed a model of conditioned learning in the pigeon for exploring cellular neurophysiological mechanisms of long-term associative learning. In this model animals are trained to respond with a transient and quantifiable increase in heart rate (the conditioned response, CR) to a conditioning stimulus (CS, a 6 s whole-field retinal illumination) by pairing the CS with an unconditional stimulus (US) consisting of a 0.5 s foot shock. After an initial training period of 30–50 paired-stimulus trials, further CS without US reliably evokes conditioned responses. The properties of this CR in the pigeon are very robust, remaining stable for long periods (up to weeks) without habituating (Cohen, 1980, 1984). Such longevity facilitates electrophysiological investigations of changes in properties of neurons involved in the development of

associative learning in this system. Using this model as a platform, Cohen and co-workers have anatomically and physiologically characterized the central visual pathways for the CS, the somatosensory pathways for the US, and the descending tracts converging on the autonomic motor neurons of the final common pathway efferent to the heart in the pigeon. Much of this group's work on the efferent components of this system has already been cited in the description of the neuronal circuitry controlling cardiac function appearing earlier in this chapter.

The central and peripheral nervous pathways involved in the CR have been reviewed in detail by Cohen (1980, 1984) and are briefly summarized here. Ganglion cells throughout the retina respond with a phasic burst of APs at the start of a 6-s period of whole-field retinal illumination. This phasic wave of excitation is transmitted synchronously along multistage pathways in the central nervous system to preganglionic sympathetic and parasympathetic motor neurons in the spinal cord and brainstem, respectively. These preganglionic neurons in turn control pools of cardiac postganglionic autonomic neurons in a synergistic manner, acting to potentiate a transient sympathetic cardioacceleration and to facilitate concurrent withdrawal of parasympathetic cardioinhibition.

Studies of the development of conditioned responses after lesioning selected components of the central visual pathways and electrophysiological studies during the conditioning process in pharmacologically immobilized pigeons have shown that the CS is conveyed in parallel through multiple pathways to the visual area of the telencephalon. These include (1) a thalamofugal pathway involving the principal optic nucleus (the avian homolog of the mammalian lateral geniculate nucleus) and (2) a tectofugal pathway projecting through the optic tectum and the nucleus rotundus (Cohen, 1980). In addition, there may be a third visual input pathway implicated in the conditioned response, projecting through the pretectal area and the thalamus. While retinal responses to repeated CS are not modified during the development of conditioning, responses of second and higher-order neurons in the CS pathway are facilitated during this process. The time course of these changes parallels the time course of the development of the conditioned heart rate response, so neurons or their impinging synaptic fields in successive stages in the CS pathways are likely sites for modulation of cardiovascular control during associative learning.

The descending pathways involved in this conditioned cardiac response have been well established. Neurons in the medial region of the hypothalamus, along with those located in the ventral brainstem, project to preganglionic sympathetic and parasympathetic cardiomotor neurons. The medial hypothalamus in turn receives inputs from the avian homolog of the mammalian amygdala, an area which, in both groups of animals, evokes marked cardioactive effects when stimulated.

Furthermore, lesions of the avian amygdala or its hypothalamic projection either produce deficits in conditioning or can prevent development of the conditioned response (Cohen, 1980). The telencephalic projections conveying visual information to the avian amygdala have, however, not as yet been established in detail. Convergence of the CS and US has been demonstrated at each of the established stages in the central pathway of this response. It thus appears that training-induced modification of the CS works through long-term heterosynaptic facilitation in this pathway, and such facilitation constitutes an important element in the constellation of neurophysiological mechanisms for associative learning.

The broad outlines of the central and peripheral neural pathways involved in efferent control of the circulation in birds have been established, but relatively little is known about details of specific afferent and intermediary connections within the central pathways of any of the cardiovascular reflexes in birds. The working assumption guiding studies of these reflexes is that their pathways are similar to those in mammals, but given the differences in cardiovascular reflexogenic zones between birds and mammals, this is not necessarily a valid assumption. Birds have, for instance, only one major arterial baroreceptor site while mammals have two. In addition, most of the input from avian arterial chemoreceptors originates from the carotid bodies while in mammals both aortic and carotid chemoreceptors contribute to cardiovascular chemoreflexes. The organization of the neural circuitry for cardiovascular control in birds has not been investigated in detail, so the similarity of this circuitry to that of mammals remains an open question.

11.5.6 Development of Cardiovascular Control

Recent advancements in general knowledge of cardiovascular control mechanisms in birds have been predominately focused on the embryonic phase of avian life history. Seminal works have extensively documented anatomical maturation of the heart and vasculature. Here, we provide an overview of cardiovascular control during development in birds. It is important to recognize that the majority of studies investigating avian development have focused on the domestic chicken and the maturation of cardiovascular control is no exception.

11.5.6.1 Ontogeny of Autonomic Nervous System Control of the Heart

11.5.6.1.1 Cardiac Autonomic Innervation

The ontogeny of parasympathetic and sympathetic fiber innervation of the developing avian embryo heart differs. Branches of the vagus nerve (X) perforate the embryonic

chicken ventricle at 15% of incubation and innervate all cardiac chambers by 35% of incubation (Pappano, 1975). Cardiac and sinal branches reach the truncus and atria around 20% of incubation (Kuratani and Tanaka, 1990). In contrast, sympathetic cardiac nerves from the sympathetic ganglia do not reach the heart until 50% of incubation (Higgins and Pappano, 1979; Kirby et al., 1980) and penetrate the myocardium at 75% of incubation (Verberne et al., 1999). The sympathetic fiber origin is either the first pair of thoracic ganglia (Kirby et al., 1980) or the cervical ganglia (Verberne et al., 1999).

Field stimulation studies have found that function lags behind the anatomical appearance of innervation. A cholinergic dependent negative chronotropic response appeared as early as 60% of incubation in response to autonomic receptor drugs and atrial field stimulation. The negative chronotropic response appeared earlier, at 50% of incubation, when pretreated with the cholinesterase inhibitor physostigmine (Pappano and Löffelholz, 1974). In contrast, an adrenergic dependent, positive chronotropic response to field stimulation was not observed until hatching (Pappano and Löffelholz, 1974). An adrenergic dependent response was produced as early as 50–60% of incubation by potentiating the release of catecholamines from postganglionic neurons with tyramine (Pappano, 1975; Crossley, 1999). This potentiating effect of tyramine increased with age until 90% of incubation (Crossley et al., 2003b). Collectively the data suggest functional control by the autonomic nervous system lags behind the innervation of the heart.

11.5.6.1.2 Cardiac Cholinergic and Adrenergic Receptors

It has long been established that embryonic chicken pacemaker cells express muscarinic cholinergic receptors as early as 10% of incubation (Cullis and Lucas, 1936; Coraboeuf et al., 1970; Pappano and Löffelholz, 1974). Stimulation of these receptors produces an acetylcholine dependent negative chronotropic response that is blocked by the cholinergic antagonist atropine. There are two stages to the development of acetylcholine's negative chronotropic action (Dufour and Posternak, 1960). Between 15% and 30% of incubation, increased acetylcholine sensitivity is due to changes in membrane permeability. This is followed by functional parasympathetic innervation of the heart, which occurs between 40% and 55% of incubation (Pappano, 1977).

As early as 10% of incubation, pacemaker cells exhibit β-adrenergic receptor mediated chronotropic responses with cells expressing both β_1 and β_2 receptors (Berry, 1950; Fingl et al., 1952; McCarty et al., 1960; Lenselink et al., 1994). Pacemaker cell sensitivity to epinephrine is constant from 60% to 85% of incubation and decreases during the later 85–95% of incubation (Löffelholz and Pappano, 1974). This decrease in sensitivity is associated with increased circulating catecholamine levels during the later stage of embryonic development (Crossley et al., 2003b). The embryonic β-adrenergic receptors at 20% of incubation that respond to β-adrenergic stimulation with inotropic and chronotropic cardiac effects (McCarty et al., 1960; Shigenobu and Sperelakis, 1972; Frieswick et al., 1979; Higgins and Pappano, 1981). Maximal adrenergic stimulation produces a constant twitch force but the isoproterenol sensitivity of embryonic White Leghorn ventricular tissue increases from 75% to 90% of incubation. This is followed by a decrease prior to hatching suggesting development of a reduced adrenergic sensitivity (Higgins and Pappano, 1981). Tyramine (10 mg/kg) produces a similar inotropic and chronotropic effect on the embryonic chicken heart during this developmental period (Crossley, 1999). An age dependent decrease in sensitivity to epinephrine over this incubation window has also been shown in a broiler strain of embryonic chickens due in part to internalization of β-adrenergic receptors (Lindgren and Altimiras, 2009). Overall, developing chickens exhibit β-adrenergic mediated inotropic and chronotropic cardiovascular responses early in incubation.

11.5.6.2 Ontogeny of Vascular Contractility

11.5.6.2.1 Vascular Reactivity Regulation

Embryonic circulation must meet the demands of a rapidly growing embryo while also developing into their adult phenotype. Adult vascular smooth muscle and endothelial cells must regulate vascular tone, blood pressure, and blood flow distribution. During vascular morphogenesis developing vascular smooth muscle and endothelial cells must proliferate, migrate, and produce the extracellular matrix, while at the same time acquiring the physiological capacity to regulate vascular tone though smooth muscle activity (Owens et al., 2004; Rzucidlo et al., 2007).

As noted in Section 11.5.2.1, smooth muscle contraction relies on phosphorylation of MLC20 by the Ca^{2+} dependent MLCK and the Rho-kinase pathway. The expression of MLC20, MLCK, and MLCP in chicken embryo vascular smooth muscle occurs as early as 50% of incubation (Ogut and Brozovich, 2000). The embryonic aorta tonically contracts in response to increased cytosolic Ca^{2+} as early as 40% of incubation. The levels of MLC20 phosphorylation plateau at 75% of incubation (Ogut and Brozovich, 2000). The Rho-kinase pathway, providing Ca^{2+} sensitization, appears to mature during embryonic development. Contractions of the femoral artery and ductus arteriosus are inhibited by the Rho-kinase pathway inhibitors Y-27632 and hydroxyfasudil (Greyner and Dzialowski, 2008; Zoer et al., 2010). The effect of Rho Kinase inhibitors increased with incubation age, suggesting a developmental augmentation

in the RhoA/Rho kinase-mediated increase in calcium sensitivity of the contractile apparatus.

11.5.6.2.2 Vascular Adrenergic Receptors

The vasculature expresses adrenergic receptors early in embryonic development. Epinephrine increases arterial pressure in the embryo after 15% of incubation demonstrating that adrenoceptors are present and functional (Hoffman and van Mierop, 1971; Girard, 1973). Pharmacological manipulation to identify receptor types with specific adrenergic receptor agonists and antagonists indicate that α-adrenergic and β-adrenergic receptors are present as early as 30% of incubation (Saint-Petery and van Mierop, 1974; Koide and Tuan, 1989). Further studies to isolate differences between vascular beds of the embryo indicate that as early as 60% incubation, the mesenteric circulation expresses α-adrenergic receptors (Rouwet et al., 2000). Chicken femoral and carotid arteries increase α_1-adrenergic receptor and receptor-independent stimulation contractile reactivity from 70% to 90% incubation (Le Noble et al., 2000). In contrast, pulmonary arteries lack α-adrenergic mediated contraction during all of embryonic development (Villamor et al., 2002). Stimulation of β-adrenergic receptors produces a relaxation in some vessels including the femoral artery. Both the sensitivity and responsiveness of the vasculature to β-adrenergic simulation increased with incubation age.

Although adrenoceptors appear functional in the arterial vasculature as early as 15% of incubation, there is a delay in sympathetic nervous control. Arterial vascular constriction to exogenous NE is present before any neurogenic responses (Le Noble et al., 2000). Sympathetic control of arterial vascular resistance seems to be restricted to the later stages of embryonic development in chickens. The femoral artery contracts in response to perivascular nerve stimulation in late-stage embryonic chickens. In contrast, neither the carotid nor pulmonary arteries respond to nerve stimulation. In summary, there is an increase in adrenergic control of the vasculature that initially comes from circulating catecholamines and later sympathetic nervous control.

11.5.6.2.3 Vascular Cholinergic Receptors and Endothelial Control

Cholinergic control of vessel reactivity appears early in the developing avian embryo. Muscarinic receptor stimulation relaxes the aorta, femoral artery, carotid artery, mesenteric arteries, pulmonary arteries, and ductus arteriosus of chicken embryos in a nitric oxide (NO)-mediated endothelium-dependent manner (Greyner and Dzialowski, 2008; Le Noble et al., 2000; Rouwet et al., 2000; Martinez-Lemus et al., 2003; Nishimura et al., 2003; Villamor et al., 2002). This endothelium-dependent, NO-mediated relaxation appears to be critical for regulating embryonic circulation during early development. There is early expression of NO synthase mRNA in multiple tissues of the developing chicken cardiovascular system as early as 15% of incubation (Groenendijk et al., 2005). As early as 50% of incubation, isolated cardiomyocytes respond to sodium nitroprusside, an NO donor, and L-arginine, the NO precursor, suggesting the NO/cGMP pathway is already functional (Ungureanu-longrois et al., 1997). Isolated chorioallantoic membrane (CAM) arteries contract in respond to acetylcholine (Lindgren et al., 2010) and NO produces increased CAM blood flow as early as 50% of incubation (Dunn et al., 2005). Early in incubation, NO donors decrease ventricular preload without changing arterial resistance, which may occur through venodilation (Bowers et al., 1996). At 45% of incubation, sodium nitroprusside produces a vasodilation, suggesting early maturation of the cellular pathway involving cGMP activation (Altimiras and Crossley, 2000). In addition, NO plays a role in maintaining systemic vascular dilation at 70 and 90% of incubation in chickens (Iversen, et al., accepted article). Finally, the endothelium-dependent relaxation of pulmonary and systemic arteries is constant during internal and external pipping (Villamor et al., 2002; Le Noble et al., 2000). The hatching chicken lacks the depression of pulmonary endothelial function observed in neonatal mammal.

Other mediators of endothelium-dependent relaxation have received limited attention in embryonic chickens. Adenosine is involved in the CAM angiogenic response to hypoxia at 50 and 65% of incubation. Embryonic whole body vascular resistance decreases in response to adenosine at 50–70% of incubation (Adair et al., 1989). Adenosine receptors have been found on embryonic red blood cells at 50% of incubation (Glombitza et al., 1996). These studies indicate that adenosine receptors are present in the developing chicken cardiovascular system.

11.5.6.3 Developmental Integration of Autonomic Cardiovascular Regulation

11.5.6.3.1 Afferent Pathways

The carotid bodies and special mechanosensory nerve endings in the aorta provide the main cardiovascular reflexes in birds. The carotid bodies constitute the primary loci for peripheral chemoreceptors sensing arterial oxygen and carbon dioxide tensions and pH (Section 11.5.4.1). Initially, carotid bodies consisting of mesenchyme-like cells appear around 25% of incubation and by 40% of incubation have migrated to the adult location (Murillo-Ferrol, 1967). At 60% of incubation, the parenchyma has a large number of dispersed granule-containing cells, glomus cells or Type I cell (Kameda, 1994). The appearance of these cells coincides with peak serotonin immunoreactivity (Kameda,

1990) and appearance of long axon synaptic junctions with glomus cells (Kameda, 1994). At 70% of incubation, the developing glomus cells already express features of mature glomus cells (Kameda, 1994). Hypoxic-induced glomus cell catecholamine secretion increases after hatching and is coupled to decreased constitutive catecholamine release (Donnelly, 2005).

Reflexogenic sensory afferents of the cardiovascular system originate from the nodose ganglion. The nodose ganglion bifurcate after emerging from the cell body with one branch to the heart and viscera and the other centrally located, making connections within the central nervous system and solitary tract nucleus. The primordium of the ganglion appears at 15% of incubation and is followed by proliferation of ganglion, peaking at 30% of incubation. An apoptosis-induced decrease in cell number occurs by the time of hatching (Harrison et al., 1994). Early neuron development is independent of neurotrophins and becomes dependent on brain-derived neurotrophic factor as the neurons develop towards their target tissues. The development of the neurons is regulated by other trophic factors such as nerve growth factor during embryonic develpoment (Hedlund and Ebendal, 1980).

Overall, the development of cardiovascular reflexogenic afferent pathway connections with the central nervous system occurs during the first half of incubation. The sensitivity of the carotid bodies increases when the animal hatches, but the changes occurring in baroreceptive areas are unknown.

11.5.6.3.2 Tonic Heart Regulation

The role of cholinergic tonic activity does not appear to be involved in maintaining baseline cardiovascular function during early embryonic development. The cholinergic muscarinic receptor antagonist atropine does not alter heart rate in White Leghorn chicken until just prior to or after hatching (Pickering, 1895; Saint-Petery and van Mierop, 1974; Tazawa et al., 1992; Crossley and Altimiras, 2000) and has no effect on arterial pressure (Tazawa et al., 1992; Crossley and Altimiras, 2000). However, this is not universal for embryonic birds, as different species differ in terms of the presence of a heart rate response to atropine administration (Crossley et al., 2003b; Swart et al., 2014). Embryonic chicken strains including broilers, black Sumatran Bantams, and red Jungle fowl vary in terms of the presence of functional cholinergic tone on heart rate, appearing as early as early as 60% to as late as 90% of incubation (Crossley et al., 2003b; Chiba et al., 2004; Crossley and Altimiras, 2012). An absence of cholinergic tone does not exclude possible recruitment and intermittent activity of the parasympathetic nervous system. Continuous recordings of instantaneous heart rate in embryonic chickens reveal heart rate decelerations likely due to transient increase parasympathetic activity (Kato et al., 2002). Although cholinergic receptors are expressed early in development and the parasympathetic efferent pathway is functional under some conditions at 60% of incubation (Pappano et al., 1973), cardiovascular function and development continues without a tonic cholinergic stimulation throughout at least the first half of incubation.

In contrast, there is clear adrenergic tone present during the majority of embryonic bird development. α-adrenergic and β-adrenergic receptor mediated stimulatory tones on both heart rate and arterial pressure appear early in development (Saint-Petery and van Mierop, 1974; Koide and Tuan, 1989; Tazawa et al., 1992; Crossley and Altimiras, 2000). As early as 30% of incubation, a positive β-adrenergic chronotropic tone on heart rate and arterial pressure appears (Saint-Petery and van Mierop, 1974; Girard, 1973). This tone is critical to basal baseline function (Tazawa et al., 1992; Crossley, 1999; Crossley and Altimiras, 2000). In chickens, the magnitude of the β-adrenergic chronotropic tone increases in strength from 10% to 20% as the embryos progress from 40% to 95% of incubation, respectively (Crossley, 1999). Baseline heart rate is unchanged after pharmacological blockade of sympathetic nervous terminals with 6-hydroxydopamine or ganglionic blockade (Tazawa et al., 1992; Crossley, 1999; Crossley et al., 2003b). This suggests that adrenergic heart rate tone in chicken embryos originates from circulating catecholamines. A similar change in the β-adrenergic heart rate tone during the final 30% of incubation has been observed in emus, domestic geese, and Canada geese (Crossley et al., 2003a; Swart et al., 2014).

Although the direct effects of β-adrenergic inhibition on the heart is mediated through direct actions on the heart and pacemaker tissue, the mechanisms regulating the depressive actions of α-adrenergic receptor antagonists on heart rate present from 40% of incubation through hatching is unclear (Koide and Tuan, 1989; Tazawa et al., 1992; Crossley, 1999; Crossley and Altimiras, 2000). While this tone is present and the magnitude is maximal between 60% and 95% of incubation, α-adrenergic receptors have been reported to be absent in the chicken heart (Crossley, 1999; Chess-Williams et al., 1991). Therefore, the bradycardic response to α-adrenergic receptor blockade may be secondary to the pronounced vasodilation after α-adrenergic receptor antagonist treatment (Crossley and Altimiras, 2000). Vasodilation may produce blood pooling in the CAM vasculature, reduced venous return, or decreasing heart rate and CO.

11.5.6.3.3 Tonic Vasculature Regulation

Total and regional vascular resistance and capacitance is regulated by the sympathetic nervous system in adult vertebrates. This vascular control is mediated by changes in catecholamine release (adrenaline and noradrenaline) from sympathetic nerve terminals as well as the adrenal medulla.

These ligands bind to adrenoceptors (AR) types that are heterogeneously distributed with the dominant AR type dependent on the vascular bed. This allows differential hemodynamic responses to systemic catecholamine release. The vascular tone resulting from activation of different receptors is dependent on the vascular areas affected and if stimulation is arising from sympathetic nerve endings or circulating catecholamines (Guimaraes and Moura, 2001).

A strong α-AR tone maintaining vasculature constriction is active in some vascular beds and is functional from 30% to 95% of incubation (Girard, 1973; Saint-Petery and van Mierop, 1974; Koide and Tuan, 1989; Tazawa et al., 1992; Crossley, 1999; Crossley and Altimiras, 2000). A α-AR mediated vascular tone prevails in the skeletal muscles and has limited effects on the heart, intestines, and yolk sac (Mulder et al., 2001). Further α-ARs are absent from the CAM vascular tree illustrating the regionalization of AR types (Lindgren et al., 2010). Although the time course has not been elucidated, a similar strong α-AR vascular tone has been observed in the black Sumatran bantam, red jungle fowl and broiler chickens (Crossley, unpublished observation; Crossley and Altimiras, 2012). In white leghorns, the receptor subtype responsible for maintaining embryonic vascular tone are likely α_1-adrenergic receptors given similar responses following a nonspecific α-AR antagonist (phentolamine) and an α_1-adrenergic receptors specific antagonist (prazosin) (Crossley and Altimiras, 2000). In white leghorn chicken embryos, there is an increase in the dependence on α-AR mediated vasoconstriction from a 10% contribution to resting arterial pressure to over 55% just prior to hatching (Crossley, 1999). Limited numbers of studies conducted in other species show that embryonic emus, domestic geese, and Canada geese possess a pronounced α-AR tone during the final 30% of incubation (Crossley et al., 2003a; Swart et al., 2014). Overall, it is clear that embryonic chickens depend on α-mediated vasoconstriction during the majority of development, which is a feature shared by the other avian species investigated.

A β-AR vasodilator tone opposes the α-AR mediated vascular tone during embryonic development. The β-AR vasodilator tone in white leghorn chickens appears at 30% of incubation, increases in magnitude from 35% to 60% of incubation where it stabilizes until the final 5% of incubation when it disappears (Saint-Petery and van Mierop, 1974; Crossley, 1999; Girard, 1973). An active β-tone depressing arterial pressure is present in other chicken strains from 60% to 90% of incubation (Koide and Tuan, 1989; Tazawa et al., 1992; Crossley, unpublished; Crossley and Altimiras, 2012). This tone reaches maximal strength at 90% of incubation in other strains of embryonic chickens and embryonic emus (Crossley, unpublished data; Crossley et al., 2003b; Crossley and Altimiras, 2012). Unlike the chickens and emus, domestic and Canada geese embryos have a β-AR vasodilator tone at 70% of incubation that is absent at 90% (Swart et al., 2014), so clearly regulatory mechanisms may differ between species.

As with adrenergic tone on heart rate, the adrenergic vascular tone during development is due to levels of circulating plasma catecholamines. This is supported by measurements following sympathectomy with 6-hydroxydopamine or hexamethonium ganglionic blockade, illustrating that resting arterial pressure in embryonic chickens is unaltered by the treatment (Crossley, 1999; Crossley and Altimiras, 2000; Crossley et al., 2003b).

11.5.6.3.4 Baroreflex Regulation

Investigations of developing baroreflex function have been limited to domestic chicken breeds and have focused on characterizing reflex parameters of the cardiac limb or heart rate responses to changes in arterial pressure only (Altimiras and Crossley, 2000; Elfwing et al., 2011; Mueller et al., 2013). Two methods have been successfully utilized to quantify changes in baroreflex gain (sensitivity) and set point during chicken development; pharmacological assessment or Oxford method and spontaneous baroreflex sensitivity assessments (Altimiras and Crossley, 2000; Elfwing et al., 2011; Mueller et al., 2013). Each approach has merits and deficiencies however collectively baroreflex function in chickens is present as early as 80% of 21day incubation period, dependent in part on the breed studied (Altimiras and Crossley, 2000; Elfwing et al., 2011). In addition to the timing of operation during chicken development, changes in baroreflex function have also been reported. Gain of the reflex is a key parameter used as an index of baroreflex maturation during chicken incubation; however, components such as set point and threshold are also informative. In white leghorn chicken embryos, the baroreflex is functional at 85% of incubation (Altimiras and Crossley, 2000), but only 17% of the embryos showed a change in heart rate after experimental manipulation of blood pressure. This rapidly increases to 33% at 90% of incubation, with a fivefold increase in baroreflex gain upon hatching (Altimiras and Crossley, 2000). Using the spontaneous assessment method in which the correlation between spontaneous fluctuations in arterial pressure and heart rate are analyzed, the reflex is functional by 80% of incubation, while the gain remains constant from this point until 95% of incubation in broiler chickens (Elfwing et al., 2011). Interestingly, spontaneous gain in embryonic broiler chickens is relatively constant from 80% to 95%, averaging 59.8 k/Pa/min. This is a higher gain than that determined with the Oxford method in the same breed, which increased progressively from 10.9 to 30 k/Pa/min over the same developmental period (Elfwing, 2007). Previous arguments regarding the utility of each methodological approach have been made (Di Rienzo, 2001; Elfwing et al., 2011) and may account

for these reported differences in ontogeny of chicken baroreflex function. Overall, while previous studies have been novel and informative about the ontogeny of avian baroreflex function, the domestic chicken has been the lone model organism. Investigations of multiple species from different avian lineages with different developmental strategies (precocial versus altricial) are crucial to identify the commonalities of the ontogeny of baroreflex function in birds.

Equally informative will be investigations of the interactions between baroreflex function and other regulatory mechanisms during ontogeny; however, modulation of baroreflex of function via systemic hormones and central neuropeptides has been unexplored. Angiotensin II (AT) is an important regulatory peptide that is crucial for blood volume homeostasis in adults and is a contributor to an integrative series of signaling pathways that impacts baroreflex function. In embryonic chickens, AT also modulates baroreflex function, decreasing both baroreflex gain and operating point at 90% of incubation (Mueller et al., 2013). This change was attributed, in part, to a decrease in vagal inhibition that may be the result of the known elevated plasma levels of AT in embryonic chickens (Crossley et al., 2010). Thus, to deepen the understanding of the development of this reflex, the ontogeny of baroreflex function must be assessed in concert with the maturation of other regulatory components of the embryonic cardiovascular system.

11.5.6.3.5 Cardiovascular Response to Hypoxia

The embryonic cardiovascular response to hypoxic exposure has been as useful tool in assessing the capacity of developing regulatory mechanisms to respond to an environmental insult in addition to exploring the maturation of a typical adult response to the stress. Hypoxia has been suggested to be a relevant nature occurrence during avian ontogeny (Andrewartha et al., 2011). Investigators have utilized two methods to characterize the cardiovascular response to reductions in oxygen: prolonged and acute exposures. In domestic chickens, prolonged bouts (>15 min) of hypoxic exposure result in a negligible heart rate response in early embryos (15–25%), a depression in heart rate during the middle of incubation (67–76%), and an increase in heart rate late (95–100%) in incubation (Khandoker et al., 2003; Andrewartha et al., 2011). Changes in arterial pressure and blood flow distributions have been yet to be investigated under prolonged periods of hypoxic exposure.

Arterial pressure responses to hypoxic exposure have been conducted primarily using acute hypoxia (<10 min). In general, hypoxia causes hypotension in embryonic chickens, which is dependent on the level of hypoxia throughout embryonic development (Tazawa, 1981; Crossley et al., 2003b). Embryonic emus respond similarly at 60% of incubation; however, they transition to a hypertensive response prior to hatching (Crossley et al., 2003a). Acute hypoxia also depresses heart rate in embryonic chickens, between 43% to 100% of incubation, with the intensity of the response dependent on the level of oxygen, unlike the response seen during prolonged exposures (Tazawa, 1981; Tazawa et al., 1985; Crossley et al., 2003a). In contrast, embryonic emus either maintain or increase heart rate during hypoxic exposures during the final 30% of incubation (Crossley et al., 2003a). Blood flow measurements during hypoxic exposures beyond 30% of incubation are limited. Tazawa et al. (1985) measured blood flow in the allantoic artery, the major artery supplying the CAM, of an embryonic chicken at ~70% of incubation and reported a slight decrease during hypoxia from the baseline value of 4.1–4.4 mL/min (Tazawa et al., 1985). Later work reported that severe hypoxia (0–5% O_2) reduces allantoic artery blood flow as much as 0.7 mL/min in embryonic chickens from 40% to 76% of incubation (Van Golde et al., 1997). Given that under normoxic conditions the CAM vascular receives between 52% and 41% of CO in embryos ranging from 50% to 90% of incubation, the depression caused by hypoxia represent an important redistribution of flow (Mulder et al., 1997). The pattern of redistribution favored the increased perfusion to the heart and brain while decreasing it to the liver, yolk and carcass (Mulder et al., 1998). Direct measures of femoral arterial blood flow also illustrate a reduction in limb perfusion during hypoxic exposures (Iversen et al., accepted article). Overall, the embryonic chicken response to acute hypoxic exposure is a depression of overall cardiovascular function.

The mechanisms that underlie the documented changes in cardiovascular function have been investigated in the embryonic chickens. In the white leghorn breed, hypoxia decreases arterial pressure in embryos from 43% to 100% of incubation (Crossley, 1999). Initially, this response was partially attributed to a direct effect of reduced O_2 on the vasculature inducing a relative dilation (Crossley et al., 2003b). From 70% to 90% of incubation, the hypoxic dilation is limited by an α-adrenergic and cholinergic receptor stimulation, with a dilatory β-adrenergic stimulation contributing in the final ~20% of incubation (Crossley et al., 2003b). Although the increased vascular cholinergic effects may resulted from a reflexive mechanisms, the adrenergic stimulations can be attributed to the elevation in plasma catecholamines reported to result from hypoxic exposures during the final 30–40% of incubation (Mulder et al., 2000; Crossley et al., 2003b). Recent investigations have identified a nitric oxide mediated vasodilation at 70 and 90% of incubation as an additional contributing factor to the hypoxic hypotension in embryonic chickens during this period (Iversen et al., accepted article).

Heart rate responses to hypoxia have been suggested to be partially due to the direct actions of low oxygen on cardiac muscle and pacemaker tissue of the embryo

(van Golde et al., 1997; Crossley et al., 2003b). During the final 10% of incubation, the hypoxic bradycardia may also be affected by an α-adrenergic stimulation and a cholinergic inhibition induced by the direct effects of low oxygen on autonomic nerve terminals as well as chromaffin tissue (Crossley et al., 2003b). It should be noted that α-adrenergic receptor-mediated redistribution of CO, including preferential perfusion of the heart, is an important component of the embryonic chicken response and inhibition may contribute to the reported chronotropic actions of α-adrenergic during hypoxia (Mulder et al., 1998, 2001).

Clearly, additional regulatory systems in multiple species must be investigated to further develop the model of how the embryonic cardiovascular system responds to periods of hypoxia however the embryo may rely on peripheral mechanisms, such as NO, with limited action from the autonomic nervous system.

11.5.6.4 Development of Humoral and Local Effectors of Cardiovascular Function

A number of hormones play an active role in cardiovascular regulation of the developing embryo. The best studied hormones include angiotensin II (AII), endothelin (ET), and natriuretic peptide (NP), and their roles in the adult have been outlined in Section 11.5.2.3. All of these hormones have been found relatively early in development of the chicken embryo.

The components of the renin-angiotensin system are present during early embryonic chicken development. The egg-laying female provisions AII converting enzyme (ACE) at measurable levels in freshly laid eggs. Over the first 2 days of development, whole embryo levels of ACE-mRNA increase (Savary et al., 2005) and pathways for angiotensin synthesis and signal transduction are present. Between 15% and 20% of incubation, cardiac tissue, brachial arch tissue, and mesonepric tissue all express AII receptor mRNA (Kempf and Corvol, 2001). The CAM expresses AII receptors during at least the last half of incubation (Moellera et al., 1996) and responds to AII at 35% of incubation (Le Noble et al., 1991, 1993).

Angiotensin II appears to be a tonic regulator of cardiovascular function in the developing chicken. *In vivo* AII produces a dose dependent increase in arterial pressure that increases in intensity from 60% of incubation until hatching (Crossley et al., 2010). In addition, embryonic chickens possess high levels of circulating AII over this same time frame and blockade of ACE results in a relative hypotension at 90% of incubation (Crossley et al., 2010; Mueller et al., 2013). Although the embryonic animal responds to AT with an increase in blood pressure similar to adult birds, the embryo lacks the initial AII induced hypotension reported in adults (Crossley et al., 2010). Embryonic chickens also do not depend entirely on α-adrenergic receptors stimulation for the AII-induced hypertension and antagonists for the AII type 1 receptor (AII1R) are ineffective in embryonic chickens until hatching (Crossley et al., 2010). The ACE is active in chicken aortas as early as 50% of incubation and it increases in activity with development (Topouzis et al., 1992). Angiotensin also relaxes isolated aortic rings of embryonic chickens at 90% of incubation (Nishimura et al., 2003). These isolated vessels are lacking the sympathetic nerve inputs that would provide a constrictive response. Collectively, the data illustrate that AII is an important component of embryonic chicken cardiovascular regulation with similarities and differences from the cardiovascular response in adult birds.

Both AII type 1 and type 2 receptors are present on the developing heart (Rabkin, 1996). Angiotensin II can act on the developing chicken heart to produce a positive inotropic effect at 85% of incubation (Freer et al., 1976). Exposure of AII during 35–90% of incubation produces cardiac hypertrophy through activation of the AII type 1 receptors (AII1R) and upregulation of myosin light chain (Mathew et al., 2004; Baker and Aceto, 1990; Aceto and Baker, 1990). The observed cardiac hypertrophy may be due to direct action of AII on the heart and/or in response to changes in embryonic vasculature function. It is clear there is a role for angiotensin in chicken cardiovascular development and regulation and *in vivo* studies are necessary to further clarify the significance of the role.

The locally produced vasoconstrictor, endothelin, is expressed ubiquitously throughout the developing chicken cardiovascular system (Kempf et al. 1998). The myocardium and the outflow tract express endothelin receptor subtype mRNA transcripts at 15% of incubation (Groenendijk et al., 2008). Endothelin converting enzyme 1 activates endothelin and is first detected at 20% of incubation (Ballard and Mikawa, 2002; Hall et al., 2004). Endothelin produces changes in cardiovascular function in both *in vivo* and *in vitro* studies. *In vivo* administration of endothelin antagonists at 20% of incubation reduce cardiac function (Groenendijk et al., 2008). An *in vitro* endothelin-mediated positive inotropic effect was observed in cultured cardiomyocytes from 50% of incubation embryos (Bézie et al., 1996). Myograph studies on isolated aorta, pulmonary arteries, and ductus arteriosus all show a vasoconstriction in response to endothelin (Wingard and Godt, 2002; Villamor et al., 2004, 2002; Martinez-Lemus et al., 2003; Agren et al., 2007). Active wall tension in response to endothelin-1 increases before hatching, which could be critical for the transition to *ex ovo* life (Martinez-Lemus et al., 2003; Villamor et al., 2004).

Natriuretic peptides help regulate sodium and water balance and maintain cardiovascular homeostasis (Takei, 2000; Toop and Donald, 2004; Trajanovska et al., 2007). Mammals express three natriuretic peptide subtypes: atrial natriuretic peptide (ANP), B-type natriuretic peptide

(BNP), and C-type natriuretic peptide (CNP). The subtypes ANP and BNP are produced and released from cardiac myocytes in response to increases in ventricular volume (Takei, 2000; Toop and Donald, 2004; Trajanovska et al., 2007). The chicken genome has four potential natriuretic peptide genes, including BNP and CNP (Houweling et al., 2005; Trajanovska et al., 2007). Natriutetic peptides produce a relaxation of the vasculature that appears as early as 20% of embryonic development (Nakazawa et al., 1990). Studies on isolated cardiomyocytes reveal a response to natriuretic peptides beginning at 50% of incubation (Bézie et al., 1996; Koide et al., 1996). These studies suggest that the receptors are present both on the heart and in the vasculature of the developing embryo. There is also some indication that endothelin and natriuretic peptide interact to regulate cardiomyocyte contractility in embryonic chickens (Bézie et al., 1996). The functional role during development remains to be fully characterized.

11.6 ENVIRONMENTAL CARDIOVASCULAR PHYSIOLOGY

11.6.1 Flight

Avian flight requires adaptations of the respiratory and cardiovascular systems to supply sufficient O_2 to the working muscles. Given the inherent complexity of measuring these parameters in active birds it is not surprising that few studies have examined cardiovascular adjustments that support flight. The two most complete studies examined cardiovascular and respiratory function in flying domestic pigeons (*Columba livia domestica*; Butler et al., 1977; Peters et al., 2005). During flight at wind tunnel speeds of 10 m/s (Butler et al., 1977) or 18.4 m/s (Peters et al., 2005) O_2 consumption increased between 10- and 17-fold. CO increased 7.4-fold and blood oxygen extraction 2.4-fold during flight, increasing convective O_2 transport to meet metabolic demands of flight muscle. During these flying bouts, heart rate (which is the primary mechanism for elevating CO in these animals) increased from a resting rate of 110 beats/min to flying rate of 663 beats/min (Peters et al., 2005). The exercise-induced increase in pigeon heart rate during flight is of a similar magnitude to that of flying bats and larger than those observed in running mammals (reviewed in Peters et al., 2005).

The magnitude of change in CO and O_2 consumption is flight mode dependent in birds. For example, during soaring and gliding, flight heart rate is similar to that of resting birds, while flapping flight increases heart rate 2.2–7.4 times, with the greatest acceleration occurring during takeoff (Peters et al., 2005; Sapir et al., 2010; Sakamoto et al., 2013). There is a strong correlation between heart rate, flight mode, and time spent flapping in the black-browed Albatross (*Thalassarche melanophrys*; Sakamoto et al., 2013). During the transition from gliding to flapping, heart rate changes almost instantaneously in the Cape gannet (*Morus capensis*; Ropert-Coudert et al., 2006). Although the method of flight is correlated with changes in heart rate, flight speed does not appear to alter this cardiovascular parameter (Ward et al., 2002; Ros et al., unpublished data). At wind speeds ranging from 0 to 16 m/s, the heart rate of flying cockatiels (*Nymphicus hollandicus*) is relatively constant, averaging 817 beats/min, which is an increase of 2.3-fold from resting levels (Ros et al., unpublished data).

Tissue perfusion is presumably modified during flight as well with an increased distribution of CO to flight muscles during activity; however this parameter has not been quantified to date. The data available quantifies skeletal muscle perfusion during walking and running. Ellerby et al. (2005) found that, during bipedal locomotion in birds, locomotory muscle perfusion increased significantly. In guinea fowl, (*Numida meleagris*) as walking speed increased to 90% of V_{O_2max}, CO increased by 4.9-fold through increased heart rate and stroke volume (Ellerby et al., 2005). The majority of this increase in CO perfused the leg muscles, while blood flow to the brain, spleen, stomach, pancreas, intestines, and kidneys did not change. Bech and Nomoto (1982) reported that sciatic artery blood flow increased 3.7 times in Pekin ducks (*Anas domesticus*) running on a treadmill, suggesting similar CO modifications occur in this species. Tissue perfusion to leg muscles in ducks increased some 5-fold in ducks swimming at close to maximum sustainable rates (Butler et al., 1988). Therefore, by extension, one could assume that similar increases in blood perfusion to flight muscle occur during moderate to energetic flapping flight. In contrast, gliding should result in limited changes in muscle flow rates, especially given the lower expected CO during these types of flying.

11.6.1.1 Altitude

Avian species, such as the Bar-headed goose (*Anser indicus*), are unique among vertebrates in that they make annual migrations across mountain ranges at altitudes between 5500 and 7250 m (Hawkes et al., 2012). At these high elevations, the inspired partial pressure of oxygen (P_{IO_2}) falls to approximately 50 mm Hg, a sea level equivalent of 7% O_2. In the O_2 cascade, maximum aerobic capacity is limited by convective movement of O_2 by the cardiovascular system (Hillman et al., 2013). Therefore, to achieve the feats of strenuous activity in a low O_2 environment at high altitudes, modifications to the cardiovascular system should be anticipated, allowing high aerobic activity. A number of studies from Dr William Milsom's group have examined cardiovascular functional adjustments of Bar-headed geese (*A. indicus*) and lowland species to decreasing levels of O_2 both at rest and during flight. Scott and Milsom

(unpublished data) compared cardiovascular parameters of resting Bar-headed geese (*A. indicus*) and Peking ducks (*A. domesticus*) while facing decreasing O_2 levels. Resting Bar-headed geese maintain mean arterial pressure at inspired O_2 levels as low as 4%, while MAP falls in the duck at 7% O_2. They found that in response to decreased inspired O_2 levels, Bar-headed geese increased heart rate from resting levels of 160 beats/min to over 300 beats/min. In contrast, Peking duck increased heart rate from 130 to 190 beats/min in response to these same hypoxic challenges. Similar differences in capacity are evident when comparing the response of the Bar-headed goose and the Barnacle goose (*Branta leucopsis*; Figure 11.57; Lague et al., unpublished data). When O_2 is decreased from 12% to 7%, the Bar-headed goose increased heart rate by over 40% and CO by over 100%, while maintaining oxygen consumption. In contrast, oxygen consumption of the Barnacle goose decreased by 18% due to a 4% reduction in heart rate and a relatively minor 10%, increase in CO.

During activity, the capacity to elevated heart rate in low O_2 environments is paramount and has been investigated in the Bar-headed goose. During flight at speeds between 45 and 55 km/h, heart rate increased roughly 2.5- to 3-fold and oxygen consumption increased 16-fold over resting values in these geese. Preliminary analysis of heart rate data for flights at 21, 10.5, and 7% O_2 suggest that these animals are able to maintain an elevated heart rate with the associated CO under hypoxic flight conditions that mirror the oxygen levels experienced during migratory behavior (Meir et al., 2013). Therefore, these animals are able to extend the cardiovascular changes observed at rest to an active hypoxic flight condition.

Coronary vasodilation is critical to maintaining O_2 delivery during bouts of reduced O_2 availability or an increase in myocardial oxygen demand. Both of these factors presumably come into play during high-altitude flight in birds. In Pekin ducks and Bar-headed geese, coronary perfusion has been reported to be 3.5 mL/min/g wet heart mass at sea level when the P_{IO_2} was 142 mm Hg (Faraci et al., 1984). Exposure to severe hypoxia (28 mm Hg P_{IO_2}) increases coronary blood perfusion 5.5 and 2.7 times, respectively, in ducks and geese (Faraci et al., 1984) via a hypoxic coronary vasodilation (Figure 11.58). Although Bar-headed geese are accomplished high-altitude fliers, in contrast to ducks, counterintuitively these animals did not increase coronary blood perfusion to the same extent under hypoxic conditions. This may be compensated for by greater ventricle capillary density in the bar-head goose compared to other species (Scott et al., 2011).

Carbon dioxide is also a potent coronary vasodilator in mammals, coupling increased aerobic metabolism in the myocardium to an increased rate of oxygen delivery, while hypocapnia increases coronary resistance and decreased coronary perfusion. This would obviously be deleterious during high-altitude migratory flight. Interestingly, the relationship between coronary blood flow and P_{aCO_2} in Bar-headed geese appears to be quite different than mammals. Over a range of P_{aCO_2} from about 30 to 60 mm Hg, there is a linear increase in coronary flow with P_{aCO_2}, as in the mammal. However, in the hypocapnic condition, when P_{aCO_2} is 30 mm Hg or lower, there appears to be no effect of P_{aCO_2} on coronary resistance (Faraci and Fedde, 1986). Whether this represents a mechanism to ensure myocardial oxygen delivery during high-altitude flight remains to be determined.

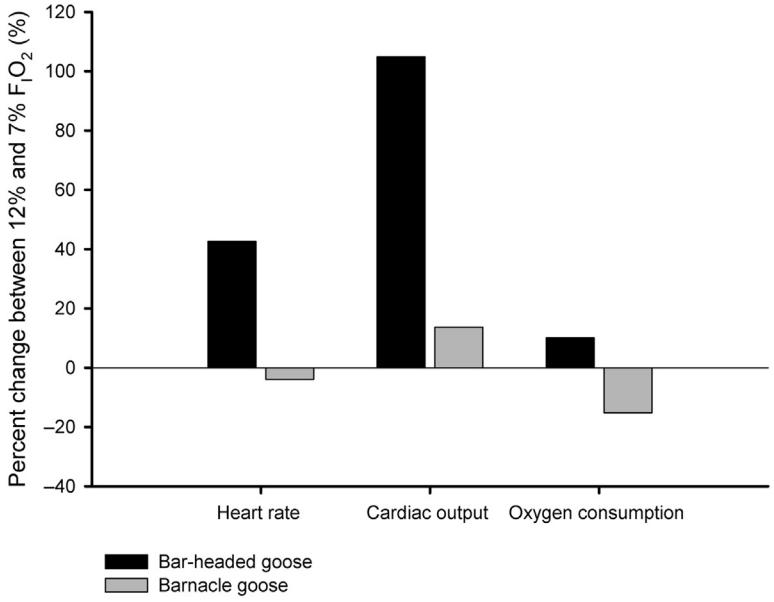

FIGURE 11.57 Percent change in heart rate, cardiac output, and oxygen consumption in response to a decrease in inspired F_{IO_2} from 12% to 7% in the resting Bar-headed goose and resting barnacle goose. *From Lague et al. (unpublished data).*

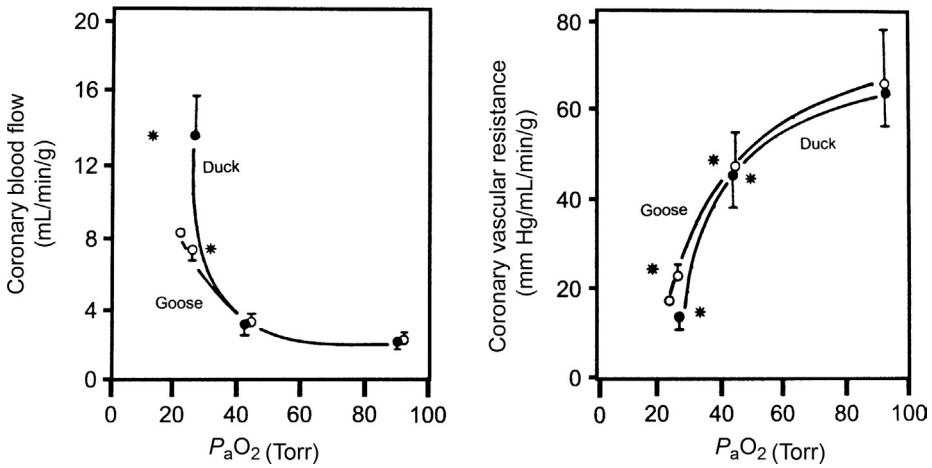

FIGURE 11.58 Responses of the coronary circulation to hypoxia in Pekin ducks and Bar-headed geese. (Left) coronary blood flow (mL/min/g); (right) coronary vascular resistance (mm Hg mL/min/g) as a function of the arterial O_2 partial pressure (P_{aO_2}). All values are means ± S.E.; $n = 5$, except at 25 Torr, where means for two geese were plotted. An asterisk represents significant difference from normoxia (highest P_{aO_2} level) at $p \leq 0.05$. *Reprinted from Faraci et al. (1985).*

Activity at high elevation subjects tissue to reduced P_{IO_2} and hypocapnia. The hypocapnia and subsequent respiratory alkalosis results from increased CO_2 washout from greater hypoxemia driven ventilation (Faraci et al., 1985; Scott and Milsom, 2007). This condition could dramatically influence tissue metabolic function with the greatest impact on highly aerobic tissues of the central nervous system. In domestic geese, cerebral blood flow decreased as P_{aCO_2} falls from 50 to 20 mm Hg but then reached a plateau; however, P_{O_2} of cerebral tissue continued to fall as P_{aO_2} fell below 20 mm Hg, suggesting differences in cerebral vascular sensitivity to these two conditions (Bickler and Julian, 1992). Carbon dioxide is normally a potent vasodilator within the cerebral circulation (Faraci and Fedde, 1986; Grubb et al., 1977); however, the cerebral vasculature is fairly insensitive in domestic geese (*Anser anser*) and Pekin ducks, while Bar-headed geese are very insensitive to severe hypocapnia (Bickler and Julian, 1992; Faraci and Fedde, 1986; Grubb et al., 1977).

Given the range of altitude that bird species inhabit and transiently experience during seasonal migration, differing degrees in flight muscle capillarity may also correlate with flight at high elevation. It could be predicted that high-elevation species would exhibit a relatively greater capillary density to muscle fiber density, increasing the total surface area of contact between capillaries and fibers. This phenotype is evident in a number of species that fly at high elevation and that have relatively higher muscle capillarity and smaller fiber sizes. In pectorals muscle from Bar-headed geese and Andean coots (*Fulica ardesiaca*) native to 4200 m, as well as some limb muscles in the coot, the number of capillaries per muscle fiber is increased compared with lowland species (Scott et al. 2009; Leon-Velarde et al., 1993). Further, in the Bar-headed goose, mitochondria of aerobic fibers are redistributed so they are adjacent to capillaries (Scott et al., 2009). These compensatory changes can be induced during ontogeny as evident in increased capillary-to-fiber ratio and possible changes in diffusion distances in Canada goose goslings (*Branta canadensis)* hatching from eggs raised under hypoxic conditions (Snyder et al., 1984; Snyder, 1987). In contrast, wild adult pigeons actively flying at 3800 m maintain similar capillary geometry and density compared to controls at sea level (Mathieu-Costello et al., 1996). Equally important are factors such as changes in $P_{50,}$ the oxygen-carrying capacity of blood or the myoglobin content of muscle fibers, which are also significant adaptations involved in the response. Increases in carrying capacity and high levels of tissue oxygen extraction have been demonstrated in unexercised pigeons acclimatized to high altitude (Weinstein et al., 1985) and Bar-headed geese (Scott, 2011). In short, while the current understanding of cardiovascular and respiratory adjustments that must accompany flight at elevation has progressed, further extensive investigations must be undertaken to explain the capacity of birds to sustain activity in low-oxygen environments.

11.6.1.2 Migration

Extensive migrations involving continuous fasting flight for long periods of time are undertaken annually by many bird species. Migrating birds exhibit extraordinary phenotypic plasticity in organ size and body mass. This organ mass plasticity manifesting as hypertrophy of the heart and other organs is akin to that observed in infrequent feeding reptiles such as snakes (Secor and Diamond, 1998; Andersen et al., 2005). For example, the barnacle goose heart hypertrophies before migration composing approximately 1.1% of body mass (Bishop et al., 1995). In contrast, the

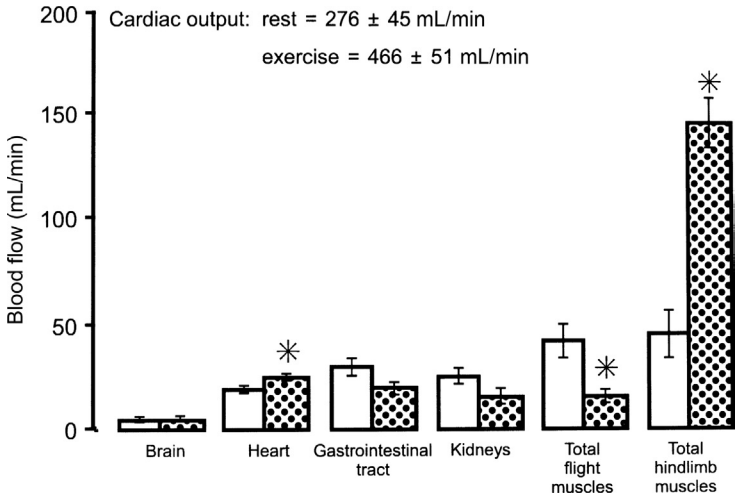

FIGURE 11.59 Histograms showing mean blood flow to selected vascular beds in six tufted ducks before (open bars) and during swimming at a mean velocity of 0.69:0.01 m/s (shaded bars). Asterisks indicate significant differences between preexercise and swimming values ($p<0.05$). *From Butler et al. (1988).*

heart of a typical bird is roughly 0.8% of body mass (Section 11.2.1.2). Heart hypertrophy of the red knot (*Calidris canutus islandica*) and bar-tailed godwit (*Limosa lapponica taymyrensis*) is correlated with increased power requirements needed for migration (Piersma et al., 1999; Landys-Ciannelli et al., 2003). The garden warbler (*Sylvia borin*) migrating across the Sahara exhibited a decrease in heart mass and flight muscle mass that was restored within 9 days of recovery feeding (Bauchinger et al., 2005). Few studies have examined the cardiovascular physiology associated with these long migrations and associated hypertrophy of the heart. During migration of Svalbard Barnacle geese (*B. leucopsis*), heart rate falls on successive days from 317 to 226 beats/min (Butler et al., 1998). Butler et al. (1998) suggested that progressive bradycardia was due to decreased O_2 demand as body mass fell while heart mass remains fixed during the migration. Thus, changes in CO appear to be influenced most heavily by heart rate changes. It remains to be seen how these changes in heart mass before, during, and after migration influence cardiovascular function and performance in these species.

11.6.2 Swimming and Diving

Bird species engage in surface swimming and submerged or diving swimming. In Tufted ducks (*Aythya fuligula*), surface swimming at maximal sustainable speeds is associated with a 70% increase in CO from 276 to 466 mL/min (Bevan and Butler, 1992). As with flight, swimming is associated with changes in regional vascular perfusion with myocardium and active leg musculature blood flow increasing by 30 and 300%, respectively, while flow to other regions remained the same or decreased (Bevan and Butler, 1992). Similar patterns are evident in the redhead duck (*Aythya americana*) during short periods of underwater swimming which results in a 200–500%, increase in hind legs perfusion (Stephenson and Jones, 1992). Clearly, selective perfusion takes place during swimming likely via an interaction between vasodilation in active muscle and vasoconstriction in visceral organs and inactive muscle (Figure 11.59; Butler et al., 1988; Bevan and Butler, 1992).

During a dive, animals must function with the limited O_2 stores carried within the body during the dive duration. The majority of dives are shorter than the aerobic, dive limit (ADL). This is the length of time that a dive can be aerobic relying on the O_2 stores in the body. A large number of diving species, such as ducks and cormorants, perform multiple short dives of less than 60 s in duration. Others species, such as the emperor penguin (*Aptenodytes forsteri*), dive for longer periods of more than 20 min (Meir et al. 2008). These different diving behaviors should by necessity result in species having different physiological capacities to ensure effective O_2 transport; however, regardless of dive duration, the pattern of cardiovascular responses is similar.

The phases of the cardiovascular response to a voluntary dive include an initial tachycardia during the immediate predive followed by a diving bradycardia. After surfacing, there is usually a postdive tachycardia. The predive and postdive tachycardia is suggested to aid in loading and replenishing O_2 stores and elimination of CO_2 (Butler and Jones, 1997). In many species, the diving bradycardia is not a true bradycardia in that the diving heart rate remains elevated in comparison to the resting heart rate.

In diving ducks, Jones and Holeton (1972), Lillo and Jones (1982), Jones et al. (1983), Smith and Jones (1992), and Bevan and Butler (1992) showed that stroke volume was maintained during the large decreases in CO generated during submersion, suggesting the primary factor dictating

CO during these events is heart rate. In addition, there is a negative correlation between minimum heart rate and dive duration as well as depth (Bevan et al. 1997; Meir et al. 2008). The extent of the diving bradycardia may be correlated with changes in blood oxygen levels, regulated by variation in parasympathetic output in ducks (McPhail and Jones, 1999). In diving cormorants (*Phalacrocorax auritus*), heart rate during a shallow dive was dependent upon the level of inspired oxygen (Enstipp et al., 2001). Predive inspiration of hypoxic gas resulted in a stronger bradycardia and predive inspiration of hyperoxic gas resulted in the opposite response. Similar changes in response to inspired oxygen levels and diving have been observed in the lesser scaup duck (*A. affinis*; Borg et al., 2004).

Penguins have been extensively studied to understand their capacity for extended active diving bouts. During dives that are greater than the ADL Emperor penguins become relatively bradycardiac just prior to returning to the surface (Meir et al., 2008). Lesser scaup ducks decrease heart rate below resting levels during forced dives only (Borg et al., 2004). During long voluntary dives of 30 min or if this species is exposed to 9% O_2, heart rate fells below resting values during the later portions of the dive suggesting that a true diving bradycardia may only occur when blood P_{O_2} levels become severely reduced (Borg et al., 2004). Changes occur in tissue perfusion have been suggested to accompany heart rate responses to diving. During long dives Emperor penguins have blood lactate levels that suggest changes occur in blood flow to the skeletal muscles during the dive (Ponganis et al., 2009). The ADL is the duration at which the dive becomes anaerobic and is indicated by blood lactate levels during postdive recovery. The majority of birds carry out multiple short dives that fall within their ADL; however, blood lactate levels remain low in animals that have passed their ADL, with levels increasing during postdive period. Data also suggest a potential arteriovenous shunt through the extremities in the emperor penguin (Ponganis et al., 2009). Ponganis et al. (2009) proposed that this shunt may be important during the initial phases of the dive by allowing enhanced transport of O_2 from the gas exchange surface to the venous system.

Regulation of the cardiovascular response to diving has been explored is some species. Baroreceptor input has been shown to have no direct role in generating or maintaining heart rate responses to voluntary submersion in diving ducks, since these animals display the same degree of bradycardia after denervation of arterial baroreceptors as before (Furilla and Jones, 1987a). However, baroreceptors may play a role in control of heart rate in dabbling ducks (*A. platyrhynchos*), which have been trained to dive voluntarily. Predive heart rate in dabblers ranged from 100 to about 500 beats/min but, regardless of the rate preceding any particular dive, rates during the dive tended to a value of approximately 250 beats/min (Furilla and Jones, 1987b). This response implies that the heart rate was being regulated at a set value during voluntary dives. Removal of baroreceptor input by bilateral section of the aortic nerves eliminated the tendency of dive heart rate to approach the

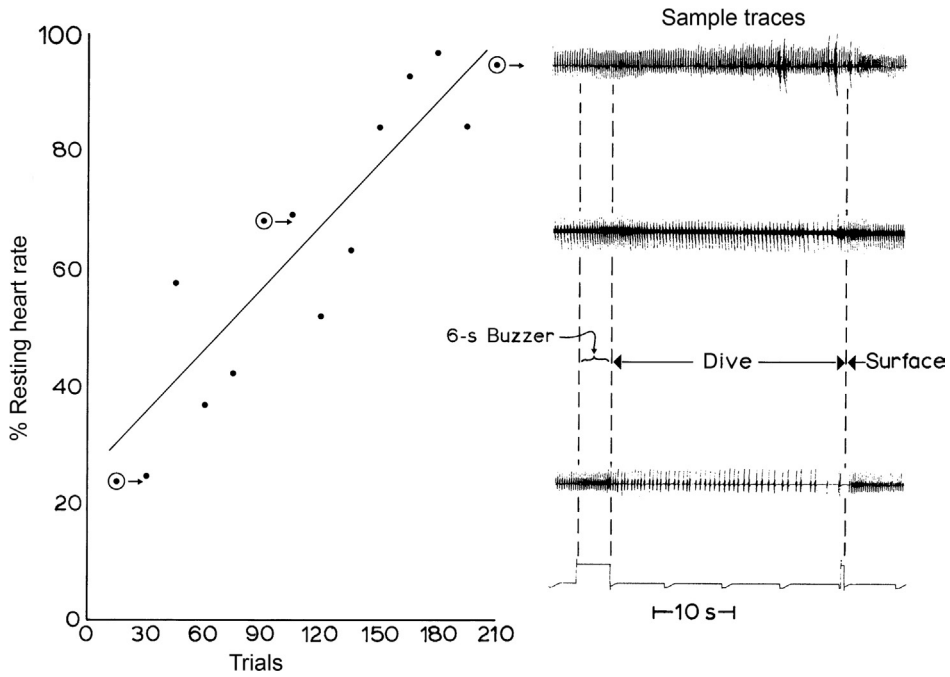

FIGURE 11.60 Reduction in degree of bradycardia attained in 40-s dives by a Pekin duck during repeated trials, each consisting of a 40-s dive immediately preceded by a 6-s buzzer. The graph is a plot of percentage of resting heart rate achieved at the end of a trial, against the number of trials. Sample electrocardiogram traces are taken from the first trial of the series (bottom trace), the 90th trial (middle trace), and the final dive (top trace). *From Gabbott and Jones (1987).*

"set point" value; after barodenervation dive heart rate varied little from the prevailing predive rate (Furilla and Jones, 1987b). Given that the baroreflex normally regulates blood pressure by adjusting CO and vascular resistance, the physiological value of a baroreceptor-dependent set point for heart rate is uncertain. The behavior of arterial blood pressure during voluntary diving in dabbling ducks has not been established. However, there may be some inherent benefit to regulating heart rate under these conditions. If this is true, then strong phasic baroreceptor input to the central nervous system during systole would represent the primary afferent feedback route for heart rate related information.

Stimulation of nasal receptors in diving ducks and chemoreceptors in dabbling ducks are the proximate causes of the development of diving bradycardia (Furilla and Jones, 1986, 1987a,b). Repeatedly submerging the head of a diving or dabbling duck in a laboratory situation causes the bradycardic response to habituate after 100 to 200 dives (Figure 11.60; Gabbott and Jones, 1987). In dabbling ducks, however, extending the period of submergence beyond 40 s virtually eliminates any attenuation of the cardiac response to submergence. Obviously, in dabbling ducks input from the carotid body chemoreceptors is too intense for habitation after 60 s submergence. Similarly, exposing habituated animals to 10 or 15% oxygen in air before submergence causes prominent bradycardia although the very next trial, after breathing room air, evokes the habituated cardiac response. Interestingly, the heart rate response to diving after breathing air with low levels of oxygen is unaffected by training. Consequently, chemoreceptor input, which will be the same in naive and habituated ducks because blood gas levels are the same after 40 s submergence, can be habituated. Habituation of the response occurs within the central nervous system, below the thalamic level. Animals with their higher brain centers surgically removed can be trained as easily as intact ducks (Gabbott and Jones, unpublished data).

Even though CO is reduced during diving, the rate of perfusion of cerebral vasculature and thoracoabdominal cavity is maintain or elevated above predive levels (Heieis and Jones, 1988; Jones et al., 1979). In mallard and Pekin ducks myocardial flow was, on average, 0.73 mL/min/g presubmersion and 0.88 mL/min/g after 144–250 s of submergence. Cerebral flow increased from 0.43 to 3.68 mL/min/g over the same time period. In Pekin ducks forcibly submerged until P_{aO_2} fell to 50 mm Hg, cerebral blood flow increased from 1.58 to 3.2 mL/min/g. Clearly, regardless of the wide range of absolute values measured, cerebral blood flow increases in forced submersion asphyxia, maintaining oxygen delivery to brain tissue. A redistribution of blood flow away from more hypoxia-tolerant regions toward more sensitive regions within the brain itself does not seem to occur in the Pekin duck (Stephenson et al., 1994). However, such heterogeneous regional changes in cerebral blood flow in response to asphyxia have been proposed to occur in neonatal mammals (Goplerud et al., 1989).

Chapter 12

Osmoregulatory Systems of Birds

Eldon J. Braun

Department of Physiology, College of Medicine, University of Arizona, AZ, USA

12.1 INTRODUCTION

To introduce the osmoregulatory strategies of birds, some aspects of osmoregulation that are common to all vertebrates are presented. Animals must have adequate water in the extracellular fluid compartment for normal cellular functions. However, this may be constrained because the environments in which animals live range from harsh deserts, where water is limited, to aquatic environments, where water is plentiful but may be brackish or marine. With respect to water and ion homeostasis, all animals can be categorized as either osmoconformers or osmoregulators of the internal environment.

Most vertebrates, including birds, are osmoregulators. The exceptions are those vertebrates that inhabit marine environments, such hagfish, skates, and sharks, which are osmoconformers (Somero, 1986). The composition of the cytosol of these osmoconformers is regulated; however, the extracellular fluids are isosmotic with the external marine aqueous media, but not isotonic with it with respect to individual ions (Somero, 1986). In some animals, the concentration of organic solutes in the extracellular fluid affects the movement of water into and out of cells. An example of animal in a marine environment is the shark, which is an osmoconforming animal (Somero, 1986). The extracellular fluid of these animals is isosmotic with seawater but not isotonic with respect to individual ions. The difference in total osmolality is made up of the organic solutes urea and trimethylamine (TMO) (Yancey and Somero, 1979). Urea cannot be the sole solute because it is toxic to proteins. TMO acts as a counteracting solute to prevent the potential negative effects of urea.

An example of a freshwater animal in which organic solutes prevent the negative effects of changes in the extracellular fluid is the tree frog in the north temperate climate zone (Zhang and Storey, 2012). In the late fall when ambient temperatures decline, the frogs burrow into the mud of freshwater ponds and freeze with their surrounding environment. The cells of the frogs do not suffer the typical damage incurred by ice crystals as tissues freeze. With onset of declining ambient temperatures, the liver of the frogs mobilizes large quantities of glucose, which functions to structure water to prevent the damaging effect of ice crystal formation (Dieni and Storey, 2010). The glucose in the cooled water forms a glass layer in a process referred to as vitrification, which prevents free flow of water across cell membranes (Brüggeller and Mayer, 1980). These are just two examples of the evolution of the effects of organic solutes on the movement of fluids across cell membranes.

12.1.1 Organs of Osmoregulation in Vertebrates

A number of avenues of osmoregulation have developed through the process of evolution to allow vertebrates to inhabit a wide variety of environments (Table 12.1). It is apparent that for all vertebrates except mammals, more than one organ and/or organ system contributes to the maintenance of osmoregulatory homeostasis. In the various groups of fish, four organs can contribute to osmoregulation. Within amphibians, individual species can be found to employ as many as five organs or organs systems in the maintenance of fluid and electrolyte balance. Reptiles are almost as diverse in the patterns of osmoregulation, as their kidneys, intestines, and bladder can function in this process. In addition, a large number of reptilian species have functional salt glands that contribute to osmoregulation. Mammals are the unusual group in terms of organs involved in osmoregulation in that only the kidney plays this role. Mammals can lose water and electrolytes though other avenues (skin, lungs, gastrointestinal tract), but not for the purpose of osmoregulation. The urinary bladder of mammals has a very limited capacity to transport ions and water; thus, it is not important in mammalian osmoregulation other than as a storage organ of urine until it can be conveniently voided (Lewis, 1977).

12.1.2 Osmoregulation by Birds

With respect to organs contributing to osmoregulation, birds fall between mammals and other nonmammalian groups because three organs can function for this purpose. Similar to reptiles, many avian species posses functional salt glands.

Sturkie's Avian Physiology.

Bladder	X	X	X		
Gills	X	X			
Salt glands			X	X	
Skin		X			

Moreover, as in reptiles, the lower gastrointestinal tract is a very important component of osmoregulatory systems in birds. Although not thoroughly investigated for reptiles, the lower gastrointestinal tract of birds may be more important for osmoregulation than for other vertebrates.

In this chapter, osmoregulation by birds will be presented in terms of the three organs involved—the kidney, lower gastrointestinal tract, and the salt glands.

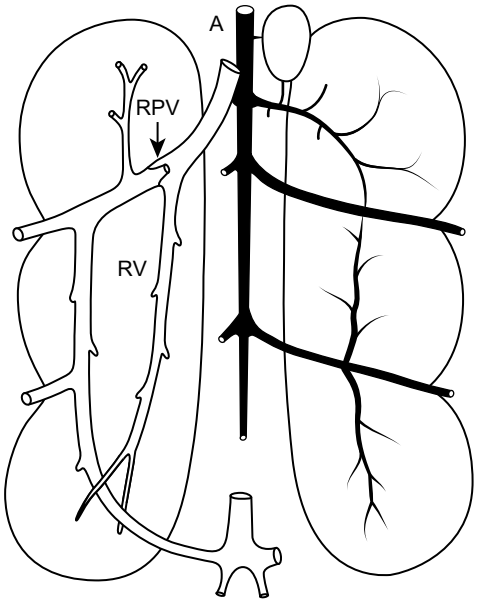

FIGURE 12.1 The surface anatomy of the avian kidney showing the lobes of the kidney, the arterial blood supply, venous drainage, and the renal portal blood flow. The arterial system is shown in black and venous system clear. RV; renal vein, RPV; renal portal valve. *Modified from Hodges (1974).*

12.2 THE AVIAN KIDNEY

From an embryologic viewpoint, the kidneys of vertebrates can be classified as being in one of four developmental categories, starting with the very primitive archinephric kidney to the most developed form found in amniotes—the metanephric kidney. Birds, being amniotes, have a metanephric kidney. Although the metanephric kidney is the functional excretory organ in posthatched birds, during embryonic development the excretory system passes through two primitive stages that recapitulate ontogeny. The first kidney forming at about 36 h of incubation is the pronephros. This kidney is present in the most primitive of the vertebrates but is wholly vestigial in birds. The mesonephros is the second excretory organ forming during development and is homologous with kidneys of adult fish and amphibians. This kidney begins to appear at about 55 h of incubation and is connected to the cloaca by the mesonephric duct, but it is not fully formed at 4 days. At about 5 days of incubation, circulation develops in the glomeruli of the mesonephros. The mesonephros' maximal period of function occurs during embryonic days 5–11. At about day 11, the metanephros becomes active and the mesonephros degenerates. During the peak functional period of the mesonephros urea is the main nitrogen excretory product. Once the metanephros becomes the active excretory organ, the metabolism switches to form uric acid as the major nitrogen excretory product (Patten, 1951).

The avian kidney does not take the classic bean shape of the unipapillate kidney found in many small mammals. It is compressed in the dorsoventral aspect of the body and typically has three divisions—anterior, middle, and posterior—although there are variations on this template (Figure 12.1; Hodges, 1974; Johnson, 1968; Braun and Dantzler, 1972). Moreover, internally the avian kidney is not divided into distinct cortical and medullary regions as is the unipapillate kidney of mammals. Typically, the cortical region of the avian kidney is composed of many cortical units that coalesce to form the medullary regions (Figure 12.2). This organization is reminiscent of the compound multirenculate kidneys of large mammals (Sperber, 1944). The cortical regions of the avian kidney are made up of a large number of small nephrons that do not have loops of Henle. These small loopless nephrons consist of a tubule that is folded upon itself four times and arranged radially around a central efferent vein. The nephrons connect to collecting ducts at right angles and therefore cannot function directly in the countercurrent multiplier (CCM) system. These nephrons essentially consist only of proximal and distal tubules. Deeper in the cortex are much larger nephrons that consist of a highly convoluted proximal tubule, loop of Henle, and a distal tubule (Figure 12.3). The transition between these morphological forms is not abrupt, but gradual. The number of loopless and looped nephrons varies from species to species, but in all species the loopless nephrons far outnumber the looped ones. At this time, there are data for very few species, but in general the total nephron

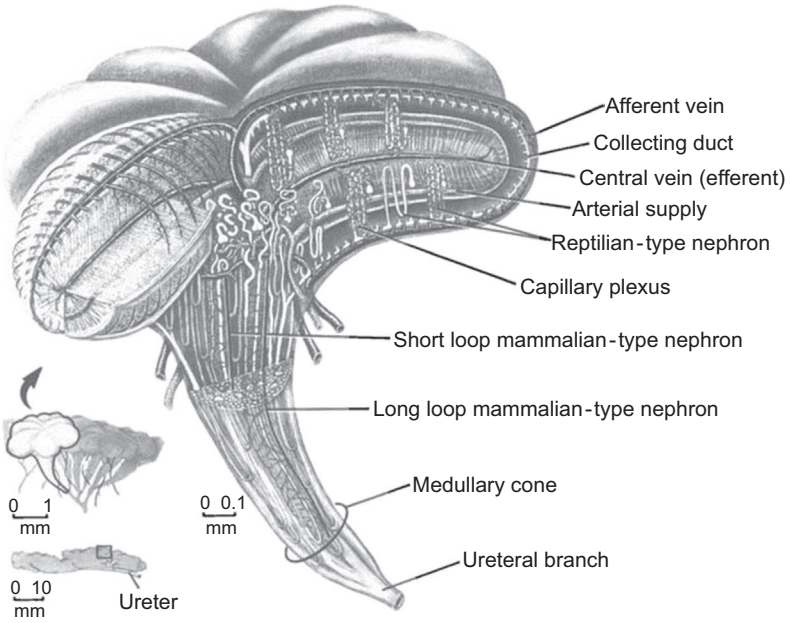

FIGURE 12.2 An illustration of the internal anatomy of the avian kidney based on dissection and observations of the desert quail kidney. The whole kidney is depicted at the lower left of the illustration. The cortical region of the kidney consists of loopless nephrons arranged around a central efferent vein. They enter collecting ducts at right angles and therefore do not function directly in countercurrent multiplication. The collecting of ducts from the loopless nephrons enter the medullary region of the kidney the output of which commingles with that of looped nephrons. Deep to the loopless nephrons are nephrons with loops of Henle of varying length. Note that there is a continuous duct from the shortest loopless nephron to the ureteral branch which eventually enters the ureter proper. Thus there is no renal calyx in the avian urinary system. *From Braun and Dantzler (1972).*

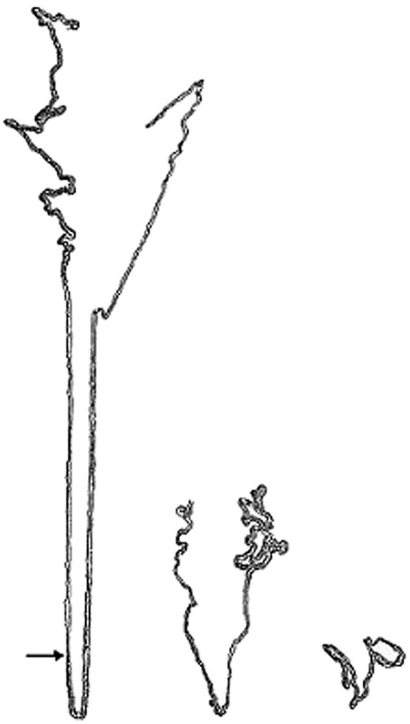

FIGURE 12.3 Nephrons isolated from the kidney of the desert quail. On the left is a large looped nephron. Arrow indicates transition from thin segment to thick descending segment. The image in the center is of shorter looped nephron. On the right is an image of a loopless nephron which appears to be a tubule folded upon itself four times. These nephrons enter collecting ducts at right angles and therefore do not function as part of countercurrent multipliers. *Modified from Braun and Dantzler (1972).*

population in avian kidneys consists of about 85% loopless and 15% looped nephrons (Braun and Dantzler, 1972).

The medullary region of the kidney is formed by small tapering structures called medullary cones. Within these cones are loops of Henle, collecting ducts, and vasa recta. This arrangement with counterflows facilitates the functioning of a CCM system, which permits the avian kidney to produce hyperosmotic urine.

12.2.1 Vascular Anatomy of the Kidney

The arterial blood supply to the avian kidney is derived from three branches of the inferior aorta (Figure 12.1). The smaller anterior and middle lobes of the kidney are supplied by separate branches and the larger posterior lobe of the kidney is supplied by a branch of the aorta that bifurcates on the surface of the kidney, such that there are two arteries that enter the parenchyma of this division. The arteries undergo a series of reductive branches until the afferent arterioles are formed, which enter the Bowman's capsule. After forming the glomerular capillaries, the vessel exits the capsule as the efferent arteriole, which forms a network around the renal tubule (peritubular capillary). The avian kidney, as with all other nonmammalian vertebrates, is also supplied with afferent venous blood by a functional renal portal system. The terminal vessels of the renal portal system join the same peritubular capillary network that is formed by the efferent arterioles (Figure 12.4). How flow in this network

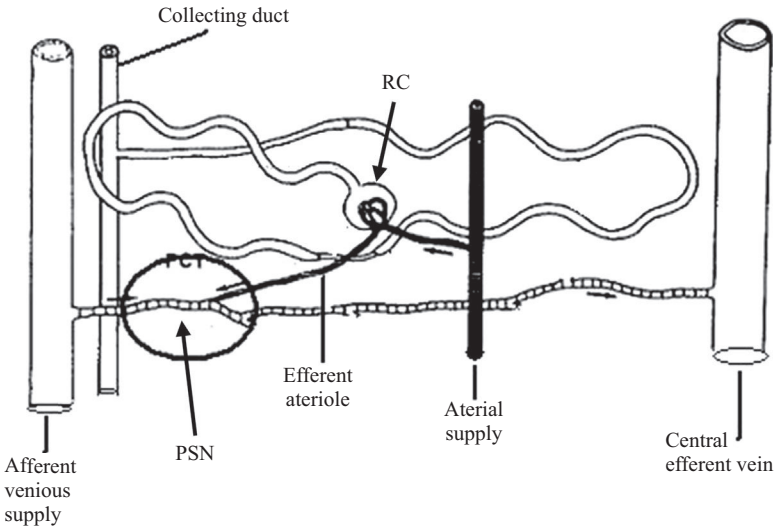

FIGURE 12.4 The pattern of blood flow within the renal cortex of the avian kidney. RC, renal corpuscle; PSN, peritubular capillary network. Note that the flow from the efferent arteriole and that of the renal portal, proximal convoluted tubule meet in the peritubular network as shown in added circle at left. *Modified from Hodges (1974).*

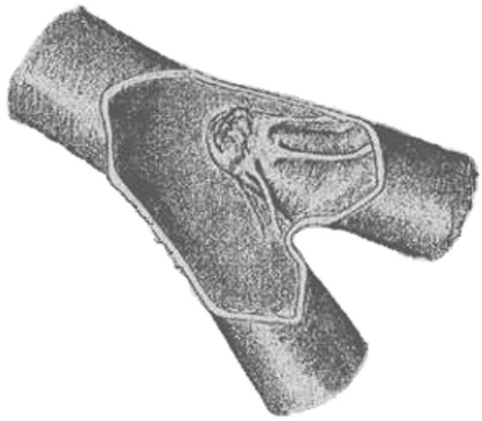

FIGURE 12.5 Artist's rendering of the valve within the renal portal system that directs blood flow into the parenchyma of the kidney or to bypass the secretory epithelia of the kidney. *Adapted from Burrows et al. (1983).*

is regulated is uncertain, but pressure measurements taken from these vessels have an oscillatory profile (Braun and Yokota, unpublished data). The renal portal system receives blood from the lower extremities (external iliac vein) and the lower gastrointestinal tract (caudal mesenteric and pudenal veins). Blood flow to the kidney from the renal portal vessels is controlled by a smooth muscle valve located in the common iliac vein (Figure 12.5). When the valve is open, flow directly enters the inferior vena cava and closure of the valve directs the flow into the renal parenchyma. Experimental data show that adrenergic stimulation closes the valve and cholinergic stimulation controls tone to open the valve (Burrows et al., 1983). One role the flow of blood in the portal system could play is to deliver substrates to the peritubular surface of nephrons to facilitate secretion by tubule cells. Portal blood flow does not enter the medullary cones (Wideman, 1988).

The venous outflow from the kidney originates from the peritubular capillary network, where the efferent arterioles and the terminal portions of the renal portal system unite. Flow from this network enters the central veins that form the core of the cortical lobules. The central veins coalesce to form interlobular veins, several of which unite before the surface of the kidney is reached, at which point they enter the renal vein. The renal veins enter the common iliac veins proximal to the point of the renal portal valve. The outflow of the vasa recta from within the medullary cones exits the base of the cones and enters the interlobular veins.

The capillaries forming the glomerular tuft within the Bowman's capsule of the avian kidney are much simpler and have a lesser degree of interconnecting branching than those that constitute glomerular tuft of most mammalian renal corpuscles. The capillary tufts of the small loopless nephrons in the cortical region of the kidney can consist of one loop—the afferent arteriole entering forming one loop and exiting as the efferent arteriole (Figure 12.6). The transition in size of the nephrons as the larger loop nephrons are reached is followed by an increase in complexity of the capillary tufts, although they are still not as complex as the mammalian capillary tufts (Figure 12.7). For many of these tufts, as the afferent arteriole enters the capsule, it forms loops at the periphery and exits as the efferent arteriole without interconnecting branches. Some of the tufts of the largest renal corpuscles do bifurcate once before the efferent arterioles are formed. As is true of all avian capillaries, those forming the glomerular tufts have larger inner diameter (7–8 μm) than those of mammals (3–4 μm). Avian red blood cells are fusiform in shape (8 × 15 μm), are nucleated, and therefore are much more ridged than those of mammals (which are 7 μm in diameter). These characteristics would make it difficult for the avian red blood cell to traverse the capillary tuft of a typical mammalian glomerulus.

FIGURE 12.6 Methyl methacralyte cast of renal vasculature showing an afferent arteriole leading to the formation of a glomerular capillary of a loopless nephron. Note that there is no branching of the afferent arteriole forming the glomerular capillary. *Adapted from Braun (unpublished).*

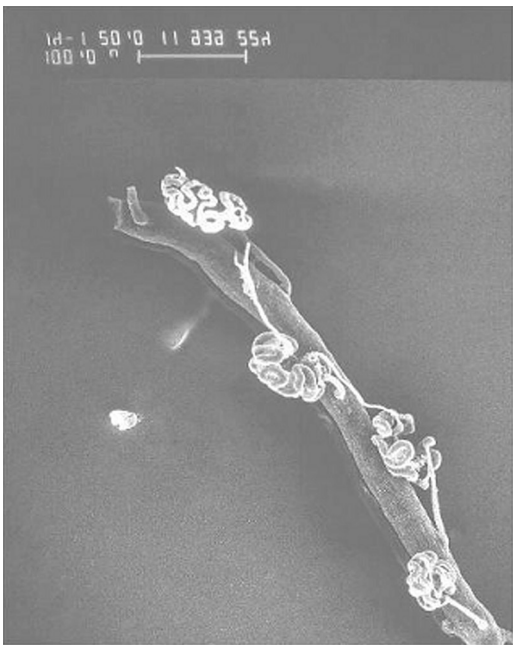

FIGURE 12.7 Scanning electron micrograph of renal vasculature showing a methylacrylate cast of a looped nephron glomerular capillary. Note simplicity of the network and/or the lack of anastomotic interconnecting branches. *Adapted from Braun (unpublished).*

Mammalian red blood cells are quite deformable and undergo "tank treading" as they pass along the small capillaries (Skotheim and Secomb, 2007).

Data on the structure of the filtration barrier formed by endothelial cells and the visceral layer of the Bowman's capsule of birds show that it is somewhat less restrictive than that of mammals (Casotti and Braun, 1996). The "pores" in the slit diaphragm of the chicken were found to be 40–80% larger than values reported for mammals. Moreover, the data indicated that there is less of a polyanionic charge on the filtration barrier of the chicken compared to data for mammals (rat) (Casotti and Braun, 1996). The combination of these two parameters suggests the filtration barrier of birds will allow somewhat larger molecules to pass and enter the filtrate. Indeed, avian ureteral urine contains on average 5 mg/mL protein, which is 100 times more than the urine of a typical mammal (Janes and Braun, 1997).

12.2.2 Glomerular Filtration

The movement of fluid and small solutes across the filtration barrier is a function of hydrostatic pressure produced by the heart. It favors movement across the barrier and colloid osmotic pressure exerted by plasma proteins, which opposes this movement. This is a passive process resulting only from the physical parameters mentioned. The rate of glomerular filtration by single nephrons (SNGFR) is rather low when birds and mammals of similar body mass are compared, but an allometric analysis shows that the total kidney glomerular filtration rates (GFR) are not significantly different between these two groups (bird $GFR = 1.24\,BM^{0.694}$, $n = 11$; mammal $GFR = 1.24\,BM^{0.765}$, $n = 4$; where BM is body mass in kg; Yokota et al., 1985). The lower SNGFR of avian kidneys is offset by a larger number of nephrons. For example, the desert quail (BM 140 g) kidney has approximately 48,000 nephrons and the laboratory rat (BM 300 g) has approximately 32,000.

SNGFRs have been quantified for only two avian species: the desert quail and the European starling (Braun and Dantzler, 1972; Laverty and Dantzler, 1982). The techniques used to make these measurements in the quail and starling were quite different. Using the sodium ferrocyanide technique, which theoretically allows for quantification of the SNGFRs of all the nephrons in the kidney at one point in time, the average SNGFR for the small loopless nephrons was 6.4 nL/min; for the larger looped nephrons, the average was 14.6 nL/min for the desert quail (Braun and Dantzler, 1972). Measurements for the starling were done by *in vivo* micropuncture, which allows the SNGFRs of only the nephrons at the very surface of the kidney to be quantified (Laverty and Dantzler, 1982). These nephrons at the surface are the smallest loopless nephrons. SNGFR values for these nephrons ranged from 0.25 to 0.5 nL/min. The data obtained by the sodium ferrocyanide technique represents an average value for the entire size range of loopless nephron. As mentioned, the transition from the smallest loopless nephrons to the largest loop nephrons is a gradual one. The distinction between the two types is made on the presence or absence of a loop of Henle and the nature of the connection to a collecting duct.

Whole-kidney GFRs of birds are more variable than those of mammals, with the state of hydration being the principle

TABLE 12.2 Orders of Birds Possessing Salt Glands

Order	Habitat	Order	Habitat
Tinamiformes	Tropical rainforests, to grasslands	Gruiformes	Aquatic, rainforests to grassland
Rheiformes	South American grasslands	Charadriiformes	Near water
Struthioniformes	Deserts to scrubland forests	Gaviiformes	Aquatic Fresh water ponds and lakes
Casuraiiformes	Tropical to temperate forests	Columbiformes	Grasslands and deserts
Aepyornithiformes	Madagascar	Psittaciformes	Tropical and subtropical
Dinornithiformes	Semi-arid and high rainfall ecological zones	Cuculiformes	Forests, savannas and wetlands
Podicipediformes	Freshwater ponds and lakes	Strigiformes	Cosmopolitan distribution
Sphenisciformes	Oceanic or coastal habitats	Caprimulgiformes	Grasslands, semi-arid deserts, woodlands
Procellariiformes	Islands, deserts	Apodiformes	Coniferous forests, desert, grassland
Pelecaniformes	Oceans, seashores	Coliiformes	Deciduous forests, grasslands
Anseriformes	Wetlands	Trogoniformes	Woodlands, grasslands, savannas
Phoenicopteriformes	Large lakes, shallow waters, inland or coastal	Coraciiformes	Tropical rainforests, woodlands near water, seacoasts
Ciconiiformes	Wetlands, swamps, forest streams,	Piciformes	Forests, woodlands
Falconiformes	Grasslands, open woodlands	Passeriformes	Grasslands, woodlands, scrublands, forests, deserts, mountains
Galliformes	Forests, deserts, scrub forests, cultivated lands		

Data on salt glands from Peaker and Linzell (1975).

determinate of this variation (Table 12.2). With water deprivation, the GFR can decrease by as much as 65% from the value at full hydration. These changes in GFR appear to be regulated in part by the avian antidiuretic hormone arginine vasotocin (AVT). Studies on desert quail, in which an osmotic load was administered by sodium chloride infusion, showed that GFR decreased with an increasing osmotic load and that this decrease could be attributed to a decreased number of filtering loopless nephrons (Braun and Dantzler, 1972). These data suggested that AVT exerts its effect through the vasculature, a vascular antidiuresis. In contrast, the infusion of increasing amount of AVT in conscious domestic fowl revealed the primary effect of AVT was on the renal tubules, presumably the collecting ducts (Figure 12.8, Stallone and Braun, 1985). Taken together, the data suggest that AVT functions to conserve water by affecting the renal vasculature and tubule epithelium. The GFR of some small birds (sun birds and probably hummingbirds) can change diurnally, driven primarily by the need to excrete large amounts of fluid containing metabolic substrates that was consumed to meet their energy requirements (del Rio et al., 2001).

The renal blood flow (RBF) and GFR of birds is autoregulated over a wide range of systemic blood pressures (Wideman, 1991). The regulation of renal blood flow has only been studied in the domestic fowl, where it was found that RBF and GFR were maintained at systemic blood pressures as low as 50 mm Hg.

12.2.3 Ion Transport by Renal Tubules

In general, the avian proximal renal tubule functions similarly to that of other vertebrate because it isosmotically reabsorbs a large fraction of the fluid that is filtered at the renal corpuscle. The fluid and electrolyte transport capabilities of the avian proximal renal tubule have been studied directly using *in vivo* micropuncture techniques, isolated tubules perfused *in vitro*, and primary cell cultures, as well as being inferred from whole animal studies (Brokl et al., 1994; Laverty and Alberici, 1987; Sutterlin and Laverty, 1998). Whole animal studies indicate that the proximal tubules as an aggregate reabsorb about 60% of the glomerular filtrate (Braun and Dantzler, 1972). To the contrary, data from *in vivo* micropuncture studies suggest that only 24% of the filtered load is reabsorbed by the proximal tubule (Laverty and Dantzler, 1982). This large discrepancy again may be due the sampling of fluid from the very small loopless nephrons at the surface,

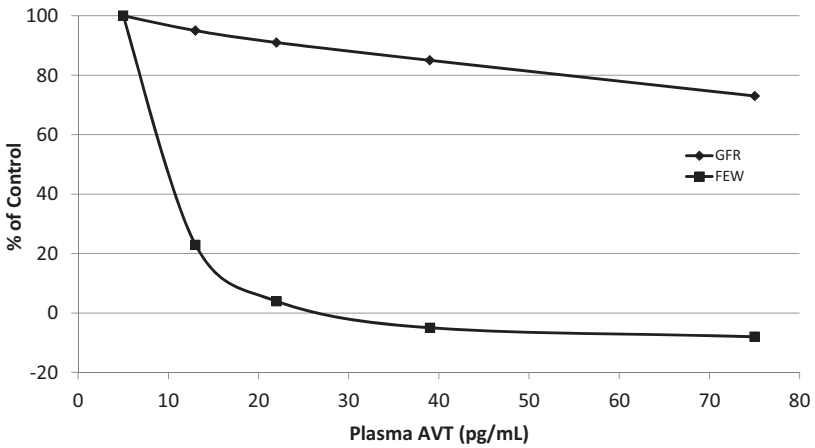

FIGURE 12.8 The effect of arginine vasotocin (AVT), the avian antidiuretic hormone, on free water clearance and glomerular filtration rate in domestic fowl. Note that free water clearance declines prior to a significant charge in the glomerular filtration rate suggesting that AVT has an effect on the renal tubules before it effects glomerular filtration. *Modified from Stallone and Braun (1985).*

which is a limitation of micropuncture techniques. Moreover, only the very early segment of the proximal tubule can be sampled because it is at the surface of the kidney. With this caveat, micropuncture data do indicate that proximal tubule reabsorption occurs in an isosmotic manner.

The avian kidney apparently has a very large capacity to reabsorb filtered glucose. Because birds have very high plasma glucose concentrations and GFRs that do not differ from that of mammals, the filtered load of glucose is very high (filtered load = plasma glucose concentration multiplied by GFR) (Morgan and Braun, 2001). Further, very little glucose appears in the ureteral urine. In mammals, glucose is reabsorbed by sodium-glucose cotransporters located in the proximal tubules (SGLTs), which have a finite capacity to reabsorb glucose (tubular maximum). Because the filtered load of glucose in birds is very high, the SGLTs must be upregulated in the avian kidney. The SGLTs of the avian kidney have not yet been studied.

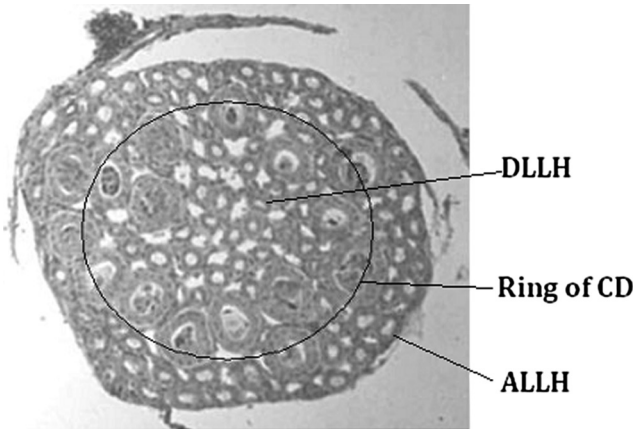

FIGURE 12.9 Cross section of paraffin embedded tissue of a medullary cone of the desert quail kidney. Note the ring-like pattern of collecting ducts with thick limbs of Henle's loop located peripheral to the collecting ducts and thin limbs tending to be located in the center of the collecting duct ring. *Adapted from Braun (unpublished).*

12.2.4 The Renal Medulla

The medullary region of the avian kidney is made up of a variable number of small tapering units called medullary cones (Figure 12.2). The number and size of the individual cones is somewhat species and habitat dependent (Johnson and Mugaas, 1970). Moreover, the size of the cones is not uniform throughout any given kidney, with the longer and larger cones generally found in the anterior division of the kidney (Johnson and Mugaas, 1970). Each cone terminates as a single, large collecting duct; several of these ducts join to form a primary ureteral branch, which enters the ureter proper on the ventral surface of the kidney. The medullary cones function as independent units because the output of one cone does not enter that of a second cone; that is, the cones function in a parallel manner and not in series. This ureteral anatomy is different from mammalian kidneys, where there is a discontinuity between the collecting ducts and the renal calyx and eventually the ureter. Therefore, in the avian kidney, there is a continuous duct from the smallest loopless nephron to the ureter. The functional significance of this anatomy is explained here.

There is definite pattern to the arrangement of the tubular and vasculature elements within the medullary cones. In the upper one-third of the cone when viewed in cross section, the collecting ducts form a ring with the thin limbs of the loop of Henle tending to be situated outside of the ring and the thick limbs of Henle inside the ring formed by the collecting ducts (Figure 12.9; Johnson and Mugaas, 1970). The vasa recta within the cones appear to form a lace-like pattern with few long, straight channels (Figure 12.10).

The pars recta of the proximal tubules enter the medullary cones to form the descending limb of Henle's loop. The transition from the pars recta to the thin descending limb of Henle's loop (DLLH) is very abrupt

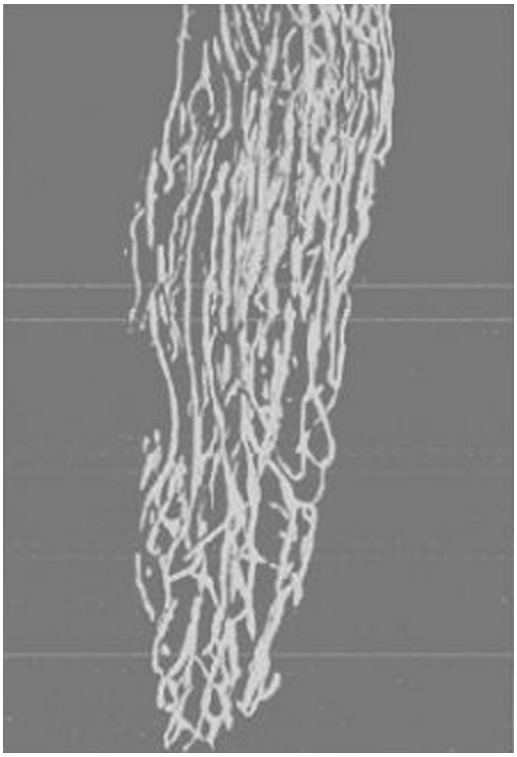

FIGURE 12.10 The blood supply and venous drainage shown by a microfil cast of the vasa recta from within a medullary cone of the desert quail kidney. The capillaries form a lace-like pattern within the medullary cone with few straight channels. *From Braun and published in previous edition of Sturkie.*

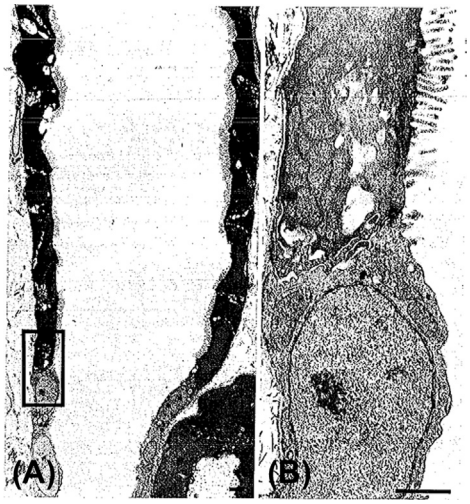

FIGURE 12.11 An electron micrograph of a longitudinal section of a renal tubule showing the abrupt transition from the proximal straight tubule to the thin descending loop of Henle. Inset shows transition at increased magnification. Note the presence and absence of microvilli from one cell to the next. *Adapted from Braun and Reimer (1988).*

(Figure 12.11; Braun and Reimer, 1988). The cuboidal cells of the pars recta give way to very low profile cells (type 3 epithelia), forming the DLLH (Braun and Reimer, 1988). The epithelium of the loop always thickens before the formation of the hairpin turn, with the thick descending limb being approximately 15% of the total DLLH length (Figure 12.3; Casotti et al., 2000). This morphology of the DLLH is markedly different from most nephrons of mammal kidneys, where the hairpin turn of the loop is formed by thin epithelium, with thick cells appearing at a variable point on the ALLH. The structure of the DLLH of the avian kidney is important to the CCM system, which functions within the medullary cones (Layton et al., 2000). NaCl transport from ascending limb thick segments contributes approximately 70% of urine concentrating capacity of the avian medullary cone (Layton et al., 2000). The ALLHs traverse up to the base of the cone, at which point they enter collecting ducts.

12.2.5 Concentration and Dilution of Urine

Along with mammals, birds have the capacity through their kidneys to conserve body water by eliminating solutes in excess of water; that is, the kidneys can produce urine with osmolalities that have greater osmotic potential than the plasma. Both groups of vertebrates have renal morphologies that permit the functioning of CCM systems. However, the details of the systems differ between birds and mammals. As described earlier, the avian renal medulla consists of many small units or medullary cones, within which there is a parallel arrangement of tubules. In these tubules, loops of Henle, (ascending and descending) collecting ducts, and vasa recta, there is countercurrent flow of fluid.

The primary excretory product of nitrogen in birds, uric acid, plays no role in the solute composition of the medullary cones because it is virtually insoluble in aqueous solutions. Moreover, birds excrete very little nitrogen as urea. On the other hand, urea, as the primary nitrogenous excretory product of mammals, makes up about 50% of the solutes in the renal medulla. In the avian kidney, there is a solute gradient from the base of the medullary cones to their tips, which is made up entirely of sodium chloride (Skadhauge and Schmidt-Nielsen, 1967). Sodium chloride is deposited in the cone interstitum by active transport from the thick segments of the loop of Henle, including the part before the hairpin turn is formed (Nishimura et al, 1986). From the interstitum, the sodium chloride passively enters the descending limb of the loop of Henle (DLLH) (Figure 12.12). Sodium chloride is thus recycled within the medullary cone. The avian DLLH has much higher diffusional permeability to sodium chloride than the DLLH of the hamster kidney (31.7×10^{-7} to 2.9×10^{-7} cm^2/s; Nishimura et al., 1986). The removal of sodium chloride from the ALLH which is impermeable to water, serves to dilute the tubule fluid as it moves to the distal convoluted tubule. In the cortical region of the kidney, the fluid in the distal convoluted tubule can equilibrate with the interstitum by water removal before the fluid enters collecting ducts to

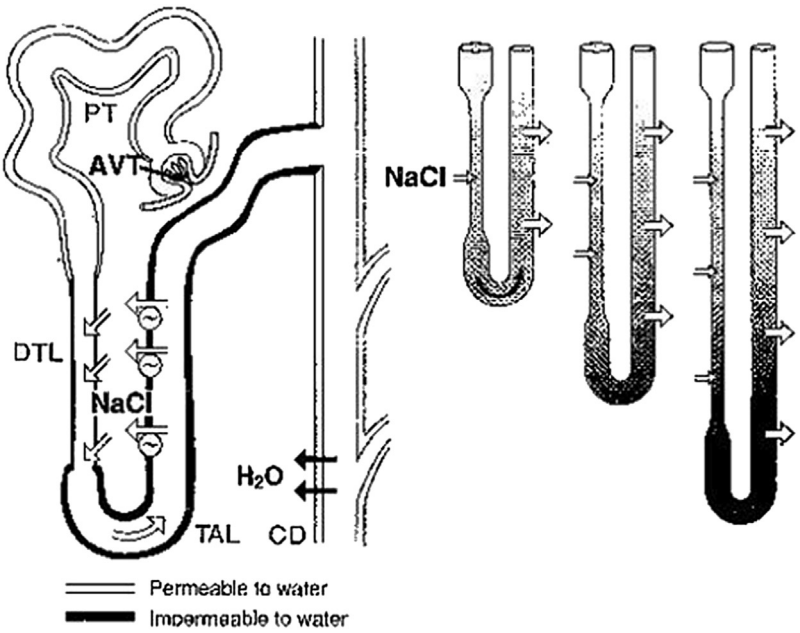

FIGURE 12.12 Model of the avian countercurrent multiplier system. Sodium chloride is actively extruded from the thick portions of Henle's loop and passively enters the thin descending limb of Henle from the high concentrations in the medullary interstitum. The process renders the fluid in the ascending limb dilute relative to the interstitum. In the presence of antidiuretic hormone (AVT), the fluid in collecting ducts equilibrates with the concentrated interstitum to become concentrated. *From Nishimura and published in previous edition of Sturkie.*

re-enter the medullary cone. In the collecting ducts within cones, the isosmotic tubule fluid is exposed to an increasing osmotic gradient and becomes hyperosmotic as it loses water to the cone interstitum. Water movement across the tubules in the cones is controlled by the antidiuretic hormone of birds' AVT.

Water flux across the tubules within the medullary cones is through water channels or aquaporins (AQPs). AQPs 3 and 4 have been localized to the basolateral membrane of collecting duct cells and the AVT-sensitive AQP 2 has been identified subapically in collecting duct cells (Nishimura, 2008). In contrast to mammalian renal medullary tissue, the avian collecting ducts are less sensitive to the antidiuretic hormone AVT in the promotion of water flux (Nishimura, 2008).

Compared with the kidneys of mammals, those of birds do not elaborate highly concentrated urine. The maximum urine to plasma osmolar ratios (U/Posms) of mammals range from 1 (mountain beaver) to 25 (desert rodents), whereas the maximum ratio for birds is approximately 2.5 (Braun, 1993). The lower capacity of birds is related to the architecture of their kidneys and the lack of urinary bladder, in which urine is stored until it can be conveniently excreted. The output from avian kidneys enters the cloaca, the terminal portion of the gastrointestinal tract. It does not remain in the cloaca but is moved by a retrograde peristalsis into the colon and cecae located at the junction between the colon and ileum. The urine is thus brought into contact with a second transporting epithelium.

As fluids move across the epithelium of the colon on concentration gradients, the lack of the ability to produce highly concentrated urine prevents the loss of body fluids by the movement of fluids in a serosal-to-mucosal direction. Data indicate that the colonic epithelium can move fluid in a mucosal-to-serosal direction against a concentration gradient of 200 mOsm/kg H_2O (Skadhauge and Kristensen, 1972). The bottom line is that the avian kidney and lower gastrointestinal tract function in concert to maintain fluid and electrolyte balance. The kidney should not produce a urine that is significantly more concentrated than the plasma as a mechanism to conserve body water.

As mentioned above, the anatomy of the avian kidney does not serve well the capacity to elaborate markedly concentrated urine. The urine of well-hydrated birds is isosmotic or only slightly hyperosmotic to the plasma. When water deprived, birds on average produce urine that is about 2.0 times more concentrated that the plasma (Table 12.3). Urine-to-plasma osmotic ratios for birds can be somewhat misleading because the plasma osmolality of birds is much more labile than that of mammals and tends to increase with water deprivation (Braun and Dantzler, 1972). There is one report in the literature of the salt marsh Savannah sparrow achieving 4–6 U/Posm when the birds were acclimated to drinking seawater (Poulson and Bartholomew, 1962). Inspection of these data suggests that the birds were not absorbing the saltwater across the gastrointestinal tract into the circulation to be excreted by the kidneys, but that the water was passing along the gastrointestinal tract and excreted. Water not being absorbed has also been observed in hummingbirds (del Rio et al., 2001).

TABLE 12.3 Glomerular Filtration Rates (GFR) of Selected Birds

Species	GFR (mL/kg/min)
Domestic fowl	2.5
Desert quail	1.8
Mallard duck	2.5
Canadian goose	1.2
Glaucous-winged gull	1.9
European starling	2.8
Budgerigar	4.4
Turkey	1.3

Data from Braun (1982).

TABLE 12.4 Urine-to-Plasma Osmolality Ratios for Selected Birds

	U/P Ratio	
Species	Ureteral Urine	Voided Fluid
Domestic fowl	2.0	
Ring-necked pheasant	1.5	
Kookaburra		2.7
Singing honey eater		2.4
Red wattlebird		2.4
Bobwhite quail		1.6
California quail		1.7
Gamble's quail		2.5
Senegal dove		1.7
English sparrow	1.7	
Song sparrow	2.2	
White crown sparrow	2.1	
White-winged dove	1.8	
Emu		1.4
Galah		2.5
Glaucous-winged gull	1.9	
Savannah sparrow	1.6	

Table modified from Braun (2009).

A second study of salt marsh Savannah sparrows carried out in the field suggested the U/Posm in these birds was 1.2 and that they did not take in seawater; rather, they stripped freshwater as dew from plant leaves (Goldstein et al., 1990).

12.2.6 Nitrogen Excretion

The major end product of nitrogen catabolism in birds is uric acid, accounting for 70–80% of the nitrogen excreted in the ureteral urine with other compounds such as urea, creatinine, and amino acids contributing minor amounts to total nitrogen excretion. Under some circumstances, such as high fluid intake required to maintain energy balance, nitrogen in the form of ammonia can account for more than 50% of the nitrogen excreted in the urine (Preest and Beuchat, 1997; Tsahar et al., 2005).

Uric acid as an end product of nitrogen catabolism is a very efficient form of excretion because it contains four nitrogen atoms and has a very low aqueous solubility compared to other nitrogen excretory products (Table 12.4). However, the metabolic cost of uric acid synthesis (nine adenosine triphosphates) is high compared with that of urea and ammonia. The low aqueous solubility has the potential of causing precipitation problems in the plasma, but using the Henderson–Hasselbach equation it can be calculated that 98% of uric acid in the plasma at pH 7.4 exists as the anionic form. The salts of uric acid have much higher aqueous solubility than the protonated form of the molecule (Table 12.4). The concentrations of urate in avian plasma vary somewhat but generally do not exceed 1.0 mmol/L. The average concentration of uric acid/urate of approximately 0.65 mmol/L is well within the solubility limit of sodium urate (8.32 mmol/L), which prevents crystal formation.

Urate, being a relatively small molecule (186 MW), freely passes the glomerular filtration barrier; however, five times more urate is excreted than is filtered. This suggests that urate is avidly secreted by the renal tubules. Indeed, data derived from different preparations substantiates this point (Brokl et al., 1994; Laverty and Dantzler, 1983; Dudas et al., 2005). *In vivo* micropuncture studies of the proximal tubules from superficial loopless nephrons demonstrated a marked secretion of urate. Moreover, preparations of isolated, perfused proximal tubules from deeper nephrons support the micropuncture data (Brokl et al., 1994). Data from the isolated, perfused proximal tubules also demonstrated that urate is taken up at the basolateral membrane against an electrochemical gradient and that this uptake could be competitively blocked by para-aminohippuric acid. The exit from the cell across the apical membrane is down an electrochemical gradient (Figure 12.13).

Once uric acid/urate enters the proximal tubule, there is the potential for crystal formation as the intraluminal concentration increases sufficiently to exceed the solubility limit of even the salt forms. The increased concentration is caused by the avid tubule secretion of urate and the normal removal of fluid from the tubule to recover water that was filtered at the glomerulus.

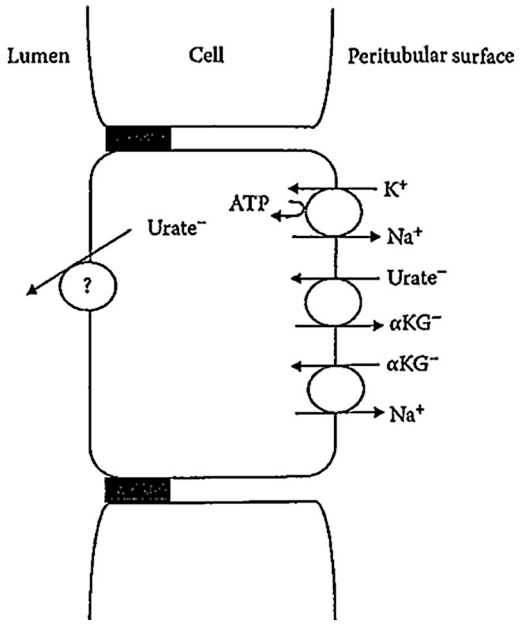

FIGURE 12.13 The suggested mechanism of urate secretion by the proximal renal tubules. Urate enters the cell on an organic acid transport protein (OAT1) in exchange for alpha-ketoglutaric acid. The movement of urate across the apical membrane into the lumen is facilitated by an unidentified carrier protein. *From Braun (2009).*

12.2.7 Form of Uric Acid in Avian Urine

Because of the low aqueous solubility of uric acid and the salts of uric acid, the potential exists for them to precipitate from solution. As mentioned above, due to water abstraction and urate secretion, the concentration of the salts in the proximal tubule exceeds their solubility limits. Crystal formation is prevented by the urate anion binding to serum albumin in the tubule lumen. A small amount of albumin passes through the glomerular filtration barrier, as this barrier in birds appears to allow some macromolecules such as albumin to pass (Casotti and Braun, 1996). Indeed, avian ureteral urine contains 100 times more protein than the urine of mammals (5 mg/mL versus 0.05 mg/mL; Janes and Braun, 1997). Early in the proximal tubule, small, spherical structures begin to form (Figure 12.14). The final ureteral urine contains an array (1–14 μM diameter) of these spherical structures (Figure 12.15). Chemical analysis of these spheres shows that they consist of about 65% urate; no crystals of uric acid are observed when spheres are sectioned and viewed with an electron microscope (Figure 12.16). This suggests a chemical binding of urate to serum albumin, which takes urate out of solution and prevents crystal formation (Figure 12.17). Moreover, because urate is not in solution, it does not contribute to the osmolality of the final urine, as does urea in the urine of mammals. This highlights the point that birds and mammals cannot be directly compared with respect to urine-to-plasma osmolar ratios because their respective end products of nitrogen metabolism contribute unequally to the total osmolality of the urine.

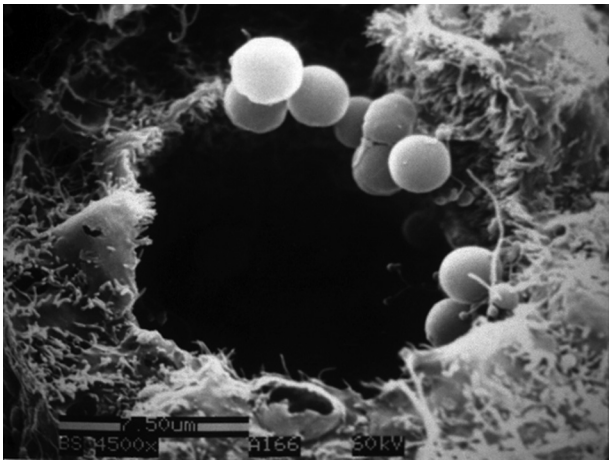

FIGURE 12.14 Urate containing spheres as they form in the proximal tubule (as indicated by the presence of the brush border) of a nephron. *Adapted from Braun (unpublished).*

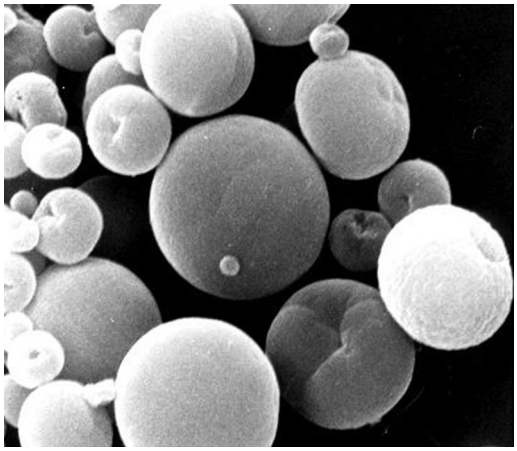

FIGURE 12.15 Scanning electron micrograph (SEM) of ureteral urine. The preparation was made by allowing ureteral urine to air dry on an electron microscope stub. Note the complete absence of urate crystals in the image. *Adapted from Braun (unpublished).*

Urine, along with the urate spheres, is conveyed to the urodeal compartment of the cloaca. All components of the urine do not remain in this part of the cloaca but are moved by retrograde peristaltic action into the colon and digestive ceca (Figure 12.18; Brummermann and Braun, 1995). The urine moves around a central fecal core and comes into contact with the epithelium of the colon and a large, diverse population of bacteria embedded in the brush border of the cells. This population of bacteria was studied and classified by Barnes and Impey (1970) and was found by Campbell and Braun (1986) to flourish on a culture containing only uric acid. Sodium dodecyl sulfate polyacrylamide gel electrophoresis gels of ureteral urine show large amounts of protein of varying molecular mass, with serum albumin being the densest mass (Figure 12.19; Janes and Braun, 1997). Similar gels of fluid excreted by birds show little or no protein (Figure 12.20; Janes and Braun, 1997). The protein is

The cloaca is at the right (4) and the "rings" (1–3) leading from the cloaca show smooth muscle contractions producing the retrograde peristalsis. *Adapted from Brummermann and Braun (1995).*

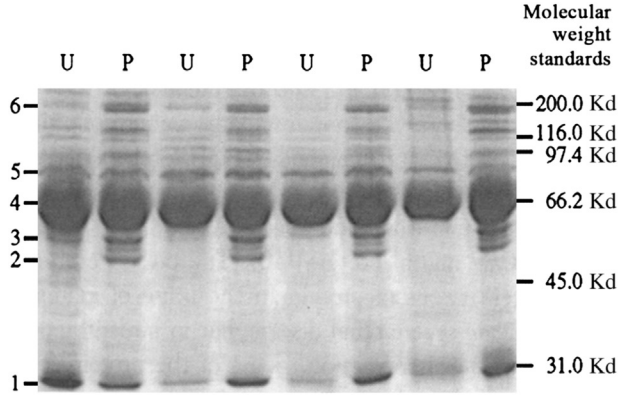

FIGURE 12.19 SDS-PAGE gel of ureteral urine and plasma samples from a domestic fowl. Note the similarity of the bands in the urine and plasma lanes. The band at 65 Kd is serum albumin. *Adapted from Janes and Braun (1997).*

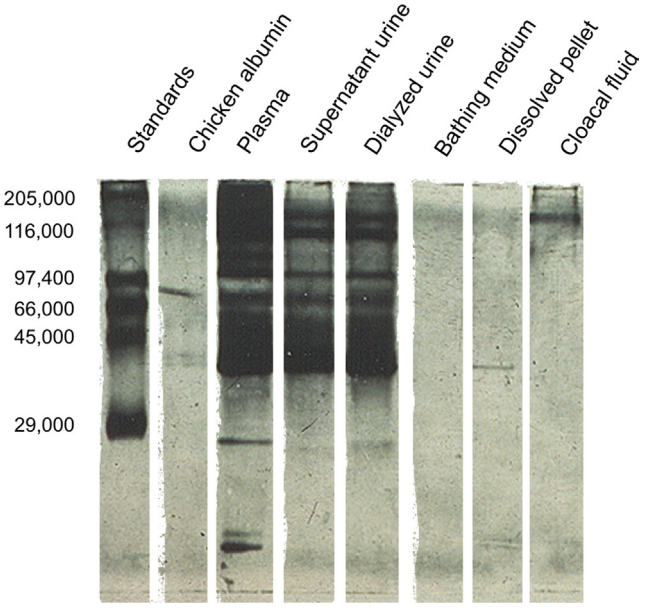

FIGURE 12.20 SDS-PAGE gel of plasma and excreted urine from a domestic fowl. Note the lack of bands in the lane containing the excreted urine. *Modified from Janes and Braun (1997).*

degraded to amino acids, di- and tri-peptides, and bacteria to produce short-chain volatile fatty acids that are absorbed by the colonic epithelium. The fatty acids serve as an energy source to enhance sodium transport and the other organics serve as substrates for the sodium/glucose cotransporter (Rice and Skadhauge, 1982). Thus, the large amount of protein (5 mg/mL) in ureteral urine is not excreted and lost by the animal. Not only is the free protein in the urine degraded, but also that binding urate in formation of the small spheres.

The uric acid molecule is also degraded by the bacteria within the lower gastrointestinal tract; among the products formed are ammonia and glutamic acid. Studies with radiolabeled glutamine have shown that it appears in the blood of the coccygeal mesenteric vein (Karasawa and Maeda, 1992). This vein enters the renal portal system, which conveys blood to the peritubular surfaces of the renal tubules. At this point, the glutamine can be transported by the basolateral membrane of cells, where the molecule can be de-ammoniated. The ammonia can be secreted into the tubule lumen to bind hydrogen ions to form neutral ammonia salts to be excreted. Thus, what was to be an excretory product can be recycled to function in acid/base balance. The recycling of the nitrogen of uric acid is very important in those birds, such as nectarivores and frugivores, which have diets low in nitrogen content.

12.3 THE AVIAN LOWER GASTROINTESTINAL TRACT

The lower gastrointestinal tract of birds (cloaca, colon, and digestive ceca) plays an important role in avian osmoregulation, although this role is variable depending on taxonomic group. As described earlier, urine produced by the kidneys enters the cloaca—specifically, the urodeum of the cloaca. The fluid is moved by a retrograde peristalsis into the coprodeum of the cloaca and farther into the colon and digestive ceca (Figure 12.18). The fluid is moved over and around a central fecal core and brought in close contact with the epithelium of the lower gastrointestinal tract. Brummermann and Braun (1995), using domestic fowl as experimental animals, demonstrated that the control of the retrograde peristalsis resides in the lower gastrointestinal tract and not with central osmoreceptors located in the hypothalamus. These experiments showed that the tonicity of the fluid entering the cloaca is monitored. If its tonicity is more than 200 mOsm/kg H_2O higher than that of the plasma, the retrograde peristalsis is slowed or stopped entirely. The *in vivo* perfusion of the colon of domestic fowl with hyperosmotic NaCl solutions decreased absorption by the colon, supporting the observation that motility was stopped by hyperosmotic solutions in the cloaca (Skadhauge and Kristensen, 1972).

Recent data generated by Vranish and Braun (2011) indicate that the element sensing the osmolality of the ureteral urine in the cloaca is a member of the transient receptor potential (TRP) family, a vanilloid type receptor; TRPV4 a moderately selective Ca^{2+}channel (Clapham et al., 2002). Vanilloid receptors are known to respond to noxious stimuli such as heat, pain, and extreme pH (Clapham et al., 2002). TRPV4 is unique in that it is the only vanilloid receptor shown to respond to deformation, such as what occurs when cells are exposed to changes in their osmotic environment (Clapham et al., 2002). TRPV4 has a basal level of inward Ca^{2+} current in isotonic conditions. When placed in hypotonic media, Ca^{2+} influx increases and a hypertonic environment leads to slowed or completely halted Ca^{2+} current (Plant and Strotmann, 2007). This protein is expressed in many mammalian tissues, including thick ascending limb and distal convoluted tubules of nephrons, alveolar epithelia, mechanosenstive neurons in the ear and eye, and the gastrointestinal tract (Brierley et al., 2008; Cohen, 2007; Holzer, 2007; Liedtke and Simon, 2004; Plant and Strotmann, 2007). Although the signaling mechanism of this channel is not fully understood, its transduction of osmolarity information—and in most cases, initiation of local responses—make it a good candidate for the sensing element in the cloaca of birds.

The transport activity of the avian colonic epithelium is modulated by several hormones. Data show that dietary salt intake affects sodium transport by electrogenic sodium channels (ENaC) in the lower intestine of the domestic fowl (Laverty and Skadhauge, 1999; Laverty et al., 2006). A low-sodium diet increases the plasma aldosterone levels, leading to a high rate of electrogenic sodium absorption in both coprodeum of the cloaca and colon. The effect in the coprodeum is marked because when aldosterone plasma concentrations are low there is little sodium transport. However, the effects on the colon are more complex: on a high-sodium diet, sodium absorption is still present but is mediated by sodium coupled co-transport with organic substrates, such as amino acids and glucose and not by EnaC channel activity. This transporter appears to be a member of the SGLT family of epithelial transporters (Laverty et al., 2001). The organic molecules are formed from the bacterial breakdown of protein that enters the lower gastrointestinal tract as a component of the urine. The continued transport of sodium facilitates the recovery of urinary water. Thus, the colonic co-transporters play an important physiological role not only in osmoregulation, but also in nutrition by assimilation of substrates derived from bacterial fermentation of protein and uric acid in the lower intestine.

A number of avian taxonomic groups (Pelecaniformes, Ciconiiformes, Falconiformes, Columbiformes, and Passeriformes) have small ceca that have been referred to as rudimentary or nonfunctional (Clench, 1999). However, a study of the house sparrow showed that these ceca have a very complex internal structure. There is a central channel with numerous side branches, giving them a bottle-brush appearance (Figure 12.21; Reyes and Braun, 2005). These channels are

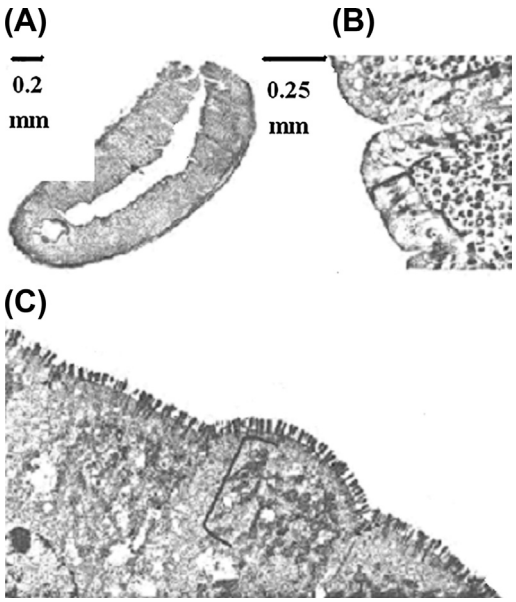

FIGURE 12.21 Histological preparation of a House Sparrow cecum. (A) At the upper left is a sagittal section of the whole structure showing a central channel. Cytological detail is depicted at two higher magnifications (B and C). Note the dense brush border (BB) and cells with a dense population of mitochondria highlighted in bracket. TJ, tight junctions. The cytological detail suggests that these small structures are not rudimentary. Moreover, the cells show high level ATPase activity. *Adapted from Reyes and Braun (2005).*

all lined with epithelia that have a very dense brush border and the cells show a very dense presence of mitochondria. This complex architecture strongly suggests that the small ceca are not rudimentary but may play an osmoregulatory role.

12.4 THE AVIAN SALT GLAND

As previously discussed, the avian kidney has a limited capacity to excrete solutes in excess of water—that is, to produce urine that is significantly hyperosmotic to plasma. Those birds that have a limited intake of freshwater do not rely entirely on the kidney to eliminate excess ions (primarily sodium) in the process of maintaining the homeostasis of the extracellular fluid. The alternate route for ion regulation is salt glands that can excrete very concentrated sodium chloride solutions. The location in the head of the birds can differ slightly: some of the glands are within the orbit of the eye, whereas others are located superior to the orbital and are commonly referred to as nasal salt glands (Peaker and Linzell, 1975). As presented in Table 12.5, salt glands have been identified in at least 15 orders of birds from a range of habitats where fresh drinking water is limited or the intake of high concentrations of electrolytes is part of the normal diet, such as carnivores or birds from desert regions of the world.

12.4.1 Structure of the Salt Glands

The anatomy of salt glands is complex, but it follows a pattern of parallel arrangement of epithelial tubules and blood

TABLE 12.5 Solubility of Nitrogen-Containing Compounds

Compound	Solubility (mmol/L)
Uric acid	0.381
Ammonium urate	3.21
Sodium urate	8.32
Potassium urate	14.75
Urea	16,650
Ammonia	∞

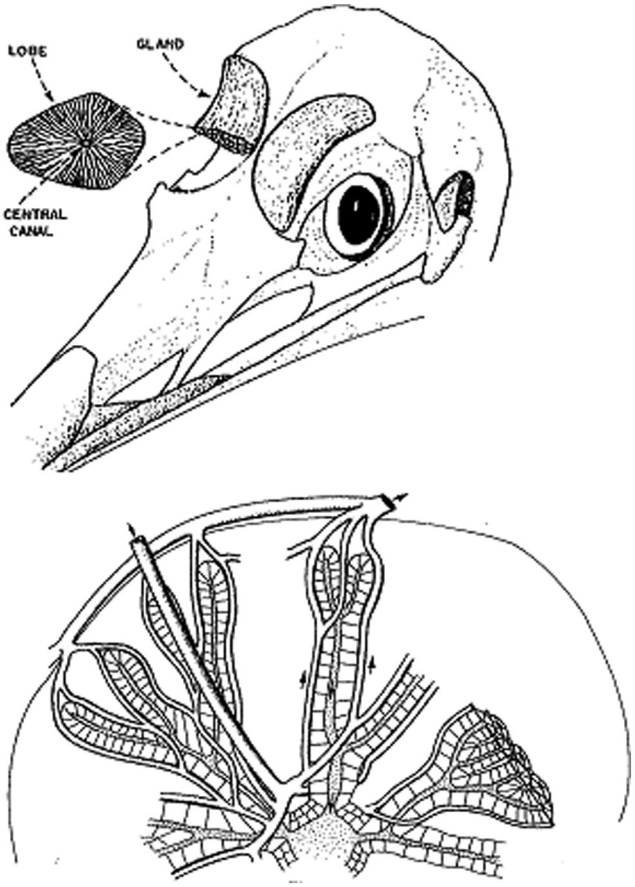

FIGURE 12.22 Upper illustration shows the location of the salt secreting gland of some birds and the lower illustration shows the counter flow pattern of blood vessels and secretory tubules. Arrows show direction of countercurrent flow in the secretory tubules and blood vessels. *Modified from Schmidt-Nielsen (1960).*

vessels, which permits counter direction of fluid flow as is present within the renal medullae of birds and mammals (Figure 12.22; Gerstberger and Gray, 1993). The glands are formed from a series of secretory tubules that coalesce like the branches of a tree. The tubules begin as blind end ducts, the cells of which display the features of a strong secretory epithelium—numerous basolateral infoldings and large

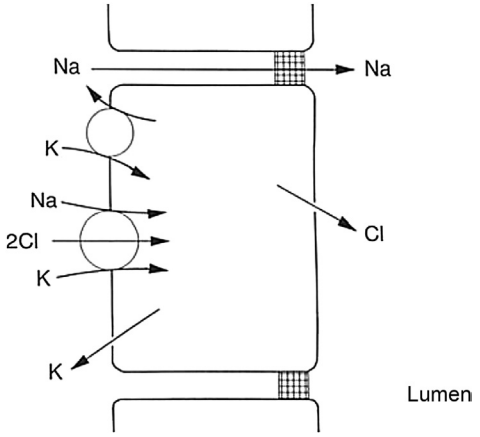

FIGURE 12.23 The suggested mechanism by which salt glands produce a secretion of concentrated sodium chloride. The process is driven by the Na/K 2Cl transporter. Chloride is extruded across the apical cell membrane with sodium moving passively through the paracellular channel. *From Shuttleworth (1995).*

numbers of mitochondria. The tubules coalesce to form two large ducts, which in most birds drain into the nasal cavity.

12.4.2 Product of Salt Gland Secretion

The salt glands produce a hyperosmotic fluid, such that the ions (primarily sodium chloride) are secreted with less water than that in which they were originally consumed. This leads to osmotically free water that is retained in the extracellular fluid. The proposed mechanism of ion secretion by the cells of the salt glands is illustrated in Figure 12.23 (Shuttleworth, 1995). The process is driven by gradients produced by the Na^+/K^+ exchange transporter on the basolateral side of the cells. The typical Na^+/K^+2Cl^- mechanism on the basolateral membrane moves Cl^- into the cell. The key process is the secondary active transport of Cl^- across the apical membrane of the cells, with Na moving passively through intercellular spaces. The net result of the process is the secretion of a fluid high in NaCl concentration into the lumen of the salt gland tubule.

12.4.3 Control of Salt Gland Secretion

Increases in the osmolality and volume of the extracellular fluid are stimuli that initiate or drive secretion by the cells of the salt gland ducts. These are due primarily to increases in sodium chloride consumption, which can in turn cause expansion of the extracellular fluid by drawing water from the intracellular compartment (Ash et al., 1969; Fänge et al., 1958). The change in extracellular fluid is reflected in changes in plasma composition, which can be detected by the central osmoreceptors. Cholinergic fibers running in the secretory nerve reach not only the tubules of the salt gland but also blood vessels running parallel to the tubules (Babonis and Brischoux, 2012). This leads to enhanced secretory activity and increased blood flow to facilitate secretion by delivering substrates to the tubules. Hormones appear not to initiate salt gland secretion, but they may play an important role in modulating the rate of secretion. For example, angiotensin II has been shown to inhibit secretion, whereas atrial natriuretic peptide has a positive effect on the gland (Gray et al., 1997).

With a kidney that does not produce large amounts free water by elaborating urine significantly more concentrated than the plasma, the capacity of salt glands to excrete excess osmotically active ions allows birds to inhabit a wide range of environments or habitats—some of which have limited sources of freshwater.

Chapter 13

Respiration

Frank L. Powell
Division of Physiology, Department of Medicine, University of California, San Diego, CA, USA

13.1 OVERVIEW

The primary function of the respiratory system is *gas exchange*—delivering oxygen from the environment to the tissues, and removing carbon dioxide from the tissues. Maintaining a constant body temperature in birds and mammals requires high levels of oxygen consumption and exercise in birds—namely flapping flight—creates the highest oxygen demand of any vertebrate. The structure of the avian respiratory system is very different from the mammalian lung and some of these differences support more efficient gas exchange, whereas others may be alternative evolutionary solutions to common problems in air breathing vertebrates.

Generally, the respiratory system acts as a servant to the rest of the organism by delivering enough oxygen and removing sufficient carbon dioxide for metabolic demands. As oxygen demand increases, a variety of respiratory responses ensure an adequate supply of oxygen, which involve the lungs, respiratory mechanics, the pulmonary circulation, transport of oxygen and carbon dioxide in blood, pulmonary and tissue gas exchange, and the coordination of all these mechanisms by the respiratory control system. Individual sections in this chapter focus on each of these physiological mechanisms. References are made to mammalian respiratory physiology, so the reader can consult the extensive literature available for more details on fundamentals concepts. In birds, the respiratory system is also critical for thermoregulation (by evaporative water loss) and nonrespiratory functions such as vocalization, but these are not covered in this chapter. Current research problems and important unanswered questions are highlighted in sections labeled *Frontiers*.

13.1.1 Oxygen Cascade

Figure 13.1 shows how these physiological transport steps function in series to transport oxygen from the environment to the cells. This is often referred to as the "oxygen cascade" because oxygen level (quantified as partial pressure, or P_{O_2}), decreases at each step in the model. Breathing movements bring fresh air into the lungs, and the heart pumps oxygen-poor blood to the lungs. Oxygen diffuses from gas to blood in the lungs, and this oxygen-rich blood returns to the heart via the pulmonary circulation. Arterialized blood is pumped to the various organs and tissues of the body via the systemic circulation. Finally, oxygen diffuses out of the systemic capillaries to metabolizing tissues and ultimately to the mitochondria inside cells. Carbon dioxide moves out of the cells to the environment through these same steps in the opposite direction from oxygen. Each of these steps is covered in the sections below, with an emphasis on respiratory structure–function relationships that are unique to birds, especially in comparison with mammals. Mammals are the only other vertebrates that achieve avian levels of oxygen demand during thermoregulation and activity.

13.1.2 Symbols and Units

Table 13.1 provides a list of abbreviations used in this chapter, which are based on a few simple conventions. Primary variables are symbolized with a capital letter, and a dot over the variable indicates the first derivative with respect to time (e.g., units for inspired ventilation, $\dot{V}_I$, are L/min). Modifiers are small capitals for the gas phase and lowercase letters for liquid or tissues. Finally, a specific gas species is indicated with a subscript. Respiratory gas volumes (e.g., ventilation) are reported for physiological conditions (body temperature and pressure, saturated) unless otherwise noted. Amounts of oxygen (O_2) or carbon dioxide (CO_2) are expressed in mmoles (e.g., O_2 concentration in mmol/L = mM). Pressure is expressed in Torr (7.5 Torr = 1 kPa).

13.2 ANATOMY OF THE AVIAN RESPIRATORY SYSTEM

The structure of the avian respiratory system is unique amongst the vertebrates, with small lungs that do not change volume during breathing, and nine large air sacs that act as bellows to ventilate the lung but do not participate directly in gas exchange (Figure 13.2). The total volume of the

Sturkie's Avian Physiology.

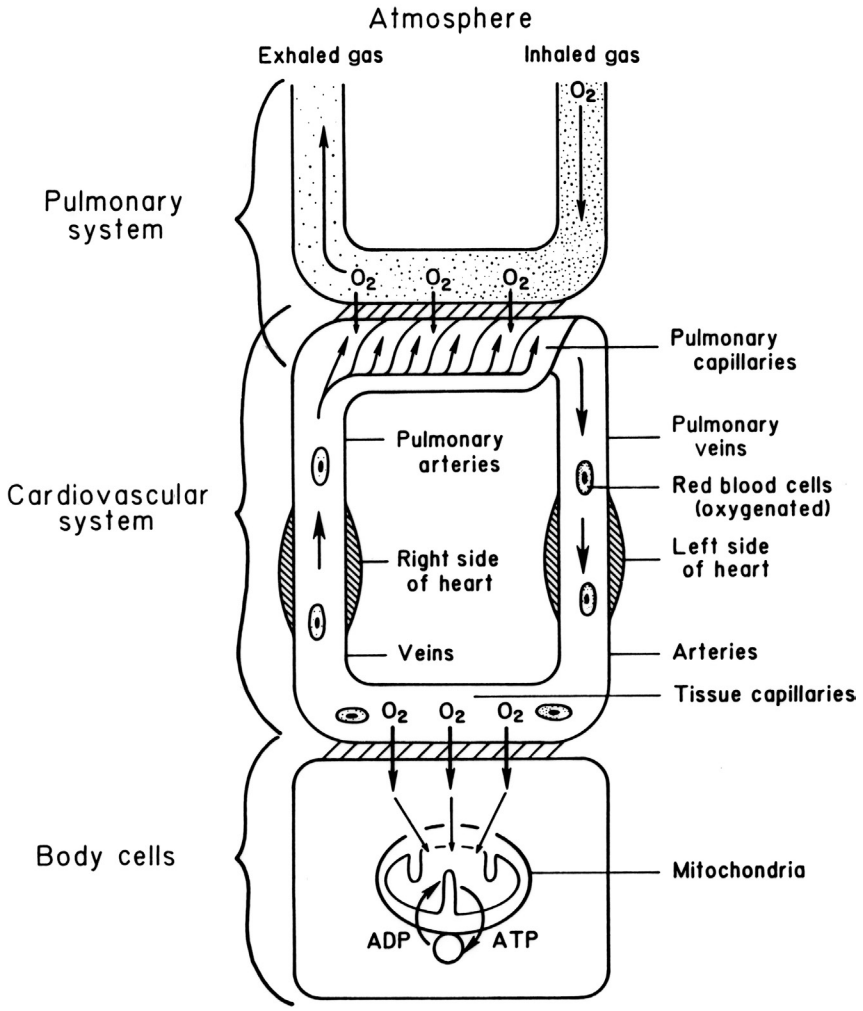

FIGURE 13.1 General model of the oxygen transport in birds. *Modified from Taylor and Weibel (1981).*

respiratory system in a bird (i.e., lungs and air sacs) is larger than that in a comparably sized mammal (~15% versus 7% of body volume), but the avian lung itself is smaller (~1–3% of body volume). Apparently, during evolution, birds segregated the functions of gas exchange and ventilation as the respiratory organ was subdivided into smaller functional units to increase gas exchange surface area. Such heterogeneous partitioning of the respiratory organ contrasts with the homogenous partitioning in mammals (Duncker, 1978). Alveoli in mammalian lungs perform both respiratory functions of ventilation and gas exchange.

Also in contrast to mammals, the avian thoracic cavity is essentially at atmospheric pressure (versus subatmospheric), and there is no diaphragm to functionally separate it from the abdominal cavity (see Section 13.3). This section covers the basic respiratory system anatomy necessary to understand respiratory function, but the reader is referred to several excellent monographs and reviews for more details (Duncker, 1971; King and Molony, 1971; Maina et al., 2010; McLelland, 1989b). Terminology according to the *Nomina Anatomica Avium* is used here (King, 1979). Details of the gas exchange surface and the anatomy of the pulmonary circulation are covered in later sections (Sections 13.4 and 13.6.3, respectively).

13.2.1 Upper Airways

Birds can breathe through the nares or mouth. Oronasal structures tend to heat and humidify inspired gas, and filter out large particles that could potentially damage the delicate respiratory surfaces. The oronasal cavity is separated from the trachea by the larynx, which opens into the trachea through the slit-like glottis. The laryngeal muscles contract with breathing, to open the glottis during inspiration and decrease the resistance to inspiratory airflow. This rhythmic opening of the glottis is useful when attempting to intubate a bird. The trachea has complete cartilaginous rings in most avian species and plentiful smooth muscle. Interesting exceptions include the "double trachea" of penguins, with a medial septum dividing the trachea into two

TABLE 13.1 Symbols in Respiratory Physiology

	Primary Variables (and Units)
C	Concentration or content (mM = mmol/L)
D	Diffusing capacity ($mmol_{O_2}/min\ Torr$)
P	Partial pressure or hydrostatic pressure (Torr or cm H_2O)
V	Gas volume (liters, L, or mL)
$\dot{V}$	Ventilation (L/min)
$\dot{Q}$	Blood flow or perfusion (L/min)
$\dot{M}$	Gas flux (mmol/min)
Modifying Symbols	
D	Dead space gas
E	Expired gas
$\dot{E}$	Mixed-expired gas
I	Inspired gas
T	Tidal gas
a	Arterial blood
c	Capillary blood
m	Membrane
t	Tissue
v	Venous blood
$\dot{v}$	Mixed-venous blood
Examples	
$P_{I_{O_2}}$	Partial pressure of O_2 in inspired gas
$P_{a_{O_2}}$	Partial pressure of O_2 in arterial blood
$P_{\dot{v}_{O_2}}$	Partial pressure of O_2 in mixed-venous blood
$\dot{M}_{O_2}$	O_2 consumption per unit time
$\dot{V}_P$	Ventilation of the parabronchi per unit time

tubes, and the slit-like opening on the ventral surface of the trachea in emus, which is responsible for their characteristic booming call (McLelland, 1989a). The anatomy and physiology of the larynx and trachea have been reviewed in detail (McLelland, 1989a).

Tracheal volume is an important determinant of "dead space" ventilation and therefore gas exchange. Hinds and Calder (1971) measured tracheal volume in 27 species of birds and found in situ volume (V in mL) was related to body mass (M_b in kg) as: $V = 3.7 M_b^{1.09}$. This equation

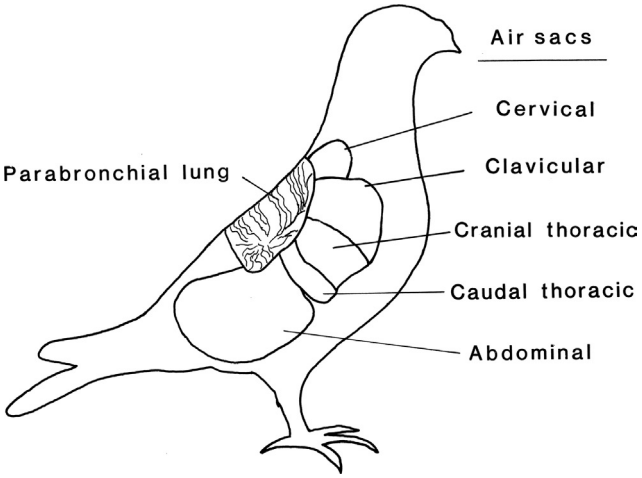

FIGURE 13.2 Respiratory system of a pigeon consisting of the parabronchial lung and air sacs.

underestimates tracheal volume in Pekin ducks (Bech et al., 1984; Hastings and Powell, 1986b) and pigeons (Powell, 1983b), and overestimates the value for male chickens (Kuhlmann and Fedde, 1976), but the error is less than 25%. Tracheal volume is 4.5 times larger in birds than in comparably sized mammals (Hinds and Calder, 1971) and birds generally compensate for this increased dead space with a deep and slow breathing pattern (Bouverot, 1978). Several species of birds possess tracheal elongations, which loop inside the neck, but their function is unknown (McLelland, 1989a).

The trachea bifurcates into two primary bronchi at the syrinx. In many species (e.g., chickens, ducks), but not all, this bifurcation occurs inside the thoracic cavity where the trachea runs through the clavicular air sac. The syrinx is responsible for vocalization in birds but relatively little is known about the precise mechanisms. Readers are referred to comprehensive reviews about this structure for details (King, 1989). Similar to the avian trachea, the syrinx shows considerable variation between species, and males in some species exhibit large bullae with unknown functions.

13.2.2 Lungs

The avian lung is located dorsally in the thoracoabdominal cavity of birds (Figure 13.2), with invaginations from spinal processes typically on the dorsal surface of the lung. Figure 13.3 shows the pulmonary bronchial branching pattern in a representative species.

13.2.2.1 Conducting Airways

In most cases, the extrapulmonary primary bronchi, between the syrinx and the lungs, are relatively short. The intrapulmonary primary bronchus travels through the entire length of the lung, entering on the medioventral aspect and

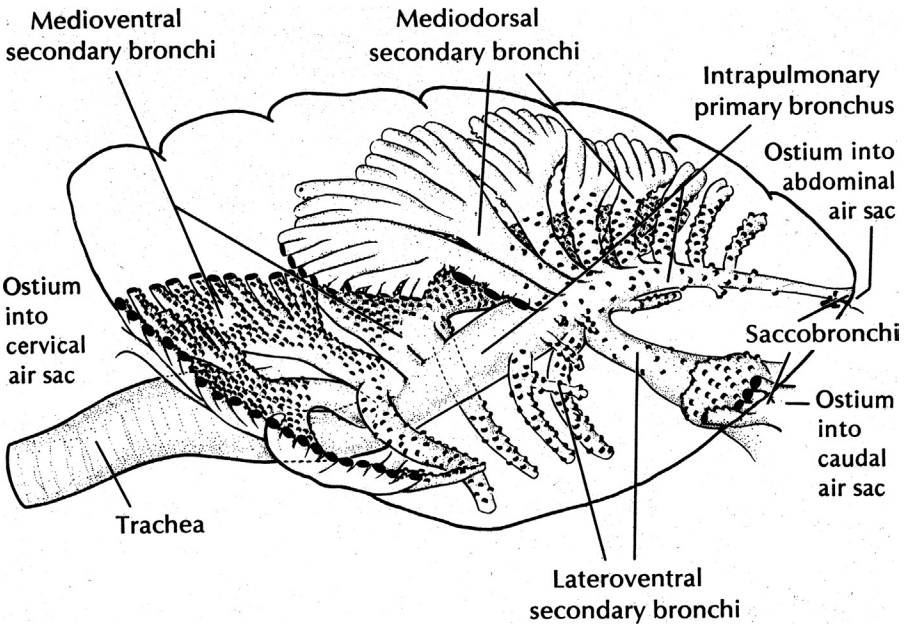

FIGURE 13.3 **Bronchial arrangement in the left lung of the mute swan (*Cygnus olor*).** *After Duncker (1971).*

exiting at the caudal border of the lung into the ostium of the abdominal air sac (see Section 13.2.3). The secondary bronchi can be considered in two functional groups based on their origin from the primary bronchus. The cranial group consists of four or five medioventral secondary bronchi, originating from the medioventral intrapulmonary primary bronchus. These cranial secondary bronchi branch further to form a fan covering the medioventral surface of the lung. The caudal group consists of 6–10 mediodorsal secondary bronchi, which also branch to form a fan over the mediodorsal surface of the lung.

A third group of secondary bronchi includes a variable number of lateroventral bronchi in most species, which also branch off caudal parts of the primary bronchus. The first or second laterobronchus forms a short connection to the posterior thoracic air sac (see below). Other lateroventral bronchi may penetrate lateroventral parts of the lung to variable degrees in different species, but they do not form a regular branching fan like the other secondary bronchi.

The primary and secondary bronchi are conducting airways because they do not participate in gas exchange. Cartilaginous semirings and smooth muscle support the primary bronchi, but the walls of the secondary bronchi are flaccid and require adhesion to the surrounding lung or pleura to remain open. The respiratory epithelium is ciliated with variable amounts of goblet cells in different species in the trachea, primary, and secondary bronchi (Duncker, 1974).

13.2.2.2 Parabronchi

Parabronchi are the functional unit of gas exchange in the avian lung. They are also called "tertiary bronchi" because they can originate from the secondary bronchi, but parabronchus is the preferred terminology because they also originate from further branches of secondary bronchi (Figure 13.3). Most of the parabronchi are organized as a parallel series of several hundred tubes connecting the medioventral and mediodorsal secondary bronchi (Figure 13.3). Such parabronchi are called *paleopulmonic* parabronchi. Together with the primary and cranial and caudal groups of secondary bronchi, they comprise the simplest scheme of bronchial branching in the avian lung (Duncker, 1972, 1974).

In all birds except some penguins, there are additional parabronchi called *neopulmonic* parabronchi (Duncker, 1972, 1974). These parabronchi are not organized as regular parallel stacks of tubes but may exhibit irregular branching patterns. Neopulmonic parabronchi may connect another set of caudal laterodorsal secondary bronchi to caudal air sacs (see Section 13.2.3), or other parabronchi. Neopulmonic parabronchi never comprise more than 25% of the parabronchi, and there are large species variations. However, it has not been possible to demonstrate any phylogenetic or evolutionary significance to neopulmonic versus paleopulmonic parabronchi, despite the implication of the terms (Maina, 1989). The functional significance of these different kinds of parabronchi is considered below (see Section 13.3.3.2).

Figure 13.4 shows the detailed structure of a parabronchus and how they are organized in parallel like a honeycomb in the lung. Gas exchange occurs in the walls of these tubes that are 0.5–2.0 mm in diameter, and they can be several millimeters long depending on the size of the bird (Duncker, 1971; Maina, 1989). The parabronchi are

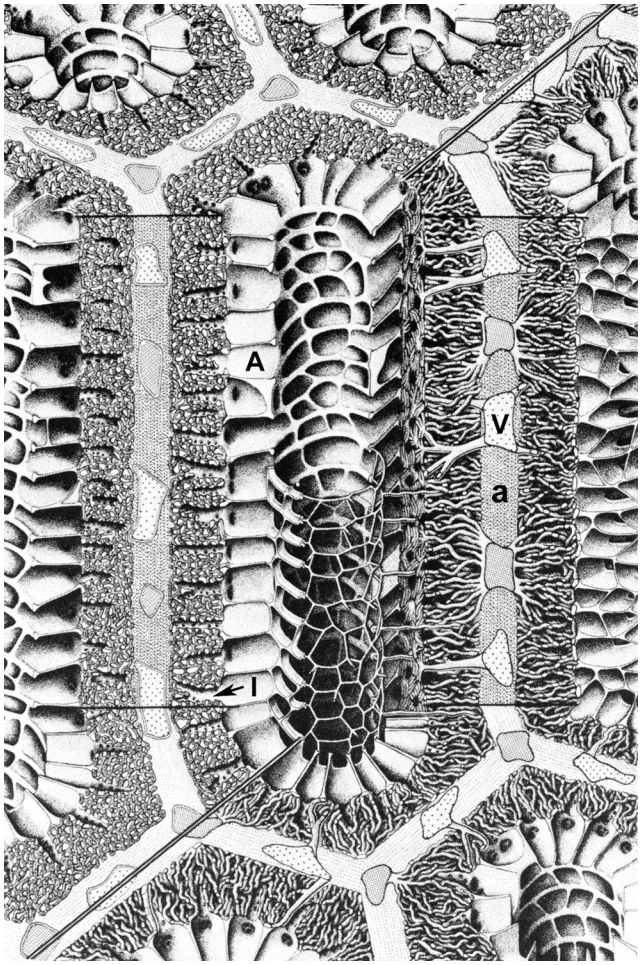

FIGURE 13.4 Cutaway drawing of a typical parabronchus (~1 mm diameter). Left side shows airflow from parabronchial lumen into the atria (A), infudibula (I), and air capillaries. Right side shows blood flow from interparabronchial arterioles (a) into blood capillaries that collect in venules near the base of the atria that flow to interparabronchial venules (v). *Modified from Duncker (1974).*

separated from each other along their length by a boundary of connective tissue and larger pulmonary blood vessels. The parabronchial lumen is lined by a meshwork of connective tissue and smooth muscle, which outlines the entrances to atria radiating from the parabronchial lumen. The atria lead to infundibulae and, ultimately, the air capillaries which are 2–10 µm in diameter and as long as about one-quarter of the total parabronchial diameter (Figure 13.4). The parabronchi are lined with cuboidal and squamous epithelial cells that become thinner moving into the atria and exclusively squamous in the infundibulae and air capillaries (Smith et al., 1986). The air capillaries intertwine with a similar network of pulmonary blood capillaries in the parabronchial mantle, where the air–blood capillary interface is the site of gas exchange.

13.2.2.3 Frontiers: Evolution of the Blood–Gas Barrier

The evolution of respiratory organs has been guided by at least two principles. First, the area of the blood gas barrier has to be very large and very thin to support oxygen uptake by diffusion (see Section 13.6.3). Subdividing the lungs into smaller compartments increases the surface-to-volume ratio, so the total surface area in a bird or mammal is more than 10 times that in a reptile with a simpler lung (Hsia et al., 2013). (Of course, the reptilian solution is adequate for the relatively lower levels of oxygen consumption in a reptile.) The second principle is keeping the blood–gas barrier extremely thin, also to facilitate diffusion, while maintaining structural integrity of the blood capillaries. This is particularly important in birds and mammals, which require high rates of blood flow to meet metabolic demands, and they have evolved separate pulmonary and systemic circulations allowing lower pressures in pulmonary than systemic capillaries. Even so, pressure can increase enough in exercise to cause stress-failure of pulmonary capillaries (West, 2011).

Birds have evolved a unique solution to these challenges, which is arguably more adaptive than the mammalian solution, with the total surface area for gas exchange being about 15% greater and 2.5 times thinner in a bird than in the same-sized mammal (Maina et al., 1989; West, 2009). The air capillaries in the avian lung are much smaller than the alveolar airspaces in mammalian lungs. This means the blood capillaries in the avian lung receive much more support than in an alveolar lung. Blood capillaries in the avian lung are extensively and uniformly supported by the epithelial bridges from the network of air capillaries (Figure 13.5). The exact biomechanics of this system remain to be determined (West et al., 2010), but such small airspaces are possible in the avian lung because they do not change volume with ventilation, in contrast to mammalian alveoli (see Section 13.3.3). Recent studies also show the air capillaries are less tubular and regular in shape than the blood capillaries (Figure 13.5), which may have consequences for gas transport (see Section 13.6.3.1).

13.2.3 Air Sacs

The air sacs are thin membranous structures connected to the primary or secondary bronchi via ostia and they comprise most of the volume of the respiratory system (Figure 13.2). Air sacs are poorly vascularized by the systemic circulation and do not directly participate in significant gas exchange but act as a bellows to ventilate the lungs. In most species, there are nine air sacs that can be considered in cranial and caudal functional groups (Duncker, 1971; Maina, 1989; McLelland, 1989b). Air sac diverticulae may also penetrate the skeleton, but there are large species differences and the

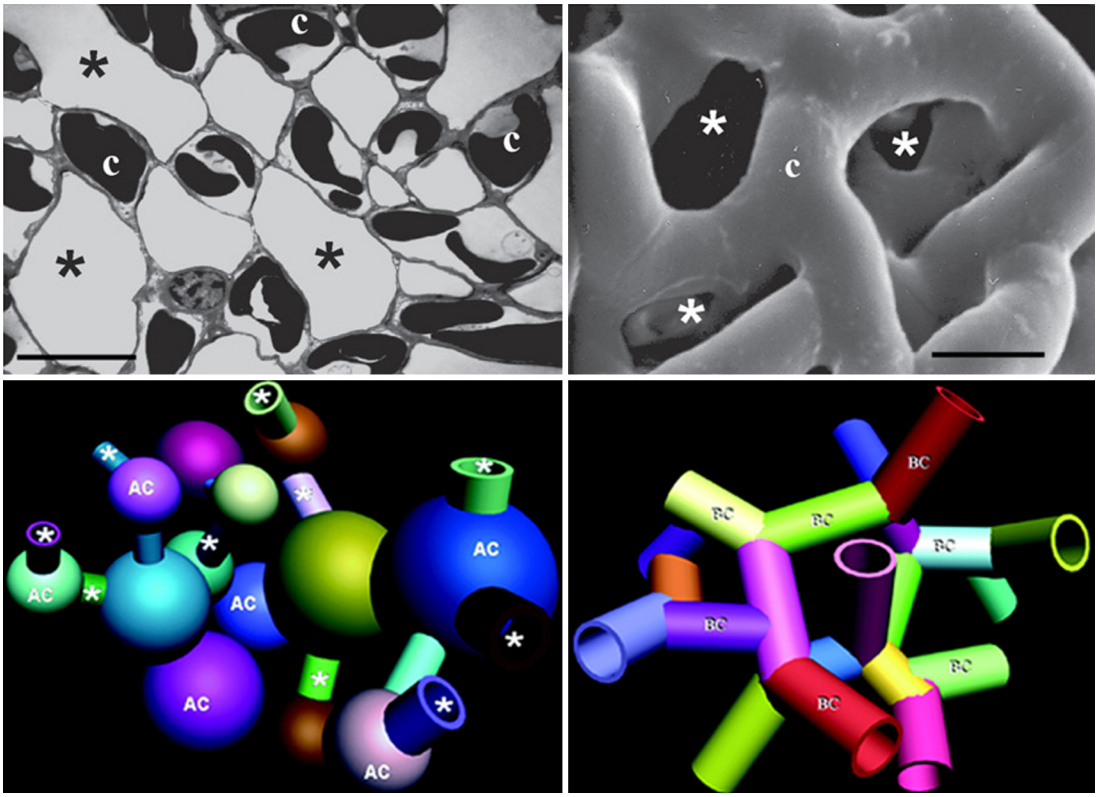

FIGURE 13.5 Top: Air (*)-blood (c) capillary network transmission electron micrograph (left) and scanning electron micrograph of case (right). Scale bar = 10 micron. Bottom: Computer–generated 3-D configuration of the air (left, AC) and blood capillaries (right, BC). AC consist of rotund spaces interconnected by short tubes (*) while BC are short interconnected tubes of similar length and diameter. *Modified from Maina (2007) and Maina et al. (2010).*

functional significance or such connections for respiration has not been established (Maina, 1989).

The cranial group consists of the paired cervical air sacs, the unpaired clavicular air sac, and the paired cranial thoracic air sacs. The cervical sacs directly connect to the first medioventral secondary bronchus. The clavicular air sac directly connects to the third medioventral secondary bronchus, and it may also have indirect connections via parabronchi to other cranial (medioventral) secondary bronchi in some species, such as chickens. The cranial thoracic air sacs generally connect to the third medioventral secondary bronchi, as well as to parabronchi originating from other cranial secondary bronchi in some species.

The caudal group consists of the paired caudal thoracic air sacs and paired abdominal air sacs. The caudal thoracic air sac is directly connected to the lateroventral secondary bronchus and may have indirect connections to other lateroventral, or even cranial (medioventral), secondary bronchi in species with large amounts of neopulmonic parabronchi, such as chickens. The abdominal air sacs connect to the caudal end of the intrapulmonary primary bronchus and may have more indirect connections to parabronchi from laterodorsal secondary bronchi and the last mediodorsal secondary bronchi. Air sac connections with parabronchi are frequently grouped into a funnel-like structure called the saccobronchus.

13.2.4 Respiratory System Volumes

The upper airways and bronchial branches proximal to the parabronchi comprise anatomical dead space, as described in Section 13.2.1. Such conducting airways are called "dead space" because they do not participate directly in gas exchange. The intrapulmonary conducting airways make a relatively small contribution to total dead space, but total dead space volume is generally larger than most mammals, consistent with the generally long neck of birds. Physiological measures of dead space are considered below (see Section 13.3.3.4).

The actual volume of air in the avian lung involved in gas exchange at any moment is in the air capillaries. This is considerably less than the volume in gas exchanging portions of alveolar lungs from comparably sized mammals (Powell and Mazzone, 1983). However, the unique pattern of airflow in the open-ended parabronchi renews this gas exchanging volume more frequently than does tidal ventilation in alveolar lungs (see Section 13.3.3.2). Therefore, birds do not need as large of a functional residual capacity (FRC) in the lungs as mammals to smooth out variations in

gas exchange, O_2, and CO_2 levels that could occur during a breathing cycle.

Most of the respiratory system volume in birds is in the air sacs, and there is no comparable volume in the mammalian lung. Unlike mammalian alveoli, which change volume during ventilation, the air sacs are not important sites of gas exchange. There is tremendous variation in the volumes of air sacs reported in the literature, because the value is very sensitive to the method of measurement. For example, the volume of plastic casting material that can be instilled under a pressure head into the air sacs of a dead bird may be much greater than the gas volume in live birds with muscle tone in the thorax and abdominal wall. Also, air sac volume *in vivo* can vary with posture, digestive, and reproductive states, as different structures in the body (e.g., eggs) displace volume. Casting under controlled pressure conditions (Duncker, 1971) and gas dilution *in vivo* (Scheid et al., 1974) are probably the most accurate methods available for determining air sac volume.

13.3 VENTILATION AND RESPIRATORY MECHANICS

Respiratory muscles generate the forces (pressures) to move air in and out of the air sacs and through the parabronchial lung. The air sacs follow changes in body volume with respiratory muscle activity and act as a bellows to ventilate the parabronchial lung that is essentially constant in volume (Jones et al., 1985; Macklem et al., 1979). In contrast to mammals, the avian lung volume is maintained by attachments to the body wall, not by a subatmospheric pressure in an intrapleural space surrounding it. Also in contrast to mammals, birds have no diaphragm separating the body cavity into separate thoracic and abdominal compartments. Hence, pressures are relatively uniform in the avian thoracoabdominal cavity, which behaves mechanically as a single compartment (Scheid and Piiper, 1989).

Ventilation $(\dot{V})$ is the product of the volume per breath, or tidal volume (V_T) and the respiratory frequency (f_R), so $\dot{V}$ can be increased by breathing faster or deeper. The distribution of gas flow in the avian respiratory system depends upon the magnitude and pattern of respiratory muscle activity, as well as the mechanical properties of the body wall, lungs, and air sacs as described below.

13.3.1 Respiratory Muscles

Figure 13.6 shows the changes in thoracic skeleton between normal inspiration and expiration in a bird (King and Molony, 1971; Zimmer, 1935). During inspiration, the sternum rocks cranially and ventrally with the coracoids and furcula rotating at the shoulder. Simultaneously, the vertebral ribs move cranially to expand the sternal ribs and thoraco-abdominal cavity laterally.

In small birds (e.g., starlings) during flight, the furcula (wishbone) and sternum are mechanically coupled, such that the wing beat assists ventilation (Jenkins et al., 1988). However, wing movements in flight and ventilation are coordinated even in larger birds (e.g., geese), so this may involve coupling of neuromuscular circuits as much as respiratory mechanics (Funk et al., 1992a,b). During rest, both inspiration and expiration require active contraction of the respiratory muscles as listed in Table 13.2. The innervation for these muscles is summarized in de Wet et al. (1967). Increases in ventilatory volumes are achieved by recruiting more motor units in active muscles and additional respiratory muscles; during expiration, the opposite occurs (Fedde et al., 1963, 1964b, 1969; Kadono and Okada, 1962; Kadono et al., 1963). Therefore, the relaxed resting volume of the avian respiratory system is midway between inspiratory and expiratory volumes (Seifert, 1896), in contrast to mammals that relax to FRC at end-expiratory volume. The costoseptal muscles control the tension of the horizontal septum covering the ventral surface of the lung, but unlike the mammalian diaphragm, these are not effective at changing lung volume (Fedde et al., 1964a).

13.3.2 Mechanical Properties

13.3.2.1 Compliance

Compliance (C) defines the effectiveness of small pressure changes (ΔP) at inducing volume changes (ΔV):

$$C = \Delta V / \Delta P$$

Because the pressure changes with breathing are essentially uniform throughout the coelom in birds, they can be measured as the difference between pressure in an air sac (P_{AS}) and atmospheric pressure outside the bird. Changes in respiratory system volume (V_{RS}) can be measured with a plethysmograph, which measures changes in whole body volume during breathing, or a pneumotachograph, which quantifies the amount of air inhaled or exhaled at the mouth or trachea. Compliance, measured as the slope of the steepest part of a graph plotting V_{RS} versus P_{AS} in an artificially ventilated bird, ranges from 10 mL/cm H_2O in chickens (Scheid and Piiper, 1969) to 30 mL/cm H_2O in ducks (Gillespie et al., 1982b). These values are similar to compliance in mammals when correcting for body size.

Different results are obtained when compliance is measured by applying small oscillations in volume on spontaneously breathing birds. Compliance measured with this forced oscillation technique is only 7.7 mL/cm H_2O in ducks (Gillespie et al., 1982b), or much less than in mammals. In contrast, compliance measured with this technique in pigeons (2.8 mL/cm H_2O, Kampe and Crawford, 1973) is 3.7 times greater than the value predicted for a similar-sized mammal (Powell, 1983b). The reasons for these differences

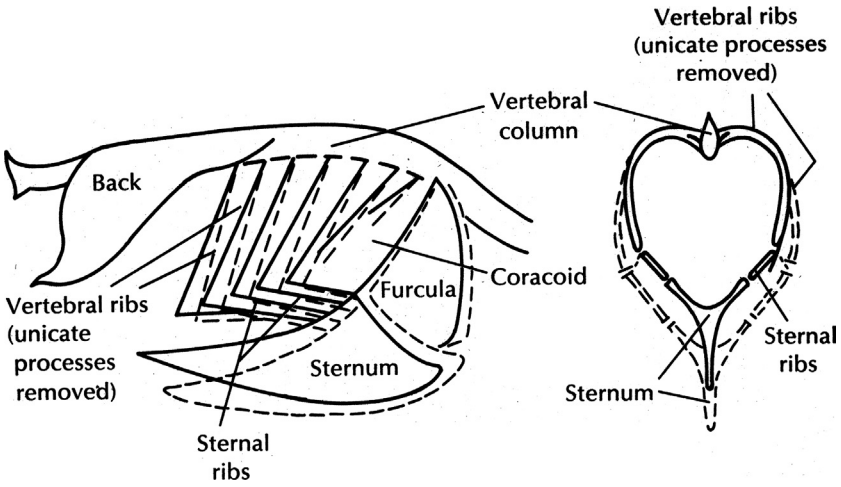

FIGURE 13.6 Changes in the position of the thoracic skeleton during breathing in a standing bird. Solid lines show thoracic position at the end of expiration and dotted lines show the end of inspiration. *After Zimmer (1935).*

	M. rectus abdominis serratus superficialis, pars cranialis and caudalis
	M. costoseptalis

are not clear, but they suggest that compliance is exquisitely sensitivity to posture and muscular tone. Compliance primarily depends on the viscoelastic properties of the body wall and air sacs in birds, in contrast to the elastic properties of the lung in mammals (Macklem et al., 1979). Therefore, compliance in birds is high when volume changes occur by "unfolding" air sacs and stretching the abdominal wall, but it is low when volume changes are opposed by muscle tone in the body wall.

13.3.2.2 Resistance

Ohm's law defines the relationship between pressure, flow, and resistance (R) for the respiratory system as:

$$R = \Delta P/\dot{V}$$

where ΔP is the pressure gradient between the atmosphere and air sacs driving ventilatory airflow $(\dot{V})$. Expiration decreases air sac volume and creates a small positive pressure, which drives airflow out of the sac across small airway resistances; the opposite occurs during inspiration. Air sac pressure changes during breathing are small and similar in all of the air sacs (±1 cm H_2O), so resistance can be measured by measuring pressure and volume changes during artificial or spontaneous breathing as described above for compliance measurements (Scheid and Piiper, 1989). Airway resistance ranges from 4.8 cm H_2O/(L/s) in ducks (Gillespie et al., 1982a) to 41 cm H_2O/(L/s) in pigeons at the resonant frequency of their respiratory system (Kampe and Crawford, 1973).

Airway geometry is an important determinant of resistance. Poiseuille's law predicts resistance to laminar airflow is directly proportional to the length of an airway, and inversely proportional to the fourth power of the airway radius. Therefore, resistance can vary between the different anatomical pathways possible for airflow in the avian

respiratory system (see Section 13.3.2.2). Different pathways presumably explain why airway resistance is generally greater during inspiration than during expiration in birds (Brackenbury, 1971, 1972; Cohn and Shannon, 1968). However, measurements using the forced oscillation technique on unanesthestized ducks find similar resistance during inspiration and expiration (Gillespie et al., 1982a). Resistance measured with this technique does not include any contributions from the body wall (Scheid and Piiper, 1989), so some differences between inspiratory and expiratory resistance may reflect muscle tone.

Physiological factors also affect airway resistance. Decreased lung P_{CO_2} increases resistance by a local effect on the openings of the mediodorsal secondary bronchi into the primary bronchus (Molony et al., 1976). However, P_{CO_2} does not affect smooth muscle contraction in the parabronchi (Barnas and Mather, 1978). Turbulent flow, which may occur in large airways at high ventilation rates or at bronchial bifurcations, can increase resistance (Brackenbury, 1972; Molony et al., 1976). Finally, resistance can change with breathing frequency. The pathway for airflow may be different with ventilation at high frequencies and small volumes (Banzett and Lehr, 1982; Hastings and Powell, 1987) and therefore affect resistance as described above. Also, the respiratory system has a resonant frequency, at which the overall impedance to breathing is minimized (e.g., 9.4 breaths/s in pigeons, Kampe and Crawford, 1973).

13.3.2.3 Air Capillary Surface Forces

Surface tension at the gas–liquid interface of the respiratory exchange surface tends to collapse the air capillaries; this decreases interstitial pressure between the air and blood capillaries. A decrease in interstitial pressure increases capillary filtration and can lead to edema and a thickening of the blood–gas barrier (see Section 13.4.4). This tendency towards edema is probably a more important consequence of surface tension than airway collapse in the parabronchial lung because the air–blood capillary network tends to maintain constant volume (Maina, 2007). Similar to alveoli, air capillaries are lined by a surfactant, which lowers surface tension and counteracts these potentially deleterious effects (McLelland, 1989b). Lamellated osmophilic bodies in the parabronchial atria secrete the surfactant, which spreads as a trilaminar substance that is unique to birds over the air capillary surface (Bernhard et al., 2001; King and Molony, 1971; McLelland, 1989b; Pattle, 1978). Surface tension in avian surfactant is about threefold greater than in mammalian surfactant when subject to volume changes, but the maximum surface tension in avian surfactant is lower than in mammals (Bernhard et al., 2001). This is consistent with the chemical composition of avian versus mammalian surfactant and the fact that air capillaries do not change volume with ventilation, so there is no selective pressure to decrease surface tension for reducing the work of breathing.

13.3.3 Ventilatory Flow Patterns

13.3.3.1 Air Sac Ventilation

The air sacs are ventilated roughly in proportion to their volume, such that the cranial group (clavicular and cranial thoracic air sacs) and caudal group (caudal thoracic and abdominal air sacs) each receive about 50% of the inspired volume (Scheid et al., 1974). The ventilation–volume ratio affects the O_2 and CO_2 levels in the air sacs (see Section 13.3.3.3). Hence, the increase in air sac volume with changes in body wall muscle tone that may accompany anesthesia can alter air sac composition (Scheid and Piiper, 1969). There is no evidence for airflow between the sacs during normal breathing (Scheid and Piiper, 1989), although this has been postulated as a mechanism to enhance pulmonary gas exchange during breath-hold diving in birds (Boggs et al., 1996).

13.3.3.2 Pulmonary Ventilation

Figure 13.7 shows the general pattern of ventilatory airflow during inspiration and expiration in the avian lung. The unidirectional flow in a caudal-to-cranial direction through the paleopulmonic parabronchi during both phases of ventilation has been established by a variety of methods (Scheid and Piiper, 1989). Early researchers noted that soot deposited primarily in the caudal regions of the lungs of pigeons collected in train stations, suggesting that inspired gas entered the lungs from a caudal direction (Dotterweich, 1930). More recently, researchers have confirmed this pattern with direct measurements of airflow (Brackenbury, 1971; Bretz and Schmidt-Nielsen, 1971; Scheid et al., 1972) and respiratory gases (Powell et al., 1981) in different parts of the lung.

Upon inspiration, about half of the tidal volume goes into the caudal air sacs and half goes into the cranial air sacs. Figure 13.7 (filled arrows) shows how inspiratory flow bypasses the cranial secondary bronchial openings in the primary bronchus, flowing directly into the caudal air sacs and caudal secondary bronchi. When gas enters the caudal secondary bronchi, it continues through the paleopulmonic parabronchi in a caudal-to-cranial direction and enters the cranial air sacs via the cranial secondary bronchi. If tidal volume is large enough, some of the inspired gas may reach the cranial air sacs via the paleopulmonic parabronchi during the same breath.

Upon expiration, the air sacs expel gas that eventually leaves the bird via the primary bronchi and trachea. Figure 13.7 (filled arrows) shows how expiratory flow from the cranial air sacs leaves the lung via the cranial secondary bronchi emptying into the primary bronchi. Expiratory flow from the caudal air sacs is routed through the paleopulmonic parabronchi in a caudal-to-cranial direction via caudal secondary bronchi. If the expired volume is large

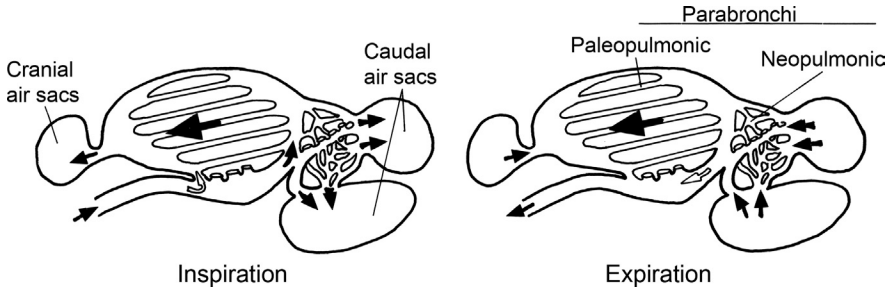

FIGURE 13.7 Pathway of airflow in the avian respiratory system during inspiration and expiration. Flow in paleopulmonic parabronchi is always caudal-to-cranial during both phases of breathing (large solid arrows) but neopulmonic flow is bidirectional. Open arrows show possible ventilatory shunts.

enough, gas from the caudal air sacs will also leave the lung through the cranial secondary bronchi and mix with the gas emptying from the cranial air sacs.

Hence, airflow in the paleopulmonic parabronchi is in a caudal-to-cranial direction during both inspiration and expiration. In contrast to the paleopulmonic parabronchi, flow is bidirectional in the neopulmonic parabronchi, which are functionally in series with the caudal air sacs (Figure 13.7). Inspiratory airflow is cranial-to-caudal through neopulmonic parabronchi and into caudal air sacs, and in the caudal-to-cranial direction during expiration (Scheid and Piiper, 1989). The implications of these flow patterns for gas exchange are discussed in Section 13.6.2.

The pattern of airflow in the avian lung is determined by "aerodynamic valving". Pressure measurements show that branch points, such as the openings of the cranial secondary bronchial into the primary bronchi, are more important than distal airway resistance for determining flow patterns (Kuethe, 1988; Molony et al., 1976). There is no evidence for anatomical valves, for example, closing the primary bronchial openings of the cranial secondary bronchi during inspiration (reviewed by Scheid and Piiper, 1989). As early as 1943, fluid dynamic models of the avian lung were used to show that these branches were critical for unidirectional caudal-to-cranial airflow in the paleopulmonic parabronchi (Hazelhoff, 1951). Modern theoretical models predict decreased effectiveness of aerodynamic valving with reduced gas density, and experiments with low-density gases show valve failure and inspiratory shunts in birds (Banzett et al., 1987, 1991; Butler and Turner, 1988; Wang et al., 1988, 1992). In contrast, expiratory aerodynamic valving is not sensitive to gas density (Brown et al., 1995). Future experiments are necessary to determine if decreased gas density at high altitude can affect aerodynamic valving.

13.3.3.3 Air Sac P_{O_2} and P_{CO_2}

This pattern of airflow is an important determinant of P_{O_2} and P_{CO_2} in the air sacs (Table 13.3). Cranial air sacs only receive gas from the parabronchi, so their P_{O_2} and P_{CO_2} levels are very near end-expired values. However, caudal air sacs contain a mixture of re-inhaled dead space gas (also end-expired P_{O_2} and P_{CO_2} levels) and fresh air, which raises their P_{O_2} and lowers their P_{CO_2}. Other factors that decrease P_{O_2} and increase P_{CO_2} in the air sacs include stratification, gas exchange across the air sac wall, and gas exchange in neopulmonic parabronchi in series with the air sacs (Geiser et al., 1984).

Gas exchange across the air sac walls is less than 5% of the total respiratory gas exchange and a minor factor in determining air sac P_{O_2} and P_{CO_2} (Magnussen et al., 1976). Stratification (i.e., incomplete mixing of freshly inspired gas and resident gas in the air sacs) has been observed in ducks (Torre-Bueno et al., 1980), but its effect on air sac gas concentrations is not clear (Powell and Hempleman, 1985). Gas exchange in neopulmonic parabronchi in series with caudal air sacs seems to be the most important factor causing differences in measured P_{O_2} and P_{CO_2} values and those predicted from re-inhaled dead space (Piiper, 1978). Bidirectional flow may also occur in a small fraction of parabronchi in the purely paleopulmonic lungs of penguins, as well as affect P_{O_2} and P_{CO_2} in the caudal lungs of these birds (Powell and Hempleman, 1985).

Considering the determinants of air sac P_{O_2} and P_{CO_2}, air sac sampling can offer valuable insights into respiratory function in birds under physiologically interesting conditions. For example, recent experiments sampling air sac gases in diving emperor penguins have been important for understanding how O_2 stores are used differently in diving birds and mammals; these differences result in similar O_2 levels in prolonged dives but the penguins maintain normal (breathing) levels of arterial saturation during the first 7 minutes of a deep dive in contrast to dramatic decreases in Weddell and elephant seals (Ponganis et al., 2011).

13.3.3.4 Effective Parabronchial Ventilation

A quantitative description of gas exchange requires a measure of the effective ventilation of the lung (see Section 13.3.3.4). By analogy with alveolar ventilation in mammals, this is defined as parabronchial ventilation $(\dot{V}_P)$ birds, and it differs from inspired ventilation $(\dot{V}_I)$ because of dead space

TABLE 13.3 Partial Pressure of O_2 and CO_2 in Air Sacs and in End-Expiratory Gas of Awake Birds

ventilation $(\dot{V}_D)$. $\dot{V}_D$ in birds includes not only anatomic dead space in the upper airways, but it may result from ventilatory shunts in which airflow bypasses the parabronchi. Figure 13.7 (open arrows) shows how gas might bypass the parabronchi during inspiration by directly entering the cranial secondary bronchi and air sacs or during expiration by flowing back out the primary bronchus (Powell, 1988).

P_{CO_2} measurements in the cranial secondary bronchi show that an inspiratory shunt, with inspired gas directly entering cranial air sacs from the primary bronchi, does not occur (Powell et al., 1981). Some inspiratory flow may enter the fourth medioventral (cranial secondary) bronchus, however, and flow in a cranial-to-caudal direction through some paleopulmonic parabronchi (Powell and Hempleman, 1985), but this would not be a shunt. In contrast, P_{CO_2} measurements indicate an expiratory shunt, with 10–25% of expired gas from the caudal air sacs gas flowing out through the primary bronchus (Powell, 1988; Powell et al., 1981). Other experiments indicate that the relative proportion of expiratory flow in a mesobronchial shunt may vary from 100 to 75% at the beginning of expiration to 0% near the midpoint of expiration (Hastings and Powell, 1986a). The magnitude of expiratory mesobronchial shunting depends on the pattern of ventilation, such as tidal volume, flow rate, and thermal panting (Bretz and Schmidt-Nielsen, 1971; Hastings and Powell, 1986a).

13.3.3.5 Artificial Ventilation

The flow-through design of the rigid parabronchial lung allows a unique form of artificial ventilation, called unidirectional ventilation (Burger and Lorenz, 1960). Fresh humidified gas can be insufflated through a cannula in the trachea or an air sac, so it flows through the parabronchi before leaving the body through another cannula. This technique can be used clinically to support gas exchange during surgery, which opens one of the air sacs (preventing effective spontaneous ventilation), to administer anesthetic gas or nebulized drugs (Fedde, 1978; Whittow and Ossorio., 1970), or for experimental studies (Burger et al., 1979; Fedde et al., 1974a). Artificial ventilation can also be performed manually by alternately compressing and lifting the sternum, such as in a bird that may be anesthetized too deeply. It is also important to note that the sternum should

not be compressed when holding a bird because this may lead to suffocation.

13.3.3.6 Frontiers: Lung Structure-Function in Dinosaurs

There is a rich literature on the evolutionary relationship between birds and dinosaurs, and the modern avian respiratory system is an important part of this story. For example, the long trachea, voluminous air sacs, and pneumatized bones are hypothesized to enhance thermoregulation in extremely large dinosaurs (Perry et al., 2009). Also, models show that air sacs could facilitate the transition from quadrupedal to bipedal locomotion, which preceded flight by improving balance and agility (Farmer, 2006). Such theories are based on fossil skeletons, and answers to most important physiological questions are lost with the soft tissues of the dinosaurs. However, recent comparative physiology studies have shown the value of experimental versus descriptive and deductive approaches to the evolution of birds. For example, unidirectional airflow has been demonstrated in alligator lungs, which have a bronchial tree similar to modern birds but no air sacs (Farmer and Sanders, 2010). This means cross-current gas exchange is possible in animals using a hepatic piston mechanism of breathing, as found in alligators and presumably quardrupedal ancestors of birds; costal breathing or bipedal locomotion are not prerequisites for cross-current gas exchange. The efficiency of cross-current gas exchange could have given avian ancestors a competitive advantage over synapsids when the basal archosaurs were evolving in times of low environmental oxygen.

13.4 PULMONARY CIRCULATION

Chapter 11 covers the basic physiology of the circulation, but this section highlights details of the pulmonary circulation that are relevant to understanding pulmonary gas exchange. The pulmonary circulation is unique because the lung is the only organ to receive the entire cardiac output. The "series" arrangement of the systemic and pulmonary circulations in birds and mammals means that the lungs receive the same amount of blood flow as the whole rest of the body. However, the resistance to blood flow in the lungs is lower, and this allows lower perfusion pressure than in the systemic circulation, with the complete separation of the left and right ventricles. This section describes the structural and functional factors that determine pressures, volumes, and flows in the pulmonary capillaries, which are also important determinants of gas exchange.

13.4.1 Anatomy of the Pulmonary Circulation

The functional anatomy of the pulmonary circulation has been studied in detail for the domestic fowl (Abdalla and King, 1975). Interparabronchial arteries arise from main rami of the pulmonary arteries and run between the parabronchi and may perfuse more than one parabronchus. These vessels give rise to intraparabronchial arteries, which perfuse the parabronchial mantle at several points along a parabronchus. The intraparabronchial arteries branch into the pulmonary blood capillaries near the outside edge of the parabronchial mantle, which form a meshwork with air capillaries, as described in Section 13.2.2.2. Pulmonary capillary blood is collected in intraparabronchial veins near the parabronchial lumen. These veins deliver blood flow to interparabronchial veins located near the outside edges of the parabronchus. The interparabronchial veins run between the parabronchi and collect blood from several points along a parabronchus and from several parabronchi. There are no anastomoses between the arterioles and veins in the lung (Abdalla, 1989).

This anatomy has two important consequences for respiratory gas exchange. First, all of the parabronchi are perfused along their entire length by oxygen-poor mixed venous blood, and the oxygenated blood returning to the heart in the pulmonary vein (i.e., systemic arterial blood) is a mixture of blood draining the entire length of all the parabronchi. This allows cross-current gas exchange to occur, which is more efficient than alveolar gas exchange as described below (Section 13.6.2). Second, it means that blood flow within the parabronchial mantle is directed from the periphery towards the lumen, which can affect the efficiency of gas exchange in the air capillaries (see Section 13.6.3.1).

13.4.2 Pulmonary Capillary Volume

Pulmonary capillary blood volume is similar in avian parabronchial lungs and mammalian alveolar lungs. A notable exception is the domestic fowl, which has a pulmonary blood capillary volume about threefold less than predicted for other birds that size (Maina et al., 1989). However, pulmonary blood capillary volume in birds is essentially constant under all conditions, in contrast to mammals that can increase pulmonary capillary volume by recruitment and distention when flow or pressure increases. Recruitment or distention of blood capillaries in a parabronchial lung would collapse the adjacent air capillaries and reduce gas exchange efficiency by causing a shunt (see Sections 13.2.2.3 and 13.6.4.2).

13.4.3 Pulmonary Vascular Pressures, Resistance, and Flow

13.4.3.1 Pulmonary Vascular Resistance

Pulmonary vascular resistance (PVR), by analogy with Ohm's law, is as follows:

$$PVR = \dot{Q} / \Delta P$$

where $\dot{Q}$ is cardiac output and ΔP is the difference between mean pulmonary artery and left atrial pressure. Pulmonary vascular pressures, cardiac output, and therefore PVR are similar in resting birds and mammals. However, PVR increases more with increases in cardiac output in birds compared to mammals. For example, doubling the blood flow through one lung of a domestic duck almost doubles mean pulmonary artery pressure but causes no change in the resistance calculated for that lung, and no change in the capillary dimensions (Powell et al., 1985). Morphometric measurements of pulmonary blood capillaries in chickens with systematic increases in pulmonary artery pressure show no recruitment and very little distention (Watson et al., 2008). The lack of distention and recruitment of avian pulmonary capillaries also implies that the major effects of gravity and pulmonary vascular pressures on determining regional blood flow in mammalian lungs are not important in birds. The so-called zone 1 and zone 2 conditions of mammalian lungs, in which alveolar pressure can collapse blood capillaries and stop or determine flow, simply do not exist in birds (West et al., 2006). Hence, other mechanisms are responsible for the distribution of pulmonary blood flow in birds, as considered in the next section.

13.4.3.2 Distribution of Blood Flow

Local and regional changes in vascular resistance are more important than overall PVR for respiratory gas exchange. For example, regional control of blood flow between parabronchi has important effects on the efficiency of gas exchange (see Section 13.6.4.3). Hypoxia has been shown to decrease local parabronchial blood flow, and gradients in P_{O_2} can explain differences in perfusion along parabronchi (Holle et al., 1978; Parry and Yates, 1979). Hypoxia and hypercapnia can also redistribute blood flow between paleopulmonic and neopulmonic parabronchi (Weidner et al., 2012). The physiological mechanism of these responses is not known. It may involve hypoxic pulmonary vasoconstriction, which is a direct effect of alveolar hypoxia on pulmonary arterioles in mammals. Smooth muscle capable of controlling local blood flow has been described for interparabronchial arteries and veins in chickens, and this could be responsible for control of blood flow between and along the lengths of parabronchi (Abdalla, 1989). It may also explain pulmonary hypertension with hypoxia in birds (Black and Tenney, 1980a; Burton et al., 1968), but the effects of hypoxia on PVR independent of changes in blood flow remains to be determined in birds.

13.4.3.3 Frontiers: Pulmonary Vascular Pressures during Exercise in Birds

How the pulmonary circulation in birds copes with large increases in blood flow on exercise is a puzzle. The observation that there is no recruitment or significant distention of blood capillaries with increased flow and pressure in bird lungs contrasts sharply with mammals. Alveolar capillary recruitment and distention is important for facilitating gas exchange during exercise by increasing the surface area for diffusion and preserving transit time for red blood cells in the capillaries to absorb oxygen by diffusion (see Section 13.6.3). In mammals, if pressures increase too much during exercise (e.g., in elite human athletes or thoroughbred horses), then pulmonary capillaries can suffer "stress failure" and blood to leaks into the alveoli (West, 2011). The blood–gas barrier in the bird may be protected by the network of air capillaries (see Section 13.1.2.3), but it is also thinner and it is not clear how it avoids stress failure on exercise. Cardiac output and therefore pulmonary blood flow increases comparably in birds and mammals, so extremely high pulmonary artery pressures are predicted with limited compliance in avian pulmonary blood capillaries. To date, there are no measurements of pulmonary circulation pressure and flow in naturally exercising birds. Experiments simulating exercise, which used drug to increase metabolic rate, did not find the large increases in pulmonary artery pressure as predicted for the increase in pulmonary blood flow (West et al., 2010). The reasons for this unexpected result, and what happens to pulmonary artery pressure in a flying bird, are experimental challenges for the future.

13.4.4 Fluid Balance

Fluid balance in the lungs, as in all organs, depends on the balance of hydrostatic and colloid osmotic pressures across the capillaries and capillary permeability. These variables are similar in birds and mammals, although lymph drainage from avian lungs has not been measured directly (Weidner et al., 2006). Volume loading increases extravascular water in the lung interstitium, especially in the interparabronchial septum, and can lead to edema (Weidner et al., 1993; Weidner and Kinnison, 2002). The detailed anatomy of lymphatic vessels and rates pulmonary lymph drainage remains to be determined in birds.

A very important problem involving the pulmonary circulation and fluid balance in poultry husbandry is ascites in fast-growing broilers (chickens) bred for meat production (Julian, 1993). Ascites (i.e., fluid accumulation in the peritoneum) is associated with pulmonary arterial hypertension (PAH) and also occurs frequently in chickens raised at high altitude. Hence, early research on the problem focused on abnormal oxygen sensitivity, which could exaggerate increases in cardiac output with fast growth and cause hypoxic pulmonary vasoconstriction (Peacock et al., 1990). However, comparisons of PAH-susceptible and PAH-resistant broilers do not consistently reveal differences in cardiac output, although vascular capacity is limited in PAH susceptible broilers (Wideman et al., 2007). Factors that

increase the pulmonary vascular resistance (e.g. hypoxia, thromboxane, endothelin-1 and serotonin) and reduce vasodilation (e.g., limited L-arginine, which is the substrate for nitric oxide) promote the onset of PAH and ascites, and appear to be under genetic control (Wideman et al., 2013).

13.5 GAS TRANSPORT BY BLOOD

Equilibrium curves, also called dissociation curves, quantify the amount of O_2 and CO_2 in blood as functions of partial pressure. It is necessary to consider *both* partial pressure *and* concentration because partial pressure gradients drive diffusive gas transport in lungs and tissues, but concentration differences determine convective gas transport rates in lungs and the circulation (see Section 13.6.1). The concentration of a physically dissolved gas in a liquid is directly, and linearly, proportional to its partial pressure according to Henry's law: $C = \alpha P$, where α = solubility in millimolar per Torr. This means that inert gases such as nitrogen, and even anesthetic gases, increase in blood in direct proportion to their partial pressure. However, O_2 and CO_2 also enter into chemical reactions with blood. These reactions result in more complex relationships between concentration and partial pressure, but they serve to (1) increase O_2 and CO_2 concentrations in blood; (2) allow physiological modulation of O_2 and CO_2 transport in blood; and (3) make respiratory CO_2 exchange an important mechanism of acid–base balance in the body.

13.5.1 Oxygen

Oxygen concentration in normal arterial blood $(C_{a_{O_2}})$ of, for example, a pigeon is about 8.3 mM. However, the physical solubility of O_2 in blood (α_{O_2}) is only 0.00124 mM/Torr at 41°C, so only 0.117 mM of arterial O_2 content is dissolved gas with a normal arterial P_{O_2} of 95 Torr in pigeons (Powell, 1983b). Most of the O_2 in blood is chemically bound to hemoglobin.

13.5.1.1 Hemoglobin

Hemoglobin is a large molecule consisting of four individual polypeptide chains, each with a heme (iron-containing) protein that can bind O_2 when iron is in the *ferrous* (Fe^{2+}) form. Methemoglobin occurs when the iron is in the *ferric* form (Fe^{3+}), and it cannot bind O_2. Small amounts of methemoglobin, which occur under normal conditions, slightly reduce the amount of O_2 that can be bound to hemoglobin. One gram of pure mammalian hemoglobin can bind 0.060 mmol of O_2 when fully saturated, and this value appears similar in birds (Powell, 1983b). Hemoglobin is concentrated inside red blood cells or erythrocytes. This cellular packaging is important for the biophysics of the microcirculation, and it provides physiological control of O_2 binding through cellular changes in the hemoglobin microenvironment (see Section 13.4.1.3).

13.5.1.2 O_2-Blood Equilibrium Curves

Figure 13.8 shows the O_2 equilibrium curve for duck blood as saturation (S_{O_2}) versus P_{O_2}, where S_{O_2} is defined as the percentage of the total hemoglobin sites available for binding O_2 which are occupied by O_2. Therefore, the maximum S_{O_2} is 100% and independent of hemoglobin concentration in blood. In contrast, O_2-hemoglobin equilibrium curves plotting concentration versus P_{O_2} quantify the absolute amount of O_2 in blood at a given P_{O_2}, and the maximum O_2 concentration depends on the amount of hemoglobin available. O_2 capacity defines the maximum O_2 concentration in blood when hemoglobin is 100% saturated with O_2. Total O_2 concentration in blood (C_{O_2}), including chemically bound and dissolved O_2, can be calculated as:

$$C_{O_2} = [O_2 \text{ capacity } (S_{O_2}/100)] + (\alpha_{O_2} P_{O_2})$$

The sigmoidal (or "*S*") shape of the blood–O_2 equilibrium curve results from cooperative, *allosteric* interactions between the four subunits of hemoglobin, which determine the three-dimensional shape of the molecule. O_2 equilibrium curves for individual hemoglobin subunits are not sigmoidal but simple convex curves, such as the O_2 equilibrium curve for myoglobin (see Section 13.7). The shape of the blood–O_2 hemoglobin equilibrium curve facilitates O_2 loading on blood in the lungs and O_2 unloading from blood in the tissues.

The cooperativity between functional subunits of hemoglobin is quantified with Hill's coefficient, n (Powell and Scheid, 1989). High values of n, exceeding the theoretical

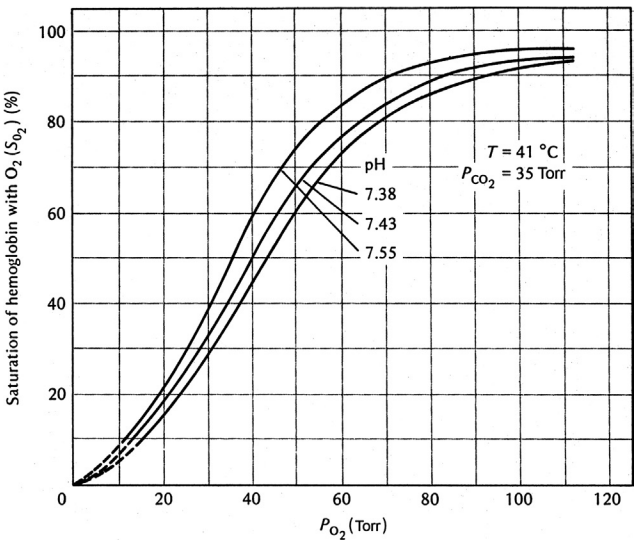

FIGURE 13.8 O_2-blood equilibrium curves for duck. Bohr effect is demonstrated by shifts of the curve as pH changes. *After Scheipers et al. (1975).*

limit of 4, have been observed in bird blood and may reflect increased cooperativity between aggregates of multiple hemoglobin molecules or interactions between different isoforms of hemoglobin within a blood sample (Black and Tenney, 1980b; Lapennas and Reeves, 1983).

The affinity of hemoglobin for O_2 is quantified with P_{50}, which is the P_{O_2} at 50% saturation. For example, a decrease in P_{50}, or a "left shift", indicates an increase in O_2 affinity because S_{O_2} is greater for a given P_{O_2}. In general, P_{50} in avian blood is greater than in mammalian blood. Table 13.4 shows P_{50} values for several common avian species in the 40 Torr range, while P_{50} in comparably sized mammals are nearer 30 Torr. Some studies have used erythrocyte suspensions (Lutz, 1980), and this might explain the low P_{50} values they have found. However, determinations of P_{50} in avian hemoglobin solutions agree well with other published values for whole blood, such as in pigeons (Powell, 1983b). Because the efficiency of O_2 uptake in the avian lung is greater than mammals, birds may have evolved blood with low O_2 affinity to maximize O_2 delivery in tissue.

Developmental changes in hemoglobin–O_2 affinity are explained by differences in the type of hemoglobin expressed in an individual. For example, the dramatic decrease of P_{50} in chickens, from 75 Torr at 8 days to 35 Torr at 14–16 days of development, is explained by the replacement fetal hemoglobin with adult hemoglobin expressed in the erythrocytes (Baumann and Baumann, 1978).

13.5.1.3 Physiological Control of O_2–Hemoglobin Affinity

The most important physiological factors that affect the P_{50} in a given species are (1) organic phosphate levels, (2) pH, and (3) temperature. These factors work by modifying the structure of the hemoglobin tetramer so it binds O_2 more or less efficiently.

Myinositol 1,3,4,5,6-pentophosphate (IPP) is the primary organic phosphate affecting P_{50} in birds (Weber and Wells, 1989). The effect of IPP binding with hemoglobin inside erythrocytes is considerable, for example, increasing P_{50} from less than 3 Torr in stripped hemoglobin from chickens, to over 40 Torr under *in vivo* conditions (Weingarten et al., 1978). Physiological changes in organic phosphates have not been studied extensively in birds (Maginniss and Kilgore, 1989; Weber and Wells, 1989). In mammals, acclimatization to conditions such as altitude can modulate P_{50} by altering organic phosphates (2,3 diphosphoglycerate, or 2,3-DPG). However, it is important to note that differences

in P_{50} between birds adapted over generations to low or high altitude cannot be explained by different organic phosphate concentrations. Erythrocyte inorganic phosphate levels are similar in the greylag and Canada goose, natives to low altitude (with $P_{50}=39$ and 42 Torr, respectively) and the bar-headed goose, which is native to high altitude (with $P_{50}=29$ Torr) (Petschow et al., 1977). Differences in the binding of IPP to hemoglobin from different species, explains such differences in P_{50} (Rollema and Bauer, 1979).

Figure 13.8 shows the effect of pH on the O_2 affinity, which is known as the Bohr effect. Increases in pH cause decreases in P_{50} (i.e., increased O_2-hemoglobin affinity) and vice versa. H^+ binds to histidine residues in hemoglobin, which changes the molecular conformation and ability of heme sites to bind O_2. The physiological advantage of the Bohr effect is that it facilitates O_2 loading in the lungs, where CO_2 is low and pH is high (see Section 13.5.3). In muscles, the opposite occurs and decreased pH facilitates O_2 unloading to the tissues. The Bohr effect is independent of saturation in most birds (Lapennas and Reeves, 1983; Maginniss, 1985; Meyer et al., 1978) and similar to values reported for mammals (Table 13.4).

In most birds, and in contrast to mammals, there is no independent effect of CO_2 on P_{50} (Meyer et al., 1978). CO_2 forms carbamino compounds with hemoglobin in mammals, and these cause small increases in P_{50}. In some birds, such as sparrows and burrowing owls, the Bohr effect is greater when pH is changed with CO_2 compared with fixed acid (Maginniss, 1985; Maginniss and Kilgore, 1989). Therefore, carbamino formation does occur and can decrease O_2 affinity in stripped avian hemoglobin. However, strong binding of IPP to hemoglobin in most birds prevents an independent CO_2 Bohr effect (Lapennas and Reeves, 1983; Weingarten et al., 1978).

The *in vivo* physiological O_2 dissociation curve is steeper than the individual *in vitro* curves in Figure 13.8 because P_{CO_2} increases and pH decreases between arterial and venous blood. This is an advantage for gas exchange because it increases the change in O_2 concentration for a given change in P_{O_2}, thereby increasing O_2 uptake or delivery. The slope of the physiological O_2-blood equilibrium curve, in terms of O_2 concentration, is called βb_{O_2} (mM/Torr) and is used for quantitative descriptions of gas exchange (see Section 13.6.1).

Because the combination of O_2 with hemoglobin is a chemical reaction that releases heat, increased temperature reduces the affinity of hemoglobin for O_2. This facilitates O_2 off-loading at exercising muscle with relatively high temperatures. It has also been hypothesized to facilitate O_2 loading in the lungs of birds flying at high altitude, when high rates of ventilation with extremely cold air might cool the respiratory exchange surfaces (Faraci, 1986, 1991). However, experiments to date have not been able to demonstrate decreased temperature of blood in the lungs. The effect of temperature on P_{50} in birds is generally similar to the effect in mammals (Table 13.4) except in the bar-headed goose, described next.

13.5.1.4 Frontiers: Hemoglobin Adaptations to High Altitude

Hemoglobin–O_2 affinity is generally greater in birds native to high altitude compared to low-altitude species, presumably as an adaptation to hypoxia (Black and Tenney, 1980b; Jessen et al., 1991; Meir and Milsom, 2013; Petschow et al., 1977). For example, P_{50} in the bar-headed goose (discussed above) is 10 Torr less than P_{50} in the closely related greylag goose, which lives on the Indian planes year round (Petschow et al., 1977). Low P_{50} will enhance O_2 loading in alveolar lungs in extreme hypoxia (Bencowitz et al., 1982) and the trend for low P_{50} in high-altitude species is observed in both birds and mammals (Powell and Hopkins, 2010). Amino acid sequences from the bar-headed goose and greylag goose revealed a single substitution on one of the four hemoglobin subunits, where two α-chains and two β-chains comprise a hemoglobin molecule (Allen, 1983). Genetically engineering this substitution into human hemoglobin decreases P_{50} by a similar amount to the difference between the geese (Jessen et al., 1991). In general, it appears that a low P_{50} in high-altitude compared with low-altitude species requires only a few amino acid substitutions, and these occur at either (1) contact points between subunits that stabilize hemoglobin in either low or high O_2-affinity conformations, or (2) binding sites for physiological modulators of O_2-affinity (Weber, 2007). Additionally, bar-headed goose hemoglobin is more sensitive to temperature than other birds (Table 13.4) and this is hypothesized to confer additional advantages. With differences in temperature and CO_2 between lungs and exercising muscle during high-altitude flight, changes in P_{50} are predicted to double O_2 delivery, relative to a fixed P_{50} in bar-headed geese (Meir and Milsom, 2013).

13.5.1.5 Factors Affecting O_2 Capacity

Changes in hemoglobin concentration, [Hb], in blood will change the O_2 capacity and therefore the O_2 concentration at any P_{O_2} as described above. [Hb] depends on both the mean corpuscular hemoglobin concentration (MCHC) and the hematocrit. Typical hematocrit and [Hb] values are given in Table 13.4; [Hb] is expressed as g/100 mL of blood instead of millimolar because the molecular weight was not known for all hemoglobins when they were originally measured. Typical values for MCHC in birds are 30–40 g Hb/100 mL of erythrocytes (Palomeque et al., 1979), or similar to the MCHC in mammals.

If [Hb] decreases, such as with decreased hematocrit in anemia, then O_2 capacity and concentration decreases at any given P_{O_2}. The O_2 capacity increases when [Hb] increases, such as by the stimulation of red blood cell production in

bone marrow by the hormone erythropoietin (EPO). EPO is released from cells in the kidneys in response to decreases in arterial O_2 levels (Sturkie, 1986). Significant gender differences in [Hb], for example in chickens, are explained by the effects of sex hormones on hematocrit (Sturkie, 1986).

13.5.2 Carbon Dioxide

CO_2–blood equilibrium (or dissociation) curves are nonlinear, but they have a different shape and position than O_2–blood equilibrium curves (Figure 13.9). CO_2 is carried in three forms by blood, so CO_2 concentrations in blood are generally much higher than O_2 concentrations. This results in a smaller range of P_{CO_2} values in the body, compared with the range P_{O_2} values, although the differences between arterial and venous *concentrations* are similar for CO_2 and O_2. The resulting physiological CO_2 dissociation curve between the arterial and venous points is much more linear than the physiological O_2 dissociation curve (Figure 13.9).

13.5.2.1 Forms of CO_2 in Blood

CO_2 solubility in water or plasma is 0.0278 mM/Torr, or about 20 times more soluble than O_2. Still, dissolved CO_2 only contributes about 5% of total CO_2 concentration in arterial blood. CO_2 can also combine with terminal amine groups in hemoglobin to form carbamino compounds (see Section 13.4.1.3). Bicarbonate ion (HCO_3^-) is the most important form of CO_2 carriage in blood. CO_2 combines with water to form carbonic acid, and this dissociates to HCO_3^- and H^+:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow HCO_3^- + H^+$$

Carbonic anhydrase is the enzyme that catalyzes this reaction, and it occurs mainly in red blood cells (Maren, 1967). The reaction is almost instantaneous with carbonic anhydrase, but the uncatalyzed reaction will occur much more slowly in any aqueous medium (requiring over 4 minutes for equilibrium). The rapid conversion of CO_2 to bicarbonate results in about 90% of the CO_2 in arterial blood being carried in that form. The H^+ produced from CO_2 reacts with hemoglobin and affects both the O_2 dissociation curve (Bohr effect), and CO_2 dissociation curve as described next.

13.5.2.2 Factors Affecting Blood-CO_2 Equilibrium Curves

Hb–O_2 saturation is the major factor affecting the position of the CO_2 equilibrium curve. The Haldane effect increases CO_2 concentration when blood is deoxygenated, or decreases CO_2 concentration when blood is oxygenated, at any given P_{CO_2} (Figure 13.9). The Haldane effect is actually another view of the same molecular mechanism causing the Bohr effect on the O_2 equilibrium curve (see Section 13.4.1.3). H^+ ions and O_2 can be thought of as competing for hemoglobin binding, so increasing O_2 decreases the affinity of hemoglobin for H^+ (Haldane effect), and increased [H^+] decreases the affinity of hemoglobin for O_2 (Bohr effect).

The physiological advantages of the Haldane effect are to promote unloading of CO_2 in the lungs when blood is oxygenated, and CO_2 loading in the blood when O_2 is released to tissues. The Haldane effect also results in a steeper physiological CO_2-blood equilibrium curve (Figure 13.9), which has the physiological advantage of increasing CO_2 concentration differences for a given P_{CO_2} difference.

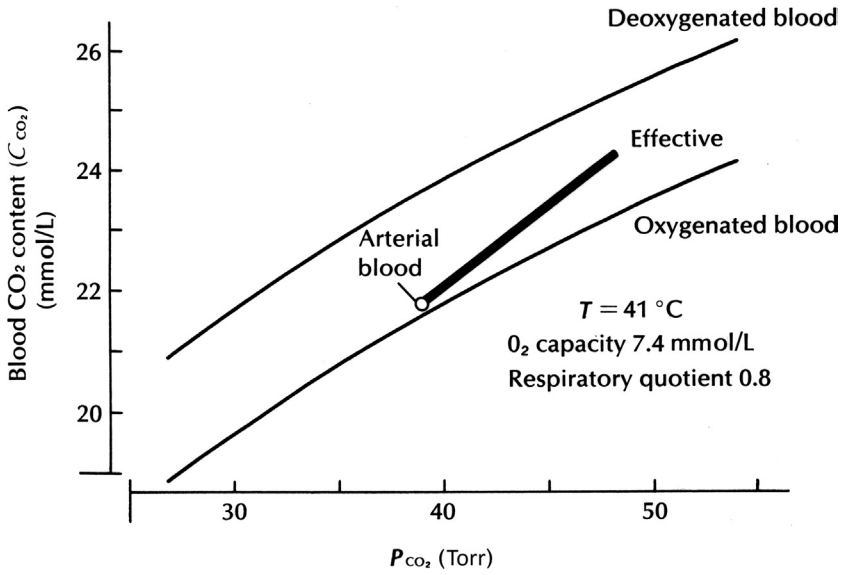

FIGURE 13.9 CO_2-blood equilibrium curves from the duck. Upper (deoxygenated blood) and lower (oxygenated blood) curves are derived from *in vitro* equilibration of blood samples. Heavy line is the physiological or *in vivo* dissociation curve from unanesthetized undisturbed birds. It illustrates the changes in CO_2 content (C_{CO_2}) in blood as it changes from arterial blood to venous blood in the tissue capillaries. *After Scheipers et al. (1975).*

Finally, the Haldane effect can cause apparent negative blood-gas CO_2 gradients when it is amplified by cross-current gas exchange in avian lungs (see Section 13.6.2.2).

13.5.3 Acid–Base

The chemical equilibrium between CO_2 and H^+/HCO_3^- ions has tremendous implications for acid–base physiology. Every mole of metabolic CO_2 produced results in 1 mol of acid, and over 95% of this acid is excreted by the lungs (Skadhauge, 1983). The ability to change blood P_{CO_2} levels rapidly by changing ventilation has a powerful effect on blood pH, so acid–base balance depends on the integrated function of respiratory and renal systems.

13.5.3.1 Henderson–Hasselbalch Equation

This equation describes the relationship between P_{CO_2}, pH, and $[HCO_3^-]$ in blood as:

$$pH = pK_a + \log\left([HCO_3^-]/\alpha P_{CO_2}\right)$$

where pK_a is $-\log_{10}$ of K_a, the dissociation constant for carbonic acid, $[HCO_3^-]$ = bicarbonate concentration in mEq/L or mM, and α is the physical solubility for CO_2 in water. A normal value for arterial pH (pH_a) in chickens is 7.52 (Table 13.5), which can be calculated from $pK_a = 6.09$ and $\alpha_{CO_2} = 0.03$ mM/Torr in chicken plasma at 41 °C (Helbacka et al., 1963), arterial $P_{CO_2} = 33$ Torr (Table 13.5), and arterial $[HCO_3^-] = 27.2$ mM. The buffer value for plasma in ducks is similar to the value for humans (Scheipers et al., 1975) if corrections are made for differences in [Hb]. At pH = 7.5, the $[H^+]$ is only 30 nM, or significantly less than many other important ions in the body, such as Na^+, Cl_3^-, HCO_3^-, which occur in the mM range. Small changes in pH, corresponding to very small changes in $[H^+]$ (see Chapter 12), can lead to dramatic changes in physiological function.

The Henderson–Hasselbalch equation shows how the physiological control of pH depends on the ratio of $[HCO_3^-]$ to $[\alpha P_{CO_2}]$. Notice that a normal pH can occur with a variety of $[HCO_3^-]$ and P_{CO_2} values, so, for example, pH = 7.52 in a chicken does not necessarily indicate normal acid–base status. The primary cause of a chronic acid–base disturbance cannot be determined from P_{CO_2}, pH, and $[HCO_3^-]$ data alone. Other details of the disease history, pulmonary function, or blood chemistry must be obtained for a proper diagnosis.

The respiratory system controls pH primarily by changing arterial $P_{CO_2}\left(P_{a_{CO_2}}\right)$. $P_{a_{CO_2}}$ is determined by parabronchial ventilation at any given metabolic rate (see Section 13.6.2). Increasing ventilation will decrease $P_{a_{CO_2}}$ and increase pHa, while decreasing ventilation will have the opposite effects. Therefore, ventilation is an extremely effective mechanism for changing pHa quickly, and ventilatory reflex responses to pH are the most important physiological mechanisms for rapid control of pH. The kidneys can also control pH by changing $[HCO_3^-]$ independent of CO_2 changes, as described in Chapter 12, but renal changes in pH generally take longer than respiratory changes in pH.

13.5.4 Blood Gas Measurements

Avian blood presents special challenges to the accurate measurement of P_{O_2}, P_{CO_2}, and pH with traditional equipment designed for humans. In contrast to mammals, avian erythrocytes are nucleated (as are most other vertebrates) and this may be the reason for high rates of O_2 consumption compared to mammals. Therefore, care must be taken to analyze arterial blood gases in birds as soon as possible after the sample is drawn, and to correct for any decreases in P_{O_2} with time if necessary. Storing the samples in ice water may help if immediate analysis is not possible, but the analyzed value can still differ from the *in vivo* value if any delay occurs, especially in normoxia where the blood–O_2 equilibrium curve is relatively flat and small O_2 content changes cause large changes in P_{O_2} (Scheid and Kawashiro, 1975). Sampling delays may also explain reports of 0 Torr P_{O_2} values in mixed venous blood from pigeons at simulated high altitude (Weinstein et al., 1985).

In addition to sampling delays, care must be taken to perform the analysis at body temperature, which is usually greater than the human value of 37 °C, or to apply temperature correction values established for avian blood (Kiley et al., 1979). Also, a blood–gas correction factor needs to be established with a tonometer to account for differences in P_{O_2} measured in the liquid phase after calibrating electrodes with a gas phase (Nightingale et al., 1968). These, and other factors which may affect O_2–hemoglobin saturation measurements, have been discussed in other reviews (Powell and Scheid, 1989).

Finally, the most important determinant of arterial blood gas values is the physiological state of the bird. Table 13.5 presents arterial blood gases for several species breathing room air, but these may not be "normal" if the bird was excited by the sampling procedure. Remote-controlled sampling devices have been used for resting ducks (Scheid and Slama, 1975), and this technology is being extended to other interesting conditions such as diving penguins (Ponganis et al., 2011) and flying geese (Meir et al., 2013).

13.6 PULMONARY GAS EXCHANGE

The unique anatomy of the avian respiratory system results, theoretically, in a model of gas exchange that is more efficient than the mammalian model (Piiper and Scheid, 1975). For a given level of ventilation to the gas exchange surfaces $\left(\dot{V}_P\right)$, cardiac output $\left(\dot{Q}\right)$ and lung diffusing capacity $\left(D_{L_{O_2}}\right)$, arterial O_2 loading, and CO_2 elimination are predicted to be better in a parabronchial lung, compared with an alveolar lung with the same inspired gases and

metabolic demands (Powell and Scheid, 1989). This section describes the structural and functional basis for this model, and how it actually behaves in nature under physiological conditions.

13.6.1 Basic Principles of Oxygen Transport

13.6.1.1 Convection

Convection, or bulk flow of gas, is used to transport oxygen into the lungs by ventilation and to the tissues by blood flow. The Fick principle, which is simply conservation of mass applied to respiratory gas transport, can be used to quantify O_2 uptake as:

$$\dot{M}_{O_2} = \dot{V}\beta_{g_{O_2}}\left(P_{I_{O_2}} - P_{\bar{E}_{O_2}}\right)$$

where $\dot{M}_{O_2}$ is O_2 uptake, $\dot{V}$ is ventilation, $\beta_{g_{O_2}}$ is the capacitance coefficient for O_2 in the gas phase (0.512 mM/Torr at 41 °C) and $(P_{I_{O_2}} - P_{\bar{E}_{O_2}})$ is the difference between inspired and mixed-expired P_{O_2} (Piiper et al., 1971; Powell and Scheid, 1989). Inspired and expired ventilation are assumed equal in this formulation of the Fick principle, so the amount of O_2 consumed is the difference between the amount of O_2 inspired and the amount expired. Mixed-expired P_{O_2} is used when total ventilation is measured; end-expired P_{O_2} is used if parabronchial ventilation $(\dot{V}_P)$ is available (see Section 13.5.4.1). The same principles described for O_2, also apply to CO_2 exchange.

The Fick principle can be written for the cardiovascular transport of O_2 out of the lungs and to the tissues also:

$$\dot{M}_{O_2} = \dot{Q}\beta_{b_{O_2}}\left(P_{a_{O_2}} - P_{\bar{v}_{O_2}}\right)$$

where $\dot{Q}$ is cardiac output and $\beta_{b_{O_2}}$ is the physiological slope of the blood–O_2 equilibrium curve (see Section 13.4.1.3). Hence, the amount of O_2 taken up by blood in the lungs is the difference between the amount of O_2 leaving the lungs in arterial blood, and the amount that entered the lungs in mixed-venous blood. In a steady state, $\dot{M}_{O_2}$ is equal at each step of the O_2 cascade, so the Fick principle can be rearranged to calculate $\dot{M}_{O_2}$, $\dot{Q}$, $\dot{V}$ or P_{O_2} from measurements of other variables in the equation. Table 13.5 lists the important variables for quantifying gas exchange in several birds under resting conditions. Changes in these variables under different physiological conditions such as exercise, hypoxia, and thermal stress have been summarized in several reviews (Brackenbury, 1984; Butler, 1991; Faraci, 1991; Powell and Scheid, 1989).

13.6.1.2 Diffusion

O_2 movement over the very short distances across the blood-gas barrier occurs effectively by the "passive" mechanism of diffusion; active transport of O_2 does not occur in the body. Fick's law of diffusion describes O_2 transport from the air capillaries to the blood capillaries as:

$$\dot{M}_{O_2} = \Delta P_{O_2} \cdot D_{L_{O_2}}$$

where ΔP_{O_2} is the average P_{O_2} gradient between the air capillary and blood in the pulmonary capillary and $D_{L_{O_2}}$ is the diffusing capacity of the lung for O_2. The equation shows that a larger $D_{L_{O_2}}$ can transport more O_2 for a given P_{O_2} gradient. Determinants of $D_{L_{O_2}}$ are described in the section on lung diffusing capacity below (see Section 13.6.3).

13.6.2 Cross-Current Gas Exchange

13.6.2.1 O_2 Exchange

Figure 13.10 shows how airflow and blood flow in the parabronchus can be viewed as occurring perpendicular to one another, and this is the basis for describing avian gas exchange with a "cross-current" model (Piiper and Scheid, 1972, 1975). In this idealized model of cross-current exchange, airflow is assumed continuous through the parabronchus, which is uniformly perfused along its length by mixed-venous blood. At the inspiratory end of the parabronchus, there is a large P_{O_2} gradient driving diffusion of O_2 into the capillary blood, which raises capillary P_{O_2} and drops parabronchial P_{O_2}. As air flows along the parabronchus, the P_{O_2} gradient driving O_2 diffusion decreases with parabronchial P_{O_2}, while $P_{\dot{V}_{O_2}}$ is constant. At the expiratory end of the parabronchus, P_{O_2} has decreased to end-expired levels, and P_{O_2} in the capillary blood leaving this part of the parabronchus is correspondingly low. However, notice that arterialized blood returning to the heart is a mixture of capillary blood draining the entire length of the parabronchus. Therefore, arterial P_{O_2} is greater than end-expired P_{O_2} in ideal cross-current gas exchange.

A negative expired-arterial P_{O_2} difference, shown in Figure 13.10 as the overlap of P_{O_2} arrows, is not possible in alveolar gas exchange. The best situation that can be achieved in ideal alveolar gas lungs is equilibrium between expired and arterial P_{O_2}, so $\left(P_{E_{O_2}} - P_{a_{O_2}}\right) = 0$. However, negative expired-arterial P_{O_2} differences are not always observed in birds and arterial P_{O_2} is similar in resting, normoxic birds and mammals (Table 13.5). As explained in the following sections, cross-current O_2 exchange is theoretically more efficient than alveolar exchange, but similar magnitudes of gas exchange limitations have larger effects in birds than in mammas (see Section 13.6.4).

Notice that the efficiency of cross-current exchange should not depend on the direction of ventilatory flow in the parabronchus. This is supported by experiments which reversed the direction of parabronchial flow in ducks and chickens and found no difference in the expired-arterial P_{O_2} differences for O_2 or CO_2 (Powell, 1982; Scheid and Piiper, 1972). It is physiologically significant because airflow is presumably bidirectional in neopulmonic parabronchi (see Section 13.2.3).

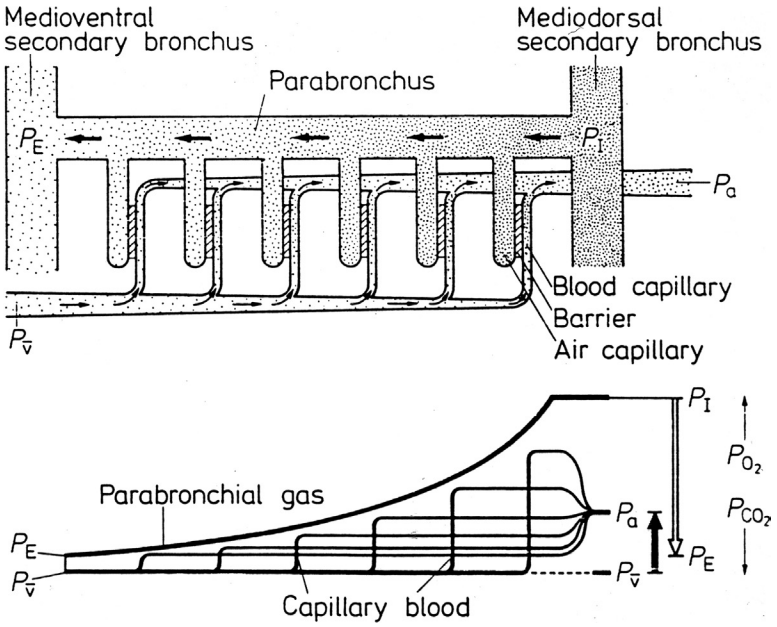

FIGURE 13.10 Cross-current model of gas exchange in the parabronchus as described in the text. Lower panel shows how $P_{a_{O_2}}$ results from a mixture of blood from capillaries all along the parabronchus, where P_{O_2} ranges from P_i to P_e. Overlap of P_{O_2} in gas (open arrows) and blood (filled arrows) shows how $P_{a_{O_2}}$ can exceed $P_{E_{O_2}}$ in birds. *From Scheid (1990).*

13.6.2.2 Cross-Current CO_2 Exchange

Figure 13.10 shows how expired P_{CO_2} can exceed arterial P_{CO_2} in a parabronchus, which is also impossible in alveolar gas exchange. This occurs similar to the "overlap" of arterial and expired P_{O_2} as explained above. However, experimental observations of expired P_{CO_2} exceeding *mixed-venous* P_{CO_2} in birds can only be explained by an interesting interaction of O_2 and CO_2 exchange in the parabronchus. Because of the shape of the O_2 and CO_2 blood equilibrium curves, the ratio of CO_2 elimination to O_2 uptake (R = respiratory exchange ratio) decreases near the expiratory ends of the parabronchus (Meyer et al., 1976). As originally postulated by Zeuthen (1942), this can lead to oxygenation of mixed-venous blood in expiratory ends of the parabronchi, and increase P_{CO_2} in capillaries by the Haldane effect. Because P_{CO_2} of oxygenated mixed-venous blood is greater than $P_{\dot{v}_{O_2}}$ (Figure 13.9), P_{CO_2} in gas equilibrating with such blood at the expiratory end of the parabronchus (i.e., $P_{E_{CO_2}}$) can exceed true $P_{\dot{v}_{O_2}}$.

Overlap between arterial and expired P_{CO_2} is more commonly observed than overlap for O_2 in birds (Table 13.5). This is because of differences in the O_2 and CO_2 blood equilibrium curves, and the fact that CO_2 is less sensitive than O_2 to some of the factors limiting the efficacy of cross-current gas exchange (Powell and Scheid, 1989).

CO_2 exchange can be affected by the same factors limiting O_2 exchange, which are considered in detail below. However, $P_{a_{CO_2}}$ is most sensitive to changes in $\left(\dot{V}_{D_{phys}}\right)$ and effective $\dot{V}_P$. CO_2 should not be diffusion limited either because O_2 and CO_2 require similar times for diffusion equilibrium (Wagner, 1977). $\dot{V}/\dot{Q}$ mismatching and shunt increases $P_{a_{CO_2}}$ less than they decrease $P_{a_{O_2}}$ because of differences between the O_2 and CO_2–blood equilibrium curves (Powell and Scheid, 1989).

13.6.3 Lung Diffusing Capacity

The diffusing capacity of the lung for O_2 $\left(D_{L_{O_2}}\right)$ is a complex variable that depends on several physiological processes (Powell, 1982; Powell and Scheid, 1989). These include gas-phase diffusion in the air capillaries, diffusion across the blood–gas barrier, and the chemical reaction between O_2 and hemoglobin.

13.6.3.1 Gas Transport in Air Capillaries

Ventilatory flow in the parabronchi prevents significant P_{O_2} gradients from developing in the lumen of the parabronchus. However, the mechanism of gas transport in the air capillaries is not clear and P_{O_2} gradients could occur between the lumen and the depths of the parabronchial mantle. Originally, it was assumed that diffusion explained gas transport over the small dimensions of the air capillary, considering the small distances involved and effectiveness of diffusive gas transport in the functional gas exchange unit of alveolar lungs. Indeed, measurements show no significant diffusive resistance to gas exchange along the air capillaries (Burger et al., 1979; Crank and Gallagher, 1978; Scheid, 1978). If diffusion is the main gas transport mechanism within air capillaries, then air–blood capillary exchange could be enhanced by an arrangement similar to counter-current exchange (Scheid, 1978). O_2 would diffuse from the lumen towards the periphery in air capillaries, which is opposite to the direction of flow in the blood capillaries (Figures 13.4 and 13.10). Therefore, blood at the end of a capillary would equilibrate with the relatively high P_{O_2} levels in air capillaries near the parabronchial lumen. However, there is no experimental evidence for this; more recent morophometric studies of the air capillary network (Figure 13.5) show extensive connections and branching, in contrast to the dead end tubes in Figure 13.10. This could result in convective flow instead of only diffusion in air capillaries (Maina et al., 2010).

13.6.3.2 Blood–Gas Barrier Diffusion

The effect of the blood-gas barrier on diffusion in the lung can be evaluated by the membrane diffusing capacity $\left(D_{m_{O_2}}\right)$, which can be estimated from morphometric measurements of the lung (Maina, 1989; Powell and Scheid, 1989). $D_{m_{O_2}}$ is directly proportional to the surface area, and inversely proportional to the thickness of the blood-gas barrier. These variables have been measured in several species of birds now, using perfusion fixation and rapid freezing to preserve tissue for electron microscopy and stereological analysis (Dubach, 1981; Maina et al., 1982, 1989; Powell and Mazzone, 1983; Powell and Mazzone, 1983). The values depend on body size (which determines metabolic levels; see Chapter 9), but in general they show that $D_{m_{O_2}}$ is larger in birds than in comparably sized terrestrial mammals (Maina, 1989). For example, $D_{m_{O_2}}$ in Canada geese is 1.7 times greater than a comparably sized mammal (Powell and Mazzone, 1983). Also, the thickness of the blood-gas barrier is 2.5 times thinner, and of much more uniform thickness, than in mammals (Maina et al., 1989; West, 2009). Interestingly, $D_{m_{O_2}}$ is similar in birds and bats of the same body size, indicating the importance of favorable diffusion for high O_2 consumption levels during flight (Maina, 1989).

13.6.3.3 O_2–Hemoglobin Reaction Rates

Finite reaction rates between O_2 and hemoglobin behave as an additional resistance to O_2 uptake across the blood–gas barrier. Consequently, $D_{L_{O_2}}$ increases if there is more hemoglobin available with increased capillary volume. Pulmonary capillary blood volume is similar in birds and terrestrial mammals of similar body sizes, except for chickens, which have a relatively low capillary volume (Maina, 1989). Also, estimates of the reaction rates between O_2 and avian

hemoglobin in birds and mammals are similar (Phu et al., 1986). Therefore, O_2–hemoglobin reaction rates probably contribute a similar amount to diffusion resistances in avian and mammalian lungs. In mammals, this is estimated to comprise about half of the diffusive resistance to O_2 diffusion.

13.6.3.4 Physiological Estimates of $D_{L_{O_2}}$

$D_{L_{O_2}}$ can be estimated from experimental measurements on birds if certain conditions are met to satisfy the assumptions necessary for an ideal cross-current analysis of the data. For example, measurements should be made in hypoxia, where the O_2–blood equilibrium curve is linear, to satisfy the assumption of constant βb_{O_2}. Physiological measurements of $D_{L_{O_2}}$ that satisfy these assumptions have been made in ducks and chickens (Burger et al., 1979; Scheid and Piiper, 1970), and they generally agree with morphometric estimates (Maina and King, 1982). Physiological $D_{L_{O_2}}$ in ducks ranges from 38 to 68 μmol/(min Torr kg) (Hempleman and Powell, 1986). Other methods for estimating potential diffusion limitations indicate complete diffusion equilibrium for O_2 in resting birds (Powell and Scheid, 1989).

Exercise and pharmacological stimulation of metabolic rate increase $D_{L_{O_2}}$ in ducks (Geiser et al., 1984; Hempleman and Powell, 1986; Kiley et al., 1985), and the change is correlated closely with increased cardiac output (Hempleman and Powell, 1986). In alveolar lungs, $D_{L_{O_2}}$ increases with cardiac output by recruitment and distention of the pulmonary capillaries, which increases surface area and capillary volume. However, these enhancements can be offset by shorter transit times in the pulmonary capillaries allowing less time for diffusion equilibrium. Recruitment and distention do not occur in avian lungs (see Section 13.3.2), so mechanisms of increasing $D_{L_{O_2}}$ in birds during exercise are not known.

13.6.4 Heterogeneity in the Lung

The avian lung is a complex structure consisting of hundreds of parabronchi. Mismatching of ventilation, blood flow, or diffusing capacity between these functional units can reduce the efficacy of gas exchange. Temporal variations in flow rates and inspired gas composition can also impair gas exchange. Under normal resting conditions at sea level, such heterogeneity in lung function is the most important factor reducing gas exchange efficacy from ideal levels in birds and in mammals.

13.6.4.1 Physiological Dead Space

Physiological dead space is defined as the difference between total inspired or expired ventilation ($\dot{V}_E$ or $\dot{V}_I$) and effective parabronchial ventilation $(\dot{V}_P)$:

$$\dot{V}_{D_{phys}} = \dot{V}_I - \dot{V}_P$$

$\dot{V}_{D_{phys}}$ includes anatomic dead space ventilation plus any heterogeneity such as inspiratory or expiratory mesobronchial shunts (see Section 13.3.3.4) or ventilation to regions of the lung with high $\dot{V}/\dot{Q}$ ratios (see Section 13.5.4.3). Therefore, $\dot{V}_{D_{phys}}$ considers ventilation "as if" total ventilation was partitioned between a single ideal parabronchus with $\dot{V}_P$ and anatomic dead space (Scheid and Piiper, 1989).

Many of the techniques used to estimate $\dot{V}_{D_{phys}}$ in alveolar lungs are not applicable to birds (Powell, 1988). However, with a computer model of O_2 and CO_2 dissociation curves and cross-current gas exchange, $\dot{V}_P$ can be calculated from measured ventilation, mixed-venous blood, and mixed-expired gas (Hastings and Powell, 1986b). $\dot{V}_{D_{phys}}$ in artificially ventilated ducks was almost 10 mL greater than anatomic plus instrument dead space, and two-thirds of the 15 mL anatomic dead space (Hastings and Powell, 1986b). This large amount of physiological dead space is consistent with relatively large amounts of total ventilation going to regions of the lung with high ventilation/perfusion ratios ($\dot{V}/\dot{Q}$; see Section 13.5.4.3), and indicates that ventilatory heterogeneity within the lung has a significant impact on $\dot{V}_P$ and gas exchange.

13.6.4.2 Shunt

Shunting of pulmonary blood flow past effective gas exchange areas is very small in birds. As described in Section 13.4.1, there are no arteriovenous anastomoses in the pulmonary circulation. Shunt ranges from less than 1% to 2.7% of cardiac output in anesthetized artificially ventilated geese and ducks, respectively, using inert gas methods to quantify true intrapulmonary shunt (Burger et al., 1979; Powell and Wagner, 1982). Oxygen can be used to quantify intrapulmonary plus extrapulmonary shunts, such as drainage of systemic venous blood from bronchial or Thebesian veins into pulmonary venous blood. Oxygen shunts average 6.3–8% of cardiac output in ducks, which is much greater than would be predicted given the magnitude of Thebesian and bronchial circulations in mammals (Bickler et al., 1986). One possible explanation for this large shunt is the connections between the vertebral venous and pulmonary circulations described for chickens (Burger and Estavillo, 1977), which also occur in ducks (Bickler et al., 1986). The sensitivity of extrapulmonary shunts to various physiological conditions has not been measured but $P_{a_{O_2}}$ is greater than predicted in hypoxia if such shunts persisted (see below).

13.6.4.3 $\dot{V}/\dot{Q}$ Mismatching

Differences in the ventilation/perfusion ratio $(\dot{V}/\dot{Q})$ between individual parabronchi is the main factor reducing arterial P_{O_2} from ideal cross-current levels in birds under resting conditions at sea level (Powell and Scheid, 1989). Ventilation and blood flow can differ between parabronchi

depending on small differences in resistance or pressure gradients that can occur along the multiple parallel pathways through the lung. Physiological mechanisms, such as smooth muscle tone in the bronchi and parabronchi (see Section 13.2.2.2) or interparabronchial arteries (see Section 13.4.3.1) may act to reduce such heterogeneity, but matching is never perfect.

It is important to point out that the effect of such spatial $\dot{V}/\dot{Q}$ heterogeneity on gas exchange is different than the effect of changes in the *overall* $\dot{V}/\dot{Q}$ ratio. The overall $\dot{V}/\dot{Q}$ ratio can affect $P_{a_{O_2}}$, so, for example, decreases in ventilation at constant cardiac output cause decreases in $P_{a_{O_2}}$. Also, the overall $\dot{V}/\dot{Q}$ ratio affects the magnitude of the arterial-expired P_{O_2} difference in a perfectly homogeneous cross-current gas exchanger (Powell and Scheid, 1989). However, spatial mismatching of $\dot{V}/\dot{Q}$ ratios between parabronchi will decrease $P_{a_{O_2}}$ further and make the arterial-expired P_{O_2} difference more positive than predicted for a homogeneous cross-current exchanger with the same overall $\dot{V}/\dot{Q}$ ratio; this is analogous to increasing the ideal alveolar-arterial P_{O_2} difference in mammals.

Several techniques have been used to measure distributions of $\dot{V}/\dot{Q}$ ratios in the avian lung, but they are relatively complicated and have not been applied yet to awake birds under many physiological conditions lung (Burger et al., 1979; Hempleman and Powell, 1986; Powell, 1988; Powell and Wagner, 1982). Significant amounts of ventilation go to high $\dot{V}/\dot{Q}$ regions of the lung in some cases (Powell and Wagner, 1982), and this contributes to physiological dead space. Heterogeneity in $\dot{V}/\dot{Q}$ ratios near the overall *parabronchial* $\dot{V}/\dot{Q}$ ratio has a large impact on O_2 exchange in birds. Compared to mammals, $\dot{V}/\dot{Q}$ heterogeneity is slightly greater (Powell and Wagner, 1982) and cross-current gas exchange is more sensitive to $\dot{V}/\dot{Q}$ mismatching than alveolar gas exchange (Powell and Hempleman, 1988; Powell and Scheid, 1989). In normoxic artificially ventilated geese, $P_{a_{O_2}}$ is 25 Torr less than the ideal level predicted for homogeneous cross-current gas exchange, which is significantly greater than the ideal-measured (alveolar-arterial) P_{O_2} difference in typical mammals (Powell and Hempleman, 1988). Hence, most of this drop in $P_{a_{O_2}}$ from ideal levels (15 Torr) is explained by $\dot{V}/\dot{Q}$ heterogeneity (Powell, 1993). The remaining 10 Torr difference between measured and ideal $P_{a_{O_2}}$ can be explained by postpulmonary shunts, which are virtually nonexistent in mammals. Pulmonary shunt is small (Bickler et al., 1986; Powell and Wagner, 1982) and there is no evidence for a diffusion limitation in normoxia at rest (Powell and Scheid, 1989).

In addition to parallel $\dot{V}/\dot{Q}$ mismatching between parabronchi, serial $\dot{V}/\dot{Q}$ mismatch can occur along a single parabronchus if the longitudinal distribution of blood flow is not even. Several studies have shown that blood flow is greater at the inspiratory ends of the parabronchi (Holle et al., 1978; Jones, 1982; Parry and Yates, 1979). However, such serial heterogeneity does not affect gas exchange unless there is a diffusion limitation (Holle et al., 1978; Powell and Scheid, 1989), and this does not occur under most conditions (see Section 13.6.3.4).

13.6.4.4 Temporal Heterogeneity

Changes in instantaneous ventilation of the parabronchi during normal breathing could in temporal variations in the $\dot{V}/\dot{Q}$ ratio. In theory, this could significantly decrease $P_{a_{O_2}}$ relative to the ideal level predicted for continuous ventilation (Powell, 1988; Powell and Scheid, 1989). For example, a ventilatory pause could act like a breath-hold, and rapidly decrease P_{O_2} in the small gas volume of the avian lung (Powell and Scheid, 1989). However, experiments indicate that this does not occur during normal breathing because the effective parabronchial gas volume is increased by mixing with larger bronchi (Scheid et al., 1977). Temporal changes in P_{O_2} entering the parabronchi during breathing could also impact $P_{a_{O_2}}$, but the effects are predicted to be relatively small (Powell, 1988). A time-averaged $P_{I_{O_2}}$ can be calculated for the parabronchi, and it is similar to caudal air sac P_{O_2} (Scheid et al., 1978).

13.6.5 Frontiers: Gas Exchange during High-Altitude Flight

How birds manage high levels of O_2 consumption for flight in extreme hypoxia at very high altitudes remains a fascinating and unanswered question. Birds are generally more tolerant of hypoxia than mammals (Tucker, 1972) and the first experiments actually measuring oxygen exchange during flight at high altitude used hummingbirds hovering in a hypobaric chamber (Berger, 1974). $\dot{M}_{O_2}$ during hovering at sea level was 32 mmol/(kg min), which is less than the maximal $\dot{M}_{O_2}$ for a hummingbird (Wells, 1993), However, this is greater than the maximal $\dot{M}_{O_2}$ for a comparably sized mammal. Furthermore, the hummingbird was able to maintain this high level of $\dot{M}_{O_2}$ at 6000 m simulated altitude, whereas maximal $\dot{M}_{O_2}$ is reduced to half the sea level value in mammals that have been studied at this altitude. Other experiments have studied $\dot{M}_{O_2}$ in hummingbirds with graded levels of exercise at different levels of O_2 (Chai and Dudley, 1996) but maximal $\dot{M}_{O_2}$ at different altitudes has not been determined in any bird to date.

Measuring the relevant physiological variables to understand how gas exchange changes in birds flying at high altitude is a huge experimental challenge. Consequently, most of the information available is from studies of resting or anesthetized birds exposed to hypoxia. Experiments on resting ducks and bar-headed geese show extremely high levels of ventilation at very high altitudes (Black and Tenney, 1980b; Powell et al., 2004), and these are predicted to eliminate the advantage of cross-current gas exchange,

compared with alveolar exchange (Shams and Scheid, 1989). However, these predictions are extremely sensitive to cardiac output, which varies greatly in the same species studied during hypoxic rest in different laboratories (Black and Tenney, 1980b; Shams and Scheid, 1989). Depending on the cardiac output, the advantage of cross-current compared to alveolar gas exchange could increase $P_{a_{O_2}}$ a couple of Torr in birds at 11 km altitude. Such a small change is physiologically significant, however, when the maximum P_{O_2} gradient between inspired gas and mixed-venous blood is only 20 Torr (Powell, 1993).

Measurements of gas exchange limitations in anesthetized ducks during hypoxia show the difference between ideal and measured $P_{a_{O_2}}$ is only a few Torr (Powell, 1993), which contrasts with the relatively large effects of gas exchange limitations in normoxic birds (see above). This is because the effects of $\dot{V}/\dot{Q}$ mismatching on $P_{a_{O_2}}$ are decreased in hypoxia, when exchange operates on the steep portion of the O_2-hemoglobin equilibrium curve (see Section 13.6.3.4). Indeed, $\dot{V}/\dot{Q}$ distributions do not change with hypoxia versus normoxia in anesthetized ducks (Powell and Hastings, 1983). A small diffusion limitation may also contribute to the difference in measured $P_{a_{O_2}}$ from the ideal value predicted for cross-current exchange in hypoxia. However, postpulmonary shunts measured in normoxia (Bickler et al., 1986) must be absent in hypoxia or $P_{a_{O_2}}$ would be lower.

Other experiments measuring all of the variables necessary for a quantitative analysis of gas exchange during exercise in hypoxia have been done in running water-fowl (Kiley et al., 1985) and emus (Schmitt et al., 2002). Such studies can reveal unique features of the avian respiratory system that could provide an advantage over alveolar gas exchange but they are limited in only increasing $\dot{M}_{O_2}$ about threefold from resting levels. Studies on the emu showed no change in $\dot{V}/\dot{Q}$mismatching in hypoxic versus normoxia, similar to results in anesthetized ducks (Powell and Hastings, 1983). However, $\dot{V}/\dot{Q}$ mismatching did not change with exercise in the emus either, which contrasts with increased $\dot{V}/\dot{Q}$ mismatching in exercising mammals and may provide an avian advantage at altitude (Powell and Hopkins, 2010).

With advances in instrumentation, it is becoming possible to measure more of the relevant gas exchange variables in flying birds. Preliminary reports of metabolic rate in bar-headed geese flying in a wind tunnel show decreases in $\dot{M}_{O_2}$ when inspired O_2 is decreased to simulate altitudes of 5500 and 8500 m while flight speed is maintained (Meir et al., 2013). This suggests flight may become more efficient in hypoxia, similar to apparent increases in swimming efficiency during prolonged dives in penguins and marine mammals (Ponganis et al., 2011). More interesting for pulmonary gas exchange, arterial P_{O_2} in the flying bar-headed geese was equal to or greater than resting values. Emus running in hypoxia also increased $P_{a_{O_2}}$ and decreased $P_{a_{CO_2}}$ (Schmitt et al., 2002), suggesting part of the advantage birds have over mammals at high altitude is greater hyperventilation. This would involve differences in ventilatory control more than lung structure and function *per se* (see Section 13.7.3.4). Other factors that may allow birds to exercise at extreme altitudes are considered in later sections of this chapter and have been reviewed elsewhere (Faraci, 1991; Fedde, 1990; Scott and Milsom, 2006). However, determining how much of an advantage the unique structure and function of the avian respiratory system provides over alveolar lungs at altitude awaits more detailed physiological measurements from birds exercising maximally in hypoxia.

13.7 TISSUE GAS EXCHANGE

O_2 moves out of systemic capillaries to the mitochondria in cells by diffusion. Therefore, O_2 transport in tissues is described by Fick's first law of diffusion, similar to diffusion across the blood-gas barrier in the lung:

$$\dot{M}_{O_2} = \Delta P_{O_2} \cdot D_{t_{O_2}}$$

where ΔP_{O_2} is the *average* P_{O_2} gradient between capillary blood and the mitochondria, and $D_{t_{O_2}}$ is a tissue diffusing capacity for O_2, analogous to the lung diffusing capacity (see Section 13.6.1.2). The main difference between O_2 diffusion in tissue and in the lung is that diffusion pathways are much greater in tissue. Tissue capillaries may be 50 µm apart, so the distance from a capillary surface to mitochondria can be 50 times longer than the thickness of the blood-gas barrier (<0.5 µm).

13.7.1 Microcirculation

13.7.1.1 Skeletal Muscle

Long diffusion distances can lead to significant P_{O_2} gradients in muscle. Also, the P_{O_2} gradient varies along the length of a capillary as O_2 leaves the blood, and capillary P_{O_2} decreases from arterial to venous levels. However, birds have some unique structural features in the skeletal muscle microcirculation to minimize diffusion distances and enhance tissue gas exchange. For example, the number of capillaries per cross-sectional area of flight muscle fiber in hummingbirds is six times greater than the value for rat soleus muscle, and the value in pigeon flight muscle is three times greater (Mathieu-Costello, 1993). This clearly decreases radial diffusion distances for O_2 leaving capillaries in birds.

In addition, skeletal muscle capillaries in birds are very tortuous and have extensive manifolds connecting capillaries running along adjacent muscle fibers (Mathieu-Costello, 1991; Mathieu-Costello et al., 1992). This geometry increases the exchange surface area so a muscle fiber is functionally surrounded by a "sheet" of capillary blood. This provides better tissue oxygenation than the traditional mammalian

model of straight capillaries running along a muscle fiber (i.e., the Krogh cylinder); Krogh's model predicts that P_{O_2} at the venous end of the capillary may be zero when O_2 supply decreases or demand increases (Mathieu-Costello, 1991).

13.7.1.2 Cerebral Circulation

Most evidence indicates cerebral blood flow increases with hypoxia but does not change with CO_2 in birds (Faraci, 1991). This results in significant improvements in tissue O_2 delivery during hypoxia (Faraci et al., 1984; Grubb et al., 1977). In mammals, hypoxia also increases cerebral blood flow, but this is partially offset by a vasoconstrictor effect of the decrease in $P_{a_{CO_2}}$ that accompanies the reflex increase in ventilation during hypoxia (see Section 13.7.3.2). This difference in cerebral vascular control may help explain how some birds are able to tolerate severe hypoxia better than some mammals (Faraci, 1986).

13.7.2 Myoglobin

Myoglobin is an O_2-binding protein, similar to a single polypeptide chain of the hemoglobin molecule (see Section 13.4.1.1), which has an extremely high affinity for O_2. For example, the P_{50} for hummingbirds myoglobin is 2.5 Torr (Johansen et al., 1987), so myoglobin can readily accept O_2 from capillary blood. Consequently, myoglobin is thought to be important for facilitating O_2 diffusion in muscle, by shuttling O_2 to sites far away from capillaries, or towards the venous end of capillaries. High levels of myoglobin are present in the heart and skeletal muscles of diving birds (Giardina et al., 1985; Weber et al., 1974), birds native to high altitudes (Fedde, 1990) and in hummingbirds with extremely high metabolism (Johansen et al., 1987). Increases in myoglobin with physical training in birds provide further evidence for the physiological significance of myoglobin in tissue gas exchange (Butler and Turner, 1988). M_b is also a significant O_2 store in diving birds, carrying about one-third of the total O_2 stores while the respiratory system and blood carry similar amounts (Ponganis et al., 2011).

13.7.3 Effects of Hypoxia and Exercise

Generally, decreases in O_2 supply (e.g., hypoxia) or increases in O_2 demand (e.g., exercise) are satisfied at the tissue level by increased O_2 extraction from blood or increasing blood flow. This is illustrated by the Fick equation (see Section 13.5.1.1) applied to the cardiovascular system:

$$\dot{M}_{O_2} = \dot{Q}\left(C_{a_{O_2}} - C_{\dot{v}_{O_2}}\right)$$

Increased O_2 extraction from the blood decreases $C_{\dot{v}_{O_2}}$ but $P_{\dot{v}_{O_2}}$ does not decrease much because the slope of the blood–O_2 equilibrium curve is steep around the venous point (Figure 13.8). High $P_{\dot{v}_{O_2}}$ levels are advantageous by keeping average capillary P_{O_2} levels high to drive O_2 diffusion into tissue. O_2 consumption is maintained in duck skeletal muscle during hypoxia without any change in blood flow (Grubb, 1981). During severe hypoxia in resting ducks and bar-headed geese, $C_{\dot{v}_{O_2}}$ can be less than 0.5 mM (Black and Tenney, 1980b). This suggests nearly complete O_2 extraction, although such low venous O_2 values could also result from measurement error (see Section 13.4.5). O_2 extraction in the cerebral and coronary circulations is not known for birds.

In exercising birds, extraction and blood flow increase to satisfy metabolic demands (Faraci, 1986; Faraci et al., 1984; Fedde, 1990). Increasing blood flow helps maintain high average capillary P_{O_2} because it raises mixed-venous O_2 concentration for any given arterial concentration and O_2 consumption (see equation above). Increases in blood flow are also observed in the ventilatory muscles of resting birds during hypoxia, which presumably reflects increased work in these muscles during increased breathing (Faraci, 1986). Under some extreme conditions of hypoxic exercise, muscle blood flow or tissue O_2 diffusion may actually limit maximal $\dot{M}_{O_2}$ in birds (Fedde et al., 1989).

Capillaries in avian skeletal muscle also show physiological plasticity and apparent genetic adaptations to hypoxia. Chronic hypoxia increases the capillary-fiber surface area contact for aerobic flight muscles in pigeons (Mathieu-Costello and Agey, 1997) and bar-headed geese have more capillaries per muscle fiber than expected for their aerobic capacity, in comparison to other geese native to lower altitudes (Scott et al., 2009). Capillaries are also denser and more evenly spaced, and mitochondria are located closer to the capillaries in the bar-headed goose compared to other geese, but the respiratory capacities, O_2 kinetics, and phosphorylation efficiencies of isolated mitochondria were not different between species (Scott et al., 2009). Hence, acclimatization and adaptation to limited O_2 appear to involve changes in O_2 delivery versus utilization (i.e., mitochondrial respiration).

13.8 CONTROL OF BREATHING

Breathing originates as rhythmic motor output from the central nervous system. This basic respiratory rhythm is modulated by several reflexes, in response to changes in activity and the environment. These reflexes are examples of negative feedback control, and tend to maintain arterial blood gases and pH homeostasis (Table 13.6). For example, if dead space increases, then $P_{a_{CO_2}}$ will increase if ventilation is constant. However, increased $P_{a_{CO_2}}$ stimulates an increase in tidal volume, which compensates for the increased dead space and returns $P_{a_{CO_2}}$ towards the control value. Like all reflexes, the ventilatory reflexes include (1) a sensory or afferent component, (2) an integrating component in the central nervous system (CNS), and (3) a motor or efferent component.

TABLE 13.6 Arterial Blood Gases and pH in Unanesthetized Birds Breathing Air

Bird	P_{O_2} (Torr)	P_{CO_2} (Torr)	pH
Female black bantam chicken (Calder and Schmidt-Nielsen, 1968)	–	29.9	7.48
Female white leghorn chicken (Kawashiro and Scheid, 1975)	82	33.0	7.52
Male white rock chicken (Calder and Schmidt-Nielsen, 1968)	–	29.2	7.53
Mallard duck (Butler and Taylor, 1983)	81	30.8	7.46
Muscovy duck (Kawashiro and Scheid, 1975)	82	38.0	7.49
Muscovy duck (Jones and Holeton, 1972)	96.1	35.9	7.46
Pekin duck (Black and Tenney, 1980b)	93.5	28.0	7.46
Pekin duck (Bouverot et al., 1979)	100	33.8	7.48
Emu (Jones et al., 1983)	99.7	33.5	7.45
Bar-headed goose (Black and Tenney, 1980)	92.5	31.6	7.47
Domestic goose (Scheid et al., 1991)	97	32	7.52
Herring gull (Calder and Schmidt-Nielsen, 1968)	–	27.2	7.56
Red-tailed hawk (Kollias and McLeish, 1978)	108	27.0	7.49
Burrowing owl (Kilgore et al., unpublished data)	97.6	32.6	7.46
White pelican (Calder and Schmidt-Nielsen, 1968)	–	28.5	7.50

This topic bridges respiratory physiology and neuroscience, but the emphasis here is on respiratory aspects and ventilatory reflex responses to changes in blood gases, often called the chemical control of ventilation. Several excellent reviews cover more details about the neuroscience of ventilatory control and control of breathing under different physiologic conditions (Bouverot, 1978; Davey and Seller, 1987; Gleeson and Molony, 1989; Jones and Milsom, 1982; Powell, 1983b; Scheid and Piiper, 1986; Taylor et al., 1999).

13.8.1 Respiratory Rhythm Generation

The basic respiratory rhythm is generated by a central pattern generator, composed of networks of neurons in the brainstem of the CNS. Respiratory rhythm can be measured in neural outputs from isolated hindbrain of chicks (Fortin et al., 1994), and transecting the brainstem between the XI and XII cranial nerve roots results in apnea and eventual death in pigeons (von Saalfeld, 1936). Reciprocal inhibition between medullary inspiratory and expiratory neurons are a common feature in birds (Peek et al., 1975), but experiments in mammals show that respiratory rhythm generation can occur without inhibitory synaptic interactions, implicating pacemaker processes (Smith et al., 1991). Other CNS structures important for sending motor outputs to ventilatory muscles in birds (Table 13.2) have been identified with stimulation experiments to study vocalization (Peek et al., 1975) and panting (Richards, 1971) in chickens or pigeons (Davey and Seller, 1987). The development of central pattern generators for bird song, which requires respiratory muscles, requires auditory feedback (Konishi, 2010) but such interactions have not been investigated for breathing.

13.8.2 Sensory Inputs

13.8.2.1 Central Chemoreceptors

In mammals, relatively discrete regions on the ventrolateral surface of the medulla in mammals show chemosensitivity to changes in $P_{a_{CO_2}}$ and local pH. These so-called central chemoreceptors can explain most of the reflex increase in ventilation when $P_{a_{CO_2}}$ increases in mammals (Bouverot, 1978; Guyenet et al., 2010). Central chemoreceptors have not been identified by neurophysiological or anatomic methods in birds. However, conscious ducks increase ventilation when $P_{a_{CO_2}}$ is increased in blood perfusing only the head, indicating an important physiological role for central chemoreceptors in birds (Milsom et al., 1981; Sèbert, 1979).

13.8.2.2 Arterial Chemoreceptors

Arterial chemoreceptors are sensitive to changes in $P_{a_{O_2}}$, $P_{a_{CO_2}}$ and pH, and they explain all of the ventilatory response to hypoxia in birds and mammals (Bouverot, 1978). They are also important for the ventilatory response to CO_2 and pH. The carotid bodies are very small (<1 mm diameter) organs located bilaterally in the thorax between the carotid artery and the nodose ganglion of the vagus nerve (Adamson, 1958; Hempleman and Warburton, 2013; Kameda, 2002). These organs are richly perfused by a branch of the carotid artery, and they are innervated by a branch of the vagus. Carotid bodies are near the parathyroid and ultimobranchial glands in birds, and are enveloped within the parathyroid gland in some species (Kobayashi, 1969; Yamatsu and Kameda, 1995); the physiological significance of this association is unknown. Arterial chemoreceptors have also been identified in other regions of the neck, along the carotid artery and aorta by anatomical and physiological methods (reviewed by Gleeson and Molony, 1989).

Figure 13.11 shows the response of carotid body arterial chemoreceptors to changes in $P_{a_{O_2}}$ and $P_{a_{CO_2}}$ in a duck. Afferent information about hypoxia or hypercapnia is transmitted to the CNS via the vagus nerve as increased frequency of action potentials from the carotid body. The pattern of action potential firing can differ in single chemoreceptors depending on the stimulus modality (O_2 versus CO_2) but the physiological significance of this is not known (Nye and Powell, 1984; Powell and Hempleman, 1990). Avian arterial chemoreceptors can also respond to oscillations in $P_{a_{O_2}}$, $P_{a_{CO_2}}$, and pH that can occur during breathing (Hempleman et al., 1992). The cell types and ultrastructure of the avian and mammalian carotid bodies are similar (reviewed by Gleeson and Molony, 1989), and similar chemoreceptor mechanisms on glomus cells in the carotid body probably explain P_{O_2} and P_{CO_2}/H^+ sensitivity in both classes. However, cellular mechanisms of arterial chemosensitivity are not completely understood (Kumar and Prabhakar, 2012).

13.8.2.3 Intrapulmonary Chemoreceptors

In contrast to mammals, the lungs of birds (and reptiles) contain intrapulmonary chemoreceptors (IPC), which respond to physiological changes in P_{CO_2} (Burger et al., 1974; Fedde et al., 1974a; Peterson and Fedde, 1968). The sensory endings of IPC have not been identified (reviewed by Gleeson and Molony, 1989), but physiological evidence indicates that these vagal afferents have multiple endings in the parabronchial mantle at several points along the length of one or more parabronchi (Hempleman and Burger, 1984). IPC can also respond to changes in CO_2 delivery to the lung by the pulmonary arteries (Banzett and Burger, 1977). Figure 13.12 shows how IPC are stimulated by *decreases* in P_{CO_2}, in contrast to arterial chemoreceptors that are inhibited by hypocapnia. However, increases in IPC activity cause ventilation to decrease, so the reflex response to CO_2 is similar in direction for central, arterial and intrapulmonary chemoreceptor reflexes (see Section 13.7.3). The mechanism of chemoreception in IPC depends on intracellular pH (Hempleman and Posner, 2004; Scheid et al., 1978), which is regulated by Na^+/H^+ exchangers (Hempleman et al., 2003), HCO_3^-/Cl^- exchangers (Shoemaker and Hempleman, 2001) and carbonic anhydrase (Hempleman et al., 2000). Calcium and potassium channels also modulate IPC sensitivity (Hempleman et al., 2006; Bina and Hempleman, 2007).

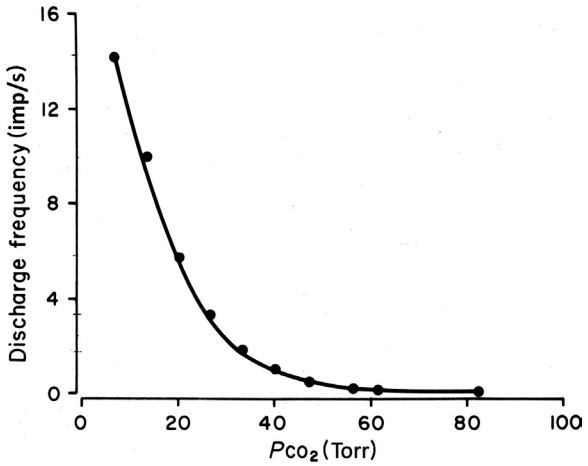

FIGURE 13.12 Average frequency of action potentials for intrapulmonary chemoreceptors ($n = 54$) exposed to CO_2 levels ranging from 7 to 82 Torr. *From Nye and Burger (1978).*

IPC are extremely sensitive to changes in P_{CO_2}, and show large overshoots or undershoots in action potential frequency with the kinds of periodic changes in P_{CO_2} that occur in the lung during normal breathing (Fedde and Scheid, 1976; Scheid et al., 1978). This makes IPC well suited for fine-tuning the pattern of ventilation, similar to the role of vagal pulmonary stretch receptors in mammals (see Section 13.7.3). However, in contrast to mammalian or reptilian pulmonary stretch receptors that are sensitive to mechanical stimuli and P_{CO_2} (Powell et al., 1988), avian IPC are not sensitive mechanical stretching of the lung (Bouverot, 1978; Fedde et al., 1974b).

13.8.2.4 Other Receptors Affecting Breathing

Ventilation also responds to changes in activity from air sac mechanoreceptors, thermal receptors in the spinal cord, proprioceptors in the skin and may be skeletal muscle, upper airway receptors sensitive to irritants, cold and water, and, perhaps, arterial baroreceptors (reviewed by Gleeson and Molony, 1989).

13.8.3 Ventilatory Reflexes

13.8.3.1 CO_2 Response

Most birds are not normally exposed to increases in ambient CO_2 levels, except perhaps in specialized nests or burrows. However, ventilatory responses to common stimuli, such as exercise, hot or cold temperatures, and altitude, are influenced by CO_2, so it is important to understand the response to CO_2. Figure 13.13 shows how ventilation increases with increasing inspired CO_2 in conscious ducks. Most species show increased tidal volume but the frequency response can vary (Bouverot, 1978). At low levels of inspired CO_2, ventilation increases sufficiently to maintain $P_{a_{CO_2}}$ at normal levels (Osborne and Mitchell, 1978).

Decreases in $P_{a_{CO_2}}$ or intrapulmonary P_{CO_2} can decrease ventilation. Hence, when ventilation is increased by another stimulus, such as hypoxia or hyperthermia, the decrease in $P_{a_{CO_2}}$ will act to inhibit ventilatory drive, and ventilation will be the net result of stimulation and inhibition. The hypercapnic ventilatory response scales with size in birds, so smaller birds have reduced CO_2 sensitivity (Williams et al., 1995). It is hypothesized that this may minimize inhibition of a strong hypoxic ventilatory response in small birds, considering the inverse scaling of the hypoxic sensitivity and size in birds (Kilgore et al., 2008 and see below).

Central chemoreceptors contribute to the ventilatory response to $P_{a_{CO_2}}$ as described in Section 13.7.2.1. Arterial chemoreceptors play an important role in the response to dynamic changes in $P_{a_{CO_2}}$ (Fedde et al., 1982; Jones and Purves, 1970; Seifert, 1896), such as $P_{a_{CO_2}}$ oscillations that may occur during breathing, and perhaps in the response to static changes in $P_{a_{CO_2}}$ also (Gleeson and Molony, 1989). IPC may contribute to the ventilatory response to changes in $P_{a_{CO_2}}$ also, although their role in this response is controversial (Bouverot, 1978; Gleeson and Molony, 1989). Experimental evidence seems to favor a role for IPC in determining the pattern of breathing, but not the overall level of ventilation in conditions where $P_{a_{CO_2}}$ increases (reviewed by Gleeson and Molony, 1989). IPC are well suited to sense breath-by-breath changes in ventilation as P_{CO_2} changes in the rigid avian lung. Therefore, IPC may play a similar role in the control of breathing to pulmonary stretch receptors in the alveolar lungs, which also sense instantaneous changes in ventilation as changes in lung volume.

13.8.3.2 Hypoxic Ventilatory Response

The hypoxic ventilatory response (Figure 13.14) is similar in birds and mammals (Black and Tenney, 1980b; Bouverot, 1978). Increasing $P_{a_{O_2}}$ above normal levels does not cause large decreases in ventilation, indicating that normoxic ventilatory drive from arterial chemoreceptors is relatively small (Gleeson and Molony, 1989). Also, ventilation does not change much until $P_{a_{O_2}}$ decreases below about 60 Torr in normal conditions, because small increases in ventilation will decrease $P_{a_{CO_2}}$ and ventilatory drive. The hypoxic ventilatory response (Figure 13.14) has a similar shape to the arterial chemoreceptor response to $P_{a_{O_2}}$ (Figure 13.11) and arterial chemoreceptors are responsible for the hypoxic ventilatory response in birds (Jones and Purves, 1970; Seifert, 1896). However, the arterial chemoreceptor response in Figure 13.11 is measured under *isocapnic* conditions, in which $P_{a_{CO_2}}$ was held constant by manipulating CO_2 levels in gas unidirectionally ventilating the lung of anesthetized birds. The hypoxic ventilatory response can be measured under isocapnic conditions also, by manipulating inspired CO_2 in awake birds. However, in contrast to mammals, such an isocapnic hypoxic ventilatory response does not measure

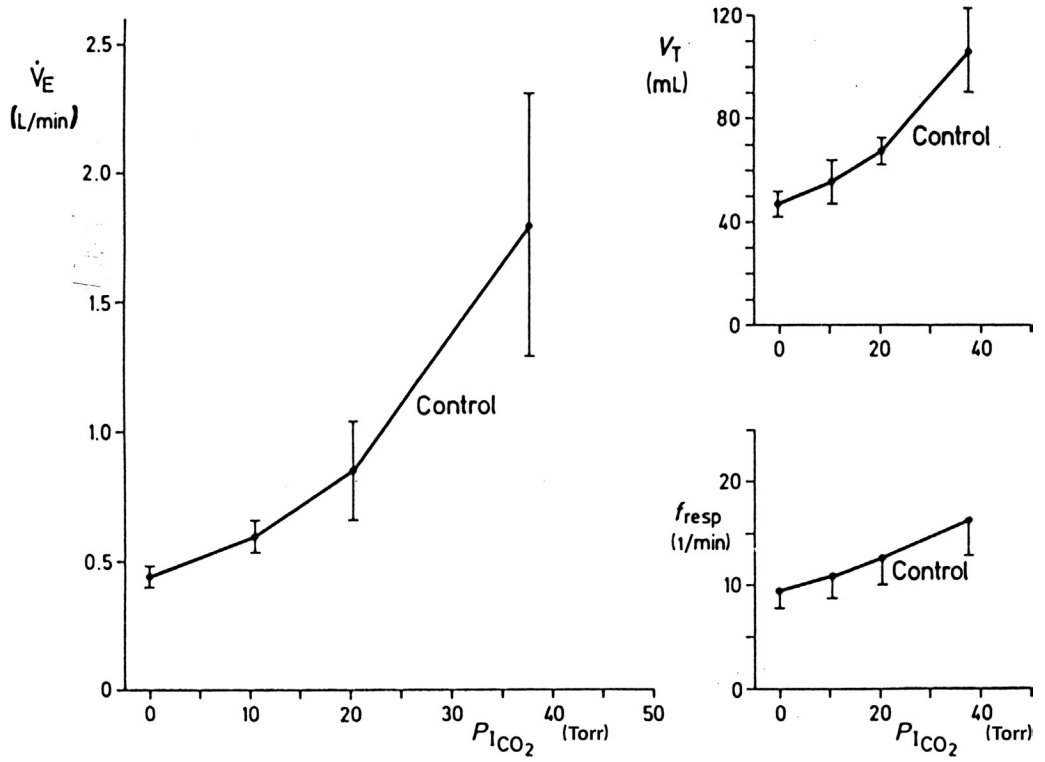

FIGURE 13.13 Ventilatory response to inhaled CO_2 in awake muscovy ducks (*Cairina moschata*). V_e = expired ventilation, V_T = tidal volume, fresp = frequency. *Modified from Powell et al. (1978).*

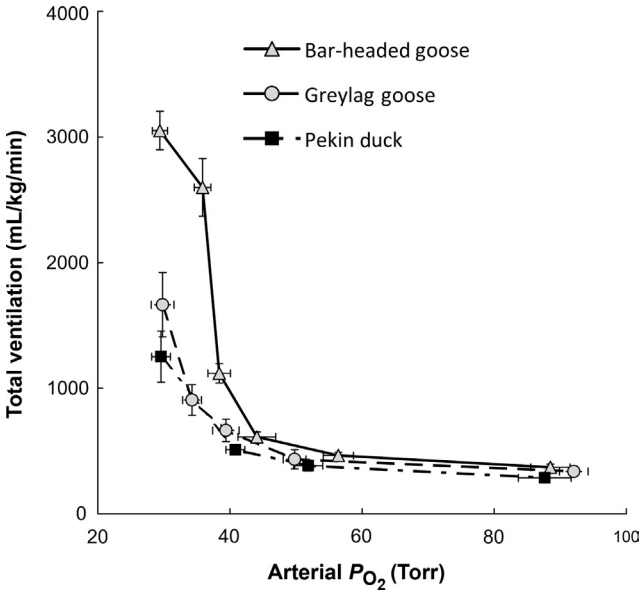

FIGURE 13.14 Hypoxic ventilatory response (isocapnic) for three species of waterfowl. *From Scott and Milsom (2007).*

of the pure effects of hypoxia on ventilation (independent of CO_2 effects). Changing inspired CO_2 can affect ventilation in birds through effects on IPC independently of $P_{a_{CO_2}}$ (Powell et al., 2000; Scott and Milsom, 2007).

Plasticity is observed in the hypoxic ventilatory response of birds with chronic changes in oxygen level. Chronic sustained hypoxia, as would be experienced during residence at high altitude, causes a time-dependent increase in ventilation above the acute response level (Black and Tenney, 1980b; Bouverot, 1985; Bouverot et al., 1976, 1979; Powell et al., 2004). This is called ventilatory acclimatization to hypoxia in mammals and involves changes in both O_2-sensitivity of arterial chemoreceptors and plasticity in respiratory centers in the CNS, which increases respiratory motor output for a given chemoreceptor afferent input (Powell et al., 1998). In mammals, ventilatory acclimatization to hypoxia causes time-dependent increases in $P_{a_{O_2}}$, but this is not observed in all avian studies. Acclimatizing Pekin ducks to 3800–5640 m altitude decreases $P_{a_{CO_2}} > 5$ Torr, indicating increased parabronchial ventilation, yet $P_{a_{O_2}}$ does not increase (Black and Tenney, 1980b; Powell et al., 2004). Apparently, other limitations to oxygen exchange increase during altitude acclimatization and offset the benefits of increased parabronchial ventilation for $P_{a_{O_2}}$.

Birds exhibit other forms of plasticity in the hypoxic ventilatory response too (Mitchell et al., 2001). Similar to mammals, ducks exhibit long-term facilitation of ventilation, in which breathing remains elevated above control levels following 3–10 brief episodes of hypoxia separated by normoxia. However, inhibitory mechanisms, such as hypoxic ventilatory decline or "rolloff" are not observed in

birds, in contrast to mammals. Such a bias towards excitatory versus inhibitory effects may provide an advantage at high altitude (see Section 13.7.3.5).

13.8.4 Ventilatory Response to Exercise

Exercise is the most common cause of increased ventilation, but the exact physiological mechanism for this is still unknown. The best evidence to date indicates that ventilation increases during exercise through a combination of "feed forward" mechanisms and feedback from chemoreceptors (Dempsey et al., 1995). Feed-forward mechanisms, also called central command, are neural signals from higher centers in the CNS that may stimulate respiratory centers directly. For example, neural signals to locomotor muscles may also stimulate ventilatory muscles, and could contribute to some of the phase locking between wing beats and respiration (Funk et al., 1992a,b). Feedback from chemoreceptors prevents ventilation from increasing too much. $P_{a_{CO_2}}$ usually decreases in exercising birds (Kiley et al., 1979), and this hypocapnia would be even worst if ventilatory chemoreflexes did not inhibit ventilation. Other ventilatory stimuli such as body temperature and hypoxia at altitude can modify the response to exercise (reviewed by Gleeson and Molony, 1989).

13.8.5 Frontiers: Extreme Hyperventilation at High Altitude

Birds hyperventilate more at high altitude than mammals (Powell et al., 2004). This theme appears in evolutionary adaptations too as bar-headed geese, which are the archetypal high altitude bird, do not show a "blunted" hypoxic ventilatory response typical of some high altitude human populations (Scott and Milsom, 2007). Hyperventilation in hypoxia decreases $P_{a_{CO_2}}$, which increases $P_{a_{O_2}}$ as well as exaggerating the Bohr effect to increase hemoglobin-O_2 affinity. Although $P_{a_{O_2}}$ does not increase further with ventilatory acclimatization to hypoxia in birds (see above), the time-dependent decrease in $P_{a_{CO_2}}$ will further increase arterial O_2 concentration by the Bohr effect. Hence, it appears that many of the advantages birds have at high altitude result from the extreme hyperventilation, hypocapnia and alkalosis in response to a strong hypoxic ventilatory response. Supporting this are observations of pigeons exposed to 9000 m simulated altitude showing only minimal stress while arterial pH is 7.85 (Lutz and Schmidt-Nielsen, 1977). Other studies show intracellular pH not changing while venous pH increases from 7.42 to 7.56 in pigeons exposed to 9000 m (Weinstein et al., 1985). This suggests that tighter regulation of the intracellular milieu may provide an avian advantage at altitude, although the hypothesis remains to be systematically tested. In any case, the control systems for ventilation and cerebral blood flow (see Section 13.7.1.2) that permit such extreme hypocapnia and alkalosis at altitude must have evolved with, or followed from, cellular adaptations preserving function with large pH changes.

Chapter 14

Gastrointestinal Anatomy and Physiology

D. Michael Denbow

Department of Animal and Poultry Sciences, Virginia Tech, Blacksburg, VA, USA

14.1 ANATOMY OF THE DIGESTIVE TRACT

The digestive tract is not only important for nutrient digestion and absorption, but it is the largest immunological organ in the body protecting against exogenous pathogens. The digestive system (Figure 14.1) has adaptations designed to facilitate flight. The length of the intestinal tract is shorter in birds relative to mammals (Table 14.1). Also, birds lack teeth and heavy jaw muscles, which have been replaced with a lightweight bill or beak. Food particles are swallowed whole and then reduced in size by the *ventriculus* or *gizzard* located within the body cavity. This chapter will not attempt to describe the many species variations in detail but will instead describe differences between birds and mammals. The reader is referred to the excellent reviews by McLelland (1975, 1979) for specific information on various species.

14.1.1 Beak, Mouth, and Pharynx

Birds have a bill or beak. This structure shows extensive anatomical variations among species, thus allowing for adaptations for different feeding styles. The upper bill is usually covered with a hard keratin. However, in some types of birds, the whole bill is relatively soft (i.e., Charadrii or shorebirds), whereas in others only the tip is hard (i.e., Anatidae or waterfowl). The culmen, the medial dorsal area of the upper beak, has a pointed protuberance in the embryo, the egg tooth, which drops off after hatching.

Birds, unlike mammals, have no sharp distinction between the pharynx and mouth. Birds lack a soft palate and a pharyngeal isthmus; the combined oral and pharyngeal cavities are referred to as the *oropharynx*. The palate contains a longitudinal fissure, the *choana*, which connects the oral and nasal cavities. Caudal to the choana is the *infundibular cleft*, which is medially located and is the common opening to the auditory tubes (Figure 14.2). The palate generally also has ridges that aid in opening the shell of seeds.

All vertebrates have a hyoid, which serves as an attachment site for muscles of the tongue and throat. Birds have a Y-shaped hyoid apparatus that extends to the tip of their tongue. Two long structures, the "horns" of the hyoid, grow backwards from the fork in the Y and provides insertion sites for protractor muscles originating on the lower jaw. The hyoid horns are modified in different species and can grow to the top of the head, around the eye socket and into the nasal cavity (Short, 1982; Wang et al., 2011). Contraction of the muscles attached to the hyoid apparatus pulls the apparatus forward and against the skull, thus thrusting the tongue outward. Lengthing the hyoid horns and attached muscles effectively gives the bird a longer tongue able to protrude further out the mouth.

The tongue shows adaptations for collecting, manipulating, and swallowing food (Harrison, 1964). In birds where the tongue is used for collecting food, it can be extended from the mouth during the collection process. Such tongues typically have lateral barbs and may be coated with mucous secreted by the mandibular salivary gland. The tongue may act as either a brush, a spear, or a dynamic tube (Rico-Guevara and Rubega, 2011), sometimes extending four times the length of the beak.

Tongues used to manipulate food, such as in piscivorous species, are nonprotruding and covered with stiff, sharp, caudally-directed papillae. In birds of prey, the tongue is a rasp-like structure, with the rostral portion frequently being very hard and rough (McLelland, 1979). On the tongue of birds that typically strain food particles (e.g., ducks), the rostral portion forms a scoop-like structure, with the lateral borders having a double row of overlapping bristles. The bristles work in conjunction with the lamellae of the bill to filter particles.

In birds where the tongue is utilized to aid in the swallowing of food, caudally-directed papillae tend to be located near the root of the tongue. These papillae function to propel food caudally. Tongues specialized for swallowing are nonprotruding.

Salivary glands also show considerable species variation. Although salivary glands are generally well developed in granivorous species, they are less developed in birds

Sturkie's Avian Physiology.

of prey, poorly developed in piscivores, and absent in the Anhinga and Great Cormorant (Antony, 1920). As a generalization, the *maxillary*, *palatine*, and *sphenopterygoid* glands are located in the roof of the mouth. The buccal gland is in the cheeks whereas the *mandibular*, *lingual*, and *cricoarytenoid* glands are in the floor of the mouth. Although the salivary glands of *Gallus* and *Meleagris* are reported to secrete little amylase, the house sparrow secretes considerable amounts (Jerrett and Goodge, 1973).

Taste buds are variably located on the upper beak epithelium, in the anterior mandible, and the mandibular epithelium posterior to the tongue. There are a small number of taste buds also located ventrolaterally on the anterior tongue. It is believed that chickens have as many as 300 taste buds, with the number in broilers being twice that of layer-type chickens (Ganchrow and Ganchrow, 1985; Kudo et al., 2008).

In some species of birds, the floor of the mouth contains sac-like diverticuli called *oral sacs*. These can act to either carry food or as a display apparatus during the breeding season.

Immediately behind the tongue is the *laryngeal mound*. It contains a narrow slit-like opening into the *glottis* of the larynx. The laryngeal mound generally contains rows of caudally-directed cornified papillae, which aid in moving food toward the esophagus during swallowing.

14.1.2 Esophagus and Crop

The esophagus is a thin-walled, distensible tube that transports food from the pharynx to the stomach, allowing birds to swallow their food whole. Thus, it contains a number of longitudinal folds that provide distensibility. The avian esophageal wall consists of four layers: mucosal, submucosal, muscle tunic, and the serosal layer; it generally contains only smooth muscle cells, with a circular muscle layer predominating (McLelland, 1979).

Unlike mammals, the avian esophagus is divided into a cervical and a thoracic region. In addition, the esophagus of birds lacks both upper and lower esophageal sphincters, which are present in mammals (see Mule, 1991).

In many, but not all (e.g., gulls, penguins, ostriches), species of birds, the cervical esophagus is expanded to form a *crop*. The crop functions to store food and may be spindle-shaped, bilobed, or unilobed. In the chicken, the crop is a ventral diverticulum of the esophagus and contains longitudinal folds on the inner surface, thus making it distensible. Beyond the crop, the esophagus continues as the thoracic esophagus to connect with the proventriculus.

A small number of species have a diverticulum or bilaterally symmetrical expansion of the cervical esophagus, the *esophageal sac*. In most species that have such a structure, it occurs only in the male and functions as a display during the breeding season and for the production of mating calls.

The esophagus and crop are lined with incompletely keratinized stratified squamous epithelia into which open numerous mucous glands. These glands are generally more numerous in the thoracic esophagus and may even be absent in the cervical region. Mucous glands are located in the crop only near the junction with the esophagus.

TABLE 14.1 Dimensions of the Digestive Tract of Various Species of Birds[1]

		Esophagus			Proventriculus and gizzard			Small intestine			Cecum		Rectum			Total

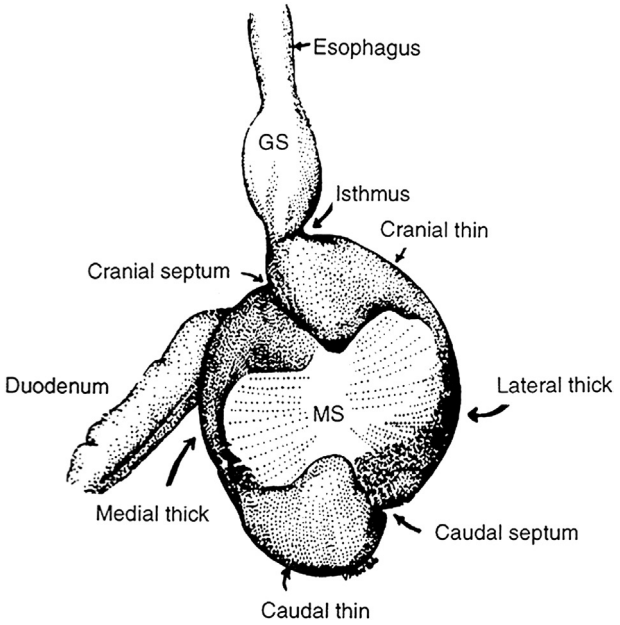

FIGURE 14.3 **Anatomical features of muscular stomach of domestic turkeys.** GS, glandular stomach; MS, muscular stomach. Note that cranial thin muscle of MS is continuous with lateral thick muscle and separated from caudal thin muscle at caudal septum. Similarly, the caudal thin muscle in continuous with the medial thick muscle and separated from cranial thin muscle by cranial septum. *From Chaplin and Duke (1990).*

The cervical esophagus is innervated by parasympathetic nerves. The thoracic esophagus is innervated by the vagus and the celiac plexus. The esophagus is innervated by a few adrenergic fibers, which synapse with the myenteric plexus rather than the muscles (McLelland, 1975; Mule, 1991).

14.1.3 Stomach

In mammals, the stomach consists of a single chamber. However, in birds, the stomach consists of two chambers, the proventriculus and gizzard, with the former being the mammalian counterpart. The proventriculus or glandular stomach is located orad to the gizzard or muscular stomach. The proventriculus is a fusiform organ varying in size and shape among species, being relatively large and distensible in aquatic carnivores while being relatively small in granivorous species. In ostriches, which lack a crop, the proventriculus is especially large. The proventriculus secretes mucus, hydrochloric acid, and pepsinogen, whereas the gizzard functions in mechanical digestion and is the site of gastric proteolysis. The pyloric region connects the gizzard to the duodenum.

There are two extremes in gastric anatomy (McLelland, 1979). The first type, characteristic of carnivorous and piscivorous species, is adapted for storage and the digestion of a relatively soft diet. The two stomach chambers contain little separation, although one chamber may be more developed than the other, depending on the species. The second stomach type, characteristic of omnivores, insectivores, herbivores, and granivores, is adapted for very hard diets. The proventriculus and gizzard are separated by an isthmus termed the *zona intermedia gastric*. The proventriculus is relatively small, while the gizzard is large and powerful. The gizzard consists of two pairs of opposing muscles, termed thick and thin pairs (Figure 14.3), which are composed of circular muscle. These pairs of muscles are lacking in some species (e.g., herons, hawks, owls).

The proventriculus, which generally lacks ridges except in fish- and meat-eating species, is lined with a mucous membrane. Projecting into the lumen are papillae on the surface, of which can be seen the openings of the compound glands that secrete gastric juices. These glands generally contain only oxynticopeptic cells and secrete hydrochloric acid, pepsin, and mucous. The proventriculus contains both a myenteric and submucosal plexus (Martinez et al., 2000).

The interior surface of the gizzard is lined with a cuticle, sometimes called *koilin*, which is produced by the mucosal glands. The cuticle protects the gizzard from acid and proteolytic enzymes secreted by the proventriculus and from injury during grinding of hard food items. The greenish or

brownish color of the cuticle is due to the reflux of bile pigments from the duodenum. Although the cuticle is continuously worn away and replaced in most birds, it is shed in some species.

The pyloric portion of the stomach shows a considerable range in development. In *Gallus*, it is only 0.5 cm long. Its mucosal glands secrete mucous instead of a cuticle. In other species, the pyloric portion is enlarged and contains a cuticle. Although the function of this region is unknown, it is believed that it may slow the movement of large particles into the duodenum (Vergara et al., 1989).

The stomach is innervated by the vagus and perivascular nerve fibers from the celiac and mesenteric plexii. The muscle cells are innervated by cholinergic fibers, while noradrenergic fibers innervate mainly blood vessels. The myenteric nerve plexus lies just under the serosa, while the submucosal plexus is lacking. Because the longitudinal muscle layer is absent, the myenteric nerve plexus is normally visible through the transparent serosa.

14.1.4 Small Intestine

The small intestine is sometimes divided into the duodenum, jejunum, and ileum. Although there is a distinct duodenal loop, the yolk stalk (i.e., Meckel's diverticulum) is often used as a landmark to separate the jejunum and ileum. Intestinal length varies considerably between species, being relatively shorter in frugivores, carnivores, and insectivores and long in granivores, herbivores, and piscivores. However, the length appears to be relatively shorter than in mammals.

The intestinal wall can contain either folds or villi, depending on the species. The type of mucosal projections are not necessarily consistent between the small and large intestine. *Gallus* species have villi, which decrease in length from 1.5 mm in the duodenum to 0.4–0.6 mm in the ilium and rectum. The number of villi decreases from 1–10 days of age, but thereafter remains constant.

Genetic selection for growth has altered villi morphology (Yamauchi and Isshiki, 1991). Compared to white leghorns, the villi of broilers are larger and show more epithelial cell protrusions from the apical surface of the duodenal villi. Nevertheless, the villi from both types of chickens form a zigzag arrangement, which is thought to slow ingesta flow.

The intestinal wall contains the same four layers as the remainder of the tract including the mucosal, submucosal, muscle tunic, and the serosal layer. The mucosal layer consists of the muscularis mucosa, lamina propria, and epithelium. However, the muscularis mucosa and lamina propria are poorly developed in birds, possibly because the villi lack a central lacteal. Although Brunner's glands, common to mammals, are absent (Calhoun, 1954), *tubular* glands (possibly homologous to Brunner's glands) are present in some species (Ziswiler and Farner, 1972). The epithelium contains chief cells, goblet cells, and endocrine cells. The crypts of Lieberkuhn are the source of epithelial cells lining the villi. The crypts contain undifferentiated cells, goblet cells, endocrine cells, and lymphocytes. Globular leukocytes and Paneth cells appear near the base of the crypts.

The intestines contain extensive innervation from both the sympathetic and parasympathetic nervous system. As described by Bennett (1974), innervation is both cholinergic and adrenergic. The enteric nerve plexuses were described by Ali and McLelland (1978). Except in the rectum, the longitudinal muscle is sparsely innervated.

The *intestinal nerve* (nerve of Remak), which runs the length of the small and large intestine, is unique to birds. Although it has no mammalian homologue, it may be analogous to the prevertebral ganglion (Hodgkiss, 1984a). This nerve is thought to be a mixed nerve containing both sympathetic and parasympathetic autonomic fibers (Hodgkiss, 1986).

14.1.5 Ceca

Arising at the junction of the ileum and rectum are the ceca. In some species, the ceca may be absent (e.g., Psittaciformes, Apodiforms, and Piciforms) or rudimentary (e.g., Columbiformes and Piciformes). In other species, they are either paired (e.g., herbivores, most granivores, and owls), singular (Ardeidae), or consist of a double pair (secretary bird). McLelland (1979) has grouped ceca into four types based on morphology: (1) intestinal, which resemble the remainder of the intestine; (2) glandular, which are long and contain many actively secreting crypts; (3) lymphoid, which are reduced in size, containing many lymphocytes and occasional nonsecreting crypts; and (4) vestigial, which are small with a reduced lumen. A correlation between diet and cecal development or between the size of the ceca and the length and width of the rectum has not been discovered (McLelland, 1989).

In chickens, a cecum can be morphologically divided into three regions (Ferrer et al., 1991). Near the ileocecal junction is the *basis ceci*, where the villi are well developed. The medial cecal region (*corpus ceci*) has longitudinal folds with small villi, while the distal cecal region (*apex ceci*) similarly has small villi and contains both longitudinal and transverse folds. The combination of villi and musculature near the ileocecal junction effectively prevents even very small particles from entering the ceca (Ferrando et al., 1987), although fluid contents do enter.

There is growing understanding of the importance of the ceca. Cecectomy results in lower metabolizability of food, greater loss of amino acids, and lower digestibility of crude fiber (Chaplin, 1989). The role of the ceca in absorption is discussed later.

14.1.6 Colon (Rectum) and Cloaca

The colon, sometimes called the rectum, is relatively short, linking the ileum with the *coprodeal* compartment of the cloaca. Although the colon of mammals has no villi and many goblet cells, the colon of birds has numerous flat villi and relatively few goblet cells (Clauss et al., 1991). In addition, the avian rectum has relatively few crypts, and they are shorter than in mammals. The simple columnar epithelium lining the colon and ceca has a well-developed brush border. As discussed in Section 14.6, the cloaca and colon have an important role in water reabsorption.

The cloaca serves as a common pathway for excretory, reproductive, and digestive wastes. It contains three chambers: *coprodeum*, *urodeum*, and *proctodeum*. The coprodeum is the most cranial portion into which empties the colon. The coprodeum lacks villi, but has mucosal folds or rugae. The urodeum is the middle and smallest compartment of the cloaca, separated from the coprodeum and proctodeum by the coprourodeal fold and the uroproctodeal fold, respectively. The urinary and reproductive tracts empty into the urodeum. The final chamber, the proctodeum, opens externally through the anus. The bursa of Fabricius, involved in immune function, projects dorsally into the proctodeum. Also projecting into the dorsal portion of the proctodeum is the dorsal proctodeal gland, sometimes called the foam gland, which secretes a white, frothy fluid. Birds lack a urinary bladder, and it has been shown that urine enters the distal lower intestine and is forced back into the colon, ceca, and possibly the small intestine (Goldstein and Braun, 1986).

14.2 ANATOMY OF THE ACCESSORY ORGANS

14.2.1 Pancreas

The pancreas is a pale yellow or red organ located within the duodenal loop, although in some species, such as the budgerigar, part of it may be found outside the loop. The gland has both an endocrine function, which will be discussed later, and an exocrine function. It is relatively small in carnivores and granivores but large in piscivores and insectivores. The pancreas is generally divided into three lobes—dorsal, ventral, and splenic—but their function in unknown (Paik et al., 1974).

The exocrine pancreas consists of compound tubuloacinar glands, which are divided into lobules. The number of pancreatic ducts varies from one to three (three in the domestic fowl). The pancreatic ducts generally drain into the distal part of the ascending duodenum and rarely drain into the descending loop of the duodenum. In domestic birds, the pancreatic and bile ducts drain into the ascending loop of the duodenum by a common papilla (Figure 14.1). The pancreas secretes amylase, lipase, proteolytic enzymes, and sodium bicarbonate.

14.2.2 Liver

The liver also functions as both an endocrine and an exocrine gland. It is divided into right and left lobes, which are joined cranially at the midline. The right lobe is larger, and, in the domestic fowl and turkey, the left lobe is subdivided into the dorsal and ventral parts. The bile canaliculi drain into the interlobular ducts. The lobular ducts then combine to form the right and left hepatic ducts. In birds, unlike in mammals, bile is transported to the duodenum via two ducts. The right and left hepatic duct combine to form the common hepatoenteric duct, which then goes to the duodenum. However, a hepatocystic duct branches from the right hepatic duct and connects to the gall bladder which, in turn, is drained by the cysticoenteric duct into the duodenum. In species without a gall bladder (e.g., pigeons, some parrots and ostrich), the branch of the right hepatic duct, called the right hepatoenteric duct, drains directly into the duodenum. The bile ducts generally drain into the duodenum at a site very near the pancreatic ducts. This generally occurs on the ascending loop of the duodenum. However, in some species, including the ostrich and *Columba*, the ducts empty into the descending loop of the duodenum.

14.3 MOTILITY

As food is broken down, it not only needs to be transported along the length of the gastrointestinal tract (GIT) (i.e., peristalsis), but there is also local, nonpropagating motility that mixes food with gastric juices and brings particles in closer proximity to the enterocytes. Motility not only occurs while an animal is eating, but also while the animal is fasted (migrating motor complexes, MMCs). The latter type of motility probably helps keep the digestive tract free from indigestible particles and dead enterocytes, among others. The enteric nervous system, part of the autonomic nervous system, controls gastrointestinal tract function, including motility.

14.3.1 Esophagus

Deglutition has been studied in *Gallus* by White (1968, 1970) and Suzuki and Nomura (1975). For prehension, the head is first lowered, after which food is grasped with the beak and then moved towards the oropharynx with the tongue. The choana reflexively closes. The oral phase of swallowing involves the rapid rostrocaudal movements of the tongue for 1–3 s, which moves the food particles caudally (Suzuki and Nomura, 1975). This movement is assisted by the caudally directed papillae.

During the next phase, the pharyngeal phase, the infundibular mound and glottis close, the hyoid apparatus becomes concave, the tongue is moved backward, and the esophagus is moved forward, thus decreasing the distance between the oral cavity and the esophagus. The head is raised and further tongue movements, assisted by the rostrocaudal movements of the infundibular mound, propel the food particles from the tongue to the esophagus.

Primary peristalsis within the esophagus moves the bolus towards the stomach (esophageal phase). Contractions are more rapid in the cranial esophagus than in the thoracic esophagus. In a fasted bird, the longitudinal muscle layer obliterates the esophago-ingluvial fissura, thus preventing a bolus from entering the crop (Ashcraft, 1930). After partial gizzard filling, the esophago-ingluvial fissura is relaxed and food can either enter the crop or stomach depending on the contractile state of the gizzard. The crop acts as a temporary food storage site (Hill, 1971). The destination of food appears to be controlled by the contractile state of the gizzard, with food entering or bypassing the crop when the gizzard is contracting or relaxing, respectively. In 6- to 10-week-old turkeys fasted overnight, almost no ingested food enters the crop during the first 4–6 h after dawn. During each meal the gastrointestinal tract fills cephalic to the upper one-third of ileum. In late afternoon meals, the crop also fills (G. Duke, personal communication).

Food is evacuated from a crop as a result of contractions by the crop wall. Such contractions last about 6 s with a force of approximately 20 cm H_2O (Fileccia et al., 1984). During primary peristalsis, there is a cessation of spontaneous electrical activity, which is associated with relaxation of the muscular wall. This is followed by a propagated, long-lasting spike burst of high amplitude. As the peristaltic wave moves aborad, it is preceded by inhibition of the muscles directly in front of the wave. The rate of emptying of the crop is not influenced by particle size or whether the compounds are soluble or insoluble (Vergara et al., 1989).

Unlike mammals, spontaneous electrical activity and contractions have been recorded in the esophagi of birds (see Mule, 1991). This activity is myogenic in origin. It occurs independent of slow waves, which are absent in the esophagi of birds. Although the function of these spontaneous contractions is unknown, they may act to clear contents from the esophagus.

Primary peristalsis is mediated entirely by the extrinsic nervous system (Mule, 1991). The enteric nervous system of birds is not responsible for propagating peristalsis, at least beyond short distances. Sectioning the glossopharyngeal or vagus nerve can disrupt peristalsis in the cervical and thoracic esophagus, respectively. Denervation of the esophagus prevents the propagation of electrical wave activity, indicating that the muscle cells act similar to multiunit smooth muscle cells.

14.3.2 Gastrointestinal Cycle

Motility of the mammalian stomach is regulated by slow waves thought to arise from the interstitial cells of Cajal, which lie adjacent to the myenteric plexus (Sanders et al., 2006). These slow waves pace the "phasic muscles", increasing the probability that voltage-gated Ca^{2+} channels will open, thus exciting the muscles. Slow waves arise from distinct pacemaker regions within different parts of the GIT, thus producing regional differences in slow-wave frequency. In the stomach, the pacemaker cells reside in the greater curvature of the stomach. The slow waves do not propagate from the stomach to the small intestine, but instead the small intestine has its own pacemaker cells. The stomachs of most birds lack longitudinal smooth muscle and do not display slow waves. As a result, gastric motility is more complex in birds than in mammals (Dziuk and Duke, 1972).

During the gastrointestinal cycle of birds, the thin muscles of the muscular stomach contract and the isthmus closes, after which the pylorus opens and gastric contents flow into the duodenum (Figure 14.4). Next, the duodenum contracts, followed by relaxation of the isthmus and a contraction of the thick muscles of the muscular stomach. This precipitates a refluxing of the contents of the muscular stomach into the glandular stomach. The cycle is completed

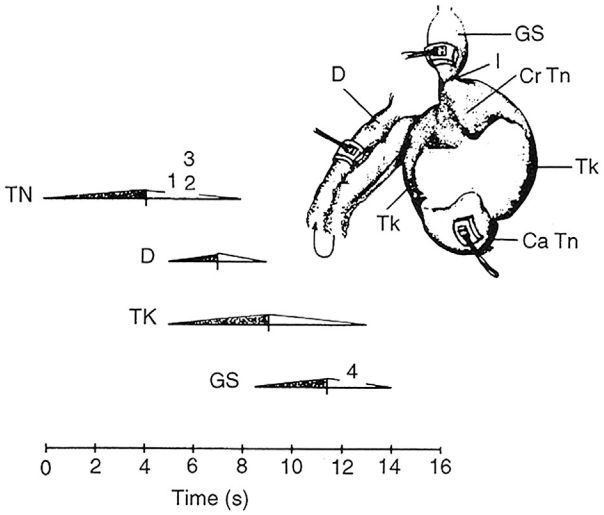

FIGURE 14.4 *Top right*: illustration of gastroduodenal apparatus of turkeys showing anatomical relationships of organs and placement of strain gauge transducers. Letters refer to organs as follows: GS, glandular stomach; I, isthmus; CrTN, cranial thin muscle of muscular stomach; TK, thick muscle pair (dorsal and ventral) of muscular stomach; CaTN, caudal thin muscle of muscular stomach; D, duodenum. *Bottom left*; triangles graphically represent sequence and duration of events in gastroduodenal cycle. Stippled areas indicate duration of contraction and clear areas indicate duration of relaxation of thin muscle pair (TN) and thick muscle pair (TK) of the muscular stomach, duodenum (D), and glandular stomach (GS). Numbers refer to noncontractile events in gastroduodenal cycle; 1, pylorus open; 2, isthmus open; 3, pylorus closed; 4, isthmus closed. *From Chaplin and Duke (1988).*

with contraction of the glandular stomach. A gastroduodenal cycle occurs with a frequency of 3.3 cycles/min in turkey (Duke, 1982). As might be expected, the largest change in intraluminal pressure is associated with contraction of the thick muscles (Figure 14.5).

As stated earlier, the pyloric region appears to control the movement of materials from the gizzard to the duodenum. Whereas soluble material is readily transported from the gizzard to the duodenum, larger particles are retained longer within the muscular stomach (Vergara et al., 1989).

Initiation of the gastrointestinal cycle is not dependent on extrinsic innervation in sated birds, suggesting that there is an intrinsic pacemaker controlling the cycle (Chaplin and Duke, 1988). Denervation of the stomach slows the rate of the gastrointestinal cycle in fasted birds and disrupts its normal synchronization (Figure 14.6), indicating that the gastrointestinal cycle is not independent of external neural input.

The pacemaker for the gastrointestinal cycle appears to reside in the isthmus (Chaplin and Duke, 1990). Destruction of the myenteric plexus in this area reduced contractions of the muscular stomach and duodenum by 50%, while simultaneously abolishing glandular stomach contractions.

The muscular stomach of raptors lack the two pairs of opposing muscles characteristic of other types of birds; as a result, the gastroduodenal cycle is simplified. It is described

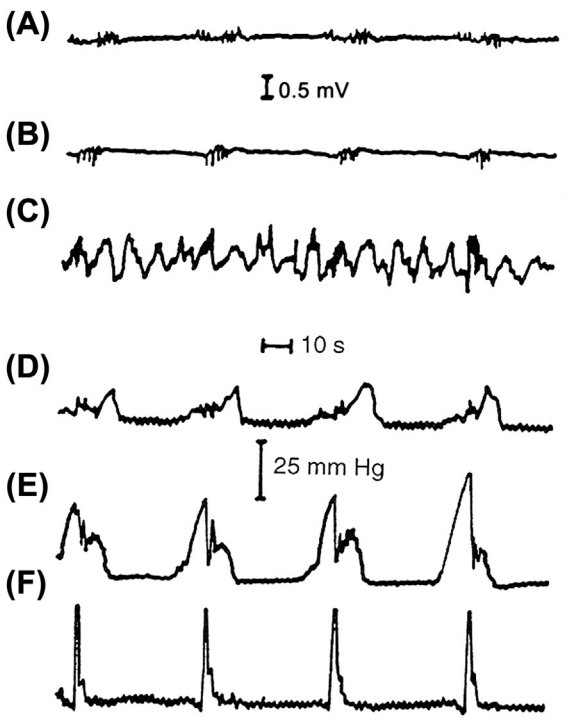

FIGURE 14.5 Tracings of typical records of electrical potential and intraluminal pressure changes from the stomach and duodenum of turkeys. (A), (B), and (C) are tracings of electrical potential changes recorded from the proventriculus, thick cranioventral muscle of the gizzard, and proximal duodenum, respectively. Slow waves with spikes are evident in the duodenum; only spikes associated with contractions are evident in the proventriculus and gizzard. (D), (E), and (F) are tracings of the corresponding intraluminal pressure changes recorded from these same organs, respectively. Time constant for electrical recordings was 1.1 s. *From Duke et al. (1975).*

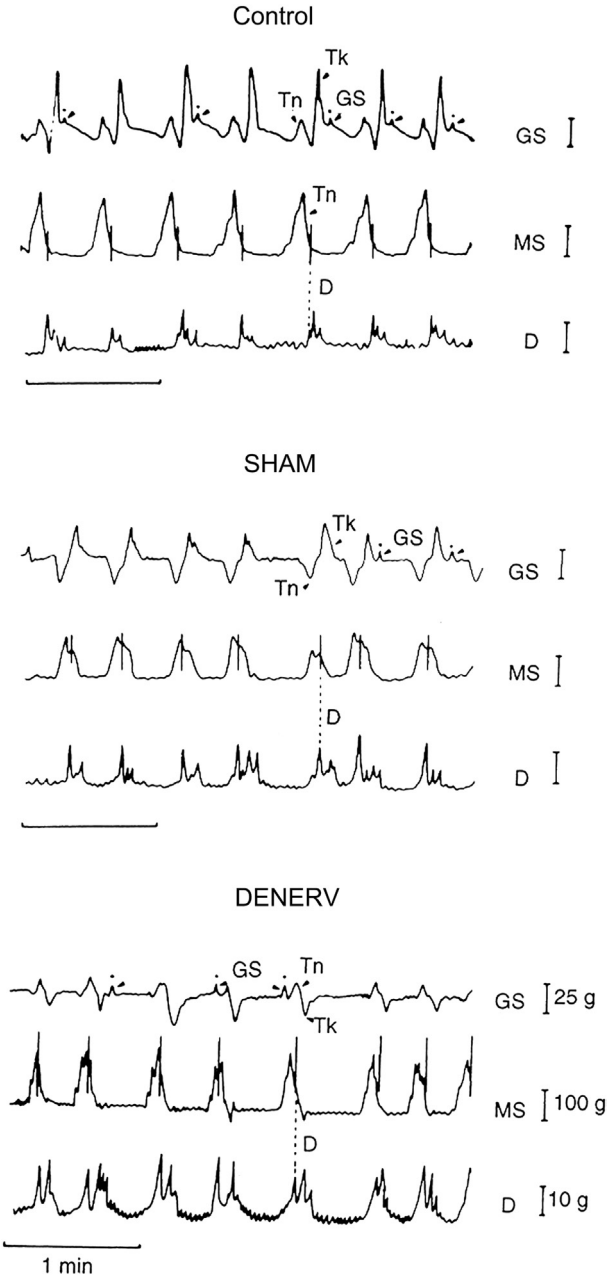

FIGURE 14.6 Tracings of recordings of glandular stomach (GS), muscular stomach (MS), and duodenal (D) contractions detected by implanted strain gauge transducers. Recordings were obtained on day 3 after surgery in three treatment groups used. Arrows and lettering identify contractions of each organ during one gastroduodenal cycle. Glandular stomach contractions are marked with an arrow and a closed circle; duodenal synchronization is identified with a dashed line. Note normal synchronization of contractions in the control tracings. *From Chaplin and Duke (1988).*

as having three phases, including mechanical, chemical, and pellet formation and egestion (Kostuch and Duke, 1975). A peristaltic wave originating in the proventriculus moves aborad through the gizzard and into the small intestine. Although the sequence of motility in the stomach of raptors resembles that in mammals, slow waves have not been recorded in these species.

Egestion is another gastrointestinal function unique to birds (Rea, 1973). This process, which involves the oral expulsion of nondigestible material, is more common in carnivores. Whenever bone, fur, or feathers are ingested, these materials are compacted and orally egested. This process is unlike regurgitation in ruminants or vomiting in mammals (Duke et al., 1976a,b). Beginning approximately 12 min prior to egestion, gizzard contractions increase in frequency and amplitude. This process both compacts the material into a pellet and moves it into the lower esophagus. Beginning 8–10 s prior to egestion, the pellet is moved orad by esophageal antiperistalsis. Neither the abdominal nor duodenal muscles are involved.

Enterogastric reflexes control gastric emptying. Simply increasing intraduodenal pressure, or administering intraduodenal injections of HCl, hypertonic NaCl, or amino acid solutions, inhibits gastric motility (Duke and Evanson, 1972; Duke et al., 1977, 1989). Inhibition was related to dose and volume; it generally occurred within 3–30 s, and it persisted for 2–35 min. Following an intraduodenal injection of a lipid solution, gastric motility decreased after 4–6 min and remained inhibited for 24–45 min. This latter response appears to involve hormonal regulation, presumably by an enterogastrone.

In addition, the presence of bile acids increases in the gizzard in proportion to the amount of wood shavings retained in the gizzard (Hetland et al., 2003). Because bile acids arrive in the intestine in the ascending loop of the duodenal duodenum, there is retrograde transport into the gizzard.

14.3.3 Small Intestine

The MMC is characterized by electrical potential changes known as slow waves, which travel aborad and are associated with periodic spike potentials and smooth muscle contraction (Figure 14.7). Although the MMC has not been extensively studied in birds, available data suggest that the MMC is similar in birds and mammals (Clench et al., 1989). The MMC has three phases: quiescence (phase 1); irregularly spaced spike activity superimposed on slow waves (phase 2); and high-amplitude, regular spike activity superimposed on slow waves (phase 3). In chickens, the MMC has a periodicity of 77–122 min, whereas in owls it is only 21 min. The duration of phase 3 lasts approximately 5–8 min (Figure 14.8). These values are similar to those in mammals. Nevertheless, the propagation speed in birds is relatively slow, ranging from 0.48 to 0.62 cm/min. Although the MMC has been observed in the duodenum of chickens, quail, and owls, it has only been observed aborad of the duodenum in turkeys (Mueller et al., 1990).

Intestinal refluxes appear unique to birds (Duke et al., 1973). Increases in intraluminal pressure of the duodenum normally follow increased pressure in the muscular stomach. However, approximately every 15–20 min in the turkey, large pressure changes were observed in the duodenum, which were associated with an inhibition of gastric motility and a reflux of intestinal contents (Figure 14.9). This has been observed in a number of other species as well, and appears more frequently as dietary fat levels increase (Duke et al., 1989).

14.3.4 Ceca

Motility in the ceca is not well understood. The ceca are filled as a result of the convergence of rectal antiperistaltic waves and ileal peristaltic waves. Due to the morphology of the ileo-cecal junction, only fluids or very small particles are allowed entrance to the ceca. In fact, 87–97% percent of cecal fluid originates from the urine (Bjornhag and Sperber, 1977). The importance of the movement of urine to the ceca is discussed below.

While MMC-like bursts of electrical activity have been observed within the cecum, this activity does not migrate and thus does not constitute an MMC (Clench et al., 1989). Two types of contractions have been recorded in the ceca of turkeys (Duke et al., 1980). One type has a low amplitude, occurring at a rate of 2.6/min, while the other has a higher amplitude and occurs at a rate of 1.2/min. Low-amplitude contractions are associated with mixing, whereas high amplitude contractions are propulsive. While aborad contractions were more common than orad contractions, the latter contractions had a greater amplitude and thus prevented the collection of digesta in the distal ceca. Peristalsis in a cecum appears to be myogenically mediated, with inhibitory neural input apparently

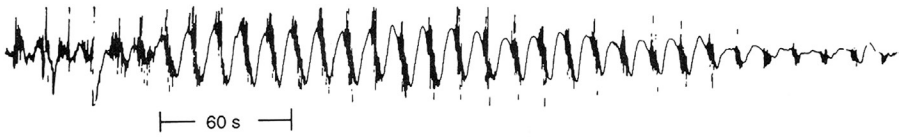

FIGURE 14.7 **Myoelectric recording of action potentials on slow waves (*Gallus*).** *From Clench et al. (1989).*

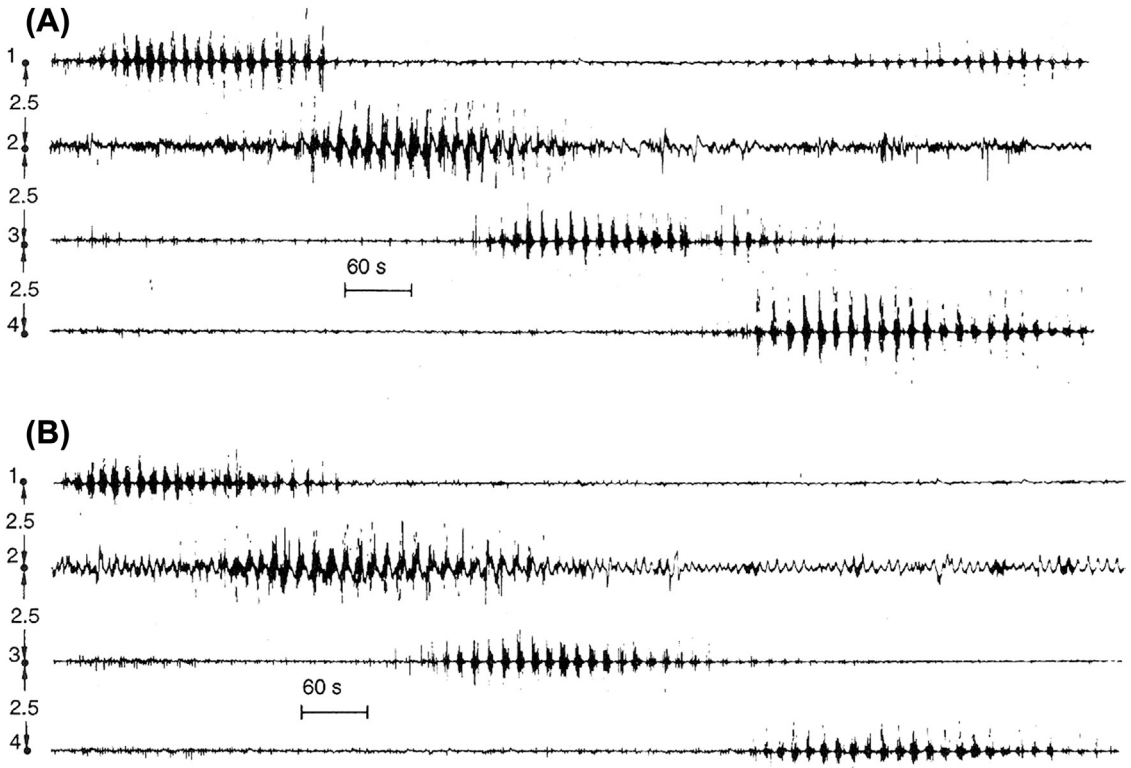

FIGURE 14.8 Representative myoelectric recording of a migrating myoelectric complex (MMC) in *Strix*. The electrodes were placed on the proximal ileum 2.5 cm apart. (A): bird in fed state. (B): bird in fasted state. High frequency of MMCs in this owl species in indicated in (A), with a second regular spike activity beginning on *lead 1* before previous complex has propagated through *lead 4*. *From Clench et al. (1989).*

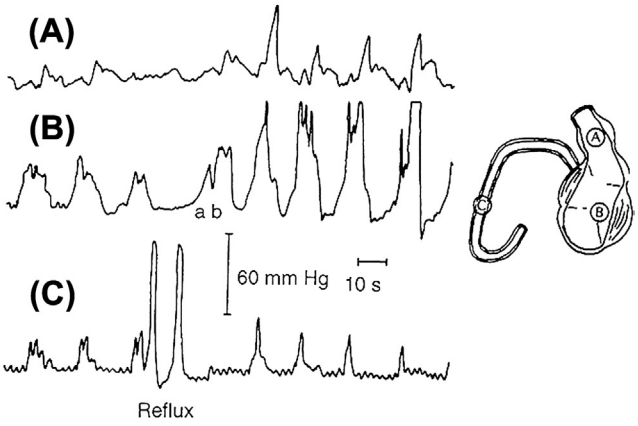

FIGURE 14.9 Tracings of typical records of pressure changes obtained from the proventriculus (A), gizzard (B), and upper proximal duodenum (C) of a turkey, showing pressure events occurring during a duodenal reflux. Positions of open-tipped tubes within GI tract are indicated by letters (A), (B), and (C) (circled) on the diagram of a sagittal section of the stomach. The biphasic patter (B) of the tracing representing the contraction of the gizzard is quite variable; two phases of one cycle are (*a*) pressure wave due to contraction of thin muscle pair; and (*b*) of thick muscle pair. *From Duke and Evanson (1972).*

able to suppress such contractions (Hodgkiss, 1984b). In mammals, distention causes an ascending stimulation and a descending inhibition, which is neurogenically mediated by the enteric nervous system and can be blocked by tetrodotoxin. By contrast, in birds, distention causes contraction of the circular muscle, which is unaffected by tetrodotoxin and thus apparently not controlled by the enteric nervous system.

The contents of the ceca are much different in consistency than that of the rectum and can therefore be easily distinguished from rectal feces. The ceca evacuate relatively infrequently compared to the rectum, with rectal evacuations preceding cecal evacuations (Duke et al., 1980). Cecal evacuations in young turkeys typically occur within 1–5 min of lights-on and again in late afternoon. There is an increase in the frequency of high-amplitude contractions, with four to seven such contractions occurring during the 2 min preceding cecal evacuation. These contractions are associated with high-amplitude electrical spiking. One high-amplitude contraction also occurs in the ileum and rectum at the time of cecal evacuation. The ratio of cecal to rectal evacuations is also influenced by diet, ranging from 1:7.3 when feeding barley to 1:11.5 when feeding corn (Roseler, 1929). As discussed in Section 14.6, the extended time that digesta spends in the ceca provides a unique role for this organ.

14.3.5 Colon

The rectum displays almost continuous antiperistalsis. Such motility is responsible for carrying urine from the urodeum

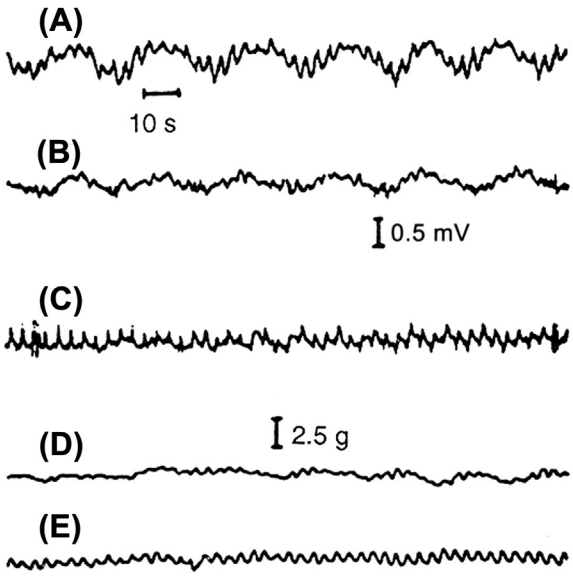

FIGURE 14.10 Electrical potential changes and contractile forces recorded from three bipolar electrodes ((A), (B), (C)) and two strain gauges ((D), (E)) in the colon of a turkey. Electrodes and strain gauges were implanted at 10, 6, and 1, and 8 and 3 cm from the cloaca, respectively. Both large and small slow waves are evident in tracings (A) and (B); only small slow waves are evident in tracing (C). Small contractions (antiperistalsis are evident in tracings (D) and (E)) but large contractions (peristalsis) can be seen only in tracings (D). *From Lai and Duke (1978).*

into the colon and ceca (Akester et al., 1967; Polin et al., 1967; Goldstein and Braun, 1986). Two types of colonic slow waves have been recorded (Lai and Duke, 1978). These include small, short duration (sSW) and large, long duration (lSW) slow waves (Figure 14.10). The sSW are associated with small contractions and, as shown with radiography, are antiperistaltic. The lSW are associated with large contractions but, radiographically, could not be associated with movements of rectal contents.

The frequencies of sSW and lSW are shown in Table 14.2. The frequency of sSW is highest in the distal colon. In contrast, the frequency of lSW is highest in the proximal colon and cannot be recorded from the distal colon. This pattern of slow waves, when compared to the motility pattern, suggests that sSW arise at the distal colon and are responsible for antiperistaltic movement, whereas the lSW begin in the proximal colon and are responsible for peristaltic movement of rectal contents.

The nearly continuous antiperistaltic activity of the colon is interrupted only near the time of defecation (Duke, 1982). Beginning approximately 10 min prior to defecation, the amplitude of the sSW begins to decrease while the frequency gradient of lSW increases. These conditions favor inhibition of antiperistalsis and stimulation of peristalsis. Defecation is associated with a strong contraction beginning at the proximal colon, moving aborally and carrying the contents the length of the colon in less than 4 s. Contraction of the rectum appears to be mediated by noncholinergic, nonadrenergic nerves (Bartlet, 1974; Takewaki et al., 1977).

14.3.6 Other Influences on Motility

Motility of the gastrointestinal tract shows diurnal variations. In turkeys, the frequency and amplitude of muscular stomach contractions increased during light periods relative to dark periods (Duke and Evanson, 1976). The increased and decreased gastric contractions coincided with just prior to "lights-on" and "lights-off", respectively. Although less pronounced, this diurnal rhythm of gastric activity continued when birds were fasted.

Birds also display cephalic, gastric, and intestinal phases of motility. In 24-hr fasted great horned owls, turkeys, and red-tailed hawks, the sight of food stimulated gastric contractions (Duke et al., 1976a). When allowed to eat, gastric activity increased further, indicative of the gastric phase. During the intestinal phase, entrance of food into the duodenum slows the frequency of gastric contractions to allow time for digestion (Duke et al., 1973). While the cephalic phase is mediated largely by the nervous system, there appears to also be an as yet unidentified endocrine component that increases motility.

Motility is influenced by many factors. For example, anesthetics, including nembutal and methoxyflurane, reduce gastroduodenal motility as well as decrease gastric secretion (Kessler et al., 1972; Duke et al., 1977). High environmental temperatures decrease gastrointestinal motility, whereas cold temperatures differentially affect motility in various parts of the digestive system but appear to have an overall effect of decreasing transit time (Tur and Rial, 1985).

14.4 NEURAL AND HORMONAL CONTROL OF MOTILITY

Extrinsic and intrinsic innervations of the avian gastrointestinal tract appears similar to mammals (Olsson and Holmgren, 2011). Extrinsic innervations is largely from the vagus nerve, nerve of Remak (ganglionic nerve running along the gut), and fibers from the splanchnic and pelvic nerves (Nilsson, 2011). Nitric oxide synthase is found in many neurons associated with the gut. Many of these neurons also contain vasoactive intestinal peptide (VIP) and pituitary adenylate cyclase-activating polypeptide. In pigeons, these nerves also contain galanin. In addition, most regions of the gut have nerves containing tachykinin-immunoreactivity, and the intestines have neurons containing gamma amino butyric acid. The myenteric plexus of the gizzard has aminergic neurons, although it has been reported that catecholamines are not present in the chicken intestine (Aisa et al., 1997).

TABLE 14.2 Mean Frequency and Amplitude of Small and Large Contractions and of Small and Large Slow Waves in the Rectum of Turkeys

	Contractions				Slow Waves			
	Small		Large		Small		Large	
	Frequency (cycles/min)	Amplitude (g)	Frequency (cycles/min)	Amplitude (g)	Frequency (per min)	Amplitude (mV)	Frequency (per min)	Amplitude (mV)
Proximal[1]	14.6±0.85	0.45±0.24	2.66±0.26	0.54±0.20	15.4±1.07	0.17±0.08	2.83±0.26	0.21±0.09
Middle	–	–	–	–	15.8±1.12	0.16±0.09	2.76±0.24	0.12±0.06
Distal	15.4±0.69	<0.70±0.33	–	–	16.4±2.16	0.25±0.12	–	–

[1]Proximal, middle, and distal refer to electrode implant sites on the colon 10, 6, and 1 cm from the cloaca, respectively, or to strain gauge transducer implants at 8 (proximal) and 3.5 (distal) cm from the cloaca. (Large contractions were not recorded from the distal strain gauge nor were large slow waves recorded from the distal electrode.)
Source: From Lai and Duke (1978).

Contractions of the esophagus are increased by acetylcholine (ACh) and vagal stimulation and unaffected by sympathetic nerve stimulation (Bowman and Everett, 1964; Ohashi and Ohgua, 1967; Taneike et al., 1988). However, there is evidence for nonadrenergic, noncholinergic (NANC) inhibition of esophageal smooth muscles (Sato et al., 1970; Postorino et al., 1985). Serotonin also causes contractions of the esophagus (Mule et al., 1987), and this effect appears to be mediated indirectly by activation of both cholinergic and NANC excitatory neurons (Fileccia et al., 1987). In addition, tachykinins cause contraction of the gut (Liu and Burcher, 2001). In contrast, epinephrine induces relaxation of the chicken rectum via alpha-adrenergic receptors (Ojewole, 1980).

The proventriculus has been shown to contain gastric inhibitory peptide (GIP), VIP, and nitric oxide synthase (nNOS), but not somatostatin, peptide histidine-isoleusine (PHI), peptide tyrosine-tyrosine (PYY), neuropeptide tyrosine (NPY), bombesin, met-enkephalin, serotonin, substance P, galanin, or calcitonin gene-related peptide (CGRP) (Martinez et al., 2000), VIP and nNOS. VIP and NO probably cause relaxation of smooth muscle. The proventriucular secretions are controlled by parasympathetic nerves and a diffuse endocrine system.

As shown in Table 14.3, many peptides have been identified within the gastrointestinal tract of birds. The function of these peptides remains to be elucidated. Although the identity of the NANC excitatory neurotransmitter was not identified, it has been shown that neurotensin can induce contraction of crop smooth muscle (Denac and Scharrer, 1987). This latter effect is a postjunctional response not mediated by acetylcholine, prostaglandins, or opioids.

Histamine interacts with cholinergic neurotransmission to control esophageal contractions (Taneike et al., 1988). Histamine dose-dependently induces esophageal contractions, but this effect is blocked by tetrodotoxin, suggesting that its effect is mediated by the release of ACh. Contractions induced by vagal stimulation are increased by the presence of histamine, whereas histamine-induced contractions were enhanced by acetylcholinesterase inhibitors. It appears, therefore, that histamine modulates, via H_1 receptors, the release of ACh to control the contraction of esophageal smooth muscle. As indicated in Figure 14.11, enkephalins also cause contraction of the esophagus, but their effect is mediated by serotonergic neurons.

The crop appears to be controlled similarly to the esophagus. Electrical stimulation of the crop causes contraction that is largely, but not completely, due to ACh release because it can be significantly blocked by atropine (Denac et al., 1990). While it is unclear as to which neurotransmitters are responsible for the contraction not blocked by atropine (i.e., NANC-induced), neurotensin, bombesin and substance P have been shown to cause atropine-resistant contractions following electrical stimulation of the crop (Denac and Scharrer, 1987, 1988). Norepinephrine caused crop muscle relaxation that was mediated by β-adrenoceptors. It appears that the crop and esophagus are controlled by three types of nerves: stimulatory cholinergic neurons, stimulatory NANC neurons (probably peptides), and inhibitory noradrenergic nerves.

Cholecystokinin octapeptide (CCK-8) is the most studied regulator of intestinal motility. Intravenous infusion of CCK-8 inhibited gastric and duodenal motility (Savory et al., 1981). CCK-8 and CCK-tetrapeptide (CCK-4) inhibited gastric electrical activity (Martinez et al., 1992). Whereas CCK-4 inhibited duodenal electrical activity, CCK-8 stimulated such activity (Figure 14.12). CCK-A and CCK-B receptor antagonists were unable to block the effects of CCK. It appears that the action of CCK on gastric and duodenal motility is similar in birds and mammals. CCK inhibits stomach motility, and the increase in duodenal activity is suggested to cause segmental contractions, and, thus, also delay gastric emptying (Martinez et al., 1992).

Vagotomy and hexamethonium blocked the response to CCK-8 in the chicken stomach (i.e., proventriculus and gizzard) but had no effect on the duodenal response (Martinez et al., 1993). Furthermore, the action of CCK-8 in the duodenum was not altered by atropine or methysergide. Phentolamine and propranolol had no effect on the gastric or duodenal response to CCK-8. It appears, therefore, that the action of CCK-8 on the stomach is mediated via the vagus, whereas the action in the duodenum probably involved a direct effect on smooth muscle cells. The action of CCK-8 on the stomach was blocked by N^G-nitro-L-arginine methyl ester (L-NAME), suggesting that the inhibitory effect of CCK involves the release of nitric oxide. Because L-NAME did not completely block the CCK effect on the caudodorsal thick muscle, it is likely that another neurotransmitter, possibly VIP, is involved in this latter response. Interestingly, CCK-8 caused an excitatory action in the stomach of vagotomized chickens, indicating that CCK-8 may, in addition to acting via the vagus, have a direct action on gastric muscles. The increase in electrical activity caused by CCK-8 in the duodenum was enhanced by L-NAME, indicating that nitric oxide may be a tonic inhibitor of duodenal electrical activity.

Chicken gastrin (cG), which belongs to the gastrin/CCK family, has been isolated from the chicken antrum (Dimaline et al., 1986). Intravenous infusions of cG caused effects similar to CCK-4 (Martinez et al., 1992). This suggests the existence of one receptor subtype in the stomach recognizing both CCK and cG, but possibly two receptors in the duodenum—one recognizing CCK-8 and the other CCK-4 and cG.

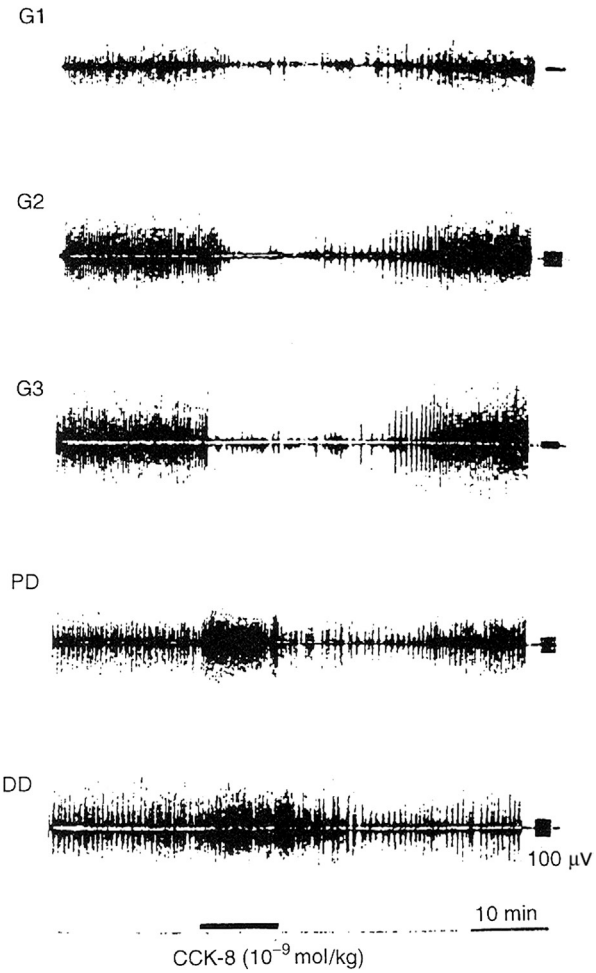

FIGURE 14.12 Recording of gastroduodenal electrical activity showing effect of cholecystokinin octapeptide (CCK-8; 10^{-9} mol kg^{-1}) infusion. Studied gastric areas are as follows: G1, proventriculus; G2, craniodorsal thin muscle; G3, caudodorsal thick muscle; PD, proximal duodenum; DD, distal duodenum. Similar responses were observed in all animals. *From Martinez et al. (1993).*

Opioid peptides appear to be involved in the MMC. Infusion of met-enkephalin, morphine, and β-casomorphin (5×10^{-7} mol/kg) induced intense electrical activity, similar to phase 3 of the MMC, in the distal duodenum which migrated through the small intestine (Jiménez et al., 1992). The effect of morphine was blocked by naloxone (5×10^{-7} mol/kg), while higher doses of naloxone reduced gastroduodenal motility. Simultaneous to increasing duodenal electrical activity, activity in the stomach is inhibited.

14.4.1 Rate of Passage

The rate of passage of material through the digestive tract has been measured in many ways. Because digesta consists of both solid and liquid components, different types of markers have been used. Insoluble markers such as chromium-mordanted rice, cerium-mordanted rice, Cr_2O_3, or radiopaque plastic pellets (Branch and Cummings, 1978; Uden et al., 1980; Ferrando et al., 1987) have been used as indicators of solid transit time, whereas a soluble marker such as Cr-EDTA (Vergara et al., 1989) or phenol red (Goñalons et al., 1982) has been used to measure liquid transit time. In general, it was found that larger particles are retained longer in the digestive tract.

In chickens, insoluble markers first appear in the excreta 1.6–2.6 h after ingestion. However, mean retention time is a better indicator of transit time than is time to initial appearance of the marker. Mean retention time for insoluble markers can vary from 5–9 h depending on the nature of the ingesta and its size.

Transit time of digesta is influenced by genetics. When comparing broiler and Leghorn-type chickens, the overall mean retention time is not different, but the time food spent in various parts of the digestive tract is different (Table 14.4.).

The rate of food passage is affected by many factors. Feed transit time through the small and large intestine increases with age (Shires et al., 1987). This may account for increases in metabolizable energy values of feedstuffs noted in older birds. Adding lipid (Sell et al., 1983) or protein (Sibbald, 1979) to the diet can increase passage time. Increases in environmental temperature also slows transit time.

14.5 SECRETIONS AND DIGESTION

At hatch, the chick has to make a transition from dependence on a lipid-rich endogenous diet coming from the

TABLE 14.4 Mean Retention Time (min) of Solid Phase Markers in Various Segments of the Digestive System of Broilers and Leghorns

yolk, to an exogenous diet rich in carbohydrate and protein (Sklan, 2001). Access to feed at hatch results in an approximately two-fold increase in small intestine length of chicks but only a 60% increase if birds remain fasted (Sklan and Noy, 2000). The increase in intestinal weight is correlated with increases in trypsin, amylase, and lipase activities, which remain unchanged in the absence of feed. Feeding a low-Na diet also decreased mucosal absorption because this is dependent on active transport of Na out of the enterocytes at the basolateral membrane.

14.5.1 Mouth

The salivary glands secrete mucous, and depending on the species, amylase. Although amylase is not present in the saliva of *Gallus* and *Meleagris*, it is found in the saliva of the house sparrow (Jerrett and Goodge, 1973) and other species (Bhattacharya and Ghose, 1971). The volume of daily salivary secretion in *Gallus* ranges from 7 to 25 ml (Leasure and Link, 1940).

Mucous functions to lubricate food and allow it to move down the esophagus. However, in some species, mucous also functions as an adhesive coating on the tongue to aid in capturing insects or as a material that cements components during the construction of nests.

14.5.2 Esophagus and Crop

The esophagus is not important in chemical digestion, as its major secretion is mucous. The secretion of esophageal mucous is nevertheless important because it is necessary to supplement the limited secretion of saliva. However, in some species, including the greater flamingo and male emperor penguin, a nutritive merocrine-type secretion is produced by the wall of the esophagus, which is fed to the young.

Some carbohydrate digestion may occur in the crop due to the presence of amylase activity (Philips and Fuller, 1983). Amylase activity at this site comes from either salivary secretions, intestinal reflux, or plant and/or bacterial sources. Bolton (1965) reported that starch is hydrolyzed within the crop where it can either be absorbed; converted to either alcohol, lactic acid, or other acids; or transported down the gastrointestinal tract. Pinchasov and Noy (1994) showed that substantial amylolysis occurs in the crop. Sucrose is also hydrolyzed within the crop. While absorption of sugars from the crop appears possible, it is probably minimal.

The crop is not essential for normal growth when access to food is sufficient. Cropectomy has no effect on growth rate of ad libitum fed chickens, but it does decrease growth rate when food intake is limited. This supports the view that the primary function of the crop is food storage, and it is not essential for digestion.

In pigeons and doves, "crop-milk" is produced during the breeding season under the influence of prolactin. Crop milk contains 12.4% protein, 8.6% lipids, 1.37% ash, and 74% water (Vandeputte-Poma, 1968). Therefore, while rich in protein and essential fatty acids (Desmeth, 1980), it is devoid of carbohydrates and calcium.

14.5.3 Stomach

The oxynticopeptic cells found in birds secrete both HCl and pepsinogen. Pepsinogen, under the influence of acid or pepsin that is already present, is converted to pepsin. While lipase has been found in gastric secretion, this is probably due to reflux from the duodenum. The basal gastric secretory rate is 15.4 mL/h and contains 93 mEq/L of acid and 247 Pu/ml of pepsin (Long, 1967) with a pH of 2.6 (Joyner and Kokas, 1971). The pH of gastric contents, however, is normally above 2.6 due to the presence of ingesta. The pH has been determined in several species immediately after sacrifice (Table 14.5.). Higher pH values have been reported when measurements were made on live birds. For example, Winget et al. (1962) reported the following values for chickens: mouth, 6.7; crop, 6.4; ileum, 6.7; rectum, 7.1. Age has no effect on pH of the digestive tract (Herpol, 1966). Acid secretion of chickens is high relative to mammals, possibly because of the rapid digestive transit time (Table 14.6).

While amylolysis occurs in the crop, it is not evident in the ventriculus. This is the result of the low pH of the stomach, which is unfavorable for amylase activity (Pinchasov and Noy, 1994).

Source: From Long (1967).

There are three phases to gastric secretion: the cephalic phase, the gastric phase, and the intestinal phase. All three phases are present in birds (Burhol, 1982). The cephalic phase entails an increase in hydrogen ion (H^+) and pepsin secretion caused by the sight, smell, or expectation of food. This phase is under vagal control.

As summarized by Duke (1986), vagal stimulation increases both gastric secretion rate and pepsin secretion. Vagal stimulation causes a greater increase in gastric secretion than do cholinergic agents (Gibson et al., 1974). This suggests, as discussed below, that gastric secretion is stimulated by other neurotransmitters acting together with ACh.

In birds, vagal stimulation causes greater pepsin than H^+ accumulation (Burhol, 1982). In contrast, insulin injection inhibits gastric H^+ secretion without affecting pepsin secretion. Therefore, H^+ and pepsin secretion may be under different control.

Pepsin from chicken and duck has been well characterized (see Pichová and Kostka, 1990). Duck pepsinogen and pepsin have 374 and 324 amino acids, respectively. Duck pepsin has a pH-optimum of 4, is stable up to pH 7.5, and is inactivated at pH 9.6.

Many hormones are involved in gastric secretion (Table 14.7). Gastrin plays a role in the gastric phase of secretion. Chicken gastrin has been isolated from the chicken pylorus, which is equivalent to the mammalian antrum (Dimaline et al., 1986). While structurally similar to cholecystokinin (CCK), cG has markedly different secretory functions (Dimaline and Lee, 1990). Infusion of cG increases both acid and pepsin secretion. Unlike CCK, gastrin has no effect on gall bladder contractions or pancreatic secretion. Another peptide, gastrin-releasing peptide, also induces acid secretion, but it is not known whether it acts via gastrin release (Campbell et al., 1991).

The intestinal phase of gastric secretion is controlled by several hormones including CCK, secretin, and avian pancreatic polypeptide (APP). APP, originally discovered in chickens (Kimmel et al., 1968; Larsson et al., 1974), is released from the pancreas postprandially in response to amino acids and HCl (Hazelwood et al., 1973; Duke et al., 1982). APP does not appear to act during the cephalic phase of gastric secretion because it is not released during sham feeding (Kimmel and Pollock, 1975). APP increases gastric acid and pepsin secretion, and this effect is independent of the vagus nerve (Hazelwood et al., 1973).

CCK (Dockray, 1977) and secretin (Nilsson, 1974) have been isolated from the duodenum and jejunum of birds. CCK stimulates gastric acid secretion while having no effect on pepsin secretion. Contrary to its effects in mammals, in which secretin inhibits acid and stimulates pepsin secretion, in chickens secretin stimulates both acid and pepsin secretion (Burhol, 1974).

TABLE 14.7 Gastrointestinal Hormones in the Domestic Fowl

Hormone	Site of Origin	Biological Actions
Gastrin	Proventriculus	Stimulates gastric acid and pepsin secretion
Cholecystokinin	Duodenum, jejunum	Stimulates gall-bladder contraction and pancreatic enzyme secretion and gastric acid secretion; inhibits gastric emptying; potentiates secretin-induced stimulation of pancreatic electrolyte secretion
Secretin	Duodenum, jejunum	Stimulates bicarbonate secretion by pancreas
Vasoactive intestinal peptide	Duodenum, jejunum	May be a more potent stimulator of pancreatic electrolyte secretion than secretin; inhibit smooth muscle contraction
Pancreatic polypeptide	Pancreas, proventriculus, duodenum	Stimulates gastric acid and pepsin secretion
Gastrin-releasing peptide (bombesin)	Proventriculus	Stimulates pancreatic enzyme secretion; stimulates crop contraction
Somatostatin	Pancreas, gizzard, proventriculus, duodenum, ileum	Inhibits secretion of other gut hormones

As in mammals, histamine is involved in gastric acid release. Injection of cimetidine, an H_2-receptor blocker, raised the pH of the proventriculus and duodenal contents (Ward et al., 1984). The increase in gastric acid secretion induced by the intravenous injection of 2-deoxy-D-glucose was also blocked by metiamide, a H_2-receptor blocker (Nakagawa et al., 1983).

14.5.4 Intestines

Intestinal digestion includes both luminal and brush-border digestion. The brush border contains sucrase-isomaltase, peptidases, and phosphatases. Chicks can hydrolyze disaccharides beginning prehatch, and sucrase-isomaltase expression increases posthatch. Glucose is transported across the enterocyte membrane via a sodium-glucose transporter (SGLT-1), which increases in expression beginning 2 days prehatch and involves a secondary active transport system driven by the active removal of sodium from the basal-lateral membrane of the enterocytes. Absorptive capacity of the intestines increases with proportionate to body weight, but the absorption rate for glucose is greatest during the first week and then declines, as does brush border SGLT-1 density (Barfull et al., 2002).

Amylase is produced by both the pancreas and intestine (Osman, 1982). While found in all parts of the small intestine, it is found in particularly high concentrations in the jejunum, with 80% of the activity found there. The high levels found in the jejunum are presumably due to the fact that the openings of the pancreatic ducts discharge near the anterior jejunum. Amylase is found in only trace amounts in the ceca. The optimum pH of the pancreatic and intestinal amylase is 7.5 and 6.9, respectively.

Intestinal enzymes provide the last step in digestion. These secretions are responsible for digesting starch, sucrose, fats, and protein (Table 14.8.). The small intestine of birds contains maltase, sucrase, palatinase, but does not contain trehalase (Siddons, 1969). Whether lactase is present appears to be debatable. However, it has been reported that lactase is not present in germ-free chicks, and that the rate of mortality of germ-free chicks fed lactose as the sole energy source is very high (Siddons and Coates, 1972). Enzyme activity is highest in the jejunum and decreases both proximally and distally. These enzymes are located in the epithelial cells of the villi. The maltase, sucrase, and palatinase activity found in the large intestine comes from the small intestine, whereas the lactase activity found in the large intestine is probably of a cecal bacterial origin.

Relatively little is known about the control of intestinal secretions in birds. Intestinal secretion is increased by duodenal distention, vagal stimulation, and secretin. Vagal stimulation has a greater effect on stimulating mucous secretion than enzyme secretion.

TABLE 14.8 Enzymes Secreted by the Intestines

Enzyme	Substrate	Product or Function
Maltase	Maltose	Glucose
Isomaltase	Dextrins	Glucose
Sucrase	Sucrose	Glucose, fructose
Enterokinase	Trypsinogen	Trypsin
Lipase	Monoglycerides	Glycerol, fatty acids
Peptidases	Di- and tripeptides	Amino acids

14.5.5 Colon

Chloride (Cl^-) ions are secreted in the rectum, ceca, and coprodeum. This is discussed in Section 14.6.

14.5.6 Pancreas

As mentioned, pancreatic and bile secretions enter the gastrointestinal tract near the anterior jejunum. Pancreatic secretions have a pH of 6.4–6.8 in chickens (Hulan et al., 1972) and 7.4–7.8 in turkeys (Duke, 1986). Secretions include an aqueous phase containing water and bicarbonate ions, as well as an enzymatic phase.

Digestive enzymes found in the pancreas of broiler type chickens are listed in Table 14.9. Although not shown, the pancreas is also reported to secrete ribonuclease and deoxyribonuclease (Dal Borgo et al., 1968). Amylase is found in the duodenum, jejunum, ileum, and colon. Both trypsin and amylase are found in highest concentrations in the jejunum (Bird, 1971; Osman, 1982), presumably because the pancreatic ducts enter near the end of the duodenum. Both pancreatic and intestinal amylase have a requirement for chloride ion. Characterization of these enzymes suggests that pancreatic amylase is similar to mammalian α-amylase, while intestinal amylase is similar to glucoamylase.

Pancreatic secretion is controlled by both nervous and hormonal mechanisms. The secretion rate is higher in birds than in mammals (Table 14.10). Secretion has both a cephalic and intestinal phase. When fasted birds are allowed to eat, pancreatic secretion increases immediately (Kokue and Hayama, 1972). This response is blocked by vagotomy or atropine and can be augmented by cholinergic agents (Hokin and Hokin, 1953).

Secretin-like activity is released in response to dilute HCl placed in the duodenum (Nilsson, 1974). Secretin, when injected intravenously, increases the aqueous component of pancreatic secretion. However, in contrast to mammals, VIP more potently stimulates the secretion of pancreatic juice (Vaillant et al., 1980). VIP is found in neurons both in the gastrointestinal tract and pancreas. It is believed that VIP, rather than secretin, is the primary regulator of pancreatic juice secretion and that this response may be either neuronally or hormonally mediated (Dockray, 1988). VIP does not stimulate pancreatic enzyme secretion.

CCK is released in response to lipids and amino acids. The administration of CCK has been shown to increase pancreatic secretion in pigeons (Sahba et al., 1970) and to increase the flow rate and protein secretion rate in turkeys (Dockray, 1975).

Two gastrin-releasing peptides (GRP), which are structurally related to bombesin, have been isolated from the proventriculus (Campbell et al., 1991). These peptides are found in endocrine cells and contain either 27 or 6 amino acids. Distension of the proventriculus with peptone stimulates pancreatic juice and enzyme secretion. This effect appears to be mediated by GRP-27, with GRP-6 being ineffective. Distension with saline is less effective.

Diet can influence the secretory rate of pancreatic enzymes. Increasing the carbohydrate and fat content of the diet increases amylase and lipase activity in pancreatic secretions (Hulan and Bird, 1972).

14.5.7 Bile

Bile, produced and secreted by the liver, is essential for fat digestion. It acts to emulsify lipid so that it can be more efficiently digested by lipase. In addition, amylase begins to appear in chicken bile at 4–8 weeks of age (Farner, 1943). Therefore, bile is also involved in carbohydrate digestion.

Relatively little is known about biliary secretion in birds possibly because of the complex anatomy in which bile enters the small intestine via both the hepato-enteric duct and the cystico-enteric duct. The biliary secretion rate is 24.2 uL/min in fasted broilers (Lisbona et al., 1981). Chenodeoxycholyltaurine and cholyltaurine are the predominant bile acids in chickens and turkeys, while chenodeoxycholyltaurine and

phocaecholyltaurine predominate in ducks (Elkin et al., 1990). These are secreted by an active transport system.

The bile salts glycocholate and taurocholate are readily absorbed through the intestinal wall. The absorption rate is higher near the distal end of the small intestine (Lindsay and March, 1967). This allows for recirculation of bile acids, thus allowing for their reuse in lipid digestion. It is estimated that 90% of bile salts are reabsorbed in the jejunum and ileum (Hurwitz et al., 1973).

Since chickens have low levels of liver glucuronyl transferase and little or no biliverdin reductase; the secretion rate of biliverdin is high relative to that of bilirubin (14.7 vs. 0.9 ug/kg/min). The green color observed in coprodeal droppings is likely due to biliverdin. The reason for the brown color associated with cecal droppings is unknown, but it may be due to bacterial reduction of biliverdin to bilirubin and a subsequent dehydrogenation (Hill, 1983).

14.6 ABSORPTION

14.6.1 Carbohydrates

Absorption of carbohydrates in birds occurs by mechanisms similar to those found in mammals. Absorption occurs more rapidly from the small intestine compared to the cecum with carbohydrates being absorbed by both active and passive mechanisms. Absorption of sugars from the distal regions of the intestinal tract may account for as much as 5% of the total capacity. Those sugars containing a six-membered ring with the hydroxyl group in the number three position oriented similar to glucose are actively transported. Active transport accounts for at least 80% of glucose absorption. D-Glucose and D-galactose are absorbed faster than D-xylose and D-fructose and D-arabinose. These sugars are absorbed faster than L-arabinose, L-xylose, D-ribose, D-mannose and D-cellobiose.

Glucose is absorbed via the apically located sodium-dependent SGLT-1 system found in both the small and large intestine. Fructose is transported by the apical GLUT5-type system (Garriga et al., 2004). Once inside the epithelial cells, these sugars are transported into the interstitial space by the basolateral GLUT2 transporter. Absorption rates appear greatest during the first week of life, and decline thereafter (Barfull et al., 2002). SGLT-1 expression is regulated by the rennin-antiotensin-aldosterone system (Garriga et al., 2004).

The absorption of sugars against a concentration gradient involves an apically located sodium-dependent, phloridzin-sensitive transport. This system is coupled to Na^+-K^+-ATPase located on the basolateral membrane. Contrary to what is believed to occur in mammals, the active transport of one molecule of carbohydrate in birds is coupled to the movement of two molecules of Na (Kimmich and Randles, 1984). Sugars leave the enterocytes on their way to the bloodstream crossing the basolateral membrane by either simple diffusion or facilitated by a Na-independent mechanism.

Within the small intestine, the greatest absorption of glucose occurs in the duodenum (Figure 14.13). Cumulatively, up to 65, 85, and 97% of ingested starch is digested through the duodenum, jejunum, and the terminal ileum, respectively (Riesenfeld et al., 1980). Virtually all of the glucose released from starch digestion is absorbed within the small intestine.

Significant absorption of glucose also occurs in the cecum (Savory and Mitchell, 1991). While the entire cecum is able of accumulate sugars at hatch, this ability is soon limited to the proximal region (Planas et al., 1986). The ability of the cecum to actively absorb sugars at low concentrations appears higher than that of the jejunum (Vinardell and Lopera, 1987).

There is a greater affinity for active transport of glucose in the ileum (Levin et al., 1983). The ileum appears well suited for transporting glucose which may not be absorbed within the jejunum.

The gastrointestinal tract also has a role in glucose homeostasis (Riesenfeld et al., 1982). Plasma glucose levels are maintained relatively constant in chickens when fed semipurified diets in which glucose is replaced with either fructose, soybean oil, or cellulose. While this is partially the result of varying glucose turnover rates, it is largely a result of varying rates of conversion of glucose to lactate by the intestine.

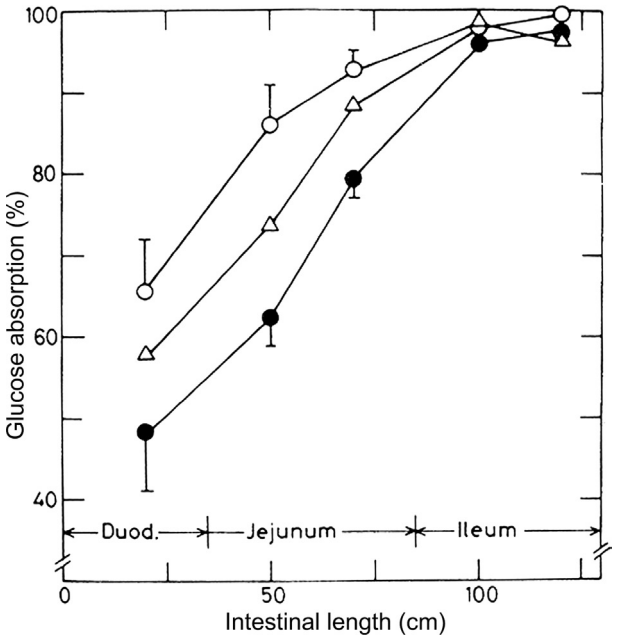

FIGURE 14.13 Cumulative percentage of glucose and starch disappearance from the intestine of 7-week-old chicks. Glucose absorption from glucose monohydrate as the sole dietary carbohydrate source (○), starch digestion (Δ), and absorption (●) in chicks fed starch as the sole dietary carbohydrate source. Values given in the figure are means of six chickens ± standard error. *From Riesenfeld et al. (1980).*

14.6.2 Amino Acids and Peptides

Amino acid and peptide absorption in birds (Gilbert et al., 2008) is similar to that in mammals. Amino acid transport occurs via a secondary active transport system as described for sugars. This process is saturable, coupled to Na^+ transport, and uses adenosine triphosphate for energy. The amino acid transport systems can be classified in four groups: (1) neutral amino acids; (2) proline, β-alanine, and related amino acids; (3) basic amino acids; and (4) acidic amino acids. Such a classification, however, is not rigid because many amino acids share transport with more than one group. For example, leucine, a neutral amino acid, can inhibit the uptake of proline and arginine, a basic amino acid. Glycine transport is partially inhibited by both proline and β-alanine.

The primary site for amino acid absorption is the small intestine, although absorption is also reported to occur in the crop, gizzard, and proventriculus. It is still unclear as to which section of the small intestine has the greatest capacity for absorption because there is a lack of agreement among studies. The rectum of hens is also capable of absorbing methionine via a saturable process. As with glucose transport, the K_m for various amino acids is lower in the ileum than in the duodenum (Table 14.11).

Peptide (i.e., di- and tripeptides) absorption can occur via paracellular movement and specific transport systems (Figure 14.14). Many amino acid transporters have been characterized. These include the neutral amino acid transporters with preference for leucine and other large hydrophobic neutral amino acids (system L), system A with preference for alanine and other small and polar neutral amino acids, and system ASC with preference for alanine, serine, and cysteine (Table 14.12). In addition, a separate nomenclature (x for anionic, y for cationic, z for neutral) has been applied to systems mediating transport of cationic amino acids (system y+) and anionic amino acids (system X^-_{AG}). With some exceptions (system L, system T), lower-case acronyms indicate Na^+-independent transporters, whereas uppercase acronyms are used for Na^+-dependent transporters.

For the absorption of di- and tripeptides, only one transport system, designated as PEPT1 (SLC15A1), is known. This is a low-affinity, high-capacity transport system and handles essentially all possible protein-derived di- and tripeptides as well as various peptidomimetics, such as

TABLE 14.11 K_m (Mm) and J_{max} (Pmol $Cm^{-2}d^{-1}$) for Saturable Amino Acid Absorption in the Chicken Small Intestine

	Jejunum		Ileum	
Amino Acid	K_m	J_{max}	K_m	J_{max}

aminocephalosporins and various prodrugs. PepT1 involves the cotransport of protons. It has been well characterized in many species, including chickens and turkeys (Gilbert et al., 2008). Peptides appear to be absorbed more rapidly than amino acids. Absorption of peptides acts to eliminate competition between amino acids for uptake and thus helps increase speed of absorption.

PepT1 expression is upregulated during feed restriction. This may be a mechanism to compensate for decreased mucosal surface area caused by reduced villi height and crypt depth observed in broilers given delayed access to feed at hatch. Increased expression of PepT1 may be mediated by peroxisome-proliferator-activated receptor α (Shimakura et al., 2006).

The ceca are also important in amino acid absorption. Proline is absorbed in the cecum via a sodium-dependent carrier-mediated transport system, with transport rates being higher in the proximal than distal cecum (Obst and Diamond, 1989). In addition, leucine, phenylalanine, proline, and glycylsarcosine are absorbed against a concentration gradient (Gasaway, 1976; Calonge et al., 1990; Moretó et al., 1991). Proline and methionine have also been shown to be transported by a Na-independent system (Moretó et al., 1991).

The ceca has a greater ability to transport amino acids than sugars (Moretó et al., 1991). This may be functionally important when considering the following: (1) uric acid, which is retrogradely carried to the ceca from the coprodeum, may be microbially converted to amino acids; and (2) proteases are in high concentration within the ceca and may release amino acids from proteins. Therefore, the ceca may be important in amino acid absorption.

14.6.3 Fatty Acids and Bile Acids

Fatty acid absorption occurs in the distal half of the jejunum and, to a lesser extent, in the ileum. Because the bile duct enters the gastrointestinal tract of birds near the distal duodenum, emulsification of fats is delayed in birds relative to mammals.

In mammals, fatty acids enter the enterocytes where they are reesterified to triglycerides and packaged into chylomicrons which enter the lymphatic system. However, in birds, after being reesterified, lipids are packaged into portomicrons, which pass directly into the hepatic portal blood supply.

14.6.4 Volatile Fatty Acids

The concentration of volatile fatty acid (VFA), mainly acetate, but some propionate and butyrate, in the ceca is high. It can reach 125 mM in the chicken (Annison et al., 1968) and 70 mM in the goose (Clemens et al., 1975). VFAs are one of the byproducts of microbial decomposition of uric acid (see Braun and Campbell, 1989). Levels of VFAs are higher in the portal blood of conventionally raised compared to germ-free birds, suggesting that VFAs formed by bacteria are absorbed from the gastrointestinal tract. VFAs are absorbed from both the small intestine and the ceca by passive transport (Sudo and Duke, 1980). Because the concentration of VFAs is higher inside the lumen, absorption occurs by the passive movement of these compounds down their concentration gradient. While the rate of absorption of propionate and butyrate is equal between the small intestine and ceca, acetate is absorbed faster within the ceca. Microbial fermentation within the ceca of the ptarmigan can provide enough VFAs to meet 11–18% of the energy needs for basal metabolic rate (Gasaway, 1976).

14.6.5 Electrolytes

The major site of calcium and phosphate absorption, which are both actively absorbed, is the upper jejunum (Levin, 1984). When fed diets adequate in phosphorus and calcium, there is a net secretion of phosphate in the duodenum. However, when fed a phosphorous-deficient diet, there is a net absorption within the duodenum.

Calcium absorption occurs via an active transport system that is influenced by the vitamin D hormone 1,25-dihydroxyvitamin D_3 ($1,25(0H)_2D_3$). While calcium enters the mucosal membrane via a diffusion-type process, it is then secreted into the blood by an active transport system located on the basolateral membrane.

The hormonal byproduct of vitamin D, $1,25(0H)_2D_3$, induces the synthesis of calbindin-D_{28k} in birds (Wasserman, 1992) and the calcium pump unit in the basolateral membrane of chicken enterocytes (Wasserman et al., 1992). Feeding chickens a calcium- or phosphorus-deficient diet, repleting vitamin D-deficient chickens with vitamin D, or injecting $1,25(0H)_2D_3$ causes an increase in plasma membrane calcium pump mRNA in the duodenum, jejunum, ileum, and rectum (Cai et al., 1993).

The absorption and secretion of Na, potassium (K), calcium (Ca), and magnesium (Mg) in the gastrointestinal tract of broilers has recently been characterized (Van Der Klis et al., 1990). Na transport is discussed below. K, Ca, and Mg are secreted in the duodenum. In addition, there is some secretion of Mg in the ileum and rectum. The major site of absorption for these minerals is the proximal jejunum, with some absorption of Ca and Mg occurring in the gizzard. This coincides with the fact that dry matter spends approximately 25% of its time in the jejunum. There is little absorption of these minerals beyond the jejunum.

14.6.6 Water, Sodium, and Chloride

Water is absorbed throughout the small and large intestine and the ceca. Absorption of water occurs as a secondary response to the active absorption of other compounds such as glucose, Na, and amino acids.

Birds generally secrete a very dilute urine. Urine can travel into the coprodeum and, via antiperistalsis, continue orad into the ceca. Note that there are exceptions, such as the ostrich, which can concentrate urine and has no movement of urine back into the colon (Elbrond et al., 2009). The excreta of cecectomized, compared to intact chickens, is higher in water, indicating that the lower part of the intestinal tract has an important role in water and salt balance.

Sodium is secreted in the proximal portion of the intestinal tract (Van Der Klis et al., 1990). The major sites for Na absorption are the proximal jejunum followed by the colon. The ileum also has a small capacity for Na absorption.

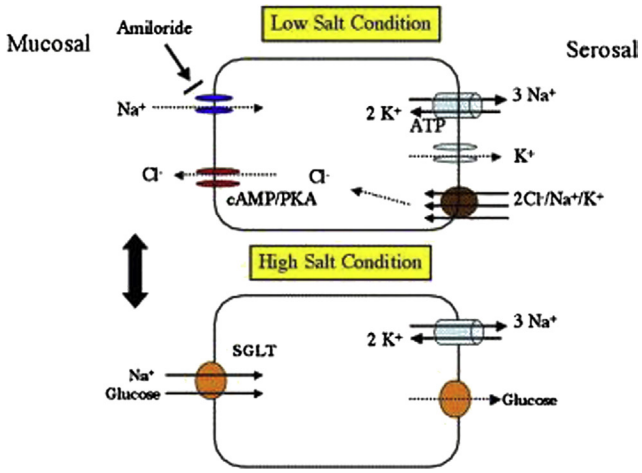

FIGURE 14.15 Working model for transport pathways in the hen lower intestine. The two panels show the different Na^+ absorptive pathways for tissues from low and high salt-acclimated hens. Example shown is for colon and would represent the extreme conditions of salt intake, in which there is a complete transition in transport pattern. SGLT-mediated glucose uptake and basolateral release via GLUT transporters is representative of several organic substrate cotransporter systems (amino acids and hexoses) expressed in the high salt-acclimated tissues. The diuretic amiloride blocks low salt ENaC channels at concentrations of 10^{-5} M. Potassium channels, shown on the basolateral or serosal side, may also be present on the apical surface and mediate K^+ secretion. For simplicity, the Cl^- secretory pathway is shown only in the low salt condition, even though it is also observed under high salt. *Laverty et al. (2006).*

The coprodeum, colon, and ceca serve an important role in Na, chloride (Cl) and water balance (Laverty et al., 2006). When fed a low-NaCl diet, there is a net absorption of Na from the coprodeum, colon, and ceca. Na^+ absorption occurs by active transport mediated by apical electrogenic and amiloride-sensitive Na^+ channels and basolateral Na^+ pumps (Na^+/K^+-ATPase) (Figure 14.15). The mucosal lining of the colon and coprodeum consist of simple, columnar epithelium with absorptive epithelial cells (AEC), goblet cells (GC), and mitochondria-rich cells (MR). On a low-salt diet, there is an extensive microvillous brush border. When fed a high-NaCl diet, absorption of Na^+ from the coprodeum nearly ceases, while that in the colon remains high provided a low concentration of hexoses and amino acids is maintained on the mucosal side. There is an increased expression of colon SGLT associated with increased dietary salt. This represents a dramatic change from electrogenic, channel-mediated Na^+ transport to organic substrate Na^+-cotransport consistent with that seen in the small intestine but not observed in the mammalian large intestine. On a high-salt diet, while the colon morphology remains the same, that of the coprodeum shows a decrease in density and length of microvilli. The adaptation to a low-salt diet is mediated by circulating aldosterone and maximizes Na^+ transport (absorption). Aldosterone suppresses SGLT expression (Laverty et al., 2001).

In addition, there is also a net secretion of Cl from the coprodeum and rectum, but the secretory ability of the coprodeum disappears in birds fed a high-NaCl diet (Skadhauge, 1989). The secretion of Cl is induced by serotonin (Hansen and Bindslev, 1989a). Receptor antagonists for 5-HT_{1A}, 5-HT_{1B}, 5-HT_{1C}, 5-HT_{1D}, 5-HT_2, 5-HT_3, adrenergic, cholinergic and histaminergic receptors were unable to block the response. However, the second messenger for serotonin-induced chloride secretion is cAMP (Hansen and Bindslev, 1989b).

The absorption of Na and secretion of Cl within the lower gut is regulated by plasma aldosterone (Clauss et al., 1991). Increases in plasma aldosterone stimulate amiloride-sensitive Na uptake in the coprodeum, rectum, and ceca. Feeding high-NaCl diets causes a decrease in plasma aldosterone, and a decrease in amiloride-dependent Na absorption. Furthermore, there is a switch to amiloride-independent hexose/amino acid stimulated Na-transport within the rectum and cecum, but a cessation of Na-transport in the coprodeum. The hexose/amino acid stimulated Na-transport in the rectum functions to counteract the osmotic water loss due to feeding a high-NaCl diet (Skadhauge et al., 1985), and is stimulated by increases in plasma arginine vasotocin and/or prolactin (Arnason and Skadhauge, 1991).

14.6.7 Vitamins

Absorption of vitamin B-6 occurs throughout the small intestine, but primarily in the duodenum (Heard and Annison, 1986). Absorption can also occur in the crop and cecum, but this is minimal. The mechanism of absorption is passive diffusion. Although microbial synthesis of vitamin B-6 does occur, this is not important in meeting a bird's vitamin requirement.

14.7 AGE-RELATED EFFECTS ON GASTROINTESTINAL FUNCTION

The small intestine grows rapidly during the later days of incubation, increasing from 1% of body weight at day 17 to 3.5% at hatch (day 21), followed by a two- to four-fold increase in intestine length through 12 days posthatch (Uni, 2006). Villi grow in length near the end of incubation and increase in size and number following hatch. Duodenal villus growth is nearly complete by day 7, whereas that in the jejunum and ileum continues beyond 14 days of age. Unlike in mammals, in which most enterocyte proliferation occurs within the crypts, in poultry proliferation occurs along the length of the villi. Enterocyte migration to the tip of the villi takes 3 days in 4-day-old chicks and 4 days in older birds.

It was hypothesized that postnatal growth rate is at least partially determined by the differential growth of various organs (Lilja, 1983). The intestinal tract grows rapidly

following hatch, with relative growth being the greatest between 5 and 7 days-of-age. The intestinal length increases two- to four-fold by 12 days of age, with the small intestine increasing 7- to 10-fold during that time.

With regards to pancreatic enzyme activity within the intestines, trypsin, protease, and amylase activity increased rapidly during the first 21 days posthatch in turkey poults (Krogdahl and Sell, 1989). However, lipase activity did not begin to increase until after 21 days of age. Feeding a high-fat diet did not significantly increase lipase activity until after 21 days of age. At least during the first few weeks posthatch, it appeared that lipase activity may be a limiting factor in digestion.

Several notable changes have been found in the development of nutrient transport systems during ontogeny in broilers (Obst and Diamond, 1992). During the first week posthatch, proline uptake by the small intestine is high relative to glucose uptake. Because the relative growth rate of broilers is greatest during the first week, it appears that amino acid uptake may parallel this growth pattern. The uptake of glucose displays a transitory increase during week 2. This increase is hypothesized to be a result of a switch from lipid metabolism to carbohydrate metabolism due to depletion of the yolk reserves. Because of the allometric growth of the intestine, during the second week posthatch the intestine displays a decrease in size relative to body weight. This may be a second reason for the increase in uptake of glucose occurring at this time. There is a transitory increase in proline uptake during week 6. This increase parallels the first postjuvenile molt and a rise in absolute growth rate.

Interestingly, the intestinal uptake capacity of broilers closely matches a bird's nutrient needs. This contrasts with results in mammals, where uptake far exceeds the animal's needs. It remains to be determined whether this may indicate that nutrient uptake represents a potential constraint for increased growth in broilers, or whether it means that broilers are better allocating resources.

Feeding immediately posthatch stimulates intestinal development. Delaying feed for 24–48 h decreased villi length, enterocyte migration rate (Geyra et al., 2001), and enterocyte number but increased goblet cells producing acid and neutral mucine (Uni et al., 2003).

14.7.1 Microflora

The gut microflora is more complex than that of its host. In fact, it is now know that there are about 150 times more microbial genes (3.3 million versus 20,000–25,000) in the human gut than in the human genome. It is well documented that some gut microflora can cause disease (e.g., *Escherichia coli*, *Clostridium*, *Salmonella*). However, it is also recognized that many gut microbes are beneficial. For example, the enzymes that make vitamin B_{12} are produced by bacteria. Providing the GIT with beneficial microbes in order to reduce the presence of harmful bacteria is now an accepted strategy to improve health and productivity in poultry (Mead, 2000).

Evidence shows that microorganisms regulate an animal's genes and immune system (Lee and Mazmanian, 2010). Commensal microbiota may "program" aspects of T-cell differentiation, thus influencing the host genome and alterning the function of the adaptive immune system. It has been shown that mice that were raised in a sterile environment and therefore lack intestinal microbiota have defective mucosa-associated lymphoid tissues, fewer Peyer's patches, less lamina propria in the small intestine, and less mesenteric lymph nodes. The gut microflora has also been linked to obesity (Raoult, 2008) and type 2 diabetes. Obese patients have significantly more *Lactobacillus* sp., whereas diabetics have a lower proportion of *Firmicutes* and a higher proportion of *Bacteroidetes* and *Proteobactgetia* (Larsen et al., 2010).

Newly hatched chicks get bacteria from the surface of the eggshell. The GIT rapidly becomes colonized, with the maximum density occurring at 5 days of age (Apajalahti et al., 2004). The composition of the microflora then changes as the chicken grows (Lu et al., 2003). Subtherapeutic levels of antibiotics have been used in poultry diets for years in order to improve growth performance, and it is generally believed that their effects are at least partially mediated through an impact on the microflora (Coates et al., 1963; Knarreborg et al., 2002). Lactobacilli, streptococci, and *Clostridia perfringens* appear most commonly in the ileum, and lactobacilli and *C. perfringens* are most affected by dietary treatments.

Providing poultry with probiotics (i.e., competitive exclusion) has been used for poultry production to improve growth (Mead, 2000). Young chicks are very susceptible to *Salmonella typhimurium*, and this susceptibility can be greatly reduced if the chicks GIT is colonized with an adult-type microflora. Hence, competitive exclusion can be used to reduce the GIT colonization of *Salmonella* and *Campylobacter jejuni*—both potential causes of food poisoning. The growth promotion appears to be associated with increases in *Lactobacillus* sp. In broilers, chicks inoculated with *Lactobacillus* increase their weight gain significantly compared to control (Angelakis and Raoult, 2010).

15.1 INTRODUCTION

Chondrogenesis, the initial development of skeletal bones, starts during embryonic development in the early stages of somitogenesis and is considered to be the earliest phase of skeletal development. It involves progenitor cell specification, cell migration, epithelial-to-mesenchymal transition, and differentiation and maturation of chondrocytes. Mesenchymal cells that undergo chondrogenesis derive from neural crest cells, which originate from the neural crest ridge of the neural ectoderm; the presegmented paraxial mesoderm that differentiates into somites to elicit the sclerotome compartment, which leads to formation of the axis skeleton; and the somatopleure of the lateral plate mesoderm, which initiates limb buds for the appendage bones. Economically, the major skeletal disorders are associated with the rapid increase in growth rate achieved during the last few decades, and understanding of the relevant mechanisms will help in developing treatments for bone-related diseases. In this chapter, we portray the events leading chondrogenesis at the cellular and molecular levels and describe the various poultry bone disorders. The aim is to provide an introduction to the field, but by no means to cover all aspects of poultry bone development and disorders.

15.2 BONE DEVELOPMENT

15.2.1 Somitogenesis and Sclerotome Formation

During gastrulation, cells migrating through the various regions of the primitive streak establish the mesoderm. According to detailed fate map studies (Garcia-Martinez and Schoenwolf, 1992; Psychoyos and Stern, 1996) cells migrating via Hensen's node will contribute to formation of the notochord and the neural floor plate (Charrier et al., 2005). Cells that migrate through the anterior region of the primitive streak (posterior to the node) will establish the paraxial mesoderm that will bud off the somites. Cells that migrate through more posterior regions of the streak will give rise to the intermediate and lateral plate mesodermal tissues. In the presegmented region of the paraxial mesoderm, cells experience several waves of signaling that elicit the so-called segmentation clock, which ends in a precisely coordinated process of somite formation (Pourquié, 2011). This region, which contains the precursors of the sclerotome, flanks the notochord in the midline region and the intermediate mesoderm in the lateral aspect and underlies the neural plate. During neurulation and closure of the neural tube, the presegmented mesoderm buds and forms the somites, which now also neighbor the dorsal surface ectoderm. The somites mature from anterior to posterior; therefore, the anteriormost somite is the first to bud and the posteriormost one is the most recently formed (Christ and Ordahl, 1995). This anterior-to-posterior maturation gradient reflects changes in timing and location of an embryonic structure that is surrounded by several other developing tissues, which suggests a very dynamic process that involves external and internal events that lead to the compartmentalization and differentiation of somitic cells.

The somite buds into the form of an epithelial sphere surrounding the somitocoele. During its maturation, several compartments are formed sequentially, starting at the third new-formed somite. At this stage, two compartments are formed: the first is the sclerotome, which is undergoing an epithelial-to-mesenchymal transition at the ventromedial part of the somite; in parallel with this, the dorsal

Sturkie's Avian Physiology.

epithelial half forms the transitory structure of the dermomyotome (Ordahl and Le Douarin, 1992; Christ and Scaal, 2008). The mediodorsal part of the epithelial somite contains the muscle-progenitor cells that migrate anteriorly and dorsolaterally to form the scaffold of the future myotome (Kahane et al., 1998), whereas the central part of the dermomyotome will give rise to the back dermis (Ben-Yair et al., 2011). Also, Huang et al. (2000) found that thoracic dermomyotomal cells contain the precursors of the caudal part of the scapula, whereas the rostral region of this bone is of somatopleure origin. As development proceeds, the dermomyotome splits along its dorsoventral axis in a complicated sequence of events that form two waves of cell migration. The myotome forms in the ventral compartment, and the dermatome compartment is established at the center of the dorsolateral region of the somite (Ben-Yair et al., 2011). A fourth compartment—the syndetome—forms from sclerotomal cells and gives rise to the tendons; it is formed between the sclerotome and the myotome during later stages (Schweitzer et al., 2001; Brent et al., 2003).

Following the epithelial-to-mesenchymal transition, the sclerotome compartment consists of mesenchymal cells, which start to migrate along several pathways; they migrate ventromedially, dorsally, and laterally to populate various domains that will give rise to the various vertebra regions, the intervertebral discs and the ribs, before the cells start to differentiate into chondrocytes. The sclerotome is resegmented along the anterior-to-posterior axis and splits into anterior and posterior halves, each of which contributes cells to two sequential vertebrae. Thus, the body of a given vertebra consists of cells that originated from the posterior half of the rostrally adjacent sclerotome and the anterior half of the caudally adjacent sclerotome (Aoyama and Asamoto, 2000; Christ and Scaal, 2008). Subsequently, cells from the rostral half of the sclerotome populate the entire spinous process and the distal rib, whereas cells that originate in the caudal half of the sclerotome populate the rostral half of the spinous process, the vertebral arch, the transverse process, and the entire rib (Aoyama and Asamoto, 2000). This process of sclerotomal resegmentation is essential to enable the movement operated by the segmental muscles that now are attached by tendons to two resegmented vertebrae. The sclerotome is further subdivided into several subdomains, each of which becomes specified according to its location. The cells located at the medial part of the sclerotome will become the meninges and the blood vessels around the spinal cord, influenced by complex signals from the neural tube and notochord (Nimmagadda et al., 2007); this region is called the meningotome (Christ and Scaal, 2008). Another region, the arthrotome, is formed in a triangular shape from the somitocoele; it points toward the notochord and consists of mesenchymal cells that do not undergo the epithelial-to-mesenchymal transition. These cells will generate the vertebral joints, the intervertebral discs and the medial parts of the ribs (Mittapalli et al., 2005). For further reading on the various parts of the vertebrae, ribs, intervertebral discs, tendons, and blood vessels, see Christ and Scaal (2008).

15.2.2 Signaling Molecules Influence Sclerotome Formation

The somite is surrounded by several tissues that influence its maturation (reviewed in Christ and Scaal, 2008). These tissues secrete signaling molecules that diffuse over the somitic morphogenetic field and thus create gradients. At a specific stage, each cell in this somitic field experiences a different and inextricable combination of signaling factor concentrations and reacts according to its location and its competence to respond to these factors (Cairns et al., 2008; Piran et al., 2009). Four sources of external signaling factors affect the somitic field at the level of the newly formed somites. The neural tube that is polarized along the dorsal ventral axis and the notochord are the midline sources: the dorsal neural tube that, at various stages, contains the neural crest ridge and the roof plate is the dorsal medial signaling source; the notochord and the neural tube floor plate constitute the ventromedial signaling source. The surface ectoderm serves as the dorsal source of signaling molecules, and the intermediate and lateral plate mesodermal tissues constitute the fourth source of signaling molecules (Monsoro-Burq, 2005). All of these tissue sources secrete different sets of signaling molecules that affect the somitic field in various ways, causing it to differentiate into its compartments and to initiate the distinct molecular cascades that lead to various cell lineages.

Several Wnt family members are secreted from the dorsal part of the neural tube and the surface ectoderm: Sonic hedgehog (Shh) is secreted from the notochord and the neural tube floor plate; bone morphogenetic protein 4 (BMP4) is secreted from the lateral plate and intermediate mesodermal tissues at early stages of the paraxial mesoderm maturation, and from the neural roof plate from the level of the third newly formed somite at later stages (Pourquié et al., 1996; Reshef et al., 1998). The BMP antagonists, noggin and follistatin, exhibit their expression patterns within the paraxial mesoderm and affect the expression of BMP4 in the neighboring tissues (Amthor et al., 1996; Hirsinger et al., 1997; Marcelle et al., 1997; Reshef et al., 1998). These members of various families of paracrine signaling molecules create a very dynamic field within the somite; within it, they interact directly and indirectly with one another in various concentrations in diverse locations to elicit the compartmentalization of the somite (Cairns et al., 2008; Piran et al., 2009).

15.2.3 Tissue Interactions and Gene Activity in Limb Development

Limb chondrogenesis involves essentially the same molecular cassette as axial chondrogenesis, driving the same process but leading to bone formation in a different tissue—the lateral plate mesoderm. At particular locations along the

anterior-posterior axis, as determined by specific combinations of *Hox* genes (Cohn and Tickle, 1999), the forelimb and hindlimb buds are formed from the flank ectoderm. These specific flank lateral plate regions express the mitogen factor FGF10 that induces the formation of a special tissue—the apical ectodermal ridge (AER)—in the competent corresponding flank ectoderm (Xu et al., 1998; Yonei-Tamura et al., 1999). This activity of FGF10 is mediated by the canonical Wnt3a, expressed in the ectoderm that induces expression of FGF8 in the AER (Niswander et al., 1993; Fallon et al., 1994; Fernandez-Teran and Ros, 2008). As the limb bud develops along the proximo–distal axis, the mesenchyme underlying the AER (a narrow ectodermal strip along the anteroposterior aspect of the distal tip of the limb bud)—the progress zone—proliferates extensively.

While cells close to the AER continue to proliferate, proximal cells gradually leave the cell cycle and start to differentiate into the various tissues of the limb, including tendons, cartilage, blood vessels, and muscle sheaths. Muscle progenitors invade the limb bud domain by migrating from the lateral aspect of the dermomyotome (Christ and Scaal, 2008). The core mesenchymal cells located in the center of the limb bud condense to form the cartilage anlagen. Condensing cells in the center of the limb bud are facilitated by TGF-β signaling factor secreted from neighboring cells and induce the expression of fibronectin and other cadherin molecules to stabilize the core of condensing cells. FGFs secreted from the surrounding ectoderm inhibit chondrogenesis via activation of the FGF receptor2, thereby keeping the cartilage anlagen (the condensed-cells core) in the center of the developing limb bud (Newman et al., 2008). Another important signaling center is the zone of polarizing activity (ZPA), which is a small piece of tissue located in the posterior region of the developing limb bud. Anterior implantation of ectopic ZPA results in a pattern of mirror-image digits, polydactyly, and can be mimicked by the signaling molecule Shh that normally is expressed in ZPA cells (Riddle et al., 1993). Complex positive and negative feedback loops of Shh, BMPs, FGFs, and their inhibitors permit the growth activity elicited by the AER. Gradient- and time-dependent exposure to Shh creates the anterior-posterior patterning of the limb in general and the digits pattern in particular. BMPs that are expressed throughout the distal mesenchyme are key factors in shaping the final form of the digits; they are expressed in the interdigital webbing mesenchyme and activate the apoptotic machinery. The strong BMP antagonists, noggin and gremlin, are expressed in the digits mesenchyme and protect these domains from apoptosis (Gilbert, 2010).

15.2.4 Molecular Mechanisms Controlling Chondrogenesis

The ventral midline tissues—the notochord and the neural tube floor plate—were shown in several studies to be the tissues that determine the ventral characteristics of the ventral somitic compartment—the sclerotome—by secreting a common signaling factor (Brand-Saberi et al., 1993; Dietrich et al., 1993, 1997; Goulding et al., 1993; Koseki et al., 1993; Pourquié et al., 1993; Ebensperger et al., 1995). The signaling properties of these tissues can be mimicked by the signaling factor Sonic Hedgehog (Shh) (Fan and Tessier-Lavigne, 1994; Johnson et al., 1994; Fan et al., 1995; Münsterberg et al., 1995; Borycki et al., 1998; Teillet et al., 1998). Mutant mice lacking Shh fail to form the sclerotome and therefore lack vertebrae (Chiang et al., 1996). Pax1 is a transcription factor that is expressed in early stages of sclerotome formation and was shown to be a Shh target (Ebensperger et al., 1995; Münsterberg et al., 1995; Šošić et al., 1997; Borycki et al., 1998; Teillet et al., 1998; Peters et al., 1999). As development proceeds, this transcription factor gradually disappears from migrating dorsal and lateral sclerotomal cells, and eventually from all cells undergoing chondrogenesis; this suggests that Shh is required only transiently in the early stages of chondrogenesis for the commitment of sclerotomal cells to become chondrocytes. This early molecular activity is regarded as the first phase of the endochondral ossification process.

The second phase is the condensation of mesenchymal cells into compact structures and their proliferation and differentiation into chondrocytes—the process that leads to cartilage cells. This process is dependent on BMP4 (Monsoro-Burq et al., 1996), which is an essential factor for limb chondrogenesis (Zou et al., 1997). However, in somite maturation and chondrocyte differentiation, its role is more complicated: several studies have shown that during early somite development BMP4 is a general inhibitor of the paraxial mesoderm, and can transform its development into the lateral plate mesoderm, as was demonstrated by the expression of lateral plate markers following overexpression of BMP4 in somite cultures and in *in vivo* experiments (Pourquié et al., 1996; Tonegawa et al., 1997; Reshef et al., 1998). Moreover, this factor is a myogenic-specific inhibitor, which suggests a role in determining the bone-to-muscle ratio that is reflected in the somitic compartment size of these two tissues (Piran et al., 2009). Several studies have shown that in the early stages of chondrogenesis there are two successive molecular phases: the first is Shh-dependent, whereas the second is Shh-independent and requires BMP4. It appears that Shh plays a role in determining the competence of sclerotomal cells to respond to a later BMP4 activity (Murtaugh et al., 1999) and that this process is mediated by the transcriptional repressor Nkx3.2 and the transcription factor Sox9, which suggests a role for these genes in maintaining the prochondrogenic response to BMP (Murtaugh et al., 2001; Zeng et al., 2002). Moreover, Sox9 and two other members of the Sox family—Sox5 and Sox6—create a complex of transcription factors that were shown to be expressed in all precartilaginous condensing cells and cartilage elements. This transcriptional complex is directly bind and activates specific genes of cartilage extracellular

proteins (Lefebvre and Bhattaram, 2010). Sox9 upregulates the expression of Sox5/6 (Akiyama et al., 2002) and was proposed to upregulate its own expression (Kumar and Lassar, 2009). Sox9 is controlled positively by the activity of the signaling pathways of three factor families—Shh, BMP, and FGF—and negatively by the activity of Wnts/β-catenin, suggesting its expression absence in dorsal somitic regions (Lefebvre and Bhattaram, 2010). Heterozygous mutations in the human Sox9 gene resulted in severe chondrodysplasia, confirming its importance in chondrogenesis (Foster et al., 1994; Wagner et al., 1994).

The third and fourth phases of chondrogenesis comprise the proliferation, spatial rearrangement, and hypertrophy of chondrocytes. In these stages, proliferating chondrocyte cells are forming the cartilage model (the third phase) and later stop dividing, change morphology, and become hypertrophic chondrocytes (the fourth phase) (Lefebvre and Bhattaram, 2010) (Figure 15.1(A)). Further studies revealed a crucial role for the Runt transcription factor family member, Runx2, in these two stages. According to these studies, the hypertrophy of chondrocyte cells is Runx2-dependent (Yoshida et al., 2004), and the competence of prehypertrophic cells to respond to this transcription factor is mediated by Nkx3.2 and Sox9 (Kempf et al., 2007) Figure 15.1(B). Moreover, it was shown that the histone deacetylase4 (HDAC4) that is expressed in prehypertrophic cells plays a role in the regulation of Runx2 in these cells (Vega et al., 2004). Expression of Runx2 in prehypertrophic proliferating chondrocytes binds and transactivates the promoter of the paracrine factor Indian Hedgehog (Ihh) (Yoshida et al., 2004), which was found to be necessary and sufficient for the expression of the parathyroid-related peptide (PTHrP) (Vortkamp et al., 1996) which, in turn, inhibits Ihh. The tight negative feedback loop controls the proliferating phase of prehypertrophic chondrocyte cells. Once these cells mature and become hypertrophic chondrocytes, they secrete collagen X and other extracellular matrix proteins, thereby altering the matrix to become mineralized by calcium phosphate (Lefebvre and Bhattaram, 2010).

This concise description of the complex molecular networks and the tight regulation of the various phases of endochondral ossification (summarized in Figure 15.1) exemplifies the importance of the precise balance among the various stages of the process to achieving the right proportions, shape, and structure in the development of bones. Nevertheless, this review relates only to chondrogenesis per se and does not explore the potential influence of other tissues on this process. For example, recent studies have shown that during embryogenesis muscle force is able to direct the bone shape to bear the optimal load capacity, and this action is executed during chondrocyte convergent extension (Sharir et al., 2011; Shwartz et al., 2012). However, the molecular mechanisms of such effects remain to be elucidated.

15.3 BONE DISORDERS

Bone development and growth is controlled by precise cellular and molecular mechanisms. Any deviation from the normal process will result in bone disorders that present a major economic problem to the poultry industry. The regulation of bone development and growth appears to be complex, with various levels of interactions among the regulating agents. Several extensive reviews of various aspects of poultry bone disorders have been written during the last few years (Orth and Cook, 1994; Cook, 2000; Edwards, 2000; Rath et al., 2000; Pines et al., 2004).

15.3.1 Inherited and Rare Bone Disorders

Nanomelia is a recessively inherited connective tissue disorder that affects cartilage development and is characterized by chondrodystrophy and shortening of the long bones. It involves low aggrecan production and diminished aggrecan mRNA levels. A stop codon has been identified in the eighth repeat of the chondroitin sulfate 2 domain of the large tenth exon (Primorac et al., 1994). Ametapodia is a mutation associated with abnormal limb development that appeared in a strain of light brown leghorn chickens; the mutants are characterized by complete absence of the tarsometatarsals, and severely hypoplastic development of the metacarpals is also present. The disease is inherited as an autosomal recessive, and the affected chicks do not normally survive beyond 2–4 days of age (Smyth et al., 2000).

15.3.2 Bone Disorders of the Spine

Scoliosis is characterized by a lateral deviation of the spine, with rotation of the vertebrae. The effect of intense light on melatonin secretion by the pineal gland is probably involved in the incidence of the disease, which can be mimicked by pinealectomy (Machida et al., 2001). Microcomputed tomography (micro-CT) can be used to evaluate the concave and convex sides of vertebrae in pinealectomized scoliotic chickens (Fu et al., 2011). The incidence of expression of a scoliotic parent line implicated three major autosomal recessive genes (McCarrey et al., 1981).

Spondylolisthesis (kinky-back) is characterized by a ventral dislocation of the anterior end of the articulating vertebra—mainly but not only the fourth thoracic vertebra—with overriding of the posterior end by the fifth, which causes pinching of the spinal cord. Damage to the spinal cord causes leg weakness that is usually followed by partial posterior paralysis (McNamee et al., 1998). In some cases, the incidence was associated with *Enterococcus cecorum* (Makrai et al., 2011) and was greatest in chickens fed *ad libitum* and kept in batteries.

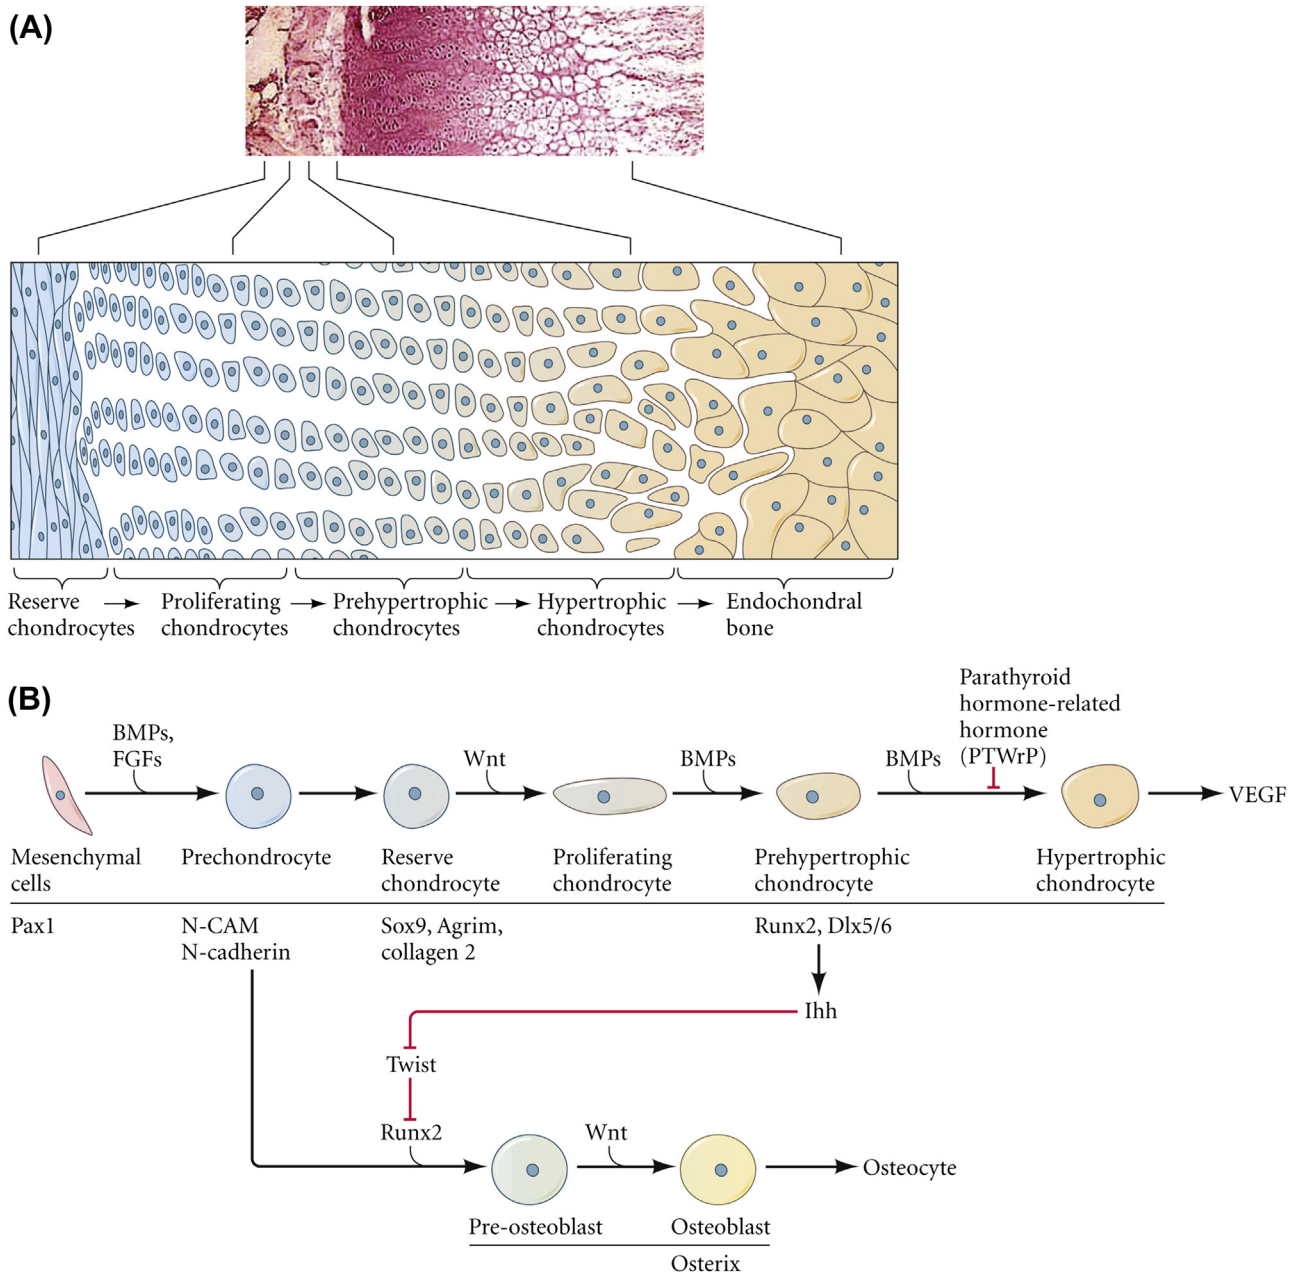

FIGURE 15.1 **Cell lineage and molecular mechanisms in endochondreal ossification.** (A) The cartilage is stained with alcian blue and the bone is stained with alizarin red. Below is a diagram of the transition zone wherein the chondrocytes (cartilage cells) divide, enlarge, die and are replaced by osteocytes (bone cells). (B) Paracrine factors and transcription factors active in the transition of cartilage to bone. The sclerotome cell can become a chondrocyte (characterized by the Sox9 transcription factor) or an osteocyte (characterized by the Osterix transcription factor) depending on the type of paracrine factors it experiences. The paracrine factor Indian hedgehog (Ihh), secreted by the growing chondrocytes, appears to repress Twist, an inhibitor of Runx2. Runx2 is critical for directing cell fate into the bone pathway, and activates Osterix, which in turn activates the bone-specific proteins. *With permission from Gilbert (2010), pp. 384–386.*

15.3.3 Bone Disorders due to Mycoplasma Infection

Leg weakness characterized by chondrodystrophy of the hock joints, clear fluid in hock joint spaces, valgus deformities and shortening of the tarsometatarsal bones, and curled toes were observed in turkey poults infected with *Mycoplasma* (Trampel and Goll, 1994). Joint lesions and curved toes were observed in turkey embryos inoculated with *Mycoplasma* and scanning electron microscopy of the tarsometatarsal joints showed fissures in the cartilage (Lam et al., 2004). Vertebral chondrodystrophy was found in some cases to be associated with *Mycoplasma iowae* (Ley et al., 2010).

15.3.4 Bacterial Chondronecrosis with Ostemyelitis—Femoral Head Necrosis

Osteomyelitis was first reported as a cause of lameness in commercial broiler chickens in Australia, and *Staphylococcus aureus* was shown to be the cause. Bacterial chondronecrosis with ostemyelitis (BCO) is a naturally occurring bone disorder that also can be induced by *S. aureus* infection (Daum et al., 1990; McNamee et al., 1999). Although *S. aureus* is the bacterium most frequently reported in BCO, other bacteria also were isolated from lesions (McNamee et al., 1998; Dinev, 2009). BCO is one of the main reasons for lameness, and live affected birds usually have a characteristic limping gait (Wideman and Prisby, 2013). The most commonly affected sites in naturally occurring BCO are the proximal ends of the femur and tibiotarsus (McNamee et al., 1998, 1999). Lesions occur less frequently in the proximal tarsometatarsus, distal femur, distal tibiotarsus, proximal end of the humerus, and vertebrae (McNamee et al., 1998). Together with the cartilaginous lesions, osteomyelitis often occurs in the metaphysis of the femur and/or tibiotarsus, and occasionally in the secondary ossification center in the proximal end of the tibiotarsus. Macroscopically, BCO may appear as focal yellow areas of exudate or lytic areas. In *S. aureus*-induced lesions, there are usually clumps of basophilic bacteria in epiphyseal or physeal blood vessels, and these are surrounded by poorly stained cartilaginous matrix containing necrotic chondrocytes (McNamee and Smyth, 2000). Computed tomography revealed that the degenerative process involved loss of trabecular bone and lesion development in the mineralized matrix appeared to be coupled with increased bone resorption, associated with excessive proliferation of pathologically altered osteoclasts and lowered protein content of the bone organic matrix (Olkowski et al., 2011). In addition, immunosuppression in broilers has been implicated in the pathogenesis of BCO, and administration of steroids resulted in lameness associated with necrosis of the proximal tibial head and proximal femoral head (Wideman and Pevzner, 2012). Broilers kept on wire flooring developed significant levels of BCO without being intentionally exposed to known pathogens (Wideman and Pevzner, 2012).

15.3.5 Angular Limb Deformities

Angular or torsional limb deformities (twisted legs) are associated with abnormal diaphyseal curvature and physeal osteochondrosis. These deformities developed from a slight deviation or torsion of the distal tibiae. The progressive bowing of the tibiae and the diaphyseal cortical hypertrophy on the weight-bearing side are probably an adaptation to the disorder (Cruickshank and Sim, 1986). A structural abnormality in the distal tibiae may predispose the distal tibiae to a slight displacement of the gastrocnemius tendon, with consequently uneven stress on the distal condyles. The incidence of this abnormality was correlated with high growth rate and rapid weight gain (Fleming, 2008; Shim et al., 2012), early-age water restriction (Toghyani et al., 2011), cellulitis (Elfadil et al., 1996), organic trace minerals (Ferket et al., 2009), and vitamin D status (Newbrey et al., 1988). A model of hemicircumferential chick periosteal stripping of the left distal tibiotarsus that resulted in significant change in metaphyseal-diaphyseal angle with time can be used for study of this disorder (Rackard et al., 2002).

15.3.6 Vitamin and Mineral Deficiencies

There are numerous studies of the involvement of vitamins, minerals, and their interactions in skeletal disorders in poultry (Williams et al., 2000; Jin et al., 2001; Zhang et al., 2003). For example, broilers suffering from pyridoxine deficiency had tibiae of reduced dry weight and cortical thickness. Histomorphometry revealed a disproportionately large eroded surface, reductions in the amount of osteoid tissue, in the width of mineralized trabeculae and in the numbers of secondary ossification centers, along with coarse trabeculation. The metaphyseal cartilage showed irregular trabeculae and a markedly reduced amount of collagen and, probably, impaired collagen cross-linking (Masse et al., 1990, 1994). The effects of deficiencies of other minerals and vitamins such as manganese, biotin, and choline also have been studied (Stock and Latshaw, 1981; Liu et al., 1994).

The involvement of vitamin D and its metabolites is by far the most studied factor in relation to poultry bone disorder (Edwards, 2000; Dinev, 2012). Decreased extracellular phosphate, which is associated with vitamin D deficiency, probably plays a key role in rickets, and Ben-Bassat et al. (1999) studied the involvement of vitamin D in longitudinal bone growth and, especially, that of the growth plates at the ends of the long bones. In rickets, the width of the hypertrophic zone of the growth plate is increased and its mineralization is defective. The effects of vitamin D on the growth plate are mediated primarily through the vitamin D receptor that are expressed in intestinal epithelial cells, which exhibit increased calcium and phosphate absorption from the intestinal lumen. However, vitamin D metabolites also may act directly on the growth plate; for example, injection of 24,25-dihydroxyvitamin D_3 directly into rachitic chick growth plates resulted in healing (Lidor et al., 1987). *In vitro*, 24,25-dihydroxyvitamin D_3 stimulated differentiation but partly inhibited proliferation in resting-zone cells, whereas 1,25-dihydroxyvitamin D_3 decreased proliferation in both the resting and the proliferative zones (Boyan et al., 2002). The effects of vitamin D (Atencio et al., 2005), 1α-hydroxycholecalciferol (Driver et al., 2005), and 25-hydroxycholecalciferol (Bar et al., 2003) on bone development and disorders have been evaluated: the addition of phytase, in combination with 1α-hydroxycholecalciferol

or 1,25-dihydroxyvitamin D_3, ameliorated leg problems or decreased the incidence of rickets, respectively (Mitchell and Edwards, 1996; Driver et al., 2005).

15.3.7 Tibial Dyschondroplasia

Tibial dyschondroplasia (TD) is one of the most common skeletal abnormalities that result in deformed bones and lameness (Leach and Gay, 1987; Orth and Cook, 1994; Pines et al., 2004); it is a disease of rapidly growing birds, especially of broilers (Leach and Lilburn, 1992) and turkeys (Wyers et al., 1991) growing at their maximal genetic potential. Comparison between fast-growing and slower-growing strains revealed less mineralization, more porous cortical bone, and increased Ca-to-P ratios in the former strain (Williams et al., 2000a). The porosity was a result of rapid primary osteon formation at the periosteal surface and incomplete infilling of the resulting canal with osteoblasts. These reductions in density and mineral content resulted in altered biomechanical properties, which caused high rates of bone breakage during catching, transport, and handling at the processing plant. Use of feed restriction led to the hypothesis that the rapid growth rate and not the genetic potential was responsible for the changes in the biochemical properties of the bones (Williams et al., 2004), which implies that genetic selection for growth rate has actually resulted in increased TD incidence (Figure 15.2).

Various factors have been found to be involved in the etiology of the disease, including dietary (Rennie et al., 1993), environmental (Riddel and Classen, 1992), and genetic (Leach and Lilburn, 1992; Kapell et al., 2012) factors. TD can occurs spontaneously in the field and can also be selected for (Ling et al., 2000) or induced by nutritional manipulations or by toxic agents (Orth and Cook, 1994; Rath et al., 2004). Thus, the various protocols that result in TD may initially act via distinct pathways, but downstream they probably share common pathway(s) that lead to the same phenotype (Pines et al., 2004).

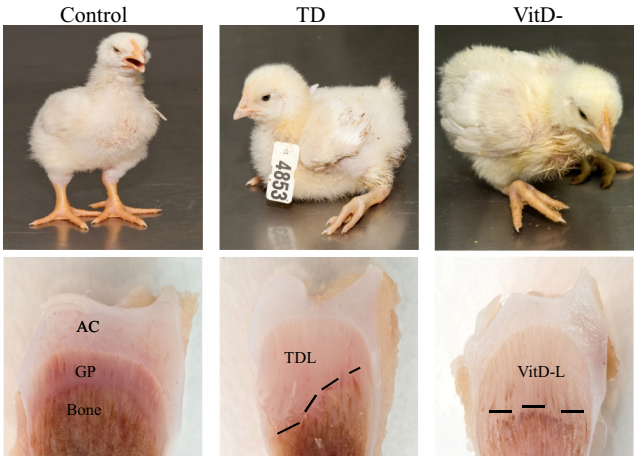

FIGURE 15.2 Chicks (upper panel) and their tibial growth plates (lower panel) of 12 day old broilers afflicted with thiram-dependent tibial dyschondroplasia (TD) and vitamin D-deficient rickets (VitD-). Note the lameness of the TD and VitD- chicks and the increase in the tibial growth plates (GP). AC, articular cartilage; TDL, tibial dyschondroplasia lesion; VitD-L, vitamin D-deficient lesion.

TD is a disease of the growth plates at the ends of the long bones: it is characterized by the appearance of a plug of unvascularized, unmineralized, opaque white cartilage, which dominates the proximal metaphysis of the tibiatarsus and, occasionally, the tarsometatarsus. In TD, the chondrocytes that populate the growth plates fail to undergo the complete differentiation that normally leads to cartilage vascularization and mineralization (Knopov et al., 1995; Pines et al., 1999). Various strategies were used in attempts to understand the causes of TD, and investigated aspects included mechanisms involved in chondrocyte differentiation (Knopov et al., 1997; Pines et al., 1999; Farquharson et al., 2001); chondrocyte apoptosis (Rath et al., 1998), effects of hormones and their receptors (Ben-Bassat et al., 1999; Webster et al., 2003), and fingerprint techniques to compare gene expression in normal and TD chondrocytes (Jefferies et al., 2000; Tian et al., 2013). TD was associated with copper deficiency (Lilburn and Leach, 1980) and could be induced by copper-chelating agents (Pines et al., 2004).

As in TD, the growth plate of rachitic chicks is enlarged, with an increased number of chondrocytes, and is unvascularized. Existence of an association between TD and rickets was demonstrated by the finding that supplementation of high doses of vitamin D or its analogs could ameliorate TD in selected lines (Edwards, 2000; Whitehead et al., 2004; Atencio et al., 2005). Divergent selection of broilers for low or high TD altered the physiological response to nutritionally inadequate levels of dietary D_3 (Shirley et al., 2003). Although TD and rickets have differing etiologies, inhibition of the heat shock protein 90 (Hsp90) resulted in a major improvement in the growth plate histopathology and ameliorated lameness of both TD and vitamin D-deficient chicks, suggesting similar pathways (Herzog et al., 2011). However, it is of the utmost importance to distinguish between the two lesions when studying and designing strategies to prevent TD or rickets; this is especially important because, in some cases, TD-afflicted birds have a background of rickets. It is possible to distinguish between the two conditions visually, but determination of molecular markers such as PTHR gene expression is much more accurate. In TD, normal expression of PTHR is observed, whereas in rickets the receptor is downregulated because of high parathyroid hormone levels, and no expression of the receptor is observed (Ben-Bassat et al., 1999).

15.4 CONCLUSIONS

A high degree of precision in the genetic control of developmental chondrogenesis is essential, and deviation beyond a certain threshold would cause abnormal bone

growth. Multidisciplinary research at various levels, such as the genomic and proteomic approaches, cell culture methodology, genetic selection, nutritional manipulation, and environmental approaches, will provide us with a better understanding of the molecular mechanisms underlying bone disorders. Such understanding might enhance our knowledge and perhaps help in the design of rational strategies for the treatment of bone-related diseases. The enormous losses attributed to skeletal disorders in poultry are caused by increases in mortality and condemnations at the processing plant, and further downgrading caused by the trimming of breasts and legs. From the economic point of view, the major skeletal disorders are associated with the rapid increase in growth rate that has been achieved during the last few decades. Whether the disorders are direct effects of the rapid growth rate or indirect effects that result from increased body weight and inadequate development of bone, muscles and/or tendons is still to be determined. The economic dilemma facing the industry lies in the balance between continued selection for rapid growth, on the one hand, and the losses caused by bone and other metabolic disorders, on the other hand.

Chapter 16

Skeletal Muscle

Sandra G. Velleman and Douglas C. McFarland
The Ohio State University/OARDC, Wooster, OH, USA, South Dakota State University, Brookings, SD, USA

16.1 INTRODUCTION

This chapter covers the development and growth of avian skeletal muscle, beginning with a discussion of the structural diversity of skeletal muscle in different bird species. The chapter then proceeds to overview the embryonic origins of muscle, posthatch development, and growth, with a focus placed on the satellite cells. Satellite cells are adult myoblast stem cells that are responsible for all posthatch muscle growth. The next portion of the chapter deals with muscle fiber types, the mechanism of skeletal muscle contraction, and role of myogenic transcriptional regulatory factors. New emerging areas in avian skeletal muscle biology are also discussed, including satellite cell heterogeneity, extracellular matrix regulation of muscle growth and development, maternal inheritance of muscle morphological structure in turkeys, and the identification of novel genes involved in avian myogenesis.

16.2 DIVERSITY OF AVIAN SKELETAL MUSCLE

The ability to fly has allowed avian species the widespread utilization of many diverse environments and habitats. Perhaps due to this mobility, they may be the most successful terrestrial vertebrate in terms of numbers of species and body forms (Welty, 1982). There are approximately 8900 living species of birds compared to 3000 amphibians, 6000 reptiles, and 4100 mammals. The structure of the musculoskeletal system of birds varies tremendously among species depending on their flight characteristics or whether they are flightless. Most prominent on the sternum of flying birds is a large keel structure to which the powerful flight muscles are attached. Although the penguin is unable to fly, the keel serves as an anchor for muscles controlling the vestigial wings called flippers used for swimming. Flightless birds either lack a keel (ostrich) or the structure is minimal. Other skeletal structures peculiar to birds include a greatly lengthened pelvis fused with the synsacrum, covering approximately half the length of the body. Consequently, there is relatively little dorsal musculature in birds. The majority of the muscle tissue in birds is on the ventral side of the torso, but great differences exist among species. For instance, birds such as hummingbirds and swallows are highly accomplished fliers, but they are limited on the ground; approximately 25–35% of their body weight is devoted to flight musculature and only about 2% to the leg muscles. On the other hand, shore birds that rely more on running than flying have larger leg muscles than wing muscles. Additionally, raptors, which rely on strong grasping of prey, have very strong leg muscles.

The principal flight muscles are the large pectoralis and the supracoracoideus. In some birds, these two muscles may account for 25% of the total mass of the animal. In commercial poultry, genetic selection has largely focused on the size of these muscles because they are the most economically important part of the carcass. Both of these muscles arise from the keel with the supracoracoideus lying dorsal to and under the pectoralis muscle. The pectoralis attaches to the humerus and is responsible for depressing the wings. The supracoracoideus attaches to a tendon that passes dorsally through a foramen and attaches to the dorsal surface of the humerus. This "rope-and-pulley" arrangement allows for the upward movement of the wings. Additionally, there are many other smaller muscles that cause changes in the angle of the wings.

Throughout the skeletal muscular systems of birds, there are many variations in structure that allow this diverse class of vertebrates to adapt to environmental niches and feed sources. For instance, the jaw closing muscles of birds that feed on coarse seeds are stronger than those that feed on smaller grains or noncoarse materials. As will be discussed below, movement requirements of each muscle must be properly matched with the appropriate type of contractile fibers, metabolic characteristics, and neural signal.

Members of the class *Aves* are classified as either precocial or altricial in their developmental patterns. Precocial

Sturkie's Avian Physiology.

birds hatch with open eyes and a coat of down feathers; they leave the nest within 2 days. Altricial birds hatch with closed eyes, with little or no down feathers, and must be fed by parents. Included in the latter group are passerine birds, the largest order of birds. Additionally, there are birds that fall in between these two classification, which are referred to as semiprecocial or semialtricial. Among the precocial birds include aquatic species such as gulls, terns, ducks, geese, and rails. These species are able to run and swim in the first day following hatching. However, they cannot fly until fully grown (Dial and Carrier, 2012). The early maturation of the leg skeletal muscle system versus the wings allows these species to escape predators without relying on the ability to fly. Although not capable of walking following hatching, altricial birds are capable of performing alternating stepping movements following hatch, indicating that the locomotor program is in place early in development (Muir, 2000). Some of the differences between precocial and altricial species are explained by the immaturity of the neurological system in the latter species (Oppenheim, 1972). However, the sequence of movements leading to pipping and emergence from the egg remains the same in all avian species examined except for members of the family Megapodiidae (Oppenheim, 1972).

It has long been known that thyroid hormones play an important role in skeletal muscle development. Using the precocial Japanese quail and altricial Ring doves, McNabb et al. (1984) compared thyroid function between these two species. It was found that thyroid function and body growth were quite different between the quail and doves despite similar incubation periods, adult body weights, and adult serum thyroid hormone levels. The precocial quail thyroid activity was high in the perinatal period, declined shortly following hatching, and then gradually increased to adult levels. The altricial doves lacked a perinatal peak in thyroid activity; in fact, levels were low at hatching, increasing steadily to adult levels. It is likely that the differences in thyroid activity profiles and maturity of the neurological system play major roles in the marked differences in precocial and altricial skeletal muscle growth patterns.

16.3 EMBRYONIC ORIGINS OF SKELETAL MUSCLE

There are many excellent books on the embryology of vertebrates, including birds. Therefore, this section will focus only on those cells of the embryo that lead to the development of the skeletal musculature (for a review, see Gilbert, 2000). Following gastrulation, or the transformation of the spherical blastula into an elongated tubular structure, three primary germ layers are defined. The outer structure comprises the ectoderm and the inner surface comprises the endoderm. Between these layers is the mesoderm, which is the source of cells that lead to the formation of the skeletal muscle and other internal structures. As the embryo elongates due to lengthening of the structure called the notochord, the mesoderm grows as "slabs" on both sides of the notochord with the ectoderm above and the endoderm below. The mesodermal cells continue to proliferate during the elongation period. Eventually, the cells separate into blocks of cells called somites beginning at the anterior end and terminating at the posterior of the embryo. The cells of the somites become different structures depending on their location. Cells that are near the notochord are termed the sclerotome and eventually give rise to the vertebrae and ribs. Cells that are adjacent to the dorsal surface are the dermatome and give rise to the dermis of the trunk. The cells that lie between the sclerotome and dermatome are termed the myotome; they give rise to most of the skeletal muscles of the body.

At appropriate gestational ages, the primordial muscle cells (embryonic myoblasts) migrate out of the somites into future muscle beds and continue to proliferate. Some of the myoblasts fuse with one another and form primary muscle fibers. They have centrally located nuclei and form myofibrils. The remaining single-celled myoblasts continue to proliferate and eventually begin to fuse to form the secondary fibers. The secondary fibers form alongside the primary fibers, which serve to orient the developing muscles so that they will function properly. In most animals, fiber formation is essentially complete at the time of birth or hatching. Subsequent muscle growth is due to enlargement of the existing fibers and is called hypertrophy. The details as to how hypertrophy occurs remained a mystery until the 1960s; much of what is now known about posthatch or postnatal muscle growth was gained from studies with chickens. Smith (1963) demonstrated that fiber number increases occurred in chickens prior to hatching and subsequent growth was due to hypertrophy. The importance of initial fiber number following hatching was further demonstrated by studies with different lines of chickens. A growth-selected heavy strain of chickens had a greater number of fibers that were slightly smaller in diameter at hatch than a layer strain of chickens. Following 10 weeks of growth, fiber diameters of the growth selected line were much greater than those of the layer strain (Smith, 1963).

One of the major puzzles of muscle growth in the early years of this research was what the source of the nuclei is in growing and regenerating skeletal muscle. Were the myonuclei within the existing fibers dividing or were there other sources of nuclei? To answer this question, Stockdale and Holtzer (1961) isolated chick embryonic myoblasts and allowed them to fuse to form immature muscle fibers called myotubes in culture. Tritiated thymidine was administered to the cultures, but no mitotic figures or radiolabel were seen within the myotubes. However, if tritiated thymidine was administered to proliferating cells, labeled nuclei were detected. These findings demonstrated that myonuclei

were incapable of mitotic division and that there was another cell responsible for DNA accretion. While it appeared clear that embryonic myoblasts were likely responsible for the development of muscle fibers prenatally, the source of cells leading to postnatal growth was not known.

16.4 POSTNATAL OR POSTHATCH SKELETAL MUSCLE DEVELOPMENT

In 1961, Alexander Mauro wrote a brief note about a cell that resided between the plasma membrane (or sarcolemma) and the basement membrane (or basal lamina) of frog muscle fibers (Mauro, 1961). Electron micrographic examination showed that the cell mass consisted mostly of nuclei, and there were little cytoplasm and few organelles such as mitochondria or golgi apparatus. Dr Mauro termed these cells "satellite cells" due to their peripheral location on muscle fibers. He speculated that satellite cells might be somehow activated and aid in the repair of damaged muscles. After conferring with other colleagues, he learned that these cells were also present in rat skeletal muscle, but not cardiac muscle. Were the satellite cells responsible for postnatal or posthatch growth of skeletal muscle? Evidence for the role of satellite cells in postnatal growth was reported by Moss and Leblond (1971). These researchers injected tritiated thymidine into young growing rats and followed the label in the muscle tissue. One hour following injection, the label was localized in satellite cells. For the next 24 h, the number of labeled satellite cells doubled, indicating that the satellite cells were dividing. Following this, label began to appear within myonuclei, indicating that the satellite cells had fused with the adjacent fibers. These observations established the key role of satellite cells in DNA accretion of muscle fibers.

The importance of DNA accretion in fiber hypertrophy was demonstrated by studies conducted by Moss (1968). In this work, it was shown that there was a constant ratio of muscle fiber diameter to the DNA content of the fiber. These findings demonstrated that DNA accretion via satellite cell incorporation was required for the growth of skeletal muscles. Although Mauro's initial observations reported inactive or dormant satellite cells, further work in other laboratories identified activated and dividing satellite cells, particularly in young animals (Snow, 1977). These cells had euchromatic nuclei and a prominent nucleolus. The cytoplasmic volume was larger and there were polyribosomes, more mitochondria, some rough endoplasmic reticulum, and Golgi apparatus. When examining muscles of older rats (8–30 months of age) Snow (1977) reported that the nuclei exhibited heterochromatin and a higher nuclear to cytoplasmic ratio compared to the young rats. The rough endoplasmic reticulum was fewer in number and the Golgi apparatus was poorly developed—all characteristics of dormant or inactive satellite cells. Schultz et al. (1978) injected tritiated thymidine into older mice and noted that there was a lack of radiolabel within the nuclei of satellite cells and the frequency of satellite cells was diminished compared with younger animals. In spite of the inactive state of satellite cells in mature animal muscles and their diminished numbers, satellite cells residing in older animals do have the capacity to become active and proliferate (Allen et al., 1980), but the proliferation potential is lower (Schultz and Lipton, 1982).

To determine if satellite cells were indeed involved in regeneration of damaged skeletal muscle as was proposed by Mauro (1961), Bischoff (1975) isolated individual muscle fibers from rat leg muscles and placed them in culture medium. During the first several hours, degeneration within the basement membrane occurred. Contraction clots formed and the myonuclei did not undergo mitosis. However, the satellite cells attached to the fibers began to enlarge, proliferate, and fuse and form myotubes within the sarcolemma. Eventually, the regenerated fibers exhibited contractions. These and other studies (Carlson and Faulkner, 1983; Ontell, 1986; Schultz, 1989) demonstrated the important role of satellite cells in skeletal muscle regeneration following damage. Furthermore, satellite cells have been observed to pass through the basement membrane, fuse with adjacent muscle fibers, and contribute to repair of fibers they were not associated with (Hughes and Blau, 1990).

Satellite cell activation is influenced by nutrition and exercise. The proportion of fiber nuclei residing in satellite cells versus myonuclei is diminished with malnutrition (Hansen-Smith et al., 1979). Furthermore, the satellite cells of malnourished individuals are largely quiescent. Following nutritional recovery, satellite cells enlarge and become mitotically active (Hansen-Smith et al., 1978). Darr and Schultz (1987) utilizing an untrained exercised rat model, demonstrated that exercise induced activation of satellite cells. Accompanying exercise was a small percentage of necrotic fibers (<3%). However, the extent of satellite cell activation was greater than that needed to support fiber regeneration. Microscopic examination of these muscles revealed fibers with centrally located myonuclei, which are characteristic of newly repaired muscle fibers.

16.5 SKELETAL MUSCLE GROWTH

Much of what has been learned about the factors regulating the proliferation and differentiation of satellite cells has been derived from cell culture studies and the development of serum-free media formulations for various species. Satellite cells were first isolated and cultured by Bischoff (1974) from the skeletal muscles of adult rats. The cells were capable of proliferating and differentiating into multinucleated myotubes. Since then, satellite cells have been isolated and cultured from many species including humans (Blau and Webster, 1981) and the major agriculturally important

animals (for a review, see Dodson et al., 1996), including the chicken (Johnson et al., 1983; Matsuda et al., 1983; Yablonka-Reuveni et al., 1987) and turkey (McFarland et al., 1988).

As the serum component of typical cell culture media formulations contains variable levels of known and unknown hormones and growth factors that may influence cellular activity, they are of limited value in establishing cell requirements for proliferation, differentiation, and other activities. Serum-free medium formulations have been developed for chick embryonic myoblasts (Dollenmeier et al., 1981), turkey satellite cells (McFarland et al., 1991), and both chicken and turkey satellite cells (McFarland et al., 2011). Using these tools, researchers have been able to examine the effects of individual and combinations of growth factors on proliferation and differentiation. Similarities have emerged between findings with avian species and with mammals. The most studied growth factors are the insulin-like growth factors (IGF), fibroblast growth factors (FGF), platelet-derived growth factors (PDGF), hepatocyte growth factor (HGF), transforming growth factor-beta (TGF-β), and myostatin. At the present time, the role, if any, of epidermal growth factor (EGF) in avian skeletal muscle is unclear. McFarland et al. (1993) reported that EGF in combination with either IGF or FGF or both had no effect on turkey embryonic myoblast or satellite cell proliferation. However, EGF does stimulate proliferation of chick smooth muscle cells (Topouzis and Majesky, 1996) and stimulated chick cardiac cell development and function (Lau, 1993, 1994; Rabkin, 1996). A more comprehensive review of the influence of growth factors on avian satellite cells has been published previously (McFarland, 1999). The following is an overview of major findings and more recent material regarding growth factor effects on satellite cells.

Among the initial reports of IGF effects on avian skeletal muscle cells was a report by Schmid et al. (1983). This study reported that the two major forms of IGF (IGF-I and IGF-II) were equipotent in enhancing differentiation and fusion of chick embryonic myoblasts. In turkey embryonic myoblasts, however (McFarland et al., 1993), IGF-II was more potent than IGF-I in stimulating proliferation and differentiation. Exogenously added IGF-I or IGF-II were equipotent in stimulating proliferation of turkey satellite cells, but had no effect on differentiation. The presence of FGF was required for proliferation of either turkey muscle cell types to occur. FGF alone stimulated proliferation of both cell types, and there was a synergistic effect with both cells by the addition of FGF and IGF. Highest rates of proliferation of turkey satellite cells and embryonic myoblasts was seen with the combination of FGF, IGF, and PDGF. As the name implies, IGF have insulin-like activities, in both mammals and birds. For instance, IGF stimulates glucose uptake in the turkey (McFarland et al., 1994) and the chicken (Duclos et al., 1993a) satellite cells. Additionally, IGF stimulates protein synthesis and inhibits protein degradation in myotubes derived from chick embryonic myoblasts (Janeczko and Etlinger, 1984), chick satellite cells (Duclos et al., 1993b), and turkey embryonic myoblasts and satellite cells (McFarland et al., 1994). Recent evidence (Shinichi et al., 2012) demonstrated that polymorphism of the IGF-I gene is associated with pectoralis major muscle yields in chickens. This suggests that marker-assisted selection may be a useful tool to aid in improving breast muscle yields.

The FGFs are a large group of polypeptide growth factors with diverse actions on cells and tissues. Fibroblast growth factor is an important mitogen for avian skeletal muscle cells. In fact, omission of FGF from serum-free media results in no proliferation of turkey satellite cells or embryonic myoblasts, even if IGF, PDGF, or EGF is present (McFarland et al., 1993). Much of the muscle studies with FGF have focused on FGF-1 and FGF-2. Fibroblast growth factor 2 is a more potent mitogen for turkey (McFarland et al., 1993) and chicken (Wilkie et al., 1995) satellite cells than FGF-1. Fibroblast growth factor also acts as an inhibitor of differentiation. Addition of FGF-2 to cultures inhibits differentiation of chicken (McFarland et al., 1997a) and rodent (McFarland et al., 2000) satellite cells.

Platelet-derived growth factor is the major mitogen found in serum, where it is derived from the platelets following clotting of blood. Platelet-derived growth factor is also produced by many types of cells in the body, including skeletal muscle cells (Sejersen et al., 1986). In addition, PDGF was shown to be a potent mitogen for chick embryonic myoblasts (Yablonka-Reuveni and Seifert, 1993). It was shown that the BB isomer was the most potent, followed by the AB isomer, whereas the AA isomer was inactive. Similar findings were reported for the turkey embryonic myoblast and satellite cell (Ye et al., 1996). Platelet-derived growth factors also have a chemotactic effect on myoblasts. Using embryonic myoblasts isolated from Japanese quail (*Coturnix*) embryos, Venkatasubramanian and Solursh (1984) demonstrated that these cells migrated toward a gradient of PDGF, whereas nonmyogenic limb mesenchyme cells did not.

Early research by Bischoff and others described a mitogenic activity towards rodent satellite cells associated with saline extracts of crushed muscles. This so-called crushed muscle mitogen was capable of activating quiescent satellite cells residing on isolated muscle fibers (Bischoff, 1986). Using quiescent cultured satellite cells, Tatsumi et al. (2001) demonstrated that stretched cells entered the cell cycle earlier than quiescent cells cultured in static conditions. Furthermore, the conditioned media from the stretched cells activated quiescent cells. Stretch or injury released preexisting HGF from the extracellular matrix into the media. The administration of anti-HGF antibodies abolished the stretch activation of satellite cells and demonstrated that the crushed muscle mitogen was, indeed, HGF.

Hepatocyte growth factor exists in the extracellular matrix in a pro-HGF inactive form and is released in the active form by nitric oxide during the stretching process (Tatsumi and Allen, 2004). Gal-Levi et al. (1998) demonstrated that HGF affected chicken satellite cells as well. Hepatocyte growth factor increased DNA synthesis and decreased differentiation of cultured cells. Inhibition of differentiation was accomplished by inhibiting the activity of myogenic determination factors and subsequent muscle-specific protein expression. It was proposed that increasing proliferation and decreasing differentiation of satellite cells would increase the satellite cell pool size and eventually lead to more fiber formation. Hepatocyte growth factor has similar effects on the proliferation and differentiation of turkey satellite cells (Zeng et al., 2002). Addition of anti-HGF antibodies to turkey satellite cells in serum-free medium decreased proliferation, supporting the role of HGF as an autocrine or paracrine factor (i.e., locally-acting growth factor) in muscle. It was also reported that HGF has chemotactic activity toward satellite cells (Bischoff, 1997). Using chick embryos, Brand-Saberi et al. (1996) reported that HGF causes detachment of myogenic precursor cells from the somites and is therefore thought to be important in initiating the migration of these cells into muscle beds in the developing embryo.

An unknown factor secreted into media over rat liver cells was shown to inhibit the differentiation of rat L6 muscle cells (Evinger-Hodges et al., 1982). This "differentiation inhibitor" was studied in several laboratories and Florini et al. (1986) determined that this substance was identical to TGF-β. The mode of action appeared to be by blocking expression of myogenic differentiation genes, such as myogenin (Massague et al., 1991). The detection of TGF-β1 and TGF-β2 in chick embryos by day 1.5 of incubation (Jakowlew et al., 1994) and TGF-β4 expression by day 4 of incubation (Jakowlew et al., 1992) suggested that TGF-β is important in early development of avian species. In fact, these three forms of TGF-β were detected in all embryonic tissues examined and expression increased with embryonic age. Yun et al. (1997) reported that TGF-β1 inhibited both proliferation and differentiation of turkey satellite cells. Previously, Schofield and Wolpert (1990) demonstrated that, when added alone, TGF-β1 and TGF-β2 had no effect on chick embryonic myoblast differentiation. However, when added with FGF, TGF-β blocks the FGF inhibition of myoblast differentiation and the cells differentiate. It is not known whether the differences seen between the turkey and chicken cells represents species variation, media conditions used, or are due to the developmental ages of the cells.

Myostatin is a member of the TGF-β family of polypeptides. Defects in the myostatin gene result in dramatic increases in muscle mass seen in Belgian Blue and Piedmontese breeds of cattle (McPherron and Lee, 1997). Likewise, myostatin-null mice demonstrate enhanced musculature (McPherron et al., 1997). Srinivasan et al. (2004) demonstrated that levels of myostatin are elevated during muscle atrophy and Price et al. (2011) reported that photo-stimulated migrant sparrows had increased expression of myostatin. It is believed that elevated myostatin during muscle breakdown serves to prevent premature satellite cell activation while degeneration occurs. When muscle regeneration commences, myostatin levels diminish (Kirk et al., 2000). *In vitro* studies have shown that myostatin inhibits mouse C2C12 muscle cell proliferation, DNA synthesis, and protein synthesis but has no effect on protein degradation or apoptosis (Taylor et al., 2001). Administration of myostatin to muscle explants inhibits satellite cell activation and progression into the cell cycle (McCroskery et al., 2003).

Proliferation of both turkey embryonic myoblasts and satellite cells was inhibited between 26 and 45% in serum-free medium containing 20 ng/mL myostatin (McFarland et al., 2006). Myostatin also caused marked depression of differentiation in turkey satellite cells but had no effect on the differentiation of turkey embryonic myoblasts. Additionally, expression of decorin, an inhibitor of muscle growth, increased in the differentiating cells. Satellite cells isolated from the pectoralis major muscles of chickens were more responsive to the proliferation depressing effects of myostatin compared to cells from the biceps femoris (McFarland et al., 2007). Myostatin inhibited differentiation of satellite cells derived from the pectoralis major muscle but had no effect on the cells from the biceps femoris muscle. Administration of antimyostatin antibodies to proliferating cultures increased cell proliferation by 6–7% over 3 days, supporting a role of endogenous myostatin in autocrine regulation of muscle growth. Antimyostatin had no effect on differentiation of either pectoralis major or biceps femoris cells.

The above growth factors are among the most widely studied factors influencing satellite cell activity and muscle growth. Other factors influencing satellite cell or myoblast growth include granulocyte colony-stimulating factor (G-CSF). Receptors for G-CSF are expressed in developing somites and both the receptor and G-CSF are expressed in mouse embryonic myoblasts (Mie et al., 2011). Granulocyte colony-stimulating factor is also important in regeneration of damaged muscle because its receptor is transiently expressed in injured mouse muscle. Neutralizing antibodies to G-CSF impaired regeneration of damaged muscle. The G-CSF is important in muscle development and repair. Another factor, bone morphogenic protein (BMP), also appears to be an important influence on muscle growth (Ono et al., 2011). Bone morphogenic protein 4 stimulates satellite cell proliferation and inhibits differentiation. Addition of the BMP antagonist Noggin induced precocious differentiation of the cells. During satellite cell differentiation, Noggin expression increases and proliferation ceases and differentiation and cell fusion occurs. The authors conclude that BMP signaling occurs during expansion of the satellite

cell pool and at the appropriate time Noggin is activated to antagonize BMP to initiate differentiation.

16.6 SKELETAL MUSCLE FIBER TYPES

Muscle fibers differ greatly in terms of contraction rate, metabolism, and function. There is generally accepted to be three fiber types: (1) slow-twitch, oxidative (SO), type I or red fiber; (2) fast-twitch glycolytic (FG), type IIB or white fiber; and (3) fast-twitch, oxidative/glycolytic (FOG), type IIA or intermediate fiber (Allen and Goll, 2003). The fiber types housed within muscle groups varies depending on the particular requirements for motion. Additionally, the same anatomical muscle may differ greatly in fiber composition between species. For instance, when comparing the pectoralis major muscle of a duck and a chicken or a pheasant, it is obvious that the duck pectoralis major muscle is primarily an oxidative muscle due to its high proportion of myoglobin, giving it a red color. This powerful flight muscle ideally suits the duck for long, sustained flights of several hundred miles as required for migration. In migratory wild birds, the muscles will have a higher proportion of type I fibers compared to type IIb (Ashmore et al., 1972). The type I fibers have a higher aerobic capacity and higher blood supply necessary for sustained activity. In contrast, the pectoralis major muscle of the domestic chicken is composed of type IIb fibers and has a lower blood supply because prolonged flight activity is not necessary and the muscle will fatigue more quickly.

Aerobic muscles oxidize glycogen and glucose through glycolysis and the tricarboxylic acid cycle and oxidize fatty acids via β-oxidation. Consequently, these muscles contain greater numbers of mitochondria, smaller fiber diameter to facilitate oxygen diffusion, greater triglyceride levels, and greater capillary density. The chicken or pheasant pectoralis major muscle is primarily composed of glycolytic fast twitch muscles and myoglobin levels are much lower, giving the muscle a white color. Glycolytic muscles oxidize glycogen and glucose to lactate and the lactate is returned to the liver for gluconeogenesis (Cori cycle). Therefore, much less energy is derived from oxidizing glucose in these muscles, so energy is expended quickly and serves to provide a rapid (but short) burst of activity.

In addition to differences in energy metabolism between fiber types, contraction properties are determined by the protein isoforms contained in the contractile apparatus of the fibers. Fast-twitch fibers contain myosin isoforms with fast ATPase activity (generating energy quickly for rapid movements) and slow-twitch fibers contain myosin isoforms with slow ATPase activity (generating energy more slowly for sustained movements). The functional unit of movement is the motor unit consisting of the neural cell body residing in the dorsal root of the spinal cord and its axon, which extends to the muscle being innervated. The single axon splits into numerous branches (a few to hundreds) and each branch innervates an individual muscle fiber. Motor units are interspersed throughout regions of the muscle group, so individual motor units influence the contractility of a wide area (Lieber, 1992). Patterns of action potentials generated from nerves innervating slow muscle fibers differ from those that innervate fast muscles. Nerve transplantation studies have revealed that these patterns influence myosin isoform expression (Cerny and Bandman, 1987). When fast muscles were innervated by nerves normally innervating slow muscles, fast myosin isoforms were replaced by slow myosin isoforms. However, neural stimulation is not the only factor affecting the contractile fate of muscles. Fiber type is also influenced by the myoblast lineage that makes up the muscle fiber (Dimario and Stockdale, 1997).

Cross-sectional area of muscle fibers is influenced by muscle fiber type. Type I muscles have a smaller cross-sectional area than type IIb fibers (Ashmore et al., 1972). The cross-sectional area of muscle fibers is not a static situation and will change based upon usage. The flight muscles of migratory birds change in fiber diameter in anticipation of migration and during the migratory flight (Price et al., 2011). For example, during a long migratory flight, the muscle fibers may decrease in diameter to coincide with a lighter bird weight as fat is oxidized (Lindström et al., 2000). During a stopover or rest period, the muscles may rebuild for the next flight and increase in diameter (Landys-Cianneli et al., 2003).

16.7 MUSCLE STRUCTURE AND CONTRACTION

Muscle is surrounded by a connective layer, the epimysium (Figure 16.1(A)), which separates individual muscles. Within the muscle, the muscle fibers form bundles or fasciculi. The bundles are separated from each other by a connective tissue layer called the perimysium. Muscle bundles can vary in size from 50 to up to 300 muscle fibers per bundle. Each muscle fiber is separated by the endomysial connective tissue layer. The connective tissue layers are all joined together at the myotendinous junction and thus are not independent from each other. The interconnection of the three connective tissue layers provides a strong structural framework for the muscle and contains capillary beds and water-holding molecules (Allen and Goll, 2003).

Mature muscle fibers can vary in their length and diameter. Skeletal muscle is multinucleated with myonuclei located at the periphery of the muscle fiber just underneath the sarcolemma. The sarcolemma is the plasma membrane of the muscle cell and contains invaginations into the muscle fiber called the transverse tubule system. Invaginations of the transverse tubule system into the muscle fiber occur at regular intervals along the sarcomere or contractile unit

of the muscle. This system allows for calcium to be rapidly released upon sufficient membrane depolarization (Allen and Goll, 2003).

Muscle contraction is initiated by the myosin heads attaching to the actin thin filaments of the sarcomere. For a review of the muscle contraction process, see Alberts et al. (2008). Adenosine triphosphate is hydrolyzed to adenosine diphosphate, leading to the actin filaments being pushed toward the center of the sarcomere (Figure 16.1(B) and (C)). The distance from one Z band to another Z band constitutes an individual sarcomere. The thin filaments are composed primarily of actin, tropomyosin, troponins, tropomodulin, and nebulin. The filaments are anchored to the Z band through α-actinin and CapZ. The end of the thin filament closest to the M-line is capped with tropomodulin which, in part, regulates actin filament length (Fowler et al., 1993).

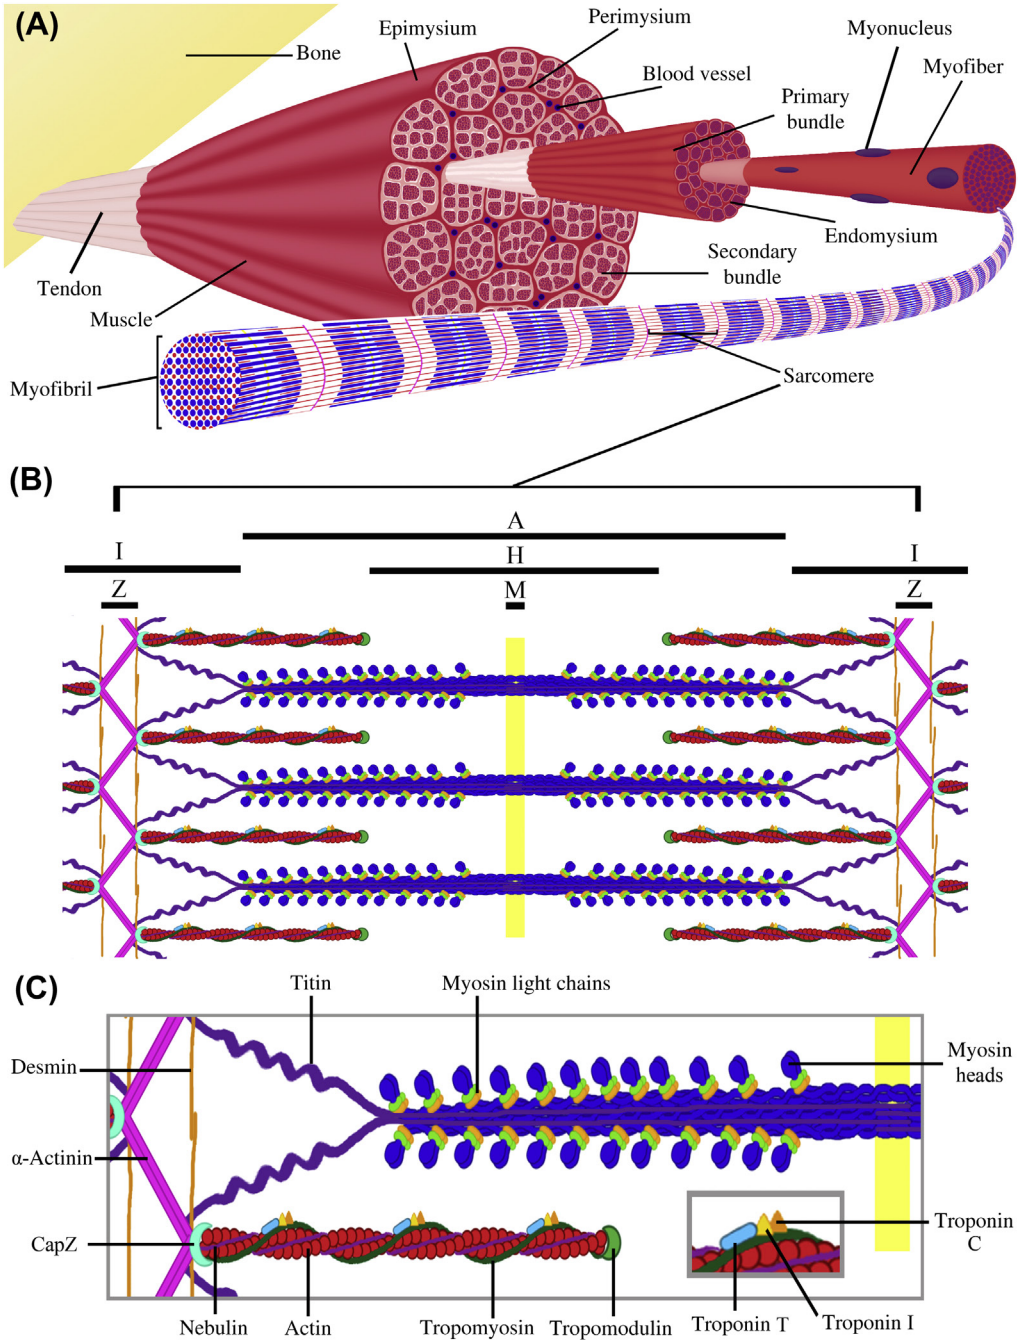

FIGURE 16.1 Schematic of muscle structure. (A) Overview of a cross-sectional area of muscle highlighting muscle fiber structure. (B) Sarcomere structure. (C) The myosin-actin overlap with the associated molecules.

Nebulin is an actin-binding protein. Nebulin knockout mice have reduced actin filament length and impaired contractile properties (Bang et al., 2006). In the I zone, the actin filaments do not overlap with the myosin filaments.

Myosin filaments in the sarcomere exists without any overlap with the actin filaments in the H zone, and in the A zone there is overlap of the myosin and actin filaments (Figure 16.1(B) and (C)). Myosin is a protein dimer composed of two heavy chains and two copies of two different light chains. The N-terminus globular domain is the region that binds to actin and is attached to an α-helical myosin tail region. Located near the globular myosin head is one copy of each of the two light chains.

Releasing the myosin heads from the actin filaments is necessary to prevent a constant state of contraction. The troponin complex containing troponin I, troponin T, and troponin C is involved in the regulation of the myosin head-actin filament interaction (Figure 16.1(C)). In the state of muscle relaxation, the troponin I–T complex causes tropomyosin to move from its natural position in the grooves of the actin helix to a position that prevents the myosin heads from binding to the actin. Following calcium being released from the sarcoplasmic reticulum, troponin C binds to the calcium, causing the troponin I–T to release from the actin. This allows tropomyosin to return to the actin groove and facilitate the binding of the myosin heads to the actin filament.

16.8 MUSCLE DEVELOPMENT: FUNCTION OF MYOGENIC REGULATORY FACTORS

When muscle precursor cells begin to differentiate into skeletal muscle, the activation of skeletal muscle-specific development during both embryonic and posthatch stages requires the precise expression of muscle regulatory factors (MRFs). The MRFs are a family of basic helix-loop-helix (bHLH) transcription factors that are expressed in a specific temporal order. They activate muscle-specific gene expression by binding to the E-box in the DNA (Olson, 1990). Myogenic determination factor 1 (MyoD) was the first identified MRF; its importance was immediately recognized because it could convert nonmyogenic cells to a skeletal muscle lineage (Davis et al., 1987; Weintraub, 1993). The expression of MyoD is necessary for myoblast and satellite cell proliferation. Myogenic factor 5 (Myf5) has functions that overlap with MyoD in that Myf5 also initiates proliferation. The absence of both MyoD and Myf5 will result in the absence of skeletal muscle formation (Rudnicki et al., 1993). However, MyoD and Myf5 are functionally redundant in that disruption of either MyoD or Myf5 will allow muscle development with just minor defects (Rudnicki et al., 1992, 1993). Myogenin is necessary to cause the expression of muscle-specific proteins needed for terminal differentiation with the fusion of myoblasts to form myotubes. Of the MRFs, myogenin is required for viability, as disruption of myogenin expression results in little or no muscle development even though myoblasts are present (Hasty et al., 1993). Myogenic regulatory factor 4 (MRF4, myogenic factor 6) is generally expressed after myogenin and is necessary for myofiber formation. However, MRF4 may play a role during cell proliferation in birds. Shin et al. (2012a) showed MRF4 expression to be high during turkey satellite cell proliferation. This biphasic expression pattern of MRF4 expression is supported by regeneration studies done in the mouse. Launay et al. (2001) reported that MRF4 expression was increased 2–3 days postinjury; its expression decreased at 8 days following the injury and subsequently upregulated at later stages of regeneration (30 days postinjury).

In addition to the MRFs, the myocyte enhancer factors (MEFs) are positive upregulators of muscle differentiation (Naya and Olson, 1999). The MEFs are not specific to skeletal muscle like the MRFs. They are also expressed in cardiac and smooth muscle. No skeletal muscle phenotype has been attributed directly to the MEFs, but they appear to function in a positive feedback manner, especially with myogenin (Ridgeway et al., 2000).

16.9 SATELLITE CELL AND MYOBLAST HETEROGENEITY

As would be expected, there is considerable heterogeneity in muscle fiber structure, metabolism, and response to stimuli, depending on the specific function of the muscle. Muscles for quick short burst movement differ from muscles for sustained movement. Postural muscles also have different properties than muscles not involved in posture.

Heterogeneity also exists among satellite cells, and subpopulations have been characterized by different criteria. Evidence for the existence of subpopulations expressing different myosin isoforms has been reported by several laboratories (Stockdale, 1990; Feldman and Stockdale, 1991; Hoh and Hughes, 1988). Schultz and Heckman-Jones (1990) demonstrated the presence of two populations of satellite cells *in vivo*. One population did not appear to divide during 7 days of extensive muscle growth. Clonal analysis of chicken satellite cells by Yablonka-Reuveni et al. (1987) identified differences in colony sizes. More than 90% of the clones gave rise to large colonies, whereas 8–9% gave rise to small colonies.

To test the hypothesis that at least some of the satellite cell heterogeneity was due to variation in response to growth factor responsiveness, McFarland et al. (1995a) isolated individual satellite cells from a suspension derived from one muscle (pectoralis major) of one 6 week old tom turkey. Using a robotic cell manipulator, 73 clones were developed, which varied greatly in the length of time taken to reach confluence in 25 cm^2 tissue culture flasks. Although there was a continuum of growth rates, the fastest growing clone

reached confluence on day 17 following cloning and the slowest reached confluence on day 30. To further investigate differences between cells, a clone that reached confluence on day 19 and one that reached confluence on day 29 were chosen for further studies. The day 19 clone retained its characteristic of proliferating more rapidly than the day 29 clone. Furthermore, the day 19 clone was more responsive to the mitogenic effects of chicken serum at all levels examined (0.5% through 15%). Cells from the two clones exhibited similar morphology and absence of biochemically detectable DNA fragmentation characteristic of apoptotic cells. When near-confluent cultures of both clones were induced to differentiate and fuse in low serum-containing medium, there was no detectable difference in the rates of differentiation of the two clones. Further examination of the two clones was focused on comparing their responses to growth factors important in muscle growth and development (Yun et al., 1997). Using serum-free media, it was demonstrated that the day 17 clone was more responsive to the mitogenic effects of FGF-2, IGF-I, insulin, and PDGF-BB than the day 29 clone. Furthermore, the day 17 clone was also more responsive to the proliferation and differentiation depressing effects of administered TGF-β. Examination of the properties of the PDGF, FGF, and IGF receptors on these two clones revealed no differences in either dissociation constants or receptor numbers per cell. The results demonstrated that there is heterogeneity in satellite cell response to growth factors. To further examine differences between the clones, two additional fast-growing clones and two additional slow-growing clones were examined in conjunction with the original clones studied (McFarland et al., 2003). The fast growing clones used in these latter studies included clones that reached confluence in 25 cm^2 flasks at day 17, 18, or 19. The three slow-growing clones reached confluence on day 28 or day 29. Fast-growing clones were all more responsive to FGF-2 and expressed greater levels of FGF-2 and the FGF receptor-1 at the onset of proliferation than did the slow-growing clones. Fast-growing clones also expressed higher levels of heparan sulfate proteoglycans (HSPG), especially during differentiation, than did slower-growing clones. Heparan sulfate proteoglycans, which are important in FGF signaling, increased during proliferation of all clones tested and decreased in all but one of the clones during differentiation. Slow-growing clones increased their expression of FGF receptor-1 through proliferation and differentiation. However, expression of the receptor in fast growing clones decreased during differentiation. The FGF receptors-2 and -3 were not detected on turkey satellite cells or myotubes using reverse transcriptase-polymerase chain reaction methodology.

To determine if the differential responses to growth factor stimuli between satellite cell clones were due to variation in the levels of activated intracellular signaling proteins, the levels of phospho-MAPK (phospho-ERK 1/2) were determined in the six clonal populations described above (McFarland and Pesall, 2008). Western blotting of satellite cell extracts demonstrated a synergistic response to addition of IGF-I and FGF-2 in both satellite cells and turkey embryonic myoblasts. When administering IGF-I and FGF-2, two of the slow-growing clones exhibited lowest levels of phospho-MAPK. One of the slow-growing clones had levels of phospho-MAPK similar to the three fast-growing clones. The results suggest that variation in responsiveness to growth factor stimuli among satellite cell subpopulations within muscles may be due to several different reasons. Some differences in cell responsiveness appear to be due to variation in phospho-MAPK generation.

Variation in the characteristics of satellite cells has been noted between muscle types. A comparison of satellite cells derived from the turkey pectoralis major, which is composed primarily of glycolytic fibers and the biceps femoris, a muscle composed largely of oxidative fibers were compared in culture (McFarland et al., 1995b). Satellite cells derived from the pectoralis major muscle were more responsive to the mitogenic effects of serum than biceps femoris cells. When administered low serum-containing medium, near-confluent cultures of the biceps femoris cells differentiated and fused to form multinucleated myotubes more rapidly than pectoralis major cells. However, biceps femoris and pectoralis major cells did not respond differently to the mitogenic effects of IGF-I, insulin, or FGF-2. Examination of growth factor receptor characteristics revealed that there were no differences between the pectoralis major and bicep femoris cells in terms of FGF and IGF receptor affinities toward their ligands and there were no differences in receptor numbers per cell (McFarland et al., 1997b). However, both receptor affinities and receptor numbers were different for the PDGF receptors on these satellite cells. Although there were a greater number of PDGF receptors on bicep femoris cells, the receptor affinity was higher for pectoralis major cells. Rates of protein degradation and synthesis were higher in myotube cultures derived from bicep femoris cells than from pectoralis major cells. Several *in vivo* and isolated muscle studies have shown that protein synthesis rates are higher in oxidative muscles than in glycolytic muscles (reviewed in Beatty and Bocek, 1969). Additionally, there were greater rates of uptake of the glucose analog 2-deoxyglucose with bicep femoris cells compared with pectoralis major cells.

16.10 MATERNAL INHERITANCE AND GROWTH SELECTION ON BREAST MUSCLE MORPHOLOGY

Although muscle is structurally composed of muscle fibers and muscle fiber bundles, the size and morphology of the fibers and fiber bundles varies between lines. Breast muscle weight, as measured by breast width, is highly heritable. The unweighted average heritability of breast width

using selected populations was 0.30 as summarized by Nestor et al. (1967). For breast width in a randomly bred population, McCartney (1961) reported a heritability of 0.42 and Nestor et al. (1967) obtained heritabilities of 0.77 (full-sib analysis) and 0.61 (mid-parent offspring regression). Studies were initiated by Velleman et al. (2003a) to determine the role of inheritance on breast muscle morphological structure. It was during these studies that the maternal inheritance of breast muscle morphological structure in turkeys was identified. Commercial turkeys are the result of a cross of a sire line (or sire line cross) and a dam line (or dam line cross). The sire lines are usually selected for increased growth rate and muscling, whereas selection within dam lines is on growth rate and reproduction traits.

In initial studies by Velleman et al. (2003a), two experiments were conducted with turkey lines having distinct breast muscle morphological structure (Figure 16.2). The lines used were the random bred control line 2 (RBC2), which is representative of the 1966 commercial turkey (Nestor et al., 1969); the F line, which was selected from the RBC2 line for only increased 16 week body weight (Nestor, 1977); and a commercial sire line B. The RBC2 line has well-defined extracellular matrix spacing (perimysial and endomysial space) and muscle fiber size was not as large as that of the commercial sire B line. The F line was characterized by greatly reduced extracellular matrix space and muscle fibers and poorly defined bundles. In the first experiment, the F line and B line were used. Offspring were obtained from the B and F lines and reciprocal crosses of the B and F lines as well as the pure F and B lines. In experiment 2, the F line and RBC2 line were used. Offspring from reciprocal crosses and the pure lines were obtained. From both the experiments, breast muscle samples were obtained and histologically evaluated. The results from both experiments consistently showed that the morphological structure of the breast muscle in males and females followed the female parent. Figure 16.3 contains representative breast muscle sections from the reciprocal crosses of the F and B lines. The maternal inheritance of breast muscle morphology in turkeys at 16 weeks of age was experimentally confirmed in subsequent experiments using F_1 and F_2 crosses of the F and RBC2 lines (Velleman and Nestor, 2004). The maternal inheritance of breast muscle morphological structure appears to be universal in turkeys as lines selected for egg production and not growth characteristics also exhibit maternal inheritance (Velleman and Nestor, 2006; Velleman et al., 2007a).

The biological cause of the maternal inheritance observed in the turkey breast muscle is not understood at this time. The observed maternal inheritance could result from mitochondrial inheritance, epigenetics or genetic imprinting, or factors in the egg. Mitochondrial DNA is predominantly maternal and gives rise to genetic asymmetry between males and females (for a review, see Wolff and Gemmell,

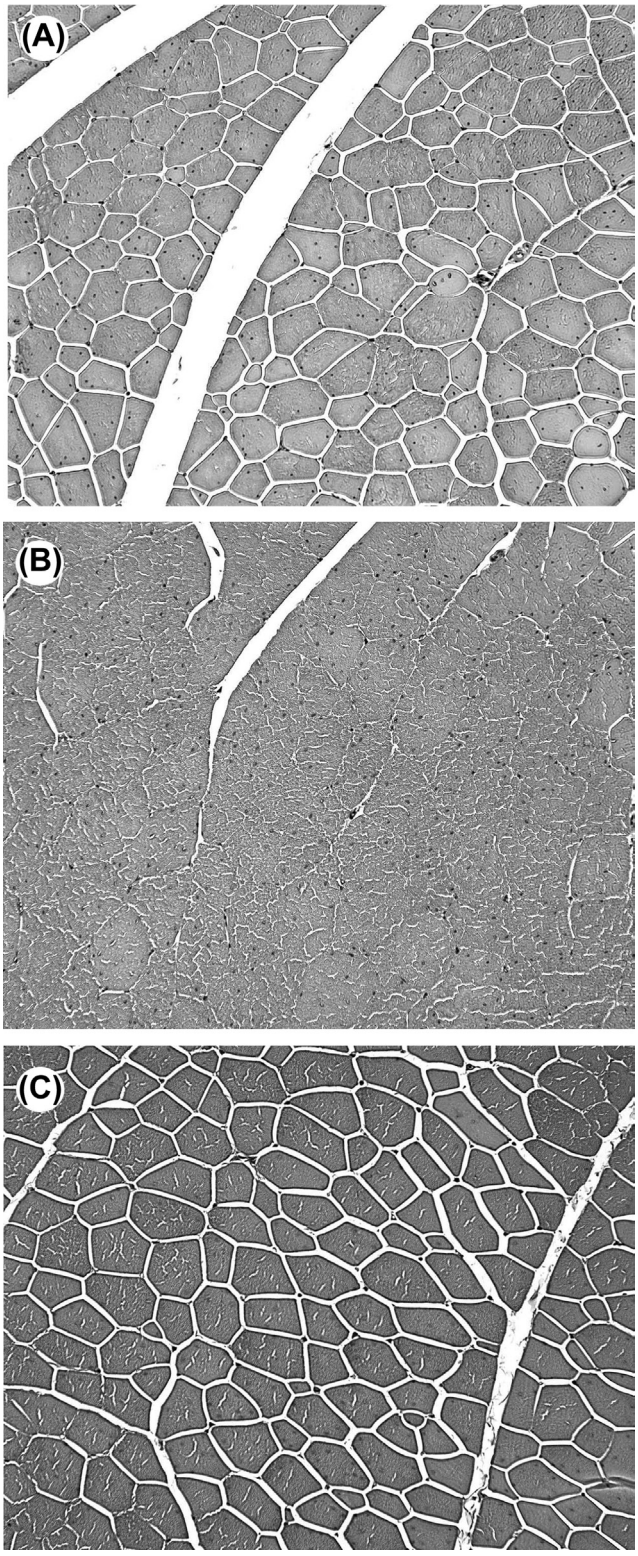

FIGURE 16.2 Representative samples at 16 weeks of age of the pectoralis major muscle from an experimental line (F) selected long term for increased body weight, a commercial line (B), and a random bred control line (RBC2) that was the base population of the F line. (A) = RBC2 line; (B) = F line; and (C) = B line. *Used by permission of Velleman et al. (2003a).*

2012). However, the mechanisms of mitochondrial inheritance and the relationship to muscle morphological structure are still not completely understood. Genetic imprinting has been shown to occur in angiosperms, mammals, and some protozoa (Pennisi, 2001). If genetic imprinting was of importance in the inheritance of turkey breast muscle morphology, some paternal inheritance should have been observed. Egg traits have been shown to influence the performance of turkeys posthatch. For example, egg weight has been shown to influence body weight up to 24 weeks of age (Scott and Phillips, 1936; Bray, 1965). It is quite likely that differences in egg traits, such as egg weight and nutritional composition of the egg, are not responsible for maternal inheritance.

Regardless of the cause of maternal inheritance of muscle morphological structure in turkeys, it is of importance to the commercial turkey industry that the type of mating used in the production of commercial crosses will have a major impact on performance. Lines with desirable characteristics in breast muscle morphology should be used as the female parent for commercial production. To use breast muscle morphological structure as a selection tool, Velleman et al. (2010) determined that the type of mating used to produce turkeys has a major effect on breast muscle morphology beginning at 12 weeks of age. At this time, it is not known if maternal inheritance of breast morphology occurs in other avian species or if other muscles exhibit maternal inheritance.

16.11 EFFECT OF SELECTION FOR INCREASED GROWTH RATE ON MUSCLE DAMAGE

The poultry breeding industry has placed major emphasis in selection for increased growth rate and breast muscling. Increased growth rates in poultry have helped the poultry industry keep up with consumer demand for economical chicken and turkey products, but these increases must be accompanied by consideration of the cellular mechanisms affecting muscle growth as both the morphological structure and biochemical properties of the muscle are affected. These changes in muscle, especially the breast muscle, have resulted in meat quality issues, which are the end consequence of muscle fiber defects. Typical muscle fiber defects found in poultry selected for increased growth rate include deep pectoral myopathy (Wilson et al., 1990; Sosnicki and Wilson, 1991), focal myopathy (Sosnicki, 1993), and pale, soft, and exudative (PSE) meat (Sosnicki, 1993; Pietrzak et al., 1997). In broiler chickens, a new meat quality issue of breast muscle white striping has recently

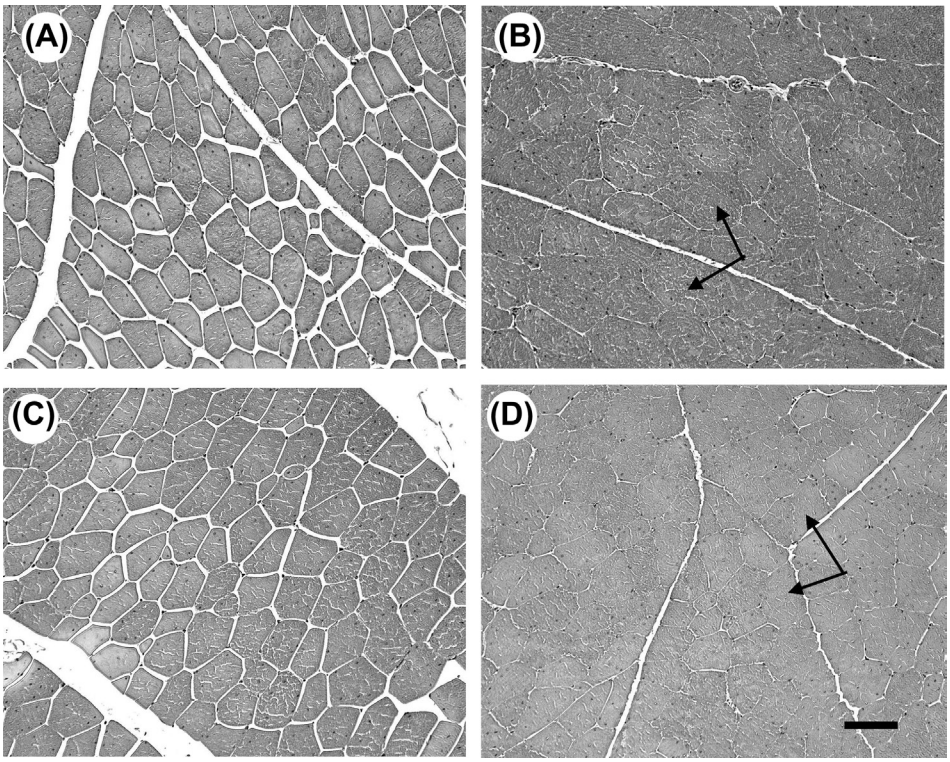

FIGURE 16.3 Representative pectoralis major muscle sections of the reciprocal crosses of a commercial sire line (B) and an experimental line (F) selected for long-term increased 16 week body weight. (A) = F sire × B dam; (B) = B sire × F dam; (C) = F sire × B dam; and (D) = B sire × F dam. Sections (A) and (B) are from males and sections (C) and (D) are from females. Scale bar = 50 μm. Arrows highlight muscle fiber fragmentation. *Used by permission of Velleman et al. (2003a).*

been reported, which is associated with heavier body weights or increased growth rates (Bauermeister et al., 2009; Kuttappan et al., 2012). The white striping defect results in white stripes or striations following the muscle fiber orientation. It does not appear to affect the quality of the cooked breast muscle but does affect the appearance. Because muscle fibers are surrounded by connective tissue, the white striping may arise from altered connective tissue deposition or structure. Kuttappan et al. (2013) reported that there is an increase in pathological changes in the breast muscle with white striping. The white striping can vary in severity and affect the morphology of the muscle. In breast muscle samples with severe or moderate levels of white striping, there is a loss of cross-striations, variable muscle fiber size, floccular or vacuolar degeneration and lysis of fibers, mild mineralization, occasional regeneration, mononuclear cell infiltration, lipidosis, and interstitial inflammation and fibrosis. In addition, the fat level is increased whereas protein is decreased in white striped muscle.

Also associated with many of these breast muscle fiber defects from chickens and turkeys selected for meat production are lighter or pale color and decreased water-holding capacity (Rémignon and Bihan-Duval, 2003). According to Owens et al. (2000), approximately 40% of the commercial turkey meat exhibits poor water-holding capacity. Muscling changes due to selection are not just limited to chickens and turkeys, but they have also been reported in ducks (Baeza et al., 1997).

Wilson et al. (1990) showed that in the turkey breast muscle, damage to the muscle fibers increased with age. Velleman et al. (2003b) traced the effect of growth selection on muscle fiber damage in turkeys from late embryonic development (day 25) through 20 weeks of posthatch age. In this study, muscle morphology comparisons were made between the RBC2, and F lines. Figures 16.4 and 16.5 show hematoxylin and eosin staining of the breast muscle from the RBC2 and F lines. Breast muscles from the unselected RBC2 line had well-structured muscle fiber and fiber bundles (Figure 16.4). Regardless of age, the muscle fiber and fiber bundles had sufficient spacing for endomysial and perimysial connective layers. In addition, the perimysial connective tissue layer contained large capillary beds, which are important in removing the byproducts of anaerobic respiration. However, at 20 weeks of age, some muscle fiber fragmentation was noted. In contrast, the F line had limited endomysial and perimysial spacing surrounding the fibers and fiber bundles by 8 weeks of age. At 16 weeks posthatch, hypercontracted muscle fibers were present in the F line and by 20 weeks significant fragmentation and degeneration of the muscle fiber bundles were present. Due to the limited connective tissue spacing, well-developed capillary beds are not present in the F line breast muscle.

The type of muscle morphological changes observed in the F line have led to some hypothesizing that poultry muscles have outgrown their muscle support systems, which results in the muscle damage. The muscle fibers undergoing fragmentation have reduced endomysial spacing. The breast muscle is a fast twitch anaerobic muscle composed predominantly of fast-twitch glycolytic (type IIb) muscle fibers. With increased breast muscle weight, there are more glycolytic fibers and anaerobic capacity is increased (Dransfield and Sosnicki, 1999; Yost et al., 2002). Lactic acid is produced by anaerobic respiration, which leads to higher acid concentrations in the muscle and decreased pH. Pale soft exudative meat is characterized by low postmortem pH. Muscles with reduced connective tissue spacing are likely to have limited circulation and lactic acid is largely removed from the muscle by the circulatory system, to be converted into glycogen by the liver (Bangsbo et al., 1991). Reduced capillaries have been found surrounding muscle in necrotic regions of turkey breast muscle fibers (Sosnicki and Wilson, 1991). The decreased ability to remove lactic acid from breast muscles with limited circulatory supply likely contributes to the reduced pH observed in PSE meat.

16.12 EXTRACELLULAR MATRIX REGULATION OF MUSCLE DEVELOPMENT AND GROWTH

As described above, muscle is surrounded by three distinct connective tissue layers: the epimysium, perimysium, and endomysium (Figure 16.1(A)). The epimysium surrounds the entire muscle and is continuous with the joining of various muscle group or the tendon attaching muscle to bone. Although the epimysium is very thick, it is not a factor in meat quality because it can easily be removed. The perimysium surrounds muscle fiber bundles and the endomysium surrounds individual muscle fibers. The connective tissue layers are responsible for many of the functional properties associated with muscle and factors affecting meat quality. Tissue structure, the elasticity of the tissue, vascular supply to the muscle tissue, and water-holding capacity are all properties linked to connective tissue, primarily of the perimysium, which can compose up to 90% of the intramuscular connective tissue. Connective tissue is made up of cells and the extracellular matrix.

The extracellular matrix is defined to include all secreted molecules that are immobilized outside cells. Thus, the cell makes its own extracellular environment. The major macromolecular components of the extracellular matrix include collagens, proteoglycans, and noncollagenous glycoproteins. The extracellular matrix was classically viewed as a structural substance that cells were embedded in and was thought to be passive in terms of affecting cell behaviors. Descriptions of the extracellular matrix referred to it as a ground substance filling space between cells. This view of the extracellular matrix

has been replaced by one showing a dynamic complex macromolecular network that regulates many mechanisms involved in tissue development, function, growth, and maintenance. The extracellular matrix regulates muscle function by being a substrate for cell migration; modulating growth factor activity; transmitting signals to the cell modulating proliferation and differentiation; and serving as a tissue structural framework necessary for normal tissue activity.

Muscle formation is dependent upon the migration of muscle cells to form multinucleated myotubes. The extracellular matrix functions as a substrate supporting cellular migration. The interaction of the cell with the extracellular matrix is largely governed by heterodimeric cell membrane integrin receptors. Integrins are widely expressed glycoproteins that are composed of α and β subunits that link the extracellular matrix to the cellular cytoskeleton. The integrins will frequently bind to the extracellular matrix glycoprotein fibronectin arginine–glycine–aspartate (RGD) cell attachment domain. This interaction of the integrins with fibronectin results in the formation of focal adhesions. Fibronectin is a multifunctional extracellular macromolecule secreted as a dimer held together by disulfide bonds at the C-terminus of the molecule. Each fibronectin subunit has a molecular weight of 235,000 to 270,000 Da. In addition to the cell binding to the RGD domain, fibronectin contains binding sites for heparin, fibrin, and collagen.

Cell migration involves a series of cellular changes, including cell extension at the leading edge, formation of stable contacts between the cell and extracellular matrix substrate, contraction of the cellular cytoskeleton, translocation of the cell, and release of the cell-extracellular matrix substrate attachment at the trail edge of the cell. Integrin expression is necessary for cellular migration and Boettiger et al. (1995) showed that inhibiting the expression of α5β1 integrin blocked both muscle cell migration and myotube development. Furthermore, increased expression of α5β1 integrin elevates the expression of antiapoptotic genes leading to cell survival and growth (Zhang et al., 1995). When muscle cells attach to the extracellular matrix substrate, they elongate and have more integrin-mediated focal adhesions, which will lead to more migration, formation of myotubes, and subsequent fiber development.

Collagen is the most abundant of the extracellular matrix molecules found in muscle, and it is localized in all three connective tissue layers (for a review, see McCormick, 1999). Types I and III fibrillar collagens are the predominant collagens found in skeletal muscle. These fibrillar collagens provide mechanical stability to the muscle and prevent overstretch of the muscle. The degree of stretch of the muscle is, in part, dependent upon the amount of crosslinking of the fibrillar collagens. The fibrillar collagens are composed of three α-polypeptide chains that form a right-handed triple helix. The helical domain of the triple helix contains repeats of the amino acids Gly–X–Y, where X and Y are frequently proline or lysine. In addition to the helical domain region, there are carboxy and amino terminal nonhelical regions that interact by interchain hydrogen bonds and the regions form intra- and interchain disulfide bonds.

Both intracellular and extracellular posttranslational modifications of the collagen triple helix take place. Intracellularly, precise lysine amino acids are glycosylated, and specific proline and lysine residues are hydroxylated. These posttranslational changes are required for collagen functionality. Once secreted into the extracellular matrix, the carboxy and amino termini are cleaved. At this point, the collagen molecules align in a quarter-stagger array pattern. The quarter-stagger array is the alignment of collagens overlapping the adjacent molecule by approximately one-quarter of its length. The array forms when the collagen fibril formation is initiated. Collagen fibers are the functional form of the collagen.

The initial collagen fibril is not a stable complex as the quarter-stagger array forms from hydrophobic and ionic interactions. Stabilization and functionality of the collagen fibril are derived from subsequent covalent bond formation called crosslinks. Both divalent and trivalent collagen crosslinking of the fibrillar collagens can form (for a review, see McCormick, 1999). The divalent or ketoamine crosslink is reversible in nature and can be transient. The ketoamine crosslink is replaced by a mature nonreversible trivalent hydroxylysl pyridinium crosslink (HP). The trivalent form of the HP crosslink increases with age and elevated levels of the HP crosslink are associated with less tender meat.

The formation of the collagen crosslinking is dependent upon the association of the proteoglycan decorin with the collagen fibril. Decorin is a member of the small leucine-rich proteoglycans, which consists of a core protein of approximately 45 kDa and a single covalently attached chondroitin or dermatan sulfate chain. Weber et al. (1996) determined that decorin is an arch shaped molecule and its concave inner surface wraps around a collagen triple helix approximately 54 nm from the amino terminal. A secondary binding site for decorin is 112 nm from the amino terminal end. Changes in the expression of decorin affect fibril formation and crosslinking (Danielson et al., 1997). Danielson et al. (1997) showed in a mouse decorin knockout model that collagen fibrils were irregular in size and diameter. Although the mice were viable, their skin was fragile and would tear with applied force. Thus decorin affects the maturation of collagen fibrils into larger fiber networks and affects the functional properties of a tissue. In the case of skeletal muscle, decorin expression levels would affect the elasticity of the muscle. An example of altered muscle elasticity is the chicken low score normal (LSN) genetic muscle

weakness, which is characterized by subnormal muscle development and function.

The LSN condition was initially detected in F_2 progeny in an outcross between chickens with hereditary muscular dystrophy and a commercial white leghorn stock (Pierro and Haines, University of Connecticut, Storrs, CT, 06,268, unpublished data). The LSN nomenclature was used to distinguish birds that had an impaired ability to right themselves when placed on their backs (exhaustion score) but had a higher level of activity than the muscular dystrophy birds. In the pectoralis major muscle of the LSN birds at 20 days of embryonic development, there is a dramatic increase in decorin protein levels (Velleman et al., 1996). Following the increase in decorin levels, LSN pectoralis major collagen HP crosslink levels are elevated by close to 200% at 6 weeks of posthatch age (Velleman et al., 1996).

In addition to decorin-regulated collagen fibrillogenesis, decorin also influences both the proliferation and differentiation of muscle cells by binding to the growth factors TGF-β (Hildebrand et al., 1994) and myostatin (Miura et al., 2006). Decorin plays a key role as a regulator of the bioavailability of these two key growth factors by directing their availability to their cellular signal transduction receptors. Both TGF-β and myostatin are strong inhibitors of muscle cell proliferation and differentiation. Myostatin is a member of the TGF-β family of growth factors but is only found in skeletal muscle.

Transforming growth factor-β binds to the decorin core protein and is sequestered from binding to its receptors, type I and II, which will diminish muscle cell responsiveness to transforming growth factor-β (Drougett et al., 2006). The binding of TGF-β to its receptors results in the formation of a heterodimer, with the type II receptor phosphorylating and activating the type I receptor. The activated receptor then phosphorylates the receptor activated Smads, which will bind to a collaborating Smad, Smad-4, to form a Smad complex. Smads are intracellular proteins that transduce extracellular signals from TGF-β. The Smad complex is translocated to the nucleus where it binds to transcription factors and regulates the transcription of target genes (Mehra and Wrana, 2002). Circulating decorin levels may, in part, be controlled by its binding to low-density lipoprotein receptor (LRP-1) followed by decorin's subsequent catabolism following endocytosis (Brandan et al., 2006), which will affect TGF-β binding to its receptor.

Decorin expression is also regulated by TGF-β levels during muscle growth. Li et al. (2006) demonstrated that TGF-β can decrease decorin expression *in vitro*. The regulation of decorin expression by transforming growth factor-β also occurs *in vivo*. When exogenous TGF-β was injected into day 3 embryonic eggs decorin mRNA expression was decreased in the pectoralis major muscle by embryonic day 10 and protein levels were subsequently decreased at embryonic day 17 and 1 day posthatch compared with the untreated pectoralis major muscle (Li and Velleman, 2009).

Decorin also appears to be involved in the modulation of muscle fibrosis through its regulation of connective tissue growth factor. Connective tissue growth factor is produced by muscle cells in response to TGF-β and lysophosphatidic acid, and results in increased muscle fibrosis and the dedifferentiation of muscle (Vial et al., 2008). Decorin binds connective tissue growth factor at its core protein inhibiting the fibrotic effects of connective tissue growth factor (Vial et al., 2011).

Myostatin functions in an analogous manner to TGF-β and also binds to the decorin core protein (Miura et al., 2006). Similar to TGF-β, decorin functions as a presenter or sequester of myostatin to its Activin Type II receptor and similar to TGF-β, affects gene expression through Smad-mediated signal transduction. When myostatin is bound to the decorin core protein, myogenic proliferation and differentiation are enhanced due to the inability of myostatin to bind to its receptor (Kishioka et al., 2008). Mutations of the myostatin gene results in a phenotype of "double muscling" (Grobet et al., 1997; Kambadur et al., 1997; McPherron and Lee, 1997). Yang et al. (2003) showed that myostatin inhibits the proliferation and differentiation of chicken embryonic myoblasts, and McFarland et al. (2006) found that myostatin inhibits turkey satellite cell proliferation and differentiation. Regulation of myostatin expression may go beyond decorin and include the skeletal muscle basement membrane proteoglycan perlecan (Xu et al., 2010). In mice with a perlecan knockout, myostatin expression was decreased and muscle fiber hyptertrophy was increased especially in the type IIb fast muscle fibers.

Decorin is an extracellular matrix macromolecule that can function in the extracellular matrix domain imparting structure to the matrix and can work close to the cell surface or directly bind to cell surface receptors initiating signal transduction pathways regulating cell growth properties. Decorin can regulate cellular growth by directly binding to the insulin-like growth factor receptor (IGFR) and epidermal growth factor receptor (EGFR). Decorin binding to IGFR: phosphorylates IGFR, which creates docking or binding sites for the intracellular docking protein insulin receptor substrate-1 (IRS-1). IRS-1 is then phosphorylated; this can activate phosphatidylinositol-3-kinase, followed by phosphorylation of its cascade effector serine/tyrosine kinase (AKT). Activation of AKT will cause downregulation of an inhibitor of cyclin-dependent kinase activity, $p21^{WAF1/CIP1}$. This will allow G1-to-S phase transition of the cell cycle and increased abundance of cell cycle–related proteins and increased cell proliferation. As documented by Moscatello et al. (1998), when decorin binds EGFR, phosphorylation events ensue, mainly through the mitogen activated protein kinase pathway

(MEK1/2 and ERK1/2), leading to upregulation of p21. Upregulation of p21 results in suppression of cyclin and cyclin-dependent kinase activity.

16.13 REGULATION OF MUSCLE GROWTH PROPERTIES BY CELL-MEMBRANE ASSOCIATED EXTRACELLULAR MATRIX MACROMOLECULES

The cell membrane associated proteoglycans can have extracellular, transmembrane, and cytoplasmic domains. Thus, these proteoglycans can play roles in organizing extracellular matrix structure, cytoskeletal organization, cell-to-cell adhesions, and cell signal transduction. The syndecans and glypicans are two families of heparan sulfate proteoglycans that are integral components in growth factor signal transduction. Fibroblast growth factor 2 is a potent stimulator of muscle cell proliferation and a strong inhibitor of differentiation (Dollenmeier et al., 1981). In particular, the growth factor FGF2 binds with a high affinity to its tyrosine kinase receptor by binding to the heparan sulfate chains of the syndecans and glypicans (Steinfield et al., 1996).

The syndecans have four family members, syndecan-1 through -4; all four types are found in skeletal muscle (Larraín et al., 1997, 1998; Brandan and Larraín, 1998; Fuentealba et al., 1999; Liu et al., 2006). All the syndecans are type I membrane glycoproteins (Deepa et al., 2004) and usually contain at least three heparan sulfate chains as well as *N*-glycosylated chains. However, the core protein can also have covalently attached dermatan and chondroitin sulfate chains. All the syndecans have extracellular, transmembrane, and cytoplasmic domains. The cytoplasmic domain for syndecan-1 through -4 have two conserved regions (C1 and C2) separated by a variable region (V). The C terminus of the cytoplasmic domain has a conserved amino acid sequence, EFYA, which allows the syndecans to function as a diverse set of cell surface receptors (Choi et al., 2011). The following describes the known functions of each of the syndecans in skeletal muscle.

Syndecan-1 is a regulator of FGF2 signal transduction and syndecan-1 is expressed at higher levels during muscle cell proliferation than differentiation (Larraín et al., 1997; Liu et al., 2004). In growth-selected turkeys, syndecan-1 expression is higher than in turkeys without selection for growth (Liu et al., 2004). The higher expression of syndecan-1 may lead to a prolonged period of proliferation, leading to a larger pool of muscle cells available to differentiate into muscle fibers.

Syndecan-2, in a manner similar to syndecan-1, is expressed at higher levels during the proliferation of avian muscle cells and expression decreases with differentiation (Liu et al., 2006). Less is known about the function of syndecan-2 in muscle than the other syndecans, but there is evidence that the cytoplasmic domain may be involved in regulating cellular responsiveness to TGF-β (Chen et al., 2004).

Recent research on syndecan-3 suggests that it may play a role in the maintenance, proliferation, and differentiation of myogenic satellite cells (Fuentealba et al., 1999; Cornelison et al., 2004; Pisconti et al., 2010). The absence of syndecan-3 leads to muscular dystrophy types of conditions characterized by impaired locomotion, fibrosis, decreased myonuclear number (Cornelison et al., 2004), and satellite cells with reduced proliferation (Pisconti et al., 2010).

Syndecan-4 is the most well studied of the syndecans in poultry muscle development. Syndecan-4 has been shown to play important roles in muscle maintenance and regeneration (Cornelison et al., 2001, 2004). In turkey satellite cells, syndecan-4 is expressed at high levels during proliferation (Velleman et al., 2007b). The primary role for syndecan-4 in muscle is in its regulation of cytoskeletal organization and muscle cell migration (Shin et al., 2012b, 2013a; Song et al., 2012a,b). In the presence of phosphatidylinositol 4,5-bisphosphate (PIP_2) bound to the V region of the syndecan-4 cytoplasmic domain, syndecan-4 functions in the translocation of inactive protein kinase Cα (PKCα) to the muscle cell membrane resulting in its activation (Song et al., 2012c; Shin et al., 2012b). Once activated, PKCα mediates the activation of downstream RhoA signal transduction, which is involved in mediating cell migration (Dovas et al., 2006; Shin et al., 2013a). Deletion of the syndecan-4 cytoplasmic domain or a knockdown of RhoA inhibits cell migration in turkey satellite cells (Shin et al., 2013a). The binding of PIP_2 also functions in the stabilization of syndecan-4 leading to the formation of syndecan-4 oligomers in turkey satellite cells (Shin et al., 2012b). The oligomerization of syndecan-4 is required for the activation of syndecan-4 as syndecan-4 in the monomer form is not able to activate PKCα (Horowitz and Simons, 1998a,b).

Syndecan-4 may have varying functions with regard to FGF2 based on cell type. For example, in endothelial cells, both the syndecan-4 heparan sulfate chains and the cytoplasmic domain have been shown to be necessary for syndecan-4 mediated FGF2 cell signaling (Volk et al., 1999). However, in turkey satellite cells, the heparan sulfate chains are not required for syndecan-4 FGF2 signal transduction, but the cytoplasmic domain and cytoplasmic domain Ser^{178} in the conserved C1 region is required for modulating satellite cell responsiveness to FGF2 (Zhang et al., 2008; Song et al., 2012c,d). Horowitz and Simons (1998a,b) found that the Ser residue in the C1 domain can be phosphorylated by growth inhibitors and dephosphorylated by the addition of FGF2. The phosphorylation of the Ser in the C1 region will decrease PKCα activation. In turkey satellite cells, the

Ser^{178} amino acid stimulates both PKCα activation and FGF2 induced proliferation (Song et al., 2012d).

16.14 REGULATION OF THE MYOGENIC REGULATORY FACTORS BY THE EXTRACELLULAR MATRIX

The heparan sulfate proteoglycans, syndecan-4 and glypican-1, have been shown to be associated with the expression of the MRFs during satellite cell proliferation and differentiation (Gutiérrez and Brandan, 2010; Shin et al., 2012a). In a study knocking down syndecan-4 and glypican-1 expression in turkey satellite cells, Shin et al. (2012a) measured the effect on the MRFs. Decreasing syndecan-4 levels primarily affected MyoD and MRF4 during proliferation by increasing the expression of these MRFs. These data suggest that syndecan-4 may affect the expression of MRFs regulating muscle number. In contrast to syndecan-4, decreasing glypican-1 expression in turkey satellite cells during proliferation and differentiation decreased the expression of all the MRFs. These data suggest that glypican-1 may be necessary for the expression of the MRFs.

16.15 NOVEL GENES INVOLVED IN AVIAN MYOGENESIS

Avian muscle growth may involve genes that have not been previously characterized to play a role in myogenesis. A complete transcriptome analysis was done in turkeys using a turkey skeletal muscle long oligonucleotide (TSKMLO) array that was constructed from the pectoralis major muscle at three developmental stages (Reed et al., 2008; Sporer et al., 2011a). The developmental stages of the TSKMLO array was the 18 day embryo and 1 day old and 16 week old turkeys. From the genes differentially expressed (Sporer et al., 2011b), three genes were studied further for their effects on the proliferation and differentiation of satellite cells. These genes were versican, matrix Gla protein, and death-associated protein.

Versican is a large chondroitin sulfate proteoglycan initially reported in cultured fibroblasts (Zimmerman and Ruoslahti, 1989). Zhang et al. (1998) showed that versican enhanced cell proliferation in NIH 3T3 fibroblasts. By knocking down versican expression in turkey satellite cells, satellite cell proliferation was increased, supporting a potential role for versican in the proliferation of satellite cells (Velleman et al., 2012). In addition, during the embryonic stages of muscle development when initial myofiber synthesis is taking place, large water-holding proteoglycans like versican may be involved. Versican has numerous chondroitin sulfate chains attached to its central core protein and ionically interacts with molecules. Because of its early expression during embryonic muscle formation, it has been hypothesized to play a role in the spacing of the developing muscle fibers (Fernandez et al., 1991).

Matrix Gla protein is highly expressed by vascular smooth muscle cells (Proudfoot and Shanahan, 2006), but prior to the report of Sporer et al. (2011b), matrix Gla protein had not been identified in skeletal muscle. Knocking down matrix Gla protein only decreased proliferation in satellite cells isolated from growth-selected turkeys (Velleman et al., 2012). At this time, it is not possible to hypothesize if matrix Gla protein has an overall function during myogenesis or is just expressed in growth selected lines.

Death-associated protein (DAP) is a highly conserved proline-rich phosphoprotein that was first identified in HeLa cells (Deiss et al., 1995). Recent studies have shown that DAP is a substrate of mTOR (Koren et al., 2010), which is a primary intracellular pathway controlling muscle hypertrophy (Bodine et al., 2001). In both turkey (Velleman et al., 2012) and chicken (Shin et al., 2013b) breast muscle satellite cells, knocking down DAP expression severely inhibits the formation of myotubes. Future studies on DAP will need to address the regulation of muscle DAP by mTOR because DAP could be a key gene in the regulation of avian myogenesis.

16.16 SUMMARY

This chapter on avian skeletal muscle biology provides a broad overview of muscle structure, the prehatch and posthatch development of muscle, effects of growth selection, extracellular matrix influences on muscle development and growth, and the identification of novel genes. Muscle development involves a wide range of cellular events that have distinct embryonic and posthatch phases. It is clear that many factors can influence the development and growth of avian skeletal muscle; as time passes, it is likely that more factors will be identified.

Chapter 17

The Avian Immune System

Pete Kaiser and Adam Balic
The Roslin Institute & R(D)SVS, University of Edinburgh, Easter Bush, Midlothian, EH25 9RG, UK

17.1 INTRODUCTION

Although our knowledge of the avian immune system and the avian immune response to disease and vaccination still lags behind that of better studied biomedical model systems, such as the human and mouse, progress since the last edition of this book has been dramatic. Thanks to the chicken genome sequence, we now have far greater understanding of the genes and molecules available to the avian immune response and, therefore, access to the tools required to enable us to understand the biology of that response in far greater detail than previously. The focus of research in avian immunology, and therefore the focus of this chapter, remains the chicken because it is the main avian species of economic importance. As we apply our knowledge of the chicken's immune system to other avian species, it is obvious that, in broad terms, the same principles hold, although the details might vary. For example, different species have different numbers of members of immune multigene families (Huang et al., 2013).

In broad terms, the immune systems and responses of mammals and birds are similar. Both mount innate and adaptive immune responses, and the bird's adaptive immune responses include both cell-mediated and humoral immune responses, leading to immunological memory. However, when one looks at the organs, cells, and molecules of the immune response in birds, one begins to understand that mammals and birds achieve the same overall responses often in quite different ways and, in many respects (but not all), the avian immune response is different.

It would be very difficult to summarize all aspects of the avian immune system in this chapter. Instead, we will concentrate on the basic anatomy of the organs of the avian immune response, as well as a description of the major cell types and major areas where the cells and molecules of the immune response differ from those of mammals—in some cases, being unique to avians.

17.2 THE ORGANS AND CELLS OF THE AVIAN IMMUNE RESPONSE

We cannot understand the avian immune response without knowledge of its basic structure. Lymphoid tissues are either of epithelial (e.g., thymus and bursa of Fabricius) or mesenchymal (e.g., spleen and bone marrow) origin and are colonized by hematopoietic cells via the blood. The primary lymphoid organs, the thymus and the bursa of Fabricius, are colonized by stem cells of hematopoietic origin that develop in situ to become immunologically competent T and B cells, respectively. This development process involves educating the T and B cells to essentially ignore self-antigens but respond to foreign antigens. These immunologically mature cells then re-enter the circulation and colonize the peripheral lymphoid organs: these include the spleen, cecal tonsils, Peyer's patches, Meckel's diverticulum, the Harderian gland, and other gut-, bronchus-, skin-, nasal- and reproductive-associated lymphoid tissues. In these peripheral tissues, there are T- and B-dependent zones occupied primarily by T and B cells, respectively.

17.2.1 Primary Lymphoid Tissues
